The diagnosis of diphtheria should be made on the basis of clinical findings, without waiting for laboratory confirmation, since any delay in treatment may have serious consequences. Definitive diagnosis relies upon isolation of the organism; swabs should be obtained urgently and the microbiology service informed of the possibility of diphtheria so that appropriate cultures can be set up and tests for toxigenicity performed.

Differential diagnoses include infectious mononucleosis, herpetic tonsillitis, Vincent’s angina, streptococcal pharyngitis and blood dyscrasias. In resource rich countries where diphtheria is a rarity it may easily be missed, and a high index of suspicion is required, particularly in patients without adequate immunization cover and in those who have recently visited an area endemic for diphtheria.

**MANAGEMENT**

Neutralization of free toxin with diphtheria antitoxin is the most important aspect of management. The antitoxin is only effective before the toxin enters cells so prompt administration is critical. Empirical dosage recommendations are given in Table 28.20.<sup>174</sup> As the antiserum is raised in horses, after preliminary sensitivity testing with 0.1 ml of a 1:1000 dilution of antitoxin, a single dose should be given to try to avoid sensitization. Facilities for resuscitation must be available, even in the absence of a reaction to the test dose.

Antibiotic therapy should be given to eliminate the organism and prevent spread, with penicillin probably the antibiotic of choice. Erythromycin may be more effective at preventing carriage but some resistant clinical isolates have been identified.<sup>175</sup> Parenteral treatment (benzylpenicillin 25 000–50 000 units/kg/d, or erythromycin 40–50 mg/kg/d for those with a history of penicillin allergy) should be started immediately, changing to oral therapy as the patient improves. Treatment should be continued for 10–14 days and the patient should be barrier nursed until eradication of the organism has been confirmed by culture of appropriate swabs. The disease is notifiable and all suspected cases should be reported immediately to the relevant authority so that measures can be taken to minimize the likelihood of spread.

Good supportive care is also critical. Emergency tracheostomy may be lifesaving in children with severe airway obstruction. However, endotracheal intubation should be avoided unless absolutely necessary in case part of the membrane becomes dislodged and obstructs the lower airways. Ventilatory support is not usually required except in those with

extensive pulmonary involvement or those with respiratory failure due to neurological dysfunction. A short course of corticosteroids is often given to patients with ‘bull-neck’ or upper airway obstruction in order to reduce local edema.

Patients recovering from moderate to severe local disease should be kept on strict bed rest for a minimum of 2 weeks until cardiac involvement has been excluded. Careful clinical examination and regular ECG and echocardiographic monitoring allow early detection of conduction disturbances and impending myocarditis.<sup>176</sup> Patients who develop mild to moderate cardiac failure but maintain normal blood pressure can usually be managed successfully with bed rest, oxygen, diuretics and ACE inhibitors. However, recovery may take many weeks and occasional patients are left with permanent conduction abnormalities. Steroids have not been shown to be of benefit for treatment or prevention of myocarditis, although the number of patients involved in formal research studies has been limited.<sup>177</sup>

The prognosis for patients developing severe conduction disturbances depends largely on the severity of the overall myocardial involvement. Profound bradyarrhythmias are usually associated with major heart muscle disease; if a low output state with hypotension and renal compromise develops, the response to cardiac pacing and/or inotropic agents is poor and the outlook is bleak.<sup>178</sup> Cardiac pacing may be helpful in those with significant conduction abnormalities in whom a reasonable stroke volume is maintained.<sup>179</sup> However, in some such cases the conduction disturbance resolves without intervention after a few days.

Later still, patients with severe neurological involvement may require assisted ventilation and nutritional support for prolonged periods, together with physiotherapy, treatment for nosocomial infections as they arise, and eventually rehabilitation.

**PROGNOSIS**

Before the introduction of antitoxin, antibiotics and routine immunization, the prognosis was grave, with mortality rates of 30–50%. Currently mortality rates of around 5–10% are usual,<sup>180</sup> with the majority of deaths in those with overwhelming disease at presentation or those who develop myocarditis. If antitoxin is administered within the first 72 h severe disease and death are rare.

**PREVENTION**

Humans are the only known reservoir for *C. diphtheriae*. The principal modes of spread are by respiratory droplets from acute cases or asymptomatic carriers, or by direct contact with infected skin lesions. Immunization with diphtheria toxoid (formalin inactivated toxin) is very effective at protecting against the effects of the toxin, but does not prevent infection with the organism. Before the vaccine era diphtheria was predominantly a disease of the young and most people acquired natural life-long immunity through repeated exposure to the organism during childhood. Vaccine induced immunity wanes gradually over time, however, and during the recent resurgence of diphtheria in the former Soviet Union many adults acquired the disease and mortality was high in this group.<sup>181</sup>

The standard schedule for routine immunization should include a minimum of 3 doses of the triple vaccine (DTP) early in the first year of life, with a DTP booster at school entry, and a further booster at school

**Table 28.20** Dosage of antitoxin recommended for various types of diphtheria

Type of diphtheria	Dosage (units)	Route
Nasal	10 000–20 000	Intramuscular
Tonsillar	15 000–25 000	Intramuscular or intravenous
Pharyngeal or laryngeal	20 000–40 000	Intramuscular or intravenous
Combined types or delayed diagnosis	40 000–60 000	Intravenous
Severe diphtheria, e.g. with extensive membrane and/or severe edema (bull-neck diphtheria)	40 000–100 000	Intravenous or part intravenous and part intramuscular

leaving using the low dose adult vaccine (usually as Td). Supplementary boosters should be given to high-risk groups including health care workers, travelers to endemic areas, alcoholics and the homeless, and periodic boosters for the general population may become routine in the future. Patients suffering from diphtheria should receive active immunization after recovery, since clinical disease may not induce adequate antitoxin levels.

## BACTERIAL INFECTIONS: *ESCHERICHIA COLI*

*Escherichia coli* was first described by Theodore Escherich in 1885. It is a Gram negative, non-spore-forming, fimbriate bacillus which is motile by means of flagella (Fig. 28.20). Although *E. coli* is responsible for the vast majority of human infections there are four other species in the genus, *E. blattae*, *E. vulneris*, *E. fergusonii* and *E. hermannii*. *E. blattae* is an intestinal commensal of cockroaches and does not cause human infection, but the other three have been described as rare opportunists. In contrast *E. coli* is a major pathogen, both primary (Table 28.21) and opportunist. It is also the major aerobic Gram negative rod found in the human (and other animals) gastrointestinal tract at a concentration of approximately  $10^8$  colony forming units (cfu) per gram. It can be found in soil and water, but this is invariably a result of fecal contamination.

The complete genome sequences of both *E. coli* K12 (a nonpathogenic laboratory strain) and *E. coli* O157 are available.<sup>182,183</sup> *E. coli* K12 encodes some 4405 genes on a large circular chromosome of 4639 kilobase pairs. *E. coli* O157, which causes hemorrhagic colitis and hemolytic uremic syndrome (HUS), has a larger genome with 1387 new genes encoded in clusters or islands not found in *E. coli* K12. *E. coli* K12 and *E. coli* O157 share a common backbone but diverged some 4.5 million years ago.<sup>184</sup> Most of the differences result from acquisition of islands of genes. These islands encode pathogenicity determinants (pathogenicity islands),

Fig. 28.20 Negative stain electron micrograph of *Escherichia coli* showing numerous fimbriae.

metabolic functions (metabolic islands) and several pro-phages (bacterial viruses whose genome has been incorporated into the bacterial chromosome). Other pathogenic *E. coli* such as enteropathogenic *E. coli* (EPEC), uropathogenic P-fimbriate *E. coli* (PFEC) and the neonatal pathogen *E. coli* K1 also encode different pathogenicity islands in their genomes.

## EPIDEMIOLOGY

*E. coli* is subdivided into a large number of serotypes based on O- or somatic (on lipopolysaccharide on the outer membrane of the bacterium) antigens, H- or flagellar antigens and K- or capsular antigens. There are

Table 28.21 *Escherichia coli* as a primary pathogen

	Serogroups	Pathogenicity determinants	Infection sites	Disease associations
<i>Gastrointestinal tract</i>				
Enterotoxigenic <i>E. coli</i> (ETEC)	06, 08, 05, 020, 025, 0128, 0139, 0148, 0153, 0159	CFA (pili), heat labile (LT) and heat stable (ST) toxins	Small bowel	Secretory diarrhea in travelers and children in resource limited countries
Enteroinvasive <i>E. coli</i> (EIEC)	028, 029, 0124, 0136, 0143	<i>lpa</i> pathogenicity island on plasmid <i>ial</i> , adhesin	Large bowel	Mild dysentery in children in resource limited countries
Enteropathogenic <i>E. coli</i> (EPEC)	055, 086, 0111, 0119, 0125, 0126, 0127, 0128, 0142	Locus of enterocyte effacement pathogenicity island (LEE), <i>tir</i> , <i>eae</i>	Small and large bowel	Acute and chronic diarrhea in neonates and infants in resource limited countries
Enterohemorrhagic <i>E. coli</i> (EHEC)	026, 0111, 0128, 0157	<i>eaeA</i> , <i>eaeB</i> , shiga toxins 1 & 2	Large bowel	Hemorrhagic colitis, hemolytic uremic syndrome, encephalopathy
Enteraggregative <i>E. coli</i> (EaggEC)	044, 0111, 0121 but most are nongroupable	Adhesin, EAST-1	Small and large bowel	Acute and chronic diarrhea in children and travelers
Diffuse adhering <i>E. coli</i> (DAEC)	075 but most are nongroupable	Adhesins	Unknown	Perhaps a cause of diarrheal disease
<i>Urinary tract</i>				
P-fimbriate <i>E. coli</i> (PFEC)	01, 02, 03, K1	P-fimbriae (adhesions) encoded on a pathogenicity island	Urinary tract, septicemia	Cystitis, pyelonephritis
S-fimbriate <i>E. coli</i> (SFEC)	01, 02, 03	S-fimbriae (adhesins)	Urinary tract, septicemia	Cystitis, pyelonephritis
<i>Neonatal meningitis and bacteremia</i>				
<i>E. coli</i> K1	01, 02, 03, K1	K1 capsule plus pathogenicity island function unclear	Urinary tract, meninges, septicemia	Urinary tract infection, meningitis, septicemia

167 different O-serogroups and at least 82 K-antigens.<sup>185</sup> Serogrouping is of importance not just for epidemiological purposes but also delineation of pathogenicity. However, a number of molecular biological techniques provide more accurate epidemiological and pathogenicity related markers. These include techniques for whole genome analysis such as pulsed field gel electrophoresis (PFGE) of macrorestricted chromosomal DNA,<sup>186</sup> analysis of housekeeping genes (multilocus sequence testing; MLST) or of insertion sequence distribution (eubacterial repetitive intergenic consensus sequences; ERICS). *E. coli* can also be divided into four main phylogenetic groups by analysis of two genes (*chuA*, *yjaA*) and an anonymous DNA fragment.<sup>187</sup> Most virulent extra-intestinal strains belong to group B2 and to a lesser extent group D, whereas most commensal strains are in group A.

*E. coli* is part of the normal flora of most mammalian species. For example, *E. coli* O157 is excreted asymptotically by cattle but can be transferred to humans as a 'food-poisoning' to cause hemorrhagic colitis, HUS and encephalopathy. The uropathogenic PFEC and the neonatal pathogen *E. coli* K1 colonize the gastrointestinal tract<sup>188</sup> thence reaching their infective sites by ascending the urinary tract and by hematogenous spread respectively. In addition the commensal *E. coli* that do not possess defined pathogenicity determinants are important opportunist pathogens, for example after gastrointestinal surgery or in patients with indwelling urinary catheters. Finally the commensal *E. coli* are an important reservoir of antibiotic resistance genes that can be transferred to more pathogenic bacteria.<sup>189</sup>

### Enteropathogens

Enterotoxigenic *E. coli* (ETEC) are solely human pathogens, although similar bacteria can cause diarrheal disease in domestic animals. They cause up to 25% of cases of diarrheal disease in children in resource limited countries and are a major cause of traveler's diarrhea (c. 80% of cases). Infection is usually acquired via food or water contaminated with human excreta. The infective dose is high (c.  $10^7$  cfu). Enteroinvasive *E. coli* (EIEC) are a minor cause of diarrheal disease, in most surveys being responsible for less than 5% of cases in children in the tropics. Enteropathogenic *E. coli* (EPEC) were responsible for epidemics of infantile diarrhea in the UK and the USA in the 1940s and 1950s but are now found predominantly in neonates and infants in resource limited countries (in one study causing 11% of cases of infantile diarrhea). The infective dose is low ( $<10^4$  cfu) so direct person-to-person spread is also possible.

Enterohemorrhagic *E. coli* (EHEC) are most often acquired as food poisoning, but since the infective dose is low ( $<10^2$  cfu), person-to-person spread in households and hospitals has been described. Enteraggregative *E. coli* (EaggEC) are the most recently described group and are responsible for cases of acute and chronic diarrhea in children and traveler's diarrhea. They are particularly associated with chronic diarrhea in children in resource limited countries. The infective dose is unknown. It is still unclear what role diffuse adhering *E. coli* (DAEC) play in diarrheal disease and little is known of their epidemiology.

### Uropathogens

Most *E. coli* causing urinary tract infection fall into serogroups O1, O2, O4, O6 and O75, have thick capsules and express adhesins. Of particular importance are PFEC which bind to the P-blood group receptor. They colonize the intestine and, in females, the vagina, perineum and anterior urethra. From there they ascend to produce cystitis and pyelonephritis.

### Neonatal sepsis

*E. coli* K1 is responsible for 40% of the cases of neonatal bacteremia and 75% of the cases of neonatal meningitis that are due to *E. coli*. The incidence rate of *E. coli* neonatal meningitis in the USA is 1 case per 1000 live births. Infection is acquired from mother-to-baby at birth or baby-to-baby and staff-to-baby in neonatal intensive care units. Approximately 50% of women of childbearing age have intestinal carriage of *E. coli* K1 and 70% of neonates born to carrier mothers will acquire carriage. The colonization to disease ratio is approximately 200–300 to 1.

## PATHOGENESIS

### Enteropathogens

ETEC cause a non-inflammatory, secretory, small intestinal diarrhea. To do this they must colonize the upper small intestine by adhering to enterocytes using fimbriae (protein spikes) termed colonization factor antigens (CFA) in human ETECs. In addition they secrete one or both of heat labile (LT) and heat stable (ST) toxins. The LTs (I and II) are subunit toxins. They consist of five (toxophore) B subunits that carry and bind the toxin to ganglioside receptors on the enterocyte surface and one A (toxin) subunit. The A subunit is activated by cleavage to A1 which activates adenosine diphosphate (ADP) ribosylation of a regulatory subunit of adenyl cyclase. This results in activation of adenyl cyclase and raised intra-enterocyte concentrations of cyclic adenosine monophosphate (AMP). This results in fluid and electrolyte secretion into the small intestinal lumen, and thus a voluminous watery diarrhea. LTI is very similar to cholera toxin. ST (a and b) are smaller (16–18 amino acids) and activate guanylate cyclase by mimicking guanylin, the endogenous modulator of cyclic guanosine monophosphate (GMP) signaling. How raised intracellular cyclic GMP levels induce diarrhea is unclear. EIEC cause colitis and an inflammatory diarrhea. They have similarity with *Shigella* spp. in that similar pathogenicity genes (on a pathogenicity island) are encoded as large plasmids in both genera. They attach to and invade colonic enterocytes (Fig. 28.21). They can then migrate laterally from colonocyte to colonocyte. How this causes colonocyte death, loss of mucous membrane integrity and an inflammatory response is unclear, but the initial stages might involve induction of colonocyte apoptosis.

EPEC produce specific ultrastructural lesions on the enterocyte surface, termed attaching effacement, in which there is very close intimate attachment of the bacteria to the enterocyte surface with local loss of the microvilli (brush border) (Fig. 28.22). Although this lesion can be detected throughout the gastrointestinal tract it is the effect on the small intestine that is most important. EPEC initially adhere to the enterocyte surface by means of bundle forming pili. This then activates a chromosomal pathogenicity island called the locus of enterocyte effacement (LEE) which assembles a type III secretion system. Through this, the bacterium injects effector molecules into the enterocyte. One is Tir (transferable intimin receptor) which inserts into the enterocyte membrane and acts as a receptor for a molecule (intimin) on the bacterial surface thus promoting intimate attachment of the bacterium to the enterocyte. Other effectors cause damage to the microfilaments of the terminal web causing loss of the microvilli (termed effacement). This causes a great loss of surface area for absorption and of the brush border disaccharidases sucrase, maltase and lactase, and leads to malabsorption and an osmotic diarrhea.

EHEC such as *E. coli* O157 have a pathogenicity island very similar to the EPEC LEE but their attaching effacement is confined to the

Fig. 28.21 Thin section electron micrograph of colonic enterocytes with numerous enteroinvasive *Escherichia coli* in the cytoplasm.

Fig. 28.22 Thin section electron micrograph showing enteropathogenic *Escherichia coli* closely adherent to duodenal enterocytes with loss of microvilli (attaching effacement).

terminal ileum and colon. In addition they elaborate Shiga toxins (ST) 1 and/or 2 (previously known as verocytotoxins). These are subunit toxins with five B (toxophore) units and one A (toxin) unit. The B units carry, protect, and bind the A subunit to the enterocyte utilizing a globoside glycolipid receptor. The A subunit inhibits protein synthesis and is one of the most potent toxins known. ST-1 is identical to Shiga toxin and both it and ST-2 are encoded on promiscuous bacteriophages. This means that these toxin genes are widely distributed in enteric bacteria, but in order to produce disease, *E. coli* must have both LEE and ST. ST kills colonocytes causing hemorrhagic colitis. If ST enters the circulation it binds to receptors on endothelial cells, in particular in the renal vasculature. This causes fibrin deposition, cell swelling and narrowing of the lumen of the vessel, and results in a microangiopathic hemolytic uremia or HUS.

EaggEC are so called because they produce a 'stacked brick' appearance when adherent to cells in culture and each other. They adhere to both small and large intestinal mucosa by means of plasmid-encoded fimbriae (AAF/I, AAF/II). They elaborate toxins including EaggEC heat stable toxin-1 (EAST-1) which resembles ETEC ST and a plasmid encoded toxin (Pet) which induces mucin release, exfoliation of cells and crypt abscesses. Recently it has been shown that a novel flagellin from EaggEC induces the release of the inflammatory chemokine IL-8 from intestinal epithelial cells.

PFEC have two pathogenicity islands in their genome which encode expression of fimbriae with a receptor binding molecule at their tip which recognizes the P-blood group antigen. This is a glycolipid with terminal digalactose residues and is expressed on most tissues including the epithelium of the urinary tract. Thus the bacteria are able to adhere and resist the flushing action of urine. How they induce inflammation is less clear but probably involves induction of cytokine and chemokine release.

*E. coli* K1 produces a thick capsule that allows it to evade the killing effects of neutrophils and complement. It, like the group B meningococcal capsule, is a homopolymer of N-acetyl neuraminic acid which is a self-antigen being expressed on neuronal tissue in particular. Further pathogenicity determinants are gradually being uncovered.

## CLINICAL FEATURES

The clinical features associated with enteropathic *E. coli* are outlined in Table 28.21. For a more detailed description of this and of urinary tract infections and neonatal sepsis, see the appropriate sections.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

### Enteropathogens

For definitive diagnosis, *E. coli* must be isolated from fecal samples. Although O-serogrouping was the method originally used to describe

the different pathogenic types it is of little value except in outbreaks. For specific diagnosis, the pathogenicity genes or their products must be detected. This is most conveniently done by polymerase chain reaction (PCR) and a number of multiplex PCR systems have been described although none is commercially available.

### Uropathogens and neonatal sepsis

Standard microbiological procedures are used to isolate *E. coli* from urine, blood or CSE. It is possible to demonstrate PFEC or *E. coli* K1 using specific antisera, although this is not entirely necessary.

## TREATMENT, PROGNOSIS AND PREVENTION

### Enteropathogens

In general, diarrheal disease should be managed by assessment of dehydration and appropriate rehydration. Antimicrobial therapy is not normally indicated and in some cases, for example with *E. coli* O157, might be harmful. However, some infections with EPEC and EaggEC can produce persistent diarrhea and in such cases antimicrobial chemotherapy directed by in vitro sensitivity testing is appropriate.

The prognosis is good with full recovery without antibiotic therapy in most cases. There are no vaccines currently available, so good hygiene and recognition of risk are the mainstay of infection prevention both in hospital and the community.

### Uropathogens

For uncomplicated infections, short course (3–5 days) antimicrobial chemotherapy will suffice. If complicated by pyelonephritis or septicemia, longer duration of treatment will be needed. For prognosis, prevention and follow-up, see the appropriate section on urinary tract infection.

### Neonatal sepsis

For pre-emptive, empiric therapy, see the section on neonatal sepsis. This will need to be modified in the light of the local antimicrobial susceptibility patterns. No vaccine is available, especially since the K1 capsule is a self-antigen.

## BACTERIAL INFECTIONS: HAEMOPHILUS INFLUENZAE

### GENERAL FEATURES AND EPIDEMIOLOGY

*Haemophilus influenzae* was first reported by Pfeiffer in 1892. A small Gram negative bacterium, it may be encapsulated or non-encapsulated (nontypable). In 1931 Pitmann<sup>190</sup> described six antigenically distinct capsular types, designated a to f. The possession of the capsule is an important virulence determinant and it is *H. influenzae* of capsular serotype b (Hib) that stands out as the most virulent strain, responsible for the great majority of invasive *Haemophilus* infections. Prior to the widespread use of effective vaccines against Hib, it was the major cause of bacterial meningitis and the predominant cause of epiglottitis in young children. In the Oxford region between 1985 and 1990 for example, the incidence of all invasive Hib disease was 36 cases/100 000 children < 5 years old.<sup>191</sup> Table 28.22 summarizes several characteristics relating to carriage and pathogenicity.

*H. influenzae* is among the bacteria normally found in the human pharynx and also colonizes the mucosae of the conjunctiva and genital tracts. Spread from one individual to another occurs by airborne droplets or by direct transfer of secretions. Exposure begins during or immediately after birth so that from infancy onwards, carriage of one or more strains for periods lasting from days to months is common. The presence of *H. influenzae* in cultures obtained from the upper (but not the lower) respiratory tract is therefore a common and normal finding. In about 3–5% of individuals, the organisms are encapsulated, most often with the serotype b antigen (in an unvaccinated population). Following widespread vaccination, however, carriage of type b strains has declined. In general, carriers of *H. influenzae*, whether colonized

Table 28.22 Carriage and pathogenicity of *Haemophilus influenzae*

Strains	Common upper respiratory tract carriage rates	Principal manifestation of pathogenicity
Non-encapsulated (nontypable)	50–80%	Exacerbations of chronic bronchitis, otitis media, sinusitis, conjunctivitis, lower respiratory tract infections Bacteremic infections rare
Encapsulated, type	2–4% b (pre-vaccine)	Meningitis, epiglottitis, pneumonia and empyema, septic arthritis, cellulitis, osteomyelitis, pericarditis, bacteremia
Encapsulated, types a and c through f	1–2%	Rarely incriminated as pathogens. May cause bacteremia and meningitis

with encapsulated or nontypable organisms, remain healthy, but occasionally disease occurs. Two contrasting patterns of *H. influenzae* disease can be identified. The more serious in its consequences is invasive infections such as meningitis, septic arthritis, epiglottitis and cellulitis; these infections typically occur in young children, are associated with bacteremia and are caused by encapsulated type b strains. The second category includes less serious, but numerically more common infections that occur as a result of contiguous spread of *H. influenzae* within the respiratory tract. *H. influenzae* is a common cause of otitis media (accounting for 23% of bacteria isolated by tympanocentesis),<sup>192</sup> sinusitis, conjunctivitis and lower respiratory tract infection. These infections are usually, but not invariably, caused by nontypable strains. These generalizations are not hard and fast; nontypable strains are a cause of neonatal sepsis, as well as sepsis and meningitis in infants and children.<sup>193</sup> They are a common cause of severe, acute lower respiratory tract infections (often accompanied by bacteremia) among young children living in resource limited countries<sup>194</sup> and are responsible for about 50% of all *H. influenzae* causing invasive disease in adults.<sup>195</sup> Epiglottitis, however, appears to be a syndrome associated overwhelmingly with serotype b. Brazilian purpuric fever is a rare disease caused by a nontypable *H. influenzae*, biotype *aegyptius*. This occurs in young children who present initially with a conjunctivitis and go on to develop a serious, potentially fatal form of septicemia which can mimic meningococemia.

## PATHOGENESIS

The host and microbial determinants of colonization by *H. influenzae* are poorly understood. In animal experiments infection is potentiated by viruses such as influenza. Adhesins facilitate attachment to mucus and to human epithelial cells and there are cell wall components that inhibit the normal ciliary function of respiratory tract epithelium. The primacy of type b capsule as a crucial factor in the pathogenesis of invasive disease has been well established. Lipopolysaccharide is also important in facilitating bloodstream survival and blood–brain barrier damage in experimental infections. In rat and primate models of *H. influenzae* type b meningitis, organisms were found to invade the submucosa of the nasopharynx and to reach the meninges as a result of bacteremia rather than by direct penetration of contiguous structures such as the cribriform plate or the inner ear. The occurrence of meningitis correlated strikingly with the duration and intensity of bacteremia; experimental manipulation of the host factors that decrease the efficiency of intravascular clearance (e.g. splenectomy) increased the incidence of meningitis.<sup>196</sup>

## IMMUNITY

Among the host factors governing susceptibility to invasive type b infection, the role of serum antibodies to polyribosyl-ribitol phosphate (PRP), the type b capsular antigen, has been shown to be critical. Serum anti-PRP antibodies in conjunction with complement-mediated bactericidal and opsonic activity mediate protective immunity against systemic infections in humans. The sera of newborns and young infants (up until about 3 months old) generally have sufficient amounts of passively acquired antibody to afford protection. Thereafter, the natural decline of these maternally derived antibodies is followed by a period lasting until the age of 2–4 years when the levels of antibody are inadequate to provide protection. The delay in the acquisition of serum anti-PRP antibodies is characteristic of children less than 2 years old and is a major reason for the high attack rates of *H. influenzae* b invasive disease in early infancy. Although some infants may be exposed to type b *H. influenzae* through nasopharyngeal carriage, the antigenic stimulus for these antibodies may also be different commensal bacteria or ingested foods, which immunize through their cross-reacting antigens.

In an infant rat colonization model, anti-PRP antibodies given intranasally are able to prevent nasopharyngeal colonization by Hib. The same effect is seen when these antibodies are given intraperitoneally and a minimum effective serum level can be defined.<sup>197</sup> If it is assumed that anti-PRP antibodies function in a similar manner on the oropharyngeal mucosa of human children, both serum-derived IgG and locally produced IgA may reduce Hib carriage and thereby protect against invasive disease. A clinical study has correlated protection against carriage of *H. influenzae* b in infants with vaccine-induced serum anti-PRP IgG antibodies of greater than or equal to 5 mcg/ml.<sup>198</sup>

## CLINICAL FEATURES

Meningitis is the most serious manifestation of invasive infection due to *H. influenzae* b. Antecedent symptoms of upper respiratory infection are common. The most common signs are fever and altered behavior – including poor feeding, vomiting, irritability and drowsiness. Thus, none of these clinical features distinguishes the child with *H. influenzae* meningitis from several other infectious diseases or other forms of meningitis. In particular, young infants have few specific signs; nuchal rigidity and a bulging fontanelle are typical, but often absent, early in the course of established meningeal infection. Seizures, cranial nerve involvement and coma may develop as the disease progresses and the effects of raised intracranial pressure, cerebral edema and vasculitis prevail. Subdural effusions are common but these very rarely require specific management and are usually sterile. Overall mortality for *H. influenzae* meningitis is less than 5% in resource rich countries but significantly higher, ranging from 22 to 40%, in resource limited countries. Sequelae occur in 15–30% of those who survive; the commonest complication is sensorineural deafness.

Acute respiratory obstruction caused by involvement of the supraglottic tissue by *H. influenzae* b (epiglottitis) is a potentially lethal disease of characteristically rapid onset. Typically, the child is aged 2–7 years and presents with sore throat, fever, dyspnea and dysphagia (causing pharyngeal pooling and then oral drooling of secretions). The child is restless and anxious and often adopts a characteristic posture in which the neck is extended and the chin is protruded in order to minimize airway obstruction. Abrupt deterioration leading to death within a few hours may occur if adequate treatment is not provided. The characteristic findings are supralaryngeal. The epiglottis is red and swollen and resembles a red cherry at the base of the tongue. Although an abrupt death is usually the result of acute airway obstruction, sudden collapse may result from less well defined mechanisms associated with acute toxemia. It should be emphasized that examination of the pharynx of a child in whom acute epiglottitis is suspected should only be attempted under conditions in which the airway can be secured immediately, otherwise the examination may precipitate respiratory arrest.

Invasive disease due to non-type-b encapsulated and nontypable *H. influenzae* is rarer but may present in a similar fashion. Presentation

may also be similar in the rare group of children who develop invasive disease with *H. influenzae* b despite vaccination, 'vaccine failures'. In both groups, predisposing host factors such as immunodeficiency should be sought.<sup>193,199</sup>

Confirmation of the clinical impression of invasive *H. influenzae* infection depends upon cultures of normally sterile fluids (e.g. CSF, blood, pleural or synovial fluid). Positive nasopharyngeal cultures are not helpful since carriage is common among healthy persons. Needle aspiration of the middle ear (tympanocentesis), sinuses, the margins of an area of cellulitis or lung may occasionally prove helpful in selected cases, especially in a very sick child in whom no diagnosis has been established. Whenever practical, the results of Gram stain should be sought immediately; in up to 70% of cases of meningitis, CSF smears show the typical pleomorphic, Gram negative coccobacilli. Detection of capsular antigen in serum, CSF or concentrated urine by immunoassay (e.g. latex agglutination) may be useful, especially in children who have received prior antibiotic treatment. This test should be interpreted with caution, however, in those who have recently received Hib vaccine, as a false positive result is possible.

## TREATMENT

Severe infections due to *H. influenzae* should be treated with parenteral third generation cephalosporins, for example cefotaxime or ceftriaxone. Ampicillin resistance has emerged among both encapsulated and nontypable strains (in the range of 10–30% for European and USA strains). Resistance is almost always mediated by beta-lactamases. This has particular relevance to the antibiotic management of less severe infections, such as otitis media and sinusitis. Although ampicillin/amoxicillin remains the antibiotic of choice, others such as amoxicillin–clavulanate or macrolides have become alternative first- and second-line choices.

The use of dexamethasone as adjunctive therapy in Hib meningitis can result in a reduction in sensorineural deafness.<sup>200</sup> Early administration, close to or even prior to the first dose of antibiotic, is preferable. Elective intubation and antibiotics are usually mandatory in cases of epiglottitis.

## PREVENTION

### Active immunization

The first generation of vaccines against Hib consisted of the purified type b polysaccharide. A trial in 1974 in Finland demonstrated efficacy in children older than 18 months of age but not in younger infants.<sup>201</sup> This led to the development of a second generation of vaccines in which the immunogenicity of PRP is enhanced by covalent linkage of the capsular polysaccharide or oligosaccharides to protein to form conjugate vaccines. Conjugate vaccines elicit significantly enhanced antibody responses when compared to PRP and, in contrast to the latter, are found to prime for a secondary antibody response. Clinical trials and national surveillance have confirmed their efficacy in infancy.<sup>202</sup> An unexpected outcome has been a reduction in Hib colonization of the upper respiratory tract and this has contributed to the near elimination of Hib disease in countries where immunization has become routine. Unfortunately, on a global scale too few countries have had the resources to use this vaccine for routine immunization. Experience from The Gambia<sup>203</sup> and Kenya<sup>204</sup> suggests that a dramatic effect on disease rates can be expected when vaccination is eventually implemented in all resource limited countries.

Children and adults who have an increased risk of invasive disease, e.g. those without spleens or with malignancy, should also receive *H. influenzae* b conjugate vaccines. These vaccines are safe and, in general, protective antibody responses are seen.

The burden of disease due to nontypable *H. influenzae* strains is also recognized and its prevention through vaccination is desirable. A recent study with an 11-valent pneumococcal polysaccharide–protein conjugate vaccine, in which the protein is protein D, a highly conserved cell surface lipoprotein of *H. influenzae*, has, for the first time, demonstrated efficacy against otitis media due to *H. influenzae*.<sup>205</sup>

## Chemoprophylaxis

Young unimmunized or partially immunized children living in the same household as a case of invasive *H. influenzae* b disease are likely to be at significantly increased risk of secondary disease. In the pre-vaccine era secondary attack rates in household contacts were estimated to be 2–4% and in 'day-care centers' up to 1.3%. It is plausible that antibiotic prophylaxis could decrease this secondary attack rate. Rifampicin (20 mg/kg, maximum dose 600 mg/d), given orally once daily for 4 days, is effective in eradicating nasopharyngeal carriage. Treatment of household contacts (children and adults) where there are susceptible children less than 4 years old should be considered, as should treatment of such children in nurseries who are contacts of a case. The course of Hib vaccines should also be completed. The index case should also receive rifampicin prior to discharge unless he or she has been treated with a third generation cephalosporin.

## BACTERIAL INFECTIONS: LEPROSY

### EPIDEMIOLOGY

Worldwide, 4 million individuals have or are disabled by leprosy. The incidence, however, remains stable at around 450 000 new cases annually with high rates of childhood cases. India dominates the global picture with 67% of the global caseload. Few childhood cases are seen in Europe and North America, but in India childhood cases comprise at least 17% of the new case detection. In the UK, all new leprosy cases acquired their infection abroad. Average incubation times of 2–5 years and 8–12 years have been calculated for tuberculoid and lepromatous cases respectively. Age, sex, household contact and BCG vaccination are important determinants of leprosy risk. Leprosy incidence reaches a peak at age 10–11 years, and equal numbers of male and female cases are seen until puberty, after which there is an excess of male cases. Improved socioeconomic conditions, extended schooling and good housing reduce the risk of leprosy. HIV infection is not a risk factor for leprosy but may worsen leprosy nerve damage, and leprosy has been reported presenting as an immune reconstitution syndrome in adults treated for HIV.

### MICROBIOLOGY AND PATHOLOGY

Leprosy is caused by *Mycobacterium leprae*, an acid-fast, intracellular organism that has the longest doubling time of all known bacteria (12 days) and cannot be cultivated on artificial media. *M. leprae* is a hardy organism, retaining viability for 5 months drying in the shade. The optimum temperature for growth is 27–30 °C, which corresponds with the clinical observation of maximal *M. leprae* growth at cool superficial sites (skin, nasal mucosa and peripheral nerves). The *M. leprae* 3.27 Mb genome has been sequenced. Less than half the genome contains functional genes: 165 genes are unique to *M. leprae*, but functions can be attributed to only 29. *M. leprae* has lost many genes for carbon catabolism and many carbon sources (e.g. acetate and galactose) are unavailable to it. The genome sequence is opening new possibilities for understanding the biological uniqueness of *M. leprae*.

Untreated lepromatous patients sneeze organisms into the environment. In Indonesia and Ethiopia, *M. leprae* DNA has been detected in nasal swabs in up to 5% of the population. After entry via the nose, *M. leprae* is inhaled, multiplies on the inferior turbinates and then has a brief bacteremic phase before binding to Schwann cells and macrophages. The skin is unimportant in leprosy transmission. Bacilli are not excreted by the skin and are rarely found in the epidermis. Untreated lepromatous leprosy mothers excrete *M. leprae* in their breast milk, but treatment renders the bacteria nonviable.

### PATHOLOGY

There are four important aspects to the pathogenesis of leprosy: bacterial load, the host immune response, the nerve damage and immune-mediated reactions. Schwann cells and skin macrophages are infected early with granuloma formation. In established infection the host immune response

determines not only the histological picture but also the clinical features of disease and the prognosis. The Ridley–Jopling spectrum describes the range of responses with tuberculoid and lepromatous poles. At the tuberculoid (TT) pole there is well-expressed cell-mediated immunity and delayed hypersensitivity control of bacillary multiplication, with formation of epithelioid cell granulomas. In the lepromatous (LL) form there is cellular anergy towards *M. leprae*, with abundant bacillary multiplication and unactivated macrophages. Between these two poles is a continuum, varying from the patient with moderate cell-mediated immunity (borderline tuberculoid, BT) through borderline (BB) to the patient with little cellular response, borderline lepromatous (BL).

Nerve damage occurs in small dermal nerves in skin lesions and peripheral nerve trunks. Acute immune-mediated reactions are serious complications because they cause nerve damage. Reversal reactions (type 1) are episodes of delayed hypersensitivity occurring at sites of localization of *M. leprae* antigens. Erythema nodosum leprosum (ENL) (type 2) reactions are due to immune complex deposition.

**CLINICAL FEATURES**

Patients commonly present with skin lesions, weakness or numbness due to a peripheral nerve lesion, or a burn or ulcer in an anesthetic hand or foot. Borderline patients may present with nerve pain, sudden palsy, multiple new skin lesions or pain in the eye. Childhood cases are frequently detected in school surveys or as household contacts of adult leprosy patients. In an Indian study based on a survey area, 30% of cases had a household contact with leprosy, usually a parent or grandparent.<sup>206</sup>

**Cardinal signs**

- Typical skin lesions, which are anesthetic at the tuberculoid end of the spectrum
- Thickened peripheral nerves
- Acid-fast bacilli on skin smears or biopsy.

**Presenting symptoms**

**Early lesions**

Indeterminate lesions are slightly hypopigmented or erythematous macules, a few centimeters in diameter, with poorly defined margins. Hair growth and nerve function are unimpaired. The indeterminate phase may last for months or years before resolving or developing into one of the determinate types of leprosy.

**Skin**

The commonest skin lesions are macules or plaques; more rarely papules and nodules are seen.

**Anesthesia**

Anesthesia may occur in skin lesions when dermal nerves are involved or in the distribution of a large peripheral nerve. In skin lesions, the

small dermal sensory and autonomic nerve fibers supplying dermal and subcutaneous structures are damaged causing local sensory loss and loss of sweating within that area.

**Peripheral neuropathy**

Peripheral nerve trunks are vulnerable at sites where they are superficial or are in fibro-osseous tunnels. Damage to peripheral nerve trunks produces characteristic signs with dermatomal sensory loss and dysfunction of muscles supplied by that peripheral nerve. The sites of predilection for peripheral nerve involvement are ulnar (at the elbow), median (at the wrist), radial, radial cutaneous (at the wrist), common peroneal (at the knee), posterior tibial and sural nerves (at the ankle), facial nerve (on the zygomatic arch), and great auricular in the posterior triangle of the neck.

**The leprosy spectrum**

Classifying patients according to the Ridley–Jopling scale is clinically useful. Table 28.23 gives the skin and nerve features of disease across the spectrum. There is also a simpler field classification of paucibacillary/multibacillary (Table 28.24) which guides the length of treatment. BB disease is unstable, and BT leprosy may be associated with rapid, severe nerve damage. BL patients are at risk of both reversal and ENL reactions.

LL has an insidious onset. The earliest lesions are ill defined with shiny erythematous macules. Gradually the skin becomes infiltrated and thickened and nodules develop; facial skin thickening causes the characteristic leonine facies. Dermal nerves are destroyed and sensory loss develops in a glove and stocking distribution. Sweating is lost. Damage to peripheral nerves is symmetrical and occurs late in disease. Testicular atrophy results from diffuse infiltration and the acute orchitis that occurs with ENL reactions.

Most studies in childhood report all types of leprosy; incidence rates and proportion of lepromatous cases increase with age. Few children present under the age of 5 years.

**Eye**

Eye damage results from both nerve damage and bacillary invasion. Lagophthalmos results from paresis of the orbicularis oculi due to involvement of the facial (7th) nerve. Damage to the ophthalmic branch of the trigeminal (5th) nerve causes anesthesia of the cornea putting it at risk of ulceration. Invasion of the iris and ciliary body makes them extremely susceptible to reactions.

**DIAGNOSIS**

Leprosy should be considered as a possible diagnosis in anyone with peripheral nerve or skin lesions who has lived in a leprosy endemic area. The diagnosis is clinical and based on finding a cardinal sign of leprosy, supported by the finding of acid-fast bacilli on slit skin smears. Where resources permit, histological examination of a skin or nerve biopsy

Table 28.23 Major clinical features of the disease spectrum in leprosy

Classification	TT	BT	BB	BL	LL
<i>Skin</i>					
Infiltrated lesions	Defined plaques Healing centers	Irregular plaques Partially raised edges	Polymorphic Punched out centers	Papules, nodules	Diffuse thickening
Macular lesions	Single, small	Several, any size	Multiple, all sizes Geographic	Innumerable, small	Innumerable, confluent
<i>Nerve</i>					
Peripheral nerve	Solitary, enlarged nerves	Several nerves Asymmetrical	Many nerves Asymmetrical	Late neural thickening Asymmetrical anesthesia and paresis	Slow, symmetrical loss Glove and stocking anesthesia
<i>Microbiology</i>					
Bacterial index (0–6)	0–1	0–2	2–3	1–4	4–6

BB, borderline; BL, borderline lepromatous; BT, borderline tuberculoid; LL, lepromatous leprosy; TT, tuberculoid.

Table 28.24 Modified WHO recommended multidrug therapy regimens

Type of leprosy	Drug treatment		
	Monthly supervised	Daily self-administered	Duration of treatment
Paucibacillary	Rifampicin 450 mg (or 10 mg/kg)	Dapsone 50 mg (or 1 mg/kg)	6 months
Multibacillary (MB)	Rifampicin 450 mg (or 10 mg/kg) Clofazimine 150 mg (or 3 mg/kg)	Clofazimine 50 mg (or 1.5 mg/kg) alternate days Dapsone 50 mg (or 1 mg/kg)	24 months
Paucibacillary single lesion	Rifampicin 450 mg, ofloxacin 200 mg, minocycline 50 mg (supplied in a single blister pack)		Single dose

WHO classification for field use when slit skin smears are not available:

- paucibacillary single lesion leprosy (one skin lesion);
- paucibacillary (2–5 skin lesions);
- multibacillary (more than five skin lesions).

In this field classification WHO recommends treatment of MB patients for 12 months only.

is ideal for accurate classification. Serological and polymerase chain reaction based diagnostic tests are not yet clinically useful.

### Skin examination

The whole body should be inspected in a good light, otherwise lesions may be missed, particularly on the buttocks in borderline disease. Skin lesions should be tested for anesthesia.

### Neurological examination

The peripheral nerves should be palpated systematically looking for enlargement and tenderness. Nerve function should be assessed by testing the small muscles of the hands and feet. Sensation on the hands and feet can be assessed and monitored using Semmes Weinsteinmonofilaments. These are now widely used in leprosy and diabetic clinics.

### Slit skin smears

These should be undertaken from suspect lesions and standard sites (earlobes, arms and buttocks). Slit skin smears should be read by experienced technicians.

Outside leprosy endemic areas doctors frequently fail to consider the diagnosis of leprosy. Diagnosis had been delayed in over 80% of new patients seen between 1995 and 1999 at The Hospital for Tropical Diseases, London.<sup>207</sup> Patients had been misdiagnosed by dermatologists, neurologists, orthopedic surgeons and rheumatologists. A common problem was failure to consider leprosy as a cause of peripheral neuropathy in patients from leprosy endemic countries. These delays had serious consequences for patients, with over half of them having nerve damage and disability.

## DIFFERENTIAL DIAGNOSIS

### Skin

The variety of leprosy skin lesions means that many skin conditions need to be included in the differential diagnosis. In suspected tuberculoïd lesions the presence of lesional anesthesia is crucial in differentiating leprosy from fungal infections, vitiligo, vitamin A deficiency and eczema. Single facial patches in children may be difficult to test for anesthesia and one may have to observe a lesion over some months. In lepromatous disease the presence of acid-fast bacilli in smears differentiates leprosy nodules from onchocerciasis and post kala-azar dermal leishmaniasis.

### Nerves

Peripheral nerve thickening is rarely seen except in leprosy. Hereditary sensory motor neuropathy type III is also associated with palpable peripheral nerve hypertrophy.

## TREATMENT

The treatment of leprosy has six main components: chemotherapy, monitoring and treating nerve damage, management of reactions and neuritis, patient education, prevention of disability and social and psychological support.

### Chemotherapy

All children with leprosy should be given an appropriate multidrug combination. The first line anti-leprosy drugs are rifampicin, dapsone and clofazimine. Table 28.24 shows the drug combinations, doses and duration of treatment.

### Rifampicin

Rifampicin is a potent bactericidal drug for *M. leprae*. Because *M. leprae* resistance to rifampicin can develop as a one-step process, rifampicin should always be given in combination with other anti-leprotics. Parents and children should be warned that their urine, sweat and tears will be red for 48 h after taking rifampicin.

### Dapsone (DDS)

Dapsone (4,4-diaminodiphenylsulfone) is only weakly bactericidal. It commonly causes mild hemolysis but rarely anemia. Glucose-6-phosphate dehydrogenase deficiency is rarely a problem.

### Clofazimine

Clofazimine has a weakly bactericidal action. It also has an anti-inflammatory effect, which has reduced the incidence of ENL reactions. Skin discoloration is the most troublesome side-effect, ranging from red to purple-black. The pigmentation usually fades slowly after stopping clofazimine. Clofazimine also produces a characteristic ichthyosis on the shins and forearms.

More than 14 million patients have been treated successfully with multiple drug treatment (MDT). Clinical improvement is rapid, toxicity rare, and duration of treatment is shortened. Monthly supervision of the rifampicin component has been crucial to success. The three drugs used for MDT are donated by Novartis free of charge for distribution in blister packs (pediatric and adult). At the end of 6 months' treatment of borderline disease there may still be signs of inflammation, which should not be mistaken for active infection. The distinction between relapse and reaction may be difficult. WHO studies have reported a cumulative relapse rate of 1.07% for paucibacillary leprosy and 0.77% for multibacillary leprosy at 9 years after completion of MDT. *M. leprae* is such a slow-growing organism that relapse only occurs after many years. Patients with a high initial bacterial load may be at greater risk of relapse and so require treatment until skin-smear negative.

Short course chemotherapy regimens have been tested for paucibacillary (PB) leprosy using either rifampicin in weekly doses or single dose chemotherapy using a combination of currently used drugs. So far all of these regimens have had higher relapse rates than the current WHO PB regimen. The fluoroquinolones (pefloxacin and ofloxacin) and the macrolide minocycline are all highly active against *M. leprae*, and because of cost are rarely used in field programs. A single dose of triple drug combination (rifampicin, ofloxacin and minocycline) has been tested in India for patients with single skin lesions and produced marked clinical improvement at 18 months in 52% of patients. Although the study had major flaws, and single dose treatment is less effective than the conventional 6-month treatment for PB leprosy, it is an operationally attractive field regimen.

### Monitoring and treating nerve damage

Nerve damage may occur before diagnosis, or during and after MDT. It may occur during a reaction or without overt signs of nerve inflammation (silent neuropathy). About 30% of newly diagnosed patients have nerve damage and at least 25% of multibacillary patients develop nerve damage during treatment. Children are at the same risk as adults of developing nerve damage and having reactions. Monitoring sensation and muscle power in a child's hands, feet and eyes should be part of the routine follow-up so that new nerve damage is detected early. Any new damage should be treated with a course of oral steroids, starting with prednisolone 0.5 mg/kg/d and reducing by 0.1 mg/d each month. Response rates vary depending on the severity of initial damage, but even when promptly treated, nerve damage will only improve in 60% of cases.

### Management of reactions and neuritis

#### Reversal (type 1) reactions

Reversal reactions manifest clinically with erythema and edema of skin lesions and tender, painful peripheral nerves. Loss of nerve function may be dramatic and foot drop can occur overnight. Awareness of the early symptoms of reversal reactions by both patient and physician is important, because, if left untreated, severe nerve damage may develop. The peak time for reversal reactions is in the first 2 months of treatment. The treatment of reactions is aimed at controlling acute inflammation, easing pain, reversing nerve damage and reassuring the patient. MDT should be continued. If there is any evidence of neuritis (nerve tenderness, new anesthesia and/or motor loss) corticosteroid treatment should be started using the regimen given above.

#### Erythema nodosum leprosum type 2 (ENL) reactions

This complication affects only BL and LL patients and presents with crops of small, pink, tender skin lesions on the face and the extensor surfaces of the limbs. In a cohort study from Hyderabad, India, 31% of children with BL/LL disease developed ENL.<sup>208</sup> The patient is usually unwell with malaise and fever. Other accompanying signs are acute iritis and episcleritis, lymphadenitis, orchitis, bone pain, dactylitis, arthritis and proteinuria. This is a difficult condition to treat and frequently requires treatment with high dose steroids (1 mg/kg daily, tapered down rapidly) or thalidomide. Since ENL frequently recurs, steroid dependency can easily develop. Thalidomide (5 mg/kg daily) is superior to steroids in controlling ENL and is the drug of choice for young men with severe ENL. Unfortunately thalidomide is unavailable in several leprosy endemic countries despite its undoubted value. Clofazimine has a useful anti-inflammatory effect in ENL and can be used at 3 mg/kg daily for several months.<sup>209</sup> Acute iridocyclitis is treated with 4-hourly instillation of 1% hydrocortisone eye drops and 1% atropine drops twice daily.

#### Neuritis

Silent neuritis should be treated similarly to reversal reaction (see above). In the Hyderabad study 24% children developed neuritis.<sup>208</sup>

### Patient education

Patients and their parents deserve a clear explanation of the etiology, diagnosis and prognosis of leprosy. It should be emphasized that

the infection is curable provided that they comply with the antibiotic regimen. It is important to stress that deformity is not an inevitable disease endpoint. It may be helpful to ask parents and older patients about their views of leprosy as there are many myths about leprosy, which can be dispelled. Lepromatous patients become non-infectious within 72 h of starting antibiotics. Patients and their families should be encouraged to lead a normal life and be reassured that family activities such as eating together, sharing baths and bed linen pose no risks to other family members. It should be emphasized that leprosy is not transmitted sexually nor is it hereditary.

### Prevention of disability

It is vital in preventing disability to create patient self-awareness so that damage is minimized. In a study from south India, 33% of children presenting to a referral center had visible deformities.<sup>210</sup> The child with an anesthetic hand or foot needs to understand the importance of daily self-care, especially protection when doing potentially dangerous tasks and regular inspection for trauma. For each patient it is helpful to identify potentially dangerous situations, such as cooking, radiators and hot food. Soaking dry hands and feet followed by rubbing with oil keeps the skin moist and supple.

An anesthetic foot needs the protection of an appropriate shoe. For anesthesia alone, a well-fitting 'trainer' with a firm sole and shock-absorbing inner will provide adequate protection. Once there is deformity, such as clawing, special shoes must be made to ensure protection of pressure points and even weight distribution.

Children should be taught to work out why an injury occurred so that the risk can be avoided in future. Plantar ulceration occurs secondary to increased pressure over bony prominences. Ulceration is treated by rest. In leprosy, ulcers heal if they are protected from weightbearing. No weightbearing is permitted until the ulcer has healed. Appropriate footwear should be provided to prevent recurrence.

Physiotherapy exercises should be taught to maximize function of weak muscles and prevent contractures. Contractures of hands and feet, foot drop, lagophthalmos, entropion and ectropion are amenable to surgery.

### Social, psychological and economic rehabilitation

The social and cultural backgrounds of the patient determine the nature of many of the problems that may be encountered. The family may have difficulty in coming to terms with leprosy. The community may reject the patient. Education, confidence from family, friends and doctor, and plastic surgery to correct stigmatizing deformity all have a role to play.

### PROPHYLAXIS

In non-endemic areas it is very unusual to see leprosy in contacts of leprosy patients. The last case of secondary transmission in the UK was reported in 1923. Household contacts of new patients should be examined for clinical signs of leprosy and advised to report any new skin lesions promptly and to tell their physicians that they have had contact with a known case of leprosy. In the UK, BCG vaccination is given to contacts under the age of 12; chemoprophylaxis is reserved for children under 10 years who are household contacts of lepromatous cases. They are given prophylaxis with rifampicin 15 mg/kg body weight given monthly for 6 months.<sup>211</sup> BCG gives variable protection, ranging from 80% in Uganda to 20% in Burma. In trials in Malawi and Venezuela, adding killed *M. leprae* to BCG did not enhance protection.

### BACTERIAL INFECTIONS: LEPTOSPIROSIS

Leptospirosis is a worldwide zoonosis transmitted to humans by infected urine of a wide range of domestic and wild animals: often the causative spirochetes are excreted asymptotically for long periods of time.

Adults usually acquire infection because of occupational exposure; children may acquire infection by playing in areas contaminated with animal urine or by playing with the animals themselves.

## PATHOLOGY

In the UK and USA the common serotypes of the genus *Leptospira* include *Leptospira icterohaemorrhagiae* (commonly acquired from rat's urine), *Leptospira canicola* (commonly acquired from dog's urine), *Leptospira pomona* (commonly acquired from pig's urine), *Leptospira hebdomadis* and *Leptospira ballum*. Correlation of named serotypes with specific syndromes is impossible because of the variability of illness produced by each serotype.

Leptospire gain entry to humans via ingestion, mucous membranes, skin abrasions or the conjunctivae. After entry, the organisms affect capillary epithelium and may cause capillary damage, hypoxia and hemorrhage into various organs. Liver damage may cause jaundice (although hemolysis may also play a part), renal damage may cause renal failure, central nervous system damage meningitis and encephalitis, and skeletal muscle involvement muscle pain. Blood clotting parameters are often not disordered enough to account for the hemorrhagic tendency. Illnesses may be biphasic with initial symptoms caused by leptospiremia and later symptoms by host immune responses.

## CLINICAL FEATURES

The incubation period is probably from a few days to just under 3 weeks.

The clinical manifestations range through asymptomatic infection to multisystem disease. With clinical disease there is usually an abrupt onset of fever with several possible accompaniments:

1. muscular pains;
2. marked constitutional upset and hemorrhagic manifestations;
3. nephritic features usually without associated hypertension;
4. jaundice with or without hemorrhages;
5. jaundice with leukocytosis or a raised erythrocyte sedimentation rate (leukocytosis and a raised sedimentation rate are unusual in viral hepatitis);
6. meningitis with injected or hemorrhagic conjunctivae, or a lymphocytic meningitis with normal biochemical parameters: this syndrome is typically associated with *L. canicola* infection;
7. persistent fever lasting up to 3 or 4 weeks, perhaps without other signs;
8. jaundice with nephritis – Weil syndrome, usually caused by *L. icterohaemorrhagiae* infection in which renal failure is a common cause of death (in contrast most patients with viral hepatitis have a low or normal blood urea and present with gradual-onset malaise and fever which usually remits once jaundice is apparent).

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Blood cultures may be positive in early illness, but some *Leptospira* resist standard culture and the diagnosis has to be confirmed by dark ground microscopy or by serology. Usually reactive antibody becomes detectable after the first week of illness. Agglutination and complement fixation tests are often used. If there is a meningitic clinical picture the CSF is usually lymphocytic; the CSF biochemistry is often normal and CSF culture may be positive. Urine culture or dark ground microscopy may be positive once infection is established, and may remain positive for several weeks.

The differential diagnosis is very wide: if a zoonosis is suspected, Q fever and brucellosis are major contenders.

## TREATMENT

Eradication of noncommercial animals (such as rats) or reducing potential exposure to animal urine is ideal. *Leptospira* are sensitive to penicillin, tetracyclines (which are contraindicated in renal failure and which, depending on the severity of illness, are contraindicated in children) and erythromycin. Usually high doses are given for 10 days. Early treatment is essential as antibiotics will do little to alleviate the immune-mediated elements of the illness. Isolation of patients

is unnecessary as person-to-person spread is unlikely. Despite serious dysfunction of infected organs in acute illness, recovery is usually complete in survivors.

## LYME DISEASE

Lyme disease is a seasonal non-occupational bacterial zoonosis which is distributed throughout the temperate zones of the world.<sup>212</sup> It was first recognized in 1975 because of a geographic clustering of children with arthritis in Lyme, Connecticut.<sup>213</sup> It is now recognized that the causative agent is an arthropod-borne spirochete called *Borrelia burgdorferi* which is transmitted by the hard tick *Ixodes dammini* or related ixodid ticks depending on the geographical distribution, e.g. *Ixodes ricinus* is predominant in Europe.<sup>214</sup> The tick, which has a wide range of hosts (deer, cattle, sheep, mice, squirrels, dogs), appears to prefer the white-footed mouse and white-tailed deer. Birds are now also recognized as reservoirs.

The anatomical location of tick bites appears important. Patients bitten on the head and neck had significantly more neurological manifestations, perhaps explaining the higher frequency of neuroborreliosis among children compared with adults.<sup>215</sup>

The illness is a multisystem disorder, which consists of a prodromal febrile illness with the characteristic rash of erythema chronicum migrans (ECM) and associated symptoms. Without antibiotic treatment a substantial number of patients will go on to cardiac, neurological and rheumatological sequelae. However, progression from early to late stage is not inevitable, even in the absence of antibiotic treatment. 'Incomplete' cases with minimal or absent rash can occur, and patients may have aseptic meningitis, facial palsy, carditis or arthritis as the first sign of disease.

## ETIOLOGY AND VECTOR

In 1982 a previously unrecognized spirochete was isolated from *I. dammini* ticks that had been collected from Shelter Island, New York. This discovery was followed in 1983 by the successful culture of the spirochete named *B. burgdorferi* from patients with Lyme disease.

The main vector species are *I. ricinus* in Europe and the *I. scapularis* group in North America.<sup>216</sup> The life cycle of the tick consists of larval, nymphal and adult stages. The larvae and nymphs primarily feed on rodents such as the white-footed mouse, the natural reservoir for *I. dammini*. The adults usually feed on large mammals like deer, sheep and horses. Furthermore, the growth of the vector population is promoted by deer and fails to occur in their absence. The nymphal stage, whose peak questing period is May through July, is primarily responsible for transmission of disease. As these immature ticks feed aggressively on more animal species they facilitate rapid transmission of the organisms and often escape detection by the human host because they remain very small, even after a feed.

## EPIDEMIOLOGY

Lyme disease is the most common vector-borne disease among children with more cases in children than in adults. However, there is substantial regional variation in the incidence of Lyme disease although most cases appear to occur during the summer months. The estimated incidence in the USA in 1992 was 3.9 per 100 000 population with Connecticut having the highest incidence (53.6/100 000). These figures are undoubtedly underestimates as only a small proportion of cases are reported. In the UK, for example, the incidence of Lyme disease is not well documented although experience suggests that serious disease is not common. Children between the ages of 5 and 10 years appear to be at highest risk in endemic areas.

## PATHOGENESIS

In early Lyme disease the spirochete is injected into the bloodstream or skin through tick saliva. It may also be deposited in fecal material on

the skin, and from there the organism may invade the skin or blood. Following an incubation period of 3–32 days the organism migrates outwards in the skin to produce the classical immune-mediated lesion of ECM. It may also spread to the lymphatics or disseminate in the blood or organs such as the brain, heart or joints or to other sites to produce the secondary lesions of late stage disease. The propensity to produce damage of a specific target organ appears to be determined by a number of factors including genospecies of *Borrelia* isolate as well as host factors such as human leukocyte antigen (HLA) phenotype. For example, *B. afzelii* is more common in patients with mainly dermatological manifestations, whereas *B. garinii* is more often associated with neurological complications. Furthermore, arthritis, which is a more common presentation of early or late Lyme disease in Europe as opposed to ECM in North America, is more commonly seen in patients with HLA-DR4 and -DR2.<sup>217</sup> There is also some evidence that patients with severe and prolonged illness, especially neurological or joint disease, have an increased frequency of the B cell alloantigen HLA-DR2.<sup>218</sup>

## CLINICAL CHARACTERISTICS

Like other spirochetal infections the illness can occur in distinct stages which may overlap or occur alone without recalling earlier features.

### Early manifestations<sup>219</sup>

Up to one third of patients remember a tick bite which often leaves a nonspecific small red macule or papule. About 1 week later this area expands to the pathognomonic warm, painless, erythematous, annular lesion called ECM which reaches a maximum diameter of 15 cm (larger areas up to 70 cm have been reported) and usually has a bright red outer border. In the largest community-based prospective study reported in children, 89% of those studied presented with a single or multiple lesions of ECM.<sup>220</sup>

This lesion, which resolves within 4 weeks without therapy, can occur at any site although the thigh, groin and axilla are particularly common. Concomitant signs and symptoms include high fever (particularly in children), malaise, regional lymphadenopathy, meningism, myalgia and migratory arthralgias. Most of the early clinical features are characteristically intermittent and fluctuating during a period of several weeks, before spontaneous resolution occurs. About 10% of patients have features suggestive of anicteric hepatitis. Cellulitis secondary to an infected insect bite is a common misdiagnosis.

Two uncommon skin lesions, acrodermatitis chronica atrophicans and lymphadenosis benigna cutis, which are rare both in children and in North America, are regarded as specific late skin manifestations in Lyme disease.<sup>221</sup>

### Late manifestations

These manifestations occur some weeks to months after the initial infection and the clinical features are dependent on the organ affected and the severity of damage.

In about 10–40% of patients, frank *neurological abnormalities* usually occur weeks to months after infection. The classical triad of early neurological disease includes a lymphocytic meningitis, cranial neuropathy and radiculoneuritis. Neuroborreliosis in children most commonly presents as mild encephalopathy, lymphocytic meningitis and cranial neuropathy.<sup>222</sup> Radiculopathy, particularly in European children, and peripheral neuropathy, both of which occur late in the disease, are rare in children. Typically patients develop a fluctuating lymphocytic meningitis about 4 weeks after the onset of ECM often with superimposed cranial (especially facial) neuritis. Patients will have a CSF lymphocytic pleocytosis. Other less common neurological complications include ataxia, spastic paraparesis due to an acute myelitis, hemiparesis, optic neuritis, hydrocephalus, Guillain-Barré syndrome and a pseudotumor cerebri-like syndrome.

*Cardiac disease*, which is relatively uncommon in children, occurs roughly 5 weeks after the tick bite. The disease spectrum includes myocarditis, cardiomegaly, left ventricular dysfunction and especially

fluctuating degrees of atrioventricular block, which may progress to complete heart block. The latter may require temporary pacing. The duration of cardiac involvement is usually brief (3 days to 6 weeks) and self-limiting. The clinical features show similarities to rheumatic fever although valvular involvement has not been reported.

*Arthritis* is a common late sequela of Lyme disease occurring in up to 60% of patients within a few weeks to 2 years after the onset of illness; 20–40% of patients do not remember having ECM. The spectrum of Lyme arthritis ranges from subjective joint pains which are often migratory, to intermittent attacks of arthritis to chronic erosive disease (10%).<sup>223</sup> The commonest pattern of joint involvement is an acute asymmetric mono- or oligoarticular arthritis primarily affecting the large joints. Most commonly (>90%) involved is the knee joint and the child typically presents with subacute effusion of the knee. The attacks of arthritis typically last for a few weeks to months and recur intermittently over several years. Fatigue is the commonest associated non-articular symptom, whereas fever or other systemic symptoms are unusual.

Numerous other rare manifestations have been associated with Lyme disease. These include ophthalmic complications (conjunctivitis, episcleritis, photophobia, uveitis), hepatitis, hepatosplenomegaly and testicular swelling. There is no clear evidence that *B. burgdorferi* causes congenital disease, although the existence of this rare syndrome cannot be ruled out.<sup>224</sup> Furthermore, transmission of Lyme disease in breast milk has not been documented.

## DIAGNOSIS

The diagnosis is not always easy, given that symptoms may be nonspecific and serology may be misleading.<sup>225</sup> The hallmark for confirming the diagnosis is to obtain appropriate fluid or tissue for culture. Such tests are unlikely to be of value in everyday clinical practice and future diagnostic tests such as polymerase chain reaction (PCR) have not yet been adequately tested. Therefore, the diagnostic tests used most frequently are serological and detect antibodies against *B. burgdorferi*. The most commonly used of these tests, which is now widely available as a pre-packed commercial kit, is the enzyme linked immunosorbent assay (ELISA). Unfortunately, this test yields many false positive reactions with other spirochetal infections, connective tissue diseases and certain viral infections.<sup>224</sup> There is also cross-reactivity with antigens of spirochetes belonging to the normal flora. The immunoblotting technique currently offers the best means of validating a positive or equivocal ELISA in a patient with a low likelihood of Lyme, although this test is not widely available and its proper interpretation is as yet unclear.<sup>226</sup>

Currently the diagnosis of early Lyme disease, especially in the presence of skin lesions, is made on clinical and epidemiological grounds since serology (*B. burgdorferi* IgM) does not usually become positive until 3–6 weeks after the onset of the erythema migrans. Also, the antibody response may be aborted in patients with early Lyme who are treated promptly with an effective antimicrobial agent. The specific IgG antibody rises slowly and may not reach a level of diagnostic significance in early disease. It usually peaks months or years later, often when arthritis is present, and can persist for many years despite adequate treatment or cure. Furthermore, a substantial proportion of people who become infected by *B. burgdorferi* never have a clinical illness but have positive serology. Serological testing is not necessary for diagnosing typical ECM but is helpful in untreated atypical skin lesions, patients with acute meningitis, neuropathies and arthritis due to Lyme. The negative and positive predictive values of currently available serological tests are very much dependent on the pretest likelihood that a patient has Lyme disease. For example, a patient with ECM who lives in an endemic area has a very high probability of having Lyme even if the serological test is negative. Conversely, a patient with vague nonspecific symptoms with a positive test is unlikely to have Lyme despite positive serology. Therefore, serological tests should not be used on patients with nonspecific symptoms but clinicians should order serological tests for Lyme disease in selected groups such as those with clinical findings suggestive of Lyme

or in highly prevalent areas so that the predictive value of the test is high.<sup>224</sup>

Notably the predictive value of positive serology in patients with erythema chronicum migrans as a single manifestation of Lyme disease is low.<sup>227</sup>

Patients reported to have Lyme disease who did not meet the United States Centers for Disease Control and Prevention (CDC) case definitions had increased symptoms and worsening quality of life indices, the implication being that such patients did not have Lyme disease.<sup>228</sup> A consensus paper noted that the risks of intravenous antibiotics in patients with nonspecific complaints outweighed potential benefits.<sup>229</sup>

The differential diagnosis is wide but includes other tick-borne diseases including ehrlichiosis and babesiosis.

## TREATMENT

Since no clinical trials of treatment have been performed in children the recommendations for treatment have been extrapolated from adult studies.<sup>230,231</sup> Doxycycline 2.5 mg/kg (max 100 mg) orally, 12-hourly for 14–21 days is the oral antibiotic of choice for children 8 years or older. For younger children, amoxicillin 25 mg/kg orally, 12-hourly for 14–21 days, is recommended. Ceftriaxone 75–100 mg/kg, IM, once daily is recommended for persistent or recurrent arthritis and either ceftriaxone or benzylpenicillin 50 000 U/kg IV, 4-hourly for carditis, meningitis or encephalitis. Lyme disease will respond well to antibiotic therapy if treated early, shortening the duration of illness and reducing the incidence of complications. The long term prognosis for this group as well as those treated for late Lyme disease is excellent.

## PREVENTION

Acquisition of Lyme borreliosis can be reduced by simple practical methods such as wearing long trousers, tucking trousers into socks, wearing boots, promptly removing any attached ticks and impregnating clothes with DEET or permethrin. A vaccine is currently under development.

## BACTERIAL INFECTIONS: MENINGOCOCCEMIA

Despite the recent introduction of an effective vaccine against group C organisms in the UK, *Neisseria meningitidis* is still the most frequent cause of septicemia in childhood, and affects otherwise healthy children of all ages after the neonatal period. In the UK, there are over 1200 microbiologically confirmed cases a year (Statutory Notifications of Infectious Diseases 1995–2006)<sup>232</sup> and probably double that number diagnosed on clinical grounds alone. About 50% will have meningitis. In the last decade, wider public awareness, better diagnosis and intensive care have improved the outcome, but mortality is still between 5 and 10%.

*N. meningitidis* is a Gram negative diplococcus which is surrounded by an outer polysaccharide capsule, an outer membrane and an underlying peptidoglycan layer. Pili or fimbriae extend through the capsule and are thought to play a role in the attachment to epithelial cells within the nasopharynx. Between 2 and 10% of the general population are colonized, but carriage rates may be much higher in outbreaks. The precise relationship between carriage and invasive disease remains unclear. Spread is predominantly by respiratory droplets from close contacts.

In Western Europe, the group B organism is still the most commonly isolated strain but is closely followed by group C organisms. In the UK, the introduction of a group C conjugate vaccine has reduced the rate of group C infections in the younger age group dramatically. Group A organisms have been responsible for large epidemics, particularly in sub-Saharan Africa, and another serogroup, W135, has caused a number of infections in pilgrims returning from the Hajj.

In spite of high colonization rates, only a relatively small number of colonized individuals develop invasive disease. Progression from nasal carriage to bacteremia is thought to be influenced by both bacterial and host factors. Certain bacterial properties, such as the presence of a capsule, pili and lipopolysaccharide (LPS) structure are known to be

associated with invasive disease. There are also some data to indicate that smoking, respiratory tract infections and mucosal injury may aid colonization. However, the most important host factor predisposing individuals to this infection is the presence of defects within the complement cascade. Deficiencies of terminal complement components C5–C9, properdin and mannose-binding lectin all lead to an increased incidence of disease, and sometimes recurrent disease.

Having gained access to the circulation, bacterial components including LPS cause a host inflammatory response with the release of pro-inflammatory mediators such as tumor necrosis factor, IL-1, IL-6 and IL-8. These cytokines influence a number of cellular and non-cellular functions including neutrophil, monocyte and endothelial cell activation, thrombotic and hemostatic pathway imbalance and complement activation. In addition, the organism can bind to vascular endothelial cells inducing adhesion molecule expression, with consequent leukocyte attachment and migration. Uninterrupted, this intense inflammatory process leads to tissue injury and ultimately to multiple organ failure and death.<sup>233</sup>

## CLINICAL FINDINGS

There are two major clinical presentations of meningococcal disease: meningitis and septicemia. A proportion of patients will have evidence of sepsis and meningitis. Once in the bloodstream, however, *N. meningitidis* can localize to other sites including joints, bones, eyes and heart. Most deaths occur in the predominantly septicemic form of the disease. The presence of meningitis is a good prognostic indicator, and may indicate that host defenses have contained the infection long enough for the bacteria to invade the blood–brain barrier. Sepsis commonly presents with nonspecific symptoms of fever, vomiting, abdominal pain and muscle aches. These patients may also have a characteristic rash, which can occur anywhere and may be purpuric or morbilliform (Fig. 28.17). The extent of the inflammatory response will influence other signs of sepsis or septic shock. In the early stages, fever, tachycardia and tachypnea may be present with the rash. Later, signs of shock develop, with poor peripheral perfusion, hypotension and oliguria. These are generally accompanied by an extensive purpuric rash and evidence of disseminated intravascular coagulopathy (DIC) (Fig. 28.16). Recent evidence indicates that polymorphisms within the cytokine and hemostatic/thrombotic pathways can influence the severity of this disease. Hemorrhage into internal organs may occur. Classically, this involves the adrenal glands in the Waterhouse–Friderichsen syndrome. In those who recover, skin necrosis or vascular occlusion may cause the loss of an extremity, though most small lesions heal with minimal scarring.

The predominantly meningitic form of the disease presents with symptoms and signs of meningitis with fever, vomiting, headache and neck stiffness. Patients with meningitis may develop convulsions, focal neurological signs, a depressed level of consciousness, coma and death due to raised intracranial pressure (see Suspected meningitis). As the organism gains access to the central nervous system (CNS) from the blood, the petechial rash may be present and helpful in the diagnosis.

Arthritis, pericarditis and pleural effusions may occur as autoimmune phenomena 5–10 days after the acute infection. This is due to immune complex formation and is self-limiting, although a large pericardial effusion may cause cardiac tamponade. A rare chronic form of meningococcal sepsis can occur and is characterized by anorexia, weight loss, fever, arthralgia or arthritis and skin rash; erythema nodosum or bacterial endocarditis may also occur.

In the differential diagnosis, other bacterial and viral infections which cause purpura must be considered. Anaphylactoid purpura and idiopathic thrombocytopenic purpura may cause similar purpuric rashes. A morbilliform rash may be confused with a drug eruption or a number of viral infections including measles. Subacute or chronic meningococemia presents a greater challenge. The differential diagnosis includes the many causes of arthritis and fever in children. However, a petechial rash in a febrile child should be considered as suggestive of meningococcal disease until proved otherwise.

## LABORATORY INVESTIGATION

The diagnosis is established by recovery of *N. meningitidis* from the blood, petechial lesions or the CSF, but lumbar puncture is contraindicated in the presence of shock, coagulopathy, reduced conscious level or focal neurological signs. The practice of giving penicillin before hospital admission to patients in whom meningococcal infection is suspected, which has saved lives, has also decreased successful culture of the organism. In these situations, meningococcal DNA may still be detected by polymerase chain reaction (PCR) in blood and CSF. Serology may confirm the clinical diagnosis retrospectively. The complete blood count may show a polymorphonuclear leukocytosis. Neutropenia is invariably present in severe disease, however, and indicates a poor prognosis (see below). There is usually also evidence of DIC with thrombocytopenia, a coagulopathy and intravascular fibrin and thrombosis within dermal vessels. The importance of platelets and neutrophils in this disease is highlighted in a number of studies, which show that reduced circulating numbers of both cell types is correlated with a worse outcome.

## TREATMENT

The most important aspect of meningococcal disease management is recognition. Recent work has shown that the classical signs of meningococcal disease with rash and meningism occur relatively late, 13–22 h after onset of illness. Early signs of disease include leg pains, cold hands and feet and pallor or mottling.<sup>234</sup> It is essential for the disease to be recognized early because, as with other forms of bacterial sepsis, bacterial load is critical, with higher bacterial concentrations leading to a more severe inflammatory response and organ dysfunction.<sup>235</sup> In patients with little capacity to limit bacterial growth within blood, a single bacterium may proliferate to more than a million organisms in under 8 h. Most deaths occur in patients with a bacterial load of more than a million organisms/ml. Early intervention with antibiotics will rapidly arrest bacterial growth and reduce levels of circulating LPS and other bacterial components. A third generation cephalosporin, such as cefotaxime or ceftriaxone, has become the standard therapy for the initial treatment of suspected meningococcal disease. Once the organism is isolated and sensitivity determined, penicillin can be used in the majority of cases. It is recommended that family doctors who see a patient with suspected meningococcal infection in the home give a dose of intramuscular penicillin immediately. Some recent data suggest that this course of action is associated with a higher mortality, but this is probably because primary care physicians administer penicillin to the sickest children.

In shocked children, vigorous resuscitation is required. Volume expansion with plasma and/or 4.5% albumin (20 ml/kg and repeat as required) is the crucial first step. Emergency transfer to the regional intensive care unit is usually advisable as inotropic and vasopressor agents, artificial ventilation and hematological support are frequently required (see section on sepsis). In very severe disease, extracorporeal membrane oxygenation may be life saving.

New therapies, which alter the immune response or inflammatory cascade, are under investigation at present, but no such agents have been shown to be effective to date. However, as in other forms of sepsis (see section on sepsis), corticosteroids, endotoxin and inflammatory modulation, activated protein C administration and endocrine manipulation may prove beneficial in the future.

## PROPHYLAXIS

Prophylaxis against invasive disease should be given to the family and close contacts of the patient. Rifampicin, given in 4 doses over 2 days, has been shown to be effective in clearing the organism. A single injection of ceftriaxone, or an oral dose of ciprofloxacin, are appropriate alternatives.

In the UK, a conjugate meningococcal C vaccine has now been introduced with evidence of a marked decline in this organism in vaccinated individuals. Polysaccharide vaccines are available for *N. meningitidis* groups A, C, Y and W135 for patients traveling to endemic areas. Trials continue on vaccines against *N. meningitidis* group B.

## PROGNOSIS

The mortality from acute meningococemia remains high at between 5 and 10%, most deaths occurring in patients with very high bacterial loads. Early recognition is the key to improved outcome. Survivors may suffer extensive tissue injury, sometimes requiring amputation and/or skin grafting. A number of prognostic scores have been developed, the most frequently quoted being the Glasgow meningococcal septicemia prognostic score. This is predominantly based upon clinical parameters such as blood pressure and coma, but as supportive care has improved, this score may no longer accurately identify patients at greatest risk of mortality. Other scores have now been developed which revolve around hematological parameters, and a simple score based on the product of the initial platelet and neutrophil count has been shown to be a better prognostic guide to mortality. This score may help to identify those patients at whom novel therapeutic agents should be targeted.<sup>236</sup>

## BACTERIAL INFECTIONS: MYCOBACTERIUM TUBERCULOSIS

In technically advanced countries, morbidity and mortality from tuberculosis have declined progressively over the decades. This is associated with improved living conditions and medical care, particularly case finding and chemotherapy. However, it is still an important problem, especially in immigrant and minority groups. In some resource limited countries, the case rate has hardly changed and any decline is offset by an increase in population.

The majority of children infected by *M. tuberculosis* are asymptomatic. However, in a small number, especially young children, the disease is serious or fatal, due to meningitis or disseminated disease, and survivors may be left with sequelae such as cerebral palsy, mental retardation or chronic lung or bone and joint disease.

## MICROBIOLOGY

The 'tubercle bacillus' was first described by Robert Koch in 1882 and is now called *Mycobacterium tuberculosis*. Mycobacteria derive their name from their mold-like appearance on culture. One of their unique characteristics is a highly complex, lipid-rich cell wall which protects the bacillus from digestion by the lysosomal enzymes of macrophages and which, when stained, resists decolorization by acid alcohol. Like *Mycobacterium leprae*, but different from other mycobacteria, *M. tuberculosis* is an obligate parasite with total dependence on the living host.

The two major species of mycobacteria infecting man are *M. tuberculosis* and *M. bovis*. *M. bovis* differs from the other types in its resistance to pyrazinamide. *M. tuberculosis* is aerophilic but *M. bovis* is micro-aerophilic (prefers reduced oxygen tension). Within the host, mycobacteria may lie dormant for many years.

*M. tuberculosis* is cultured on Lowenstein-Jensen medium and is slow growing, taking an average time of 21 days, and occasionally 1–2 months or longer. Growth of *M. tuberculosis* may be detected in 7–10 days using liquid culture media, e.g. the BACTEC radiometric or Roche biphasic systems.

There are two major methods for direct identification in specimens: Ziehl-Neelsen stain and fluorescence microscopy with auramine-rhodamine stain. The latter is the more rapid, more sensitive and more specific.

A number of serological tests have been developed using purified protein derivatives of *M. tuberculosis* in enzyme linked immunosorbent assay (ELISA) or solid-phase radioimmunoassays. However, many lack sensitivity and specificity, especially for culture-negative cases, and thus are not used for routine laboratory diagnosis.<sup>237</sup> Tests for antigen in CSF are useful, but not routinely available. Gene probes can identify mycobacteria rapidly once they have grown in culture. In adults, nucleic acid amplification (NAA) has sensitivity >90% and specificity 98% for smear positive respiratory specimens, but only 50–70% sensitivity for smear negative specimens.<sup>238</sup> Sensitivity for nonrespiratory specimens,

particularly CSF, is lower than for respiratory specimens. This is partly due to inhibitors especially in pleural, ascitic and CSF specimens. There are few studies in children and they are limited by numbers of confirmed or probable cases of tuberculosis.<sup>239,240</sup> Sensitivities for polymerase chain reaction (PCR) in gastric aspirates in children with confirmed or clinical pulmonary tuberculosis vary from 40 to 80% and generally are higher than culture. Sensitivity is increased by testing multiple samples. Specificity is reported to be 94–100%, although PCR may be positive in a third of children with tuberculous infection only. Sensitivities are no higher in bronchoalveolar lavage (BAL) than in gastric aspirates. PCR can differentiate between *M. tuberculosis* and environmental mycobacteria and PCR methods are available to detect rifampicin resistance. DNA fingerprinting is a valuable tool in studying transmission of tuberculosis.

## EPIDEMIOLOGY

In studies of tuberculosis, differentiation has to be made between tuberculous infection (as evidenced by a positive tuberculin test) and disease. In tuberculous disease there is clinical, radiological or bacteriological evidence of infection. The great majority of infected people remain asymptomatic. In England and Wales in 1949–1950, a national survey showed that nearly half of 14-year-old children were tuberculin positive. Today, less than 1% of 11–13-year-old children are tuberculin positive at routine school examination.

Three quarters of tuberculosis cases occur in resource limited countries where 0.2–1% of the population are expectorating the tubercle bacillus. A rise in case rates in adults and children has been observed in countries with a high prevalence of HIV infection, especially sub-Saharan Africa.<sup>241</sup>

In technically advanced countries, with a low prevalence of smear positive cases, the infection rate in children will be low and the majority of adults with tuberculosis will have endogenous reactivation. Conversely, in resource limited countries, the high prevalence of smear positive cases will result in a significant proportion of children and young adults developing primary tuberculosis, and exogenous reinfection in older adults will be common. Children under 14 years may comprise up to 20% of case load in the Indian subcontinent, 39% in South Africa and 5% in the United States.<sup>241,242</sup>

National surveys for England and Wales for the periods 1978–1979, 1983, 1988, 1993 and 1998 found 747 (estimate based on 6 month survey), 452, 308, 408 and 364 newly notified children under 15 years respectively.<sup>243</sup> In 1998, rates (per 100 000) for children were highest for black African (70.6) and Indian subcontinent (23.1) compared to black Caribbean (9.0) and white (1.1) groups. Although rates for the Chinese group were high (82.1), cases were low (14).

The decline in the incidence of tuberculosis began in Europe before the introduction of BCG and chemotherapy. In the decade 1979–1988 there was an average reduction in notification rates in England of 7.2% per year. However, since 1988 there has been a 21% rise in notifications, with the highest increase in the London area. In the 1998 survey, 49% of children with tuberculosis were resident in London, 44% of whom were born abroad, compared to 10% resident elsewhere.<sup>243</sup> There has also been a rise in notifications in parts of Europe and the USA. Factors associated with the rise in notifications in the USA since 1987 include HIV infection, homelessness, immigration and decline in resources for tuberculosis control. The increase is focal, mainly confined to inner cities, and 80% of childhood cases are in minority ethnic groups. Multidrug resistance is a major problem. However, with increased support for tuberculosis control, the rise in cases has reversed. In the period 1993–2003 the incidence decreased by 44%.<sup>244</sup>

Most cases of tuberculosis are caused by *M. tuberculosis*. *M. bovis*, which was an important cause of tuberculosis of the gastrointestinal tract, lymph nodes and bones, has virtually disappeared from technically advanced countries through eradication of tuberculosis in cattle and pasteurization of milk. In the UK before 1950, *M. bovis* was the cause of 33% of childhood and 10% of adult extrapulmonary disease.

However, there has been a recent increase in tuberculosis in cattle which is considered to be related to infection in badgers.<sup>245</sup> *M. bovis* infection is also an uncommon cause of tuberculosis in resource limited countries, except in communities where large amounts of raw milk are consumed, when it commonly presents with cervical adenitis. In the UK, it is still isolated from reactivated lesions in approximately 1% of adults.<sup>245</sup> *M. bovis* is resistant to pyrazinamide.

## PATHOLOGY

The pathology of tuberculosis has been described by Miller.<sup>246</sup> The first response to the presence of the tubercle bacilli at the point of entry and in the regional nodes is a serous exudate. Neutrophils accumulate, then macrophages which ingest the bacilli and may be transformed into epithelioid cells, which contain more effective digestive enzymes in their lysosomes. Fusion of either macrophages or epithelioid cells forms characteristic multinucleate giant cells. Death of cells in the center of the tubercle (granuloma) results in caseation necrosis. Lymphocytes form a zone around the tubercle and are particularly apparent during the second month of infection, which coincides with the development of tuberculin sensitivity. Healing takes place with the deposition of collagen fibrils by fibroblasts, which wall off the caseous area from healthy tissue. After 12 months or more, calcification may be seen, which remains for years but may be completely reabsorbed. It usually has a stippled appearance. Alternatively, healing may not occur, or the tubercle-containing dormant bacilli may reactivate after months or years. Extensive necrosis with caseation and liquefaction may develop. Liquefaction allows bacilli to survive, inhibits macrophage and lymphocyte function because of lack of oxygen, and prevents drug penetration. Activity and healing of the lesion may occur concurrently.

## IMMUNOLOGY

The main defense against infection by the tubercle bacillus is cell mediated. The role of B cells is unclear.

Tubercle bacilli are readily ingested, but are not killed by macrophages, in which they multiply. Toxic substances and other properties in the lipid-thick cell wall protect the bacillus against lysosomal enzymes. CD4 T lymphocytes (T helper cells), when sensitized by tubercle bacilli, produce cytokines which activate macrophages and CD8 cytotoxic T lymphocytes (CTL). CTLs lyse cells containing mycobacteria and enable macrophages to kill their ingested bacilli. The positive effect of T helper cells may be countered by suppressor activity. In advanced disease or in the presence of a large bacterial load these suppressor effects may predominate, which may explain the anergy commonly seen in these children.

Defense against tuberculosis has two major components: (1) cell-mediated immunity (CMI) controls the infection by activating macrophages which enables them to kill ingested mycobacteria, and (2) delayed type hypersensitivity (DTH) is active when the bacillary antigens reach high levels.<sup>247</sup> DTH is responsible for the tissue damage and caseation necrosis characteristic of post-primary tuberculous disease. There is no correlation between the degree of hypersensitivity and resistance to tuberculosis. The balance between hypersensitivity and resistance will influence the manifestation of tuberculosis, i.e. the former will be associated with clinical and radiological signs of the disease, whereas with the latter there will be a paucity of signs. Improved knowledge of T helper cells has enhanced understanding of the above mechanisms.<sup>248</sup> Three types of T helper cells are recognized: T<sub>H</sub>0 (naive cells), T<sub>H</sub>1 and T<sub>H</sub>2. T<sub>H</sub>0 cells differentiate into T<sub>H</sub>1 cells or T<sub>H</sub>2 cells. T<sub>H</sub>1 lymphocytes secrete IL-2, interferon-gamma (IFN-gamma) and lymphotoxin-alpha and stimulate type 1 immunity, which is pro-inflammatory and characterized by phagocytic activity and DTH. IFN-gamma and lymphotoxin-alpha promote secretion of pro-inflammatory cytokines such as tumor necrosis factor-alpha (TNF-alpha). T<sub>H</sub>2 cells secrete interleukins such as IL-4 and IL-5, which promote eosinophils and IgE and stimulate a more allergic type 2 immune response. The immunological reactions to tuberculosis

are not as clearcut in humans as in mice (in which most experimental work has been undertaken), nor as in leprosy. It would seem, however, that in humans a type 1 response is important in protective inflammation and mounting a DTH response, and a switch to a type 2 response is associated with the period of healing and granuloma organization. High or prolonged type 1 activity may result in excessive DTH reactions and tissue destruction, associated with raised IFN-gamma and TNF-alpha levels. Conversely, failure to control infection, as in immunocompromised patients, is associated with increased type 2 activity. It is suggested that, in humans, excessive tissue destruction may relate to mixed  $T_H1/T_H2$  response whereby a factor produced by type 2 cells makes tissues very sensitive to TNF-alpha.<sup>249</sup> Other important factors include transforming growth factor beta (TGF-beta) produced by mononuclear phagocytes, which may have negative effects on  $T_H1$  activity and 1,25 (OH)<sub>2</sub> vitamin D<sub>3</sub> which appears important for action of macrophages in controlling intracellular mycobacterial replication.

A number of primary factors influence the outcome of the immune response, including the number of inhaled bacilli, their virulence and the immune response by the host. These are affected by secondary factors, e.g. age of the patient, infections such as measles, malnutrition, malignancy and immunodeficiency states. Children under 5 years and adolescents (especially females) are at higher risk of developing tuberculous disease.

**PATHOGENESIS**

The first infection by tubercle bacillus occurs most commonly by inhalation through the lungs, less often by ingestion through the alimentary tract (tonsils and ileum), and rarely by infection of an open wound on the skin. Infection of the mouth, skin and eyes may result from exposure to a dental surgeon with pulmonary tuberculosis. Enlargement of the regional lymph nodes provides an indication of the site of primary focus.

**Primary infection**

The primary focus in the lung is usually single and situated just under the pleura (Ghon focus) in a well-ventilated part of the lung. Bacilli multiply at the primary focus and in the regional lymph nodes. The primary focus and nodes form the primary complex. In most cases there is hematogenous and lymphatic dissemination throughout the body and to other parts of the lungs. Certain organs favor survival of the bacilli and these may later be affected by disease, e.g. apical and subapical regions of the lungs (Simon focus), where there is a higher oxygen tension, renal parenchyma, epiphyseal lines of bones, cerebral cortex and regional nodes. At about 4–8 weeks, acquired immunity develops and usually contains the infection; sensitivity to tuberculo-protein develops simultaneously. Bacilli stop multiplying and, in the great majority of cases, die or remain dormant indefinitely within the healing tubercle or macrophages. Tubercles, especially if large and apical or subapical, may reactivate at any time in life, if the balance between the organism and the host defense is upset.

In children, the primary focus in the lung is usually small or invisible on chest X-ray, but the regional nodes are enlarged and prominent. In contrast, regional nodes are usually not prominent in primary infection in adults.

The initial infection is usually asymptomatic. Occasionally a short period of fever and malaise may have been noted. Erythema nodosum may appear within a few weeks of the primary infection, coinciding with tuberculin conversion. It is an allergic hypersensitivity reaction, which may be associated with high levels of circulating immune complexes. Phlyctenular conjunctivitis is another, though rare, manifestation of hypersensitivity.

If the infecting load of bacilli is large or the host defense inadequate there may be (Fig. 28.23):

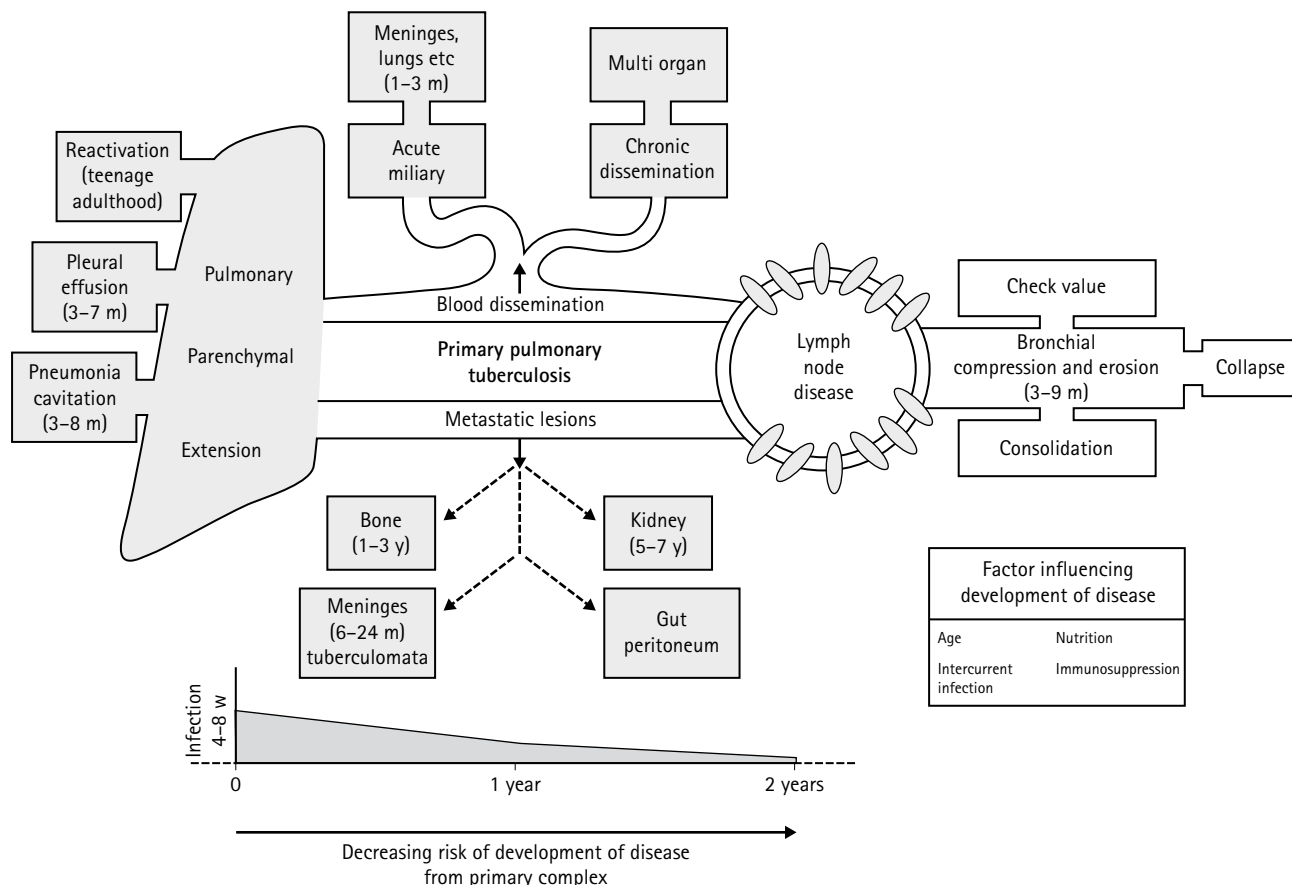

Fig. 28.23 Complications of primary pulmonary tuberculosis. Approximate interval between establishment of primary complex and development of complications in parentheses.

1. extension of the lung focus;
2. softening of the regional nodes;
3. extension of foci in other parts of the body;
4. hematogenous spread with dissemination of bacilli throughout the body (miliary tuberculosis), or chronic low grade dissemination (cryptogenic tuberculosis).

In a newly infected person the risk of developing tuberculous disease is highest in the first 2 years following a primary infection (especially in the first year). The risk is greater in infants and young children and those with malnutrition or immunosuppression. Infants have a risk of 40% or more of developing disease compared with 5% for adults. Pulmonary disease, miliary tuberculosis and meningitis are usually manifest within 1 year of infection, especially in young children, whereas bone disease presents later (within 3 years), and renal disease usually much later (over 5–7 years).

### Post-primary tuberculosis

Post-primary tuberculosis occurs when a person who has previously had tuberculosis develops active disease. Post-primary tuberculosis can develop from endogenous reactivation of a primary lesion, from exogenous reinfection or both. Though sometimes termed 'adult'-type pulmonary tuberculosis, it may be seen in children.<sup>246</sup> It is characterized by strong resistance, which keeps the disease localized to the affected organ, and an active hypersensitivity state, which results in extensive tissue destruction and necrosis. The tubercle bacillus may have reached the area through blood spread following primary infection or via the airways in exogenous reinfection. For the latter, as the apices are not well ventilated, multiple exposure will usually be necessary.<sup>250</sup> It affects particularly the apical regions of the lungs, where the oxygen tension is higher. There is widespread caseation necrosis, liquefaction with cavity formation and healing by fibrosis.

### TUBERCULIN SENSITIVITY

The intradermal tuberculin test using old tuberculin was described by Charles Mantoux in 1908. A positive response results in induration within 72 h, associated with migration of activated lymphocytes and macrophages to the site of injection.

Purified protein derivative (PPD)-S 5IU is the standard strength in many countries. PPD RT 23 Statens Serum Institute (SSI), Copenhagen is administered at a strength of 2 tuberculin units (TU). Induration of  $\geq 6$  mm with RT 23 is regarded as positive. Because the active principle of RT 23 adheres to glass walls of containers, Tween 80 is added to reduce absorption. This multiplies the strength by a factor of 4–5. Weaker and stronger products are available. In phlyctenular conjunctivitis or tuberculosis of the eye it is suggested to use a weaker strength initially as a stronger solution may result in a severe eye reaction. Stronger solutions, e.g. 10TU, are rarely indicated as they may give false positive reactions with environmental mycobacterial infections.

### Technique of tuberculin test

The skin is cleaned and dried, and the injection given *intradermally* into the upper third of the flexor surface of the forearm (Mantoux test) with a 1 ml syringe and a small needle (short bevel gauge 25–26) producing a wheal of at least 5 mm (see BCG technique). The result should be read at 48–72 h, but a valid result may be obtained at up to 96 h. In strongly tuberculin positive subjects, a wheal may appear within 24 h. Rarely, lymphangitis or a systemic reaction may develop following the tuberculin test. If necrosis and ulceration develop, local hydrocortisone ointment may relieve the discomfort.

### Interpretation

The transverse diameter of induration is measured. In older children and adults, an indurated wheal of 5 mm or less is regarded as negative, 6–9 mm is likely to be associated with infection by environmental mycobacteria, and 10 mm or greater is indicative of infection by *M. tuberculosis*, unless the person has received BCG recently. In infants

and young children with clinical evidence suggestive of tuberculosis, those with malnutrition or immunosuppression or in close contact with a case, an intermediate reaction of 6–9 mm should be considered positive. After BCG, the tuberculin response is usually less than 15 mm. A tuberculin reaction of 15 mm or greater in any child is suggestive of sensitivity to *M. tuberculosis*. Where there is doubt about interpretation of the tuberculin reaction, an IFN-gamma assay should be undertaken.

A negative or weak response in the presence of tuberculosis may occur in the following conditions: 6–10 weeks after onset of infection, but before tuberculin sensitivity has developed; malnutrition; miliary or overwhelming tuberculosis; nonrespiratory disease, especially tuberculous meningitis; tuberculosis in infants less than 6 weeks of age; recent viral infections such as measles and glandular fever, or whooping cough; recent immunization (within 6 weeks) against measles, mumps and rubella; immunosuppressive diseases including HIV, malignancy, and other debilitating diseases; and current treatment with immunosuppressive agents (including corticosteroids). In resource limited countries the tuberculin test is often negative in children with tuberculosis, probably owing to immunosuppression due to malnutrition, HIV infection and/or overwhelming disease.

When the tuberculin test is negative in children with tuberculosis due to malnutrition, overwhelming infection or other causes, if it is repeated some months after treatment when the general condition of the patient has improved, it will usually be positive. However, a small proportion of children with culture-proven tuberculosis (perhaps 5%) are consistently negative, despite the absence of adverse factors such as malnutrition, overwhelming tuberculosis or other infections.<sup>251</sup> In children infected by *M. tuberculosis* (and those given BCG), tuberculin sensitivity may revert to negative over some years, particularly in those in whom there was not a strong initial reaction or who have had prompt treatment. This does not necessarily imply that they are not protected from reinfection. Repeated administration of tuberculin in subjects sensitized by BCG or tuberculosis may enhance tuberculin sensitivity (booster phenomenon).

### Multiple puncture techniques

Multiple puncture tests such as the Heaf test are used to screen large numbers of children. Other tests include the Tine and Imotest. The Heaf test is the most reliable, but all doubtful reactions following multiple puncture techniques should be confirmed by a Mantoux test. The Heaf test was discontinued in the UK in 2005.

### Interferon-gamma assays

IFN-gamma assays are based on antigens encoded by genes located within the region of difference 1 (RD1) of the *M. tuberculosis* genome, e.g. early secretory antigenic target 6 (ESAT6) and culture filtrate protein 10 (CFP10). Neither ESAT6 nor CFP10 is present in BCG strains or in most environmental mycobacteria.

Presently there are two commercial IFN-gamma assays, the QuantiFERON-TB Gold and T SPOT-TB assays. Both measure IFN-gamma released from T cells sensitized when they are exposed to ESAT6 and/or CFP10. The former is an ELISA and the latter an enzyme-linked immunospot (ELISPOT) assay. IFN-gamma assays have similar or higher sensitivity than the tuberculin test.<sup>252</sup> A study in South African children which included those with HIV infection and severe malnutrition found that the ELISPOT had a higher sensitivity than the tuberculin test.<sup>253</sup>

The main advantage of IFN-gamma assays over the tuberculin test is the higher specificity due to lack of cross-reactivity with BCG and environmental mycobacteria and likely higher sensitivity in children with HIV infection and malnutrition.

### BCG VACCINATION

BCG vaccine is an attenuated bovine strain of mycobacteria introduced by Calmette and Guérin in France in 1921 and originally given orally. It was first used in Sweden in 1927 and in England in 1948.

After intradermal injection of BCG, there is dissemination of small numbers of bacilli to internal organs, particularly the liver and lungs, where granulomata develop. BCG sensitizes individuals so that when they are infected by *M. tuberculosis* multiplication of bacteria is curtailed and a granuloma develops quickly which walls off the infection. Systemic hematogenous dissemination is reduced, as also is secondary infection of the lung either from local extension of lesions or seeding from the blood. BCG vaccination does not prevent tuberculous infection; it particularly reduces the risk of meningitis and disseminated disease (and death), and, to a lesser extent, pulmonary disease.

## Indications

In the UK, BCG vaccination is recommended for the following groups:<sup>254</sup>

1. all neonates and infants (0–12 months) living in areas where the incidence of tuberculosis is greater than 40 per 100 000;
2. neonates, infants and children under 16 years with a parent or grandparent born in a country with an incidence of tuberculosis greater than 40 per 100 000;
3. previously unvaccinated new immigrants aged under 35 years who were born in, or lived for more than 3 months in a country with an incidence of tuberculosis greater than 40 per 100 000;
4. contacts of those with respiratory tuberculosis;
5. individuals at occupational risk aged under 35 years including health care workers and laboratory staff who are likely to have contact with patients, clinical materials or derived isolates, veterinary and other staff who handle animal species susceptible to tuberculosis, and staff working directly with prisoners, in care homes for the elderly, or in hostels or facilities for the homeless or refugees;
6. individuals aged under 35 years intending to live or work with local people for more than 1 month in a country with an incidence of tuberculosis greater than 40 per 100 000.

## Contraindications

BCG vaccination is contraindicated in patients with immunosuppressive disorders or malignancy, those receiving corticosteroids or immunosuppressive treatment, and in generalized infective conditions. If eczema exists, vaccination should be given in an area free from skin lesions. An interval of 3 weeks should be allowed between administration of BCG vaccine and other live vaccines, with the exception of oral polio vaccine. BCG vaccination is not given to tuberculin positive subjects

The recommendations for BCG vaccination of infants born to mothers infected by HIV vary according to the prevalence of tuberculosis. In industrialized countries, BCG is contraindicated in infants suspected of HIV infection. In countries where both HIV infection and tuberculosis are endemic, routine BCG immunization of newborns is recommended. However, in resource limited countries where neonatal BCG is routine, a small proportion of recipients with perinatal HIV infection or congenital immunodeficiency syndromes will develop distant or disseminated disease with a high mortality.<sup>255,256</sup>

## Technique

BCG is given to subjects whose tuberculin reaction is <6 mm. Re-vaccination is unnecessary for people with a definite BCG scar, even if the tuberculin test is negative. A pre-vaccination tuberculin test is not required in children <6 years old unless they have stayed >1 month in a country with an incidence of tuberculosis >40 per 100 000 or had contact with a person with tuberculosis.

BCG vaccine is injected intradermally, usually into the left upper arm at the insertion of the deltoid muscle: 0.1 ml is given with a 1 ml syringe and a short bevelled needle gauge 25–26 (as per Mantoux test). It is advised that neonates and infants <12 months are given 0.05 ml because of the increased risk of local lymphadenopathy. Proper technique is essential. The needle should be inserted, bevel upwards, into the superficial layers of the dermis (almost parallel with the surface) for about 3 mm and a wheal of at least 5–7 mm produced. If resistance is not felt during injecting, the needle has been inserted too far (or the fluid

has leaked externally) and it should be withdrawn. Injecting the vaccine subcutaneously may result in an abscess or large ulcer. Normally a small papule develops at the site of vaccination within 2–6 weeks. Sometimes it may ulcerate and discharge but it usually heals after about 2–3 months, leaving a small scar (for management see Complications).

## Accelerated BCG reaction

If BCG vaccine is given to persons infected by tuberculosis or who have received BCG previously, an accelerated reaction may result: a papule appears within 24–48 h, a pustule by 5–7 days, and a scab by 2 weeks. In malnourished children with tuberculosis, the tuberculin test is often negative, but there may be an accelerated reaction to BCG which could potentially be used as a diagnostic test for tuberculosis. A papule of 5 mm or more appearing by the third day is regarded as positive. BCG is considered to be equivalent to 20–50 TU PPD. Because of the risk that a malnourished child has HIV infection, this practice is now not recommended.

## Complications

If >1% of recipients develop an adverse local reaction to BCG, this usually indicates incorrect dosage or bad technique. The commonest complication is the development of a local abscess or large ulcer. Unless there is superinfection with a pyogenic organism, the abscess is non-tender and the child afebrile. Swelling of local lymph nodes with or without sinus formation is more likely in young infants. These complications usually result from an inadvertent subcutaneous injection.

Nonfluctuant enlarged nodes should be left untreated. Abscesses should be aspirated. If repeated aspiration of fluctuant nodes does not result in resolution they may be excised. Discharging ulcers should be cleaned with an antiseptic two or three times a day, left uncovered as much as possible, and, when necessary, a non-adherent dressing should be used. For ulcers that do not respond to these methods, isoniazid 6 mg/kg/d for 6 weeks usually results in healing. Hypertrophic or keloid scars may develop at the site of vaccination, especially if given at sites other than insertion of the deltoid. Excision is not always successful. Local injection of triamcinolone at monthly intervals for 3–4 doses may result in atrophy.

Other rare complications of BCG vaccination include anaphylactic reactions, satellite lesions, bone lesions, meningitis or overwhelming infection. The latter usually occurs in immunodeficient infants (see above under Contraindications and HIV infection).<sup>257</sup> Focal lesions such as osteitis may occur in apparently immunocompetent infants and in some cases have been associated with increased potency of the vaccine.<sup>258</sup> Osteitis may develop 6–9 months to some years after vaccination. In HIV-infected infants, enlarged lymph nodes (usually ipsilateral to BCG injection) with sinus formation may develop months to years after the vaccination has apparently healed, coinciding with the onset of immunosuppression or administration of antiretroviral therapy.<sup>256</sup>

## Efficacy

The effectiveness of BCG in preventing tuberculosis, particularly meningitis and disseminated disease, has been demonstrated in a number of prospective trials and case control studies.<sup>259–261</sup> It also provides some protection against leprosy and Buruli ulcer. Protection persists for up to 10 years. However, results of studies vary between different communities and are influenced by factors such as the prevalence of and exposure to tuberculosis, distance from the equator, the prevalence of environmental mycobacteria, the administration and potency of the vaccine, and the age and nutritional status of the population.<sup>262</sup>

Schoolchildren in the UK vaccinated at around 13 years have demonstrated a consistent level of protection of about 75%, persisting for 15 years.<sup>263</sup>

Two controlled trials of BCG in the newborn, one in North American Indians living in Saskatchewan, the other in Chicago, have shown 75–80% protection, and some case control studies have also demonstrated over 70% protection.<sup>259,261</sup>

In the northern hemisphere, BCG continues to provide substantial protection against tuberculosis overall and up to 80% for meningitis and disseminated disease.

### Tuberculin sensitivity after BCG vaccination

When the technique and potency of vaccine is adequate, most vaccinated infants will have a scar and >90% will be tuberculin positive ( $\geq 6$  mm). Low grade tuberculin sensitivity will remain in most children for at least 5–12 years.<sup>264,265</sup> Preterm infants and those with severe intra-uterine growth retardation may have a reduced response to BCG vaccination, possibly due to impaired cell-mediated immunity. Scars are less likely to persist in infants vaccinated in the neonatal period.

In resource limited countries, tuberculin sensitivity following neonatal BCG wanes considerably over the first few years. After 2–3 years most children will be tuberculin negative or have low sensitivity.<sup>266</sup> Thus neonatal BCG should not affect the interpretation of the tuberculin test in these areas. In children recently vaccinated with BCG, who are in contact with a smear positive case of tuberculosis, a Mantoux reaction of  $\geq 15$  mm should be interpreted as likely infection by *M. tuberculosis*. Repeat BCG vaccination is associated with larger tuberculin reactions. An IFN-gamma assay should help in identifying a false positive tuberculin test.

### New vaccines

Vaccines are required which are more effective in preventing exogenous reinfection, especially in adolescents and adults, in people already infected by environmental mycobacteria and in those who have received conventional BCG. Candidate vaccines include live attenuated vaccines comprising BCG or *M. tuberculosis* subunit vaccines and fusion proteins formulated in various adjuvants.<sup>267</sup> Phase 1 trials have been completed for some and phase 2 trials are in progress or planned.

## PREVENTION AND CONTACT TRACING

In the UK today, the majority of children in whom tuberculosis is diagnosed are detected through contact tracing of smear positive cases of tuberculosis. Children with primary tuberculosis (as opposed to adolescents with cavitary disease) and patients with nonrespiratory tuberculosis are rarely infectious. However, children with tuberculosis and their visitors should be segregated from the rest of the ward until family and visitors have been screened. Smear positive adults who receive drug regimens which include rifampicin usually have a negative sputum culture within 2 weeks.

Procedures for control and prevention of tuberculosis in the UK have been outlined.<sup>268</sup> When a case of tuberculosis is diagnosed, household contacts should be screened. Children and young adults should have a tuberculin test and, when positive, a chest X-ray. Older adults and those who have received BCG vaccination should have a chest X-ray. If the tuberculin test is negative, it should be repeated after 6 weeks as the first test may have been done too early in the course of infection. Tuberculin negative subjects should be offered BCG. Tuberculin positive subjects with a normal chest X-ray should be given chemoprophylaxis (see below).

Young children are usually infected in the home. For older children it may be necessary to search outside the home, e.g. staff at school, a swimming pool attendant or a youth leader. In tuberculosis of the face or gums, the possibility of infection by a dentist should be considered.

### Chemoprophylaxis and follow-up of contacts

This section outlines the recommendations for chemoprophylaxis of contacts of a known case of tuberculosis.

Chemoprophylaxis is indicated for tuberculin positive children ( $\geq 10$  mm) or those with a positive IFN-gamma assay with a normal chest X-ray, who have not had BCG. It should be considered in those with  $\geq 15$  mm who have received BCG. Guidelines for children < 2 years in close contact with smear positive pulmonary disease are as follows:

1. *No prior BCG*: give chemoprophylaxis irrespective of tuberculin test. Repeat tuberculin test after 6 weeks: if negative, stop chemoprophylaxis and give BCG; if positive (and chest X-ray excludes disease) give full chemoprophylaxis.
2. *Prior BCG*: if tuberculin test is strongly positive ( $\geq 15$  mm) give chemoprophylaxis. If tuberculin test is weak ( $\leq 10$  mm), repeat in 6 weeks. If there is no change, no further action is required. If size of reaction increases (and chest X-ray excludes disease), give full chemoprophylaxis. Routine follow-up chest X-rays are only required for those who are eligible for, but did not receive, chemoprophylaxis.

For chemoprophylaxis, isoniazid (INH) plus rifampicin (RIF) should be given for 3 months, or INH only 6 mg/kg/d should be given for 6 months. In young infants exposed to smear positive patients, or in contacts at any age when the source is suspected to harbor INH-resistant *M. tuberculosis*, RIF may be added to INH and the combination given for 4–6 months. If INH resistance is confirmed, RIF alone may be given for 6 months.<sup>268,269</sup>

## CLINICAL FORMS OF TUBERCULOSIS

The commonest presentation of tuberculosis is respiratory disease, followed by involvement of lymph nodes.<sup>243</sup> In resource limited countries, extrapulmonary disease accounts for 35–40% of tuberculosis, compared to around 20% in the USA.<sup>241</sup> It is important to remember that tuberculosis can infect virtually any part of the body. [Figure 28.23](#) shows an outline and a time scale of some of the complications of primary tuberculosis.

### Intrathoracic tuberculosis

#### Primary pulmonary tuberculosis

The primary complex consists of a focal lesion usually 1–2 cm in diameter which may be found in any part of the lung, and enlarged hilar nodes or, in heavier infections, paratracheal nodes. Lymph node enlargement is particularly prominent in infants and young children ([Figs. 28.24b and 28.25a](#)). The primary complex is usually asymptomatic and discovered during contact tracing or a routine tuberculin test. Often the primary focus has resolved or is not visible and the diagnosis is based on enlarged regional nodes. Calcification of the focus and, more often, the nodes may occur after about 12 months, generally within 2–3 years of the infection, and remains an indication of previous infection. Calcification usually indicates healing of the tuberculous process, but healing and progression of the disease may continue concurrently. In many cases the calcium slowly resolves leaving clear lung fields, which explains the common finding in adults where the tuberculin test is positive and the chest X-ray normal.

In older children and adolescents, the lung component is more prominent and commonly presents as an enlarging upper lobe infiltrate and cavitation, usually without lymph node enlargement, and is indistinguishable from postprimary tuberculosis. Pleural effusion is more common at this age.

#### Progression of primary tuberculosis

Progression of primary tuberculosis may result from extension of the pulmonary focus (progressive primary tuberculosis) or, more commonly, softening of regional lymph nodes. Extension of the pulmonary focus may cause bronchopneumonia or rupture into the pleura resulting in pleural effusion. Tuberculous empyema may result from rupture of caseous material into the pleural space, which may be complicated by pneumothorax (pyopneumothorax). Evacuation of caseous material into a bronchus may result in the appearance of a cavity. Cavities in primary pulmonary tuberculosis are not uncommon in malnourished and debilitated infants with progressive primary tuberculosis ([Fig. 28.24b](#)).

Complications from enlargement or softening of regional nodes have a variety of manifestations. The bronchus may be compressed externally; more likely, the wall is eroded and caseous material either partly or completely blocks the lumen (endobronchial tuberculosis); or rupture

**Fig. 28.24** (a) A 2½-year-old asymptomatic girl with a strongly positive tuberculin test was in contact with a smear positive case of tuberculosis. Chest X-ray shows a nonspecific opacity in the right upper zone. (b) She was put on chemoprophylaxis with isoniazid plus rifampicin but did not comply with treatment. Chest X-ray taken 2 months later shows an enlarged right mediastinal node with compression of the trachea, collapse/consolidation in all three zones of the right lung, a cavity in the upper lobe and hyperinflation of the right lower lobe. She now had symptoms – cough, stridor and wheeze. This case demonstrates progression of untreated primary tuberculosis.

of the wall results in bronchopneumonia. Partial obstruction may result in a ball-valve effect with lobar emphysema (Fig. 28.24b). This is often transient, because either the bronchus blocks completely or the material is coughed up with clearing of the obstruction.<sup>270</sup> More commonly, there is *segmental* collapse with or without consolidation. Rupture of caseous material into the bronchus may result in a predominantly allergic response with exudation, or, if there are a large number of bacteria present, a progressive tuberculous bronchopneumonia. The former may be associated with marked changes on chest X-ray but which clear spontaneously, whereas the latter, which is more often seen in debilitated children, may prove fatal if not treated. Spread of infected material into both main bronchi may result in bilateral bronchopneumonia.

Rarely, a caseous node may rupture into the trachea, resulting in bilateral obstructive emphysema or asphyxia, into the esophagus resulting in a fistula or the development of an esophageal pouch, or into the pericardium. Other complications from enlarged nodes include superior vena cava obstruction and recurrent laryngeal or phrenic nerve compression.

There may be nonspecific symptoms of irregular fever, anorexia and weight loss. In severe or long-standing cases, the child may be severely wasted. Compression of the bronchi may result in a spasmodic cough simulating whooping cough. When there is obstructive emphysema, the symptoms may be mistaken for asthma, though clinical examination will usually demonstrate signs of mediastinal shift. In long-standing cases, the child may present with clubbing of the fingers and bronchiectasis.

### Adolescent tuberculosis

In adolescents, infection is usually in the upper lobes or the superior segments of the lower lobes, and is usually confined to the lungs with

no hematogenous spread. In some cases it results from reactivation of a former primary lesion (post-primary tuberculosis) and, though usually associated with adults, this may occur in children and adolescents (Fig. 28.25a, b). Evidence of a previous primary pulmonary complex may be detected.<sup>270</sup> In other cases it is a primary exogenous infection. Common symptoms include a productive cough, especially in the morning, and there may be hemoptysis, fever, night sweats, malaise and weight loss.

Chest X-ray may show a variety of lesions including nodular or patchy shadows, cavities and various stages of healing with fibrosis and calcification. Both lungs may be affected and there may be a pleural effusion.

### Diagnosis

The diagnosis of primary pulmonary tuberculosis is based on a positive tuberculin test (10 mm) and/or a positive IFN-gamma assay and enlarged nodes on chest X-ray with or without a pulmonary infiltrate. History of contact provides strong support. Enlarged lymph nodes may not be easily demonstrated; a lateral chest X-ray may be helpful. Persistent pulmonary infiltrate(s) in the presence of a positive tuberculin test is highly suggestive of tuberculosis.

Chest X-ray usually shows enlarged nodes with opacities more often in the right than left lung, due to collapse and/or consolidation. Bilateral disease may be seen in 25% of cases. In progressive disease, cavities may be seen. Lymph nodes may be detected on CT scan in children with normal chest X-rays.<sup>271</sup> The tuberculin test may be negative in debilitated children. This is a common problem in resource limited countries where, in the absence of facilities for mycobacterial culture, the diagnosis is often based on the response to a trial of chemotherapy.

(a)

(b)

**Fig. 28.25** (a) An 8-year-old boy was in contact with his grandmother who had smear-positive tuberculosis. His tuberculin test was negative. Although the chest X-ray shows an enlarged right hilar node it was regarded as normal and he did not receive chemoprophylaxis. He was given BCG and developed an accelerated reaction to it. (b) Four years later he presented with a cough for 6 months, dyspnea and weight loss. Chest X-ray shows loss of volume of the right lung with multiple cavities and fibrosis in the right upper lobe and a cavity in the left apex and left mid zone and a miliary pattern. Sputum smear was strongly positive for acid-fast bacilli. This is an example of post-primary tuberculosis. (Fig. 28.25b Reproduced with permission from the *Journal of Medical Microbiology* 1996; 44:7, Fig 1.)

In older children with post-primary or adult type tuberculosis, diagnosis is made by smear and culture of sputum. For younger children, if sensitivities of the contact are not available or diagnosis is unclear, three early morning gastric aspirations should be undertaken while the child is recumbent and has been fasted overnight. If the gastric aspirate (usually 5–10 ml) is very small or the tube is blocked, sterile water (<20 ml) may be injected and after a few minutes aspirated. If there is delay in transporting the specimen to the laboratory, the acid should be neutralized (pH 7.0) by adding approximately 3 ml of sodium bicarbonate (100 mg/ml). Smear is seldom positive on gastric aspirates in industrialized countries and in some cases it may be due to environmental mycobacteria. However, in resource limited countries where the infective load of *M. tuberculosis* may be high, 10–15% of patients may have a positive smear. Culture is positive in no more than 30–50% of cases.<sup>272</sup> It is more likely to be positive in infants (75%) and those with extensive parenchymal disease.<sup>273</sup> However, it may be positive in children with only enlarged intrathoracic nodes and rarely in those with normal chest X-ray. Gastric aspiration undertaken in an ambulatory clinic has generally lower sensitivity for culture than when taken in the early morning.

Alternative methods to obtain sputum include induced sputum, laryngeal swab and nasopharyngeal aspirate.<sup>274</sup> Laryngeal swabs or nasopharyngeal aspirates are useful for ambulatory clinics and when gastric aspiration is not possible.<sup>275–277</sup> Induced sputum is increasingly used for diagnosis of tuberculosis and may be undertaken in infants, or in adolescents without productive sputum.<sup>278,279</sup> Culture of respiratory secretions obtained through induced sputum, laryngeal swab or nasopharyngeal aspirate is less sensitive (25–30%) than gastric aspirate (30–50%).<sup>276–279</sup> Bronchoscopy is no more sensitive for culture

of *M. tuberculosis* than gastric aspiration.<sup>280,281</sup> If diagnosis is important for management, biopsy of enlarged lymph nodes should be considered.

The blood count usually shows a normal white cell count. A raised ESR is associated with activity of the disease but otherwise has no diagnostic value.

A *pleural effusion* is due to an allergic response to the mycobacteria and thus the tuberculin test is usually strongly positive, except in very debilitated children. If large, or required for diagnostic purposes, it should be aspirated. The fluid is usually clear and straw-colored, but may be opalescent if there is a high cell count. Lymphocytes will be seen on microscopy, but early in the disease neutrophils may also be present. The protein content will be raised, >40 g/L, and the glucose low, <1.7 mmol/L. Mycobacteria are often not detected on direct smear, but in about half the cases they may be cultured, especially if a large volume of fluid is centrifuged. Mycobacteria are more likely to be cultured from an empyema. Pleural biopsy may also be taken for histology.

### Management

*Uncomplicated primary infection* usually heals without treatment. The main purpose of chemotherapy is to prevent hematogenous spread and progression of disease, which is more likely in young, debilitated or malnourished children. Segmental collapse may occur despite chemotherapy, but tuberculous bronchopneumonia or pleural effusion is usually prevented. Radiological changes resolve slowly and 50% of children may still have evidence of the primary complex after 18 months. Lymph nodes may enlarge during chemotherapy, but there is usually no necessity to prolong therapy because of this.

Standard three-drug chemotherapy is isoniazid (INH), rifampicin (RIF) and pyrazinamide (PZA) for 2 months followed by INH and RIF for 4 months. Ethambutol (EMB) is added if drug resistance is suspected or burden of infection is high. If PZA is not given, INH + RIF should be given for 9 months. For alternative regimens see section on Chemotherapy. For hilar lymphadenopathy alone a three-drug regimen followed by INH + RIF for just 2 months or INH + RIF for 6 months may be adequate.<sup>282</sup>

**Bronchial obstruction.** Incomplete bronchial obstruction with air trapping and the development of *obstructive emphysema* may respond to corticosteroids (see Management). However, the transient nature of this lesion should be remembered, i.e. it may resolve or the bronchus may become completely obstructed. Complete obstruction will result in absorption collapse, and bronchoscopy should be performed to exclude other pathology, such as foreign body, and to suck out as much of the caseous material in the bronchial lumen as possible. Unfortunately, the obstruction may be difficult to visualize, especially in young infants.

**Pleural effusion.** The infective load in pleural effusion is low and responds quickly to treatment. The addition of corticosteroids may enhance the absorption of fluid but long term benefit regarding reduction of pleural thickening and adhesions has not been demonstrated.<sup>283</sup> In the presence of empyema, surgical drainage may be required.

### Pericarditis

*M. tuberculosis* may reach the pericardium by lymphatic extension from mediastinal lymph nodes, direct extension from caseous lung tissue or lymph nodes, or from hematogenous spread. It is more common in resource limited countries.<sup>284</sup> A loud pericardial rub may be heard in dry pericarditis. Occasionally, there is a large effusion, which may cause tamponade. An effusion will be detected by echocardiography. Pericardial aspirate is often blood-stained, and polymorphonuclear leukocytes may be seen in the early stages, after which lymphocytes predominate. *M. tuberculosis* may be cultured in over half the cases, and in up to 75% using double strength Kirchner culture medium. Diagnosis may also be made by culture and histology of a pericardial biopsy. Constrictive pericarditis may ensue in spite of treatment.

Standard antituberculous treatment is given. Open drainage may prevent subsequent requirement for pericardial aspiration. Corticosteroids may enhance the rate of improvement and reduce the requirement for aspiration, but seem not to reduce the need for pericardectomy.<sup>285,286</sup>

### Extrathoracic tuberculosis

Nonrespiratory disease usually results from hematogenous spread. Virtually any organ may be affected. Some of the common types are described below. Tuberculosis may also affect the larynx, middle ear and mastoid bones. Middle ear disease may be associated with HIV infection. Virtually any part of the eye may be infected and tuberculosis should be remembered as a cause of an orbital mass. Tuberculosis of the skin may result from primary inoculation, from hematogenous dissemination, or from a cold abscess in an underlying structure.

### Lymph node tuberculosis

Superficial lymph node tuberculosis commonly occurs in the cervical or supraclavicular, and, less often, the axillary or inguinal regions. As in primary tuberculosis of the lungs, the regional nodes enlarge in response to a focus. Less commonly, enlargement of a number of superficial lymph nodes results from hematogenous spread. The focus may be the tonsils, gums, lungs or elsewhere. In cervical adenitis, the commonest focus is the upper lung fields. Enlarged axillary or inguinal nodes may be due to disseminated disease or infection of the skin. In the UK, in the majority of cases of white children with histological evidence of mycobacterial infection of the cervical glands, it is associated with environmental mycobacteria such as *M. avium-intracellulare*. *M. tuberculosis* is more common in immigrant children.

Initially the nodes are discrete, mobile and non-tender, later becoming matted together. Without treatment, softening of nodes usually

develops within 6 months of infection, and nodes may discharge forming a sinus or track along the fascial planes. Swelling and softening may occur in up to a third of patients during treatment or even years after the node is calcified and apparently healed. This phenomenon of paradoxical enlargement may be due to hypersensitivity to tuberculo-protein, released at intervals from the lesion, and does not usually indicate active infection.

The tuberculin test is usually positive and a chest X-ray should be taken to exclude pulmonary tuberculosis. Calcification within the node may be detected radiologically. Ultrasound or MRI is helpful in confirming that the lesion is a lymph node and in detection of caseous necrosis. Fine needle aspiration for smear and culture, or preferably excision biopsy, will usually confirm the diagnosis. All specimens, either from biopsy or aspiration, should be cultured as it is important to ascertain whether the infection is caused by *M. tuberculosis* or environmental mycobacteria. However, culture may be positive in only two thirds of cases. The main differential diagnosis is from a cervical pyogenic abscess. Local viral or streptococcal infection of the tonsils may cause enlargement of existing tuberculous nodes. Other differential diagnoses include glandular fever, HIV infection, cat-scratch disease, malignancy or an infected branchial or thyroglossal cyst and, in HIV endemic regions of sub-Saharan Africa, Kaposi sarcoma.

Treatment with standard chemotherapy is adequate. If softening of the node occurs, it may be aspirated. If excision is necessary, the primary node should be removed intact, or, if not feasible, as much of the caseous material as possible.<sup>246</sup> Cold abscesses are frequently of the 'collar stud' variety, and will recur if the abscess in the deep fascia is not adequately drained.

### Disseminated tuberculosis

Hematogenous dissemination of small numbers of bacilli probably occurs in the majority of children with primary uncomplicated tuberculosis. In resource limited countries, a liver biopsy for an unconnected disease may show tuberculous granulomata in children not known to have had tuberculosis. These rarely become symptomatic. Massive hematogenous spread is referred to as acute miliary tuberculosis and if untreated is usually rapidly fatal. It may be associated with caseous necrosis involving a blood vessel or inadequate immunological response to the infection. It may be found at autopsy without being evident on chest X-ray. A more chronic form, cryptogenic disseminated, also occurs. In both forms, disease may develop in virtually any organ of the body.

**Acute miliary tuberculosis.** Acute miliary tuberculosis (miliary means 'millet seed') is most common in young children and usually occurs within a year of the primary infection. The most important complication is meningitis. The onset is usually insidious. Presenting signs include pyrexia, dyspnea, anemia, hepatosplenomegaly and lymphadenopathy.<sup>287</sup> Anorexia and weight loss are common and variable degrees of malnutrition will be evident depending on the length of the illness. The lungs show a 'snowstorm' picture on chest X-ray. Rarely, respiratory failure with adult respiratory distress syndrome may develop. Choroid tubercles are pathognomonic of the disease. Cutaneous lesions include macules, papules, purpura and papulonecrotic tuberculides.

Except in the early stages, the diagnosis will usually be evident from a chest X-ray. Miliary disease may be detected on CT scan when the chest X-ray is normal. There may also be lobar infiltrates and hilar lymphadenopathy. The tuberculin test may be weak or negative in the early stages or if the child has severe debility. A lumbar puncture is essential in all cases to exclude meningitis. Bacteriological confirmation will be obtained in the majority of children, particularly from culture of gastric contents, and also CSF and urine. In difficult cases the diagnosis is sometimes made on liver, lung or marrow biopsy.

Acute miliary disease usually responds promptly to chemotherapy. Most deaths are related to meningitis and/or late diagnosis. A short course of corticosteroids will speed the resolution of symptoms, especially if there is alveolar capillary block. Standard chemotherapy is adequate. Prolonged (9 months) therapy may be required in complicated cases or meningitis.

**Chronic disseminated (cryptic) tuberculosis.** In chronic disseminated tuberculosis, small numbers of bacilli seed the bloodstream at intervals and produce metastatic foci in organs throughout the body. Apart from the lung lesions, there is usually generalized lymphadenopathy and often hepatosplenomegaly, and involvement of the pleural, pericardial and peritoneal cavities, bones and kidneys may occur. There may be multiple bone involvement with dactylitis or involvement of the skin with papulonecrotic tuberculides. In some cases the chest X-ray is normal and the primary site is unknown. A variety of hematological abnormalities may be seen, e.g. pancytopenia, or leukemoid reactions, which suggest leukemia or a lymphoma. The tuberculin test may be negative. Bone marrow biopsy may show necrotic foci with little cellular reaction but teeming with mycobacteria.

Treatment is similar to that of acute miliary disease. Corticosteroids may be of benefit in debilitated children.

### ***Tuberculosis of the central nervous system***

Tuberculosis of the central nervous system may have a variety of manifestations.<sup>288</sup> There may be generalized inflammation affecting brain and spinal cord; less commonly, single or multiple tuberculomata enlarge and present as an intracranial space-occupying lesion or rarely tuberculous disease may be confined to the spine.

**Tuberculous meningitis.** Tuberculous meningitis is most common in children under 5 years of age, often occurring within 6 months and usually within 2 years of primary infection, but it may occur at any age. It results from rupture of one or more tubercles (Rich focus) into the subarachnoid space. The tubercle(s) is commonly situated in the sub-cortex of the brain, and less often in the meninges or spinal cord. Characteristically, the severe inflammatory response results in a thick gelatinous exudate and adhesions around the base of the brain with hydrocephalus and spinal block. Involvement of cranial nerves may result in single or multiple palsies. Arteritis may cause thrombosis and infarction of nervous tissue with permanent damage. Occasionally there is little exudate and the illness is termed *serous meningitis*. Spontaneous recovery without treatment has been described in some of the latter cases.

Symptoms develop over some weeks and may be grouped into stages, which give a guide to prognosis. Initially, the symptoms are nonspecific and include irritability, malaise, anorexia, vomiting, constipation and low grade fever. Unless the child is a contact of tuberculosis or there is a high index of suspicion, the diagnosis is rarely made at this stage. Within a few weeks specific features in addition to the above become apparent: there is headache, disorientation, meningism, focal neurological signs, such as cranial nerve palsy, hemiplegia or visual defect, and seizures may develop. In young infants the fontanelle may be distended. Fundoscopy may demonstrate choroid tubercles, especially when there is miliary disease, papilledema or the development of optic atrophy. The third and often terminal stage is manifest by coma, a posture of decerebrate rigidity, dilated pupils, and the child is usually wasted.

**Diagnosis.** The diagnosis is based on CSF findings with or without a positive tuberculin test. There may be radiological evidence of pulmonary disease, or clinical evidence of disease elsewhere in the body. The tuberculin test may be negative in over a third of cases, especially in the advanced stages when there is wasting.

The CSF is clear, unless there is a high cell count, when it may appear turbid. The cell count is usually less than 500/mm<sup>3</sup> and mainly lymphocytic, except in the very early stages when neutrophils may predominate. Neutrophils may also increase after commencement of chemotherapy. The protein is usually raised (0.8–4 g/L) and in spinal block may be > 10 g/L, and the CSF is xanthochromic. The glucose is usually low. However, it should be remembered that the first lumbar puncture may be normal, that the cell count, protein and glucose levels may fluctuate from day to day, and that the cell count and protein may be lower in ventricular than in spinal fluid.<sup>289</sup> The chance of detecting tubercle bacilli microscopically is higher if a large amount of CSF is obtained and centrifuged; the success rate claimed varies from 30 to 90% depending on the volume of CSF and the care taken in examining the fluid. Brain

imaging will be abnormal in 75–100% of cases; usually there is hydrocephalus, parenchymal disease and basilar meningitis. Tuberculomata may be detected on initial brain scans or appear later. If raised intracranial pressure is suspected, CSF should be taken off slowly with a fine needle or from the ventricles. The CSF should always be cultured for mycobacteria, but is positive in less than half the cases. It may be possible to detect tubercle bacilli after chemotherapy has commenced. Occasionally, tuberculous meningitis may be complicated by pyogenic meningitis. Studies of tuberculous meningitis, mainly in adults, have demonstrated sensitivities and specificities for PCR in CSF ranging from 33 to 100% and 88 to 100%, respectively, and generally higher sensitivity than culture.<sup>238</sup>

**Spinal tuberculosis.** Spinal tuberculosis is usually secondary to downward extension of the tuberculous process, and usually occurs during treatment of tuberculous meningitis. There is pain and stiffness in the spine at the level of the lesion and symptoms are related to involvement of the spine or nerve roots. The CSF protein is high and there is evidence of a spinal block, which can be confirmed by MRI scan or a myelogram.

Rarely, diffuse tuberculous spinal subarachnoiditis may occur as a result of extension of a primary focus in the spine. It presents as a subacute, transverse or ascending myelitis with upper and lower motor neurone signs and may be mistaken for other causes of cord compression and polyneuritis.

**Tuberculoma.** A tuberculoma is a tuberculous focus, which enlarges within brain tissue. It may be single or multiple. It may give rise to signs of raised intracranial pressure or a hemiplegia, or cranial nerve palsy if in the brainstem. A skull X-ray may show calcification. CT scan usually shows a hypodense mass and ring enhancement with contrast. MRI scan is more sensitive for detecting tuberculomas, infarcts and spinal lesions. Tuberculomas may expand weeks to months after commencing treatment for meningitis or pulmonary tuberculosis and result in raised intracranial pressure sometimes requiring surgical decompression.<sup>290,291</sup> This phenomenon of paradoxical enlargement may be a hypersensitivity response (as in cervical lymphadenitis).

**Management.** The key to success in treating tuberculous meningitis is early diagnosis and immediate treatment. If there is doubt, antituberculous chemotherapy should be commenced, along with conventional antimicrobials for bacterial meningitis if necessary.

Optimal chemotherapy is a combination of drugs with good penetration into the CSF and low toxicity. Standard chemotherapy is INH (15–20 mg/kg) and RIF (15–20 mg/kg) given for 9–12 months, with the addition of PZA (40 mg/kg) for the first 2 months of treatment. If drug resistance is suspected, ethionamide or prothionamide 20 mg/kg, or ethambutol (EMB) [or streptomycin (SM)] should be added. A 6-month course may be adequate in most cases.<sup>292,293</sup>

A study of 99 children in Cape Town, of whom 96% had stage II or III, treated for 6 months with INH 20 mg/kg, RIF 20 mg/kg, PZA 40 mg/kg and ethionamide 20 mg/kg, had a satisfactory outcome, with only one probable relapse.<sup>293</sup>

Drugs cross the blood–brain barrier more readily in the first 2–3 months of the disease when the meninges are inflamed. INH and PZA achieve high levels in the CSF, even when meninges are not inflamed. Ethionamide has adequate, RIF and EMB moderate to poor, and SM poor penetration across the meninges.<sup>294–296</sup> Ethionamide is useful for isoniazid-resistant *M. tuberculosis*. In children who are vomiting, INH, RIF and SM can be given parenterally and other drugs by nasogastric tube. Controlled trials on the value of corticosteroids in tuberculous meningitis have demonstrated benefit especially in stage II and III disease.<sup>295,297–299</sup>

The rationale is based on their ability to reduce the inflammatory exudate and thus prevent the development of adhesions which result in internal hydrocephalus and basilar arachnoiditis. In South Africa, 141 children with stage II–III disease were randomized to receive prednisolone 4 mg/kg or placebo for 1 month.<sup>298</sup> The prednisolone treated group had a reduced mortality in stage III, a better cognitive function in survivors and a reduction in size of existing, and development of new, tuberculomas. Dexamethasone 0.6 mg/kg/day or prednisolone 4 mg/kg/day may be given for 2–3 weeks then tailed off over 2–3 months. A higher

dose of corticosteroids was used in the South African study because of theoretical concerns about interaction with rifampicin, but others have used a more conventional dose of prednisolone to equal effect.

Serial brain imaging will detect cerebral edema and the presence or development of hydrocephalus or tuberculomas. In the presence of cerebral edema, controlled ventilation (with monitoring of intracranial pressure if necessary) may be indicated. Obstructive hydrocephalus is common and is not always clinically evident. If it is symptomatic, it should be treated by a ventriculo-peritoneal shunt. In the initial stages, before the drugs have controlled the infection, the shunt may be exteriorized.

Spinal arachnoiditis with a CSF block may develop during treatment. If not improved by corticosteroids, release of pressure by surgery may be necessary.

Tuberculomas are treated on similar lines to meningitis. Most of the small and medium-sized lesions resolve completely with chemotherapy. Rarely, large lesions and those not responding to chemotherapy may require excision. Enlargement during treatment of pulmonary or tuberculous meningitis can cause raised intracranial pressure or cranial nerve palsies. Corticosteroids should be tried and, failing this, a ventriculo-peritoneal shunt may be necessary. Most patients with unresolved tuberculomas have been given prolonged antituberculous therapy, e.g. 12–18 months or more. In some cases of meningitis, a second course of corticosteroids may be indicated for treatment of tuberculomas.

**Prognosis.** The prognosis for meningitis is related to age of the child (young children have a worse prognosis) and the stage of the disease at which therapy is commenced. The stages have been classified as follows:

**Stage I:** consciousness undisturbed; no, or only mild and focal, neurological signs.

**Stage II:** consciousness disturbed, but patient not comatose or delirious. Mild or moderate neurological signs, such as paraparesis, hemiparesis, and cranial nerve palsies, may be present.

**Stage III:** patient comatose or delirious with mild, moderate or severe neurological signs.

In a study of 199 children in Hong Kong, complete recovery occurred as follows: stage I 96%, stage II 78% and stage III 21%. Of children in stage III, 17% died as opposed to 1% in stage II.<sup>300</sup> Resolution of neurological disability may continue for many months after commencement of therapy.

### Abdominal tuberculosis

Abdominal tuberculosis usually results from swallowed sputum or *M. bovis*-infected milk, but may be associated with extension from thoracic nodes or hematogenous dissemination, or may be an extension of pelvic tuberculosis post menarche. The primary focus is usually in the terminal ileum. Symptoms of disease in children are usually due to enlargement or softening of regional mesenteric nodes and/or involvement of the peritoneum. In adults with cavitary pulmonary disease, there may be a chronic enteritis and fistula in an area resembling Crohn's disease or other inflammatory bowel disease.

Common symptoms are abdominal pain, fever, weight loss and abdominal swelling or there may be symptoms of intestinal obstruction. Enlarged mesenteric lymph nodes or a mass associated with adhesions of the omentum and intestines may be palpated, usually on the right side of the abdomen.

Peritonitis may be the dominant condition and is often unassociated with demonstrable pulmonary disease. It may result from extension of a mesenteric node or hematogenous spread. In the latter situation, rarely there may be a polyserositis with involvement of the pleura and pericardium. The ascitic fluid has a predominance of lymphocytes and a protein concentration above 25 g/L (usually lower than in a tuberculous pleural exudate). Mycobacteria are not often identified and the culture may be positive in only a quarter of cases.

Diagnosis is made on the basis of a positive tuberculin test, peritoneal aspiration and bacteriological and histological examination of specimens obtained by laparoscopy, endoscopy, or at laparotomy.

Ultrasonography and CT scan are useful for diagnosis and guidance for needle aspiration. Calcification may be detected on abdominal X-ray.

Treatment is by standard chemotherapy.

### Tuberculosis of bones and joints

Tuberculosis of bones and joints results from hematogenous spread, usually affecting a single or a few joints within 6–36 months of primary infection. The spine is affected in over half the cases (Pott disease), followed by the knee, hip and ankle. In chronic disseminated tuberculosis, multiple large or small joints may be affected, with or without associated abscesses, or there may be dactylitis of one or both hands. Sometimes punched out cystic lesions are seen with few inflammatory changes affecting surrounding tissue. Lesions confined to the skull may resemble eosinophilic granuloma of bone, or, if associated with miliary disease, the systemic form of Langerhans' cell histiocytosis.

Infection usually starts in the well-vascularized metaphyses near the epiphyseal line of long bones, or, less commonly, in the synovium of the joint. Typically there is minimal periosteal reaction or new bone formation. Progression of the disease may result in destruction of the joint, and/or abscess or sinus formation. The cold abscess may track a considerable distance from the primary focus. For example, a cold abscess from the cervical vertebrae may present as a retropharyngeal mass or, from the lumbar vertebrae, as a psoas abscess pointing in the groin.

Treatment is standard 6-month chemotherapy. However, if evacuation of necrotic sequestrum and abscesses is not adequate, drug penetration might be impaired and a longer course (9–12 months) necessary.<sup>301</sup> Ambulatory chemotherapy without surgery has been found the most satisfactory treatment for spinal disease in resource limited countries. Acute cord compression may respond to chemotherapy alone, but if the necessary technical expertise is available, early spinal decompression is the treatment of choice. A bone graft may be necessary in cases of extensive destruction of vertebrae or weightbearing bones, such as the neck of the femur.

### Genitourinary tuberculosis

Tuberculosis of the kidneys is uncommon in children as it usually presents 5–7 years or more after the primary infection, although it may occur sooner. The first symptom is dysuria and typically there is a sterile pyuria with or without red cells. There may not be any symptoms and even in advanced disease there may be very few leukocytes in the urine. Culture of urine for mycobacteria is usually positive.

Glomerulonephritis with immune complex disease complicating miliary tuberculosis has been described, and may be found to be more common if actively sought.<sup>302</sup>

Tuberculous epididymitis is seen in young boys and epididymo-orchitis in older boys.<sup>246</sup> The development of a cold abscess may be the first manifestation of disease. In girls, tuberculosis of the uterus or Fallopian tubes occurs after the onset of puberty and may be complicated by peritonitis.

Tuberculosis of the kidneys and genital tracts should be treated by standard chemotherapy.

### Management during pregnancy and of the newborn

Active tuberculosis during pregnancy is associated with infection of the placenta in approximately half the cases; congenital tuberculosis is rare. The main considerations are of the mother during pregnancy and management of the infant at birth.

The only commonly used drug absolutely contraindicated during pregnancy is SM because of its ototoxic effect on the fetus. INH and RIF are given for 6 months and PZA is added during the first 2 months of treatment. Pyridoxine supplements should be given with INH because of increased requirements during pregnancy.

At birth, if the mother has completed treatment or has inactive disease, the infant is given BCG. If she has active disease and/or is receiving treatment, the infant is given INH 6 mg/kg/d for 3 months and is then given a tuberculin test (and a chest X-ray if necessary). If these are negative INH may be stopped (presuming the mother is not

infectious) and BCG given. If respiratory symptoms develop a chest X-ray should be taken. Where it is doubtful that the mother will comply with treatment, BCG may be given at birth and the infant also given INH for 3–6 months. The extent to which INH may interfere with BCG vaccination is not clear, but is probably small.<sup>303</sup> It is not necessary to use isoniazid-resistant BCG.

If the tuberculin test is positive (> 5 mm), full investigation for tuberculosis should be undertaken. If no clinical or bacteriological evidence of disease is detected, INH should be continued for a total of 6 months. If disease is detected, full treatment as for congenital infection should be given.

Unless the mother has multidrug resistant tuberculosis she should not be separated from her child and should continue breast-feeding, once both are on appropriate chemotherapy. Small amounts of antituberculous drugs are excreted in breast milk, but they are not harmful to the infant. Consideration should be given to testing mother and infant for HIV infection.

### Perinatal tuberculosis

Perinatal tuberculosis is uncommon, although increasing numbers are reported in areas where HIV/tuberculosis coinfection of women has risen.<sup>304</sup> Whether the infection is contracted before birth (congenital) or in the neonatal period is probably only of epidemiological significance. There are three possible routes for congenital infection:

1. transplacental, when the primary infection will be in the liver, or it may possibly bypass the liver through the ductus venosus and be detected in the lungs;
2. aspiration of infected amniotic fluid or infected material in the genital tract, when the lungs will be infected;
3. ingestion, when presumably the liver will be infected.

Symptoms of congenital infection may occur from birth up to 2 months of age with the majority presenting within 2–5 weeks. In neonatal infection, onset of symptoms is later (1–2 months). Common clinical features are respiratory distress, fever, hepatosplenomegaly, lymphadenopathy, poor feeding, and failure to thrive. There may also be skin lesions, ear discharge, jaundice and, in late diagnosed cases, meningitis. The tuberculin test is usually negative but may become positive 6 weeks or more after birth. An IFN-gamma assay may help in assessing whether the baby is infected. Chest X-ray may show bronchopneumonia, sometimes resembling staphylococcal pneumonia, or miliary changes but may not be abnormal in the early stages. Mycobacteria are often isolated from gastric aspirates, tracheal aspirates or ear discharge. The diagnosis may also be made from CSF, or liver, lung or lymph node biopsy. PCR should be undertaken on all specimens. Placental histology or endometrial curettage may confirm a prenatal source of infection. The mortality is high in overwhelming or late-diagnosed cases and pre-term infants. Other bacterial or viral infections may be superimposed.

Treatment is with standard chemotherapy. If drug resistance is suspected, SM or kanamycin should be added for the first 2 months and then replaced by ethambutol. Duration of chemotherapy should be 9 months. There are no studies on the efficacy of chemotherapy for the newborn.

### HIV infection

In industrial countries, tuberculosis/HIV coinfection is not a major problem.<sup>305</sup> In sub-Saharan Africa, in contrast, there has been a marked increase in frequency of children treated for respiratory tuberculosis since the mid-1980s, and 60–70% of cases may be HIV seropositive. Because of confounding factors, including the high prevalence of HIV infection in mothers and of tuberculosis in the household, difficulty in confirming both HIV infection in infants and tuberculosis generally, and confusion with HIV-related pulmonary disease, the true incidence of tuberculosis/HIV coinfection is unknown.<sup>306</sup> What is clear is that in HIV-infected children not receiving antiretroviral therapy the cure rate for tuberculosis is reduced, there is a higher rate of both relapse and reinfection, and mortality is increased.<sup>306–308</sup> For most cases there is no difference in the radiological features between HIV-infected and

non-infected children with tuberculosis, except possibly a tendency for increased frequency of disseminated disease in the more immunosuppressed. Coinfection with systemic environmental mycobacteria is also a feature in the latter group. In children presenting with tuberculosis and HIV-related pulmonary disease with bilateral reticulo-nodular changes, hilar lymphadenopathy and finger clubbing, the diagnosis of tuberculosis has to depend on methods other than radiology such as contact history, tuberculin test and culture of *M. tuberculosis*. Although the tuberculin test is often negative, it should always be undertaken as it is positive in a proportion of HIV-infected children.

Because of reports of slow eradication of *M. tuberculosis* and/or relapse, at least 9 months of chemotherapy is advised.<sup>308</sup> For HIV-infected children with a positive tuberculin test and no evidence of tuberculosis, 12 months of INH chemoprophylaxis is advised.<sup>309</sup> In HIV-endemic areas, SM should be avoided because of risks from unsterilized needles. Thiacetazone may cause severe skin reactions in HIV-infected children and is contraindicated.

The interaction of rifampicin with non-nucleoside reverse transcriptase inhibitors, nevirapine and efavirenz, and with protease inhibitors is a problem. Also an immune reconstitution inflammatory syndrome may occur, usually within 6 weeks of commencing antiretroviral therapy, comprising fever, lymphadenopathy and worsening of the chest X-ray.

### General principles of chemotherapy

A 6 month short-course therapy is standard for respiratory and most nonrespiratory disease.<sup>268,282,310,311</sup> There are still differences of opinion regarding dosage of drugs, especially INH, and the management of meningitis, bone or joint disease, HIV infection and drug resistance. Duration of therapy need not exceed 1 year, except in unusual circumstances such as drug resistance or noncompliance. Intermittent therapy is useful where compliance may be in doubt and is cheaper, although probably only of practical value in areas where supervision is possible. Drugs are usually given twice- or thrice-weekly. Directly observed therapy (DOT) is indicated where there is poor compliance.<sup>312</sup>

Different drugs are effective (in order of efficacy) in:

1. killing actively dividing bacilli, e.g. in open cavities – INH, RIF, SM;
2. killing dormant, intermittently or nondividing bacilli, e.g. in closed caseous lesions – RIF, INH; or within macrophages – PZA, RIF, INH;
3. suppressing drug-resistant mutants – INH, RIF.

PZA is particularly active against bacteria inhibited by an acid environment (e.g. within macrophages and in areas of acute inflammation). Killing actively dividing bacilli and clearing the sputum of live infective bacilli can be accomplished rapidly but for cure or 'sterilization' a prolonged course of treatment is necessary to eradicate dormant and intracellular bacilli. Failure to do this may result in relapse. Mycobacteria may survive for years in a dormant state when metabolism is inhibited by low oxygen tension or low pH.

The most commonly used drugs are bactericidal, e.g. INH (the most potent), RIF, PZA, SM. INH can kill up to 90% of the bacillary population during the first few days of chemotherapy. Bacteriostatic drugs may be used along with bactericidal drugs to prevent emergence of resistance to the bactericidal drugs, e.g. EMB (bactericidal in large doses), ethionamide, thiacetazone and p-aminosalicylic acid (PAS).

The *standard regimen*, used for most types of tuberculosis, is INH + RIF for 6 months, with addition of PZA for the first 2 months. EMB is advised as a fourth drug for the first 2 months if drug resistance is a possibility or there is a high burden of organisms. A longer duration of 9–12 months is advised for some types of disease as indicated in the respective sections. Other schedules are shown in Table 28.25. Caution is advised for EMB in children < 5 years old, because they are too young to report symptoms of optic neuritis, although it is unlikely that problems would arise at a dose of 15 mg/kg.<sup>269</sup> Visual testing should be undertaken where possible. In Table 28.26, the drug dosage and common side-effects are shown. The doses for INH (6 mg/kg) and RIF are minimal and they should be rounded up rather than down. Higher doses, 15–20 mg/kg, are advised for serious forms of tuberculosis such

Table 28.25 Drug regimens

Regimen	Duration
<i>Standard daily</i>	
HRZ(E): 2 months, then HR: 4 months	6 months
HR: 9 months	9 months
HRZ: 2 months, then HR: 2 months	4 months <sup>a</sup>
<i>Intermittent thrice weekly</i>	
HRZ: 2 months, then HR thrice weekly: 4 months	6 months
<i>Alternative less potent daily:<sup>c</sup></i>	
HRZ(E): 2 months, then HE: 6 months	8 months

<sup>a</sup> Add E if drug resistance is suspected or burden of organisms is high.

<sup>b</sup> For hilar lymphadenopathy alone.

<sup>c</sup> Resource limited countries.

H, isoniazid; R, rifampicin; Z, pyrazinamide; E, ethambutol.

as meningitis. Adverse reactions are reported in approximately 1–2% of patients.<sup>313</sup> They are less common in children and usually apparent within 6–8 weeks of starting treatment. Peripheral neuropathy as a complication of INH is rare in children. Slow acetylators are at increased risk and pyridoxine will prevent it. Pyridoxine 10 mg is indicated only for children on meat- or milk-deficient diets, breast-feeding infants, malnourished children, and during pregnancy. Higher doses may interfere with the activity of INH.

The main complication is hepatic toxicity.<sup>314</sup> Transient elevation of transaminases occurs in 7–17% of children taking INH, is dose-related and is more likely if RIF is also given. There are case reports of hepatocellular toxicity and death from INH therapy in children.<sup>313</sup> There is no need to monitor serum transaminases unless there is pre-existing liver disease or high doses of these drugs are administered, e.g. in meningitis. Parents should be asked to report persistent nausea, vomiting, malaise and especially jaundice. Children who are rapid acetylators do not have an increased risk of hepatitis when exposed to INH.

Cutaneous reactions, if mild, may not require cessation of treatment, but generalized hypersensitivity will. If toxicity occurs, all drugs should be stopped and reintroduced sequentially in the order INH, RIF and PZA in a small dose (approximately a quarter of the full dose) the first day, increasing to full dose over the next 2–3 days.<sup>314</sup>

Corticosteroids reduce the host's inflammatory response, which may contribute to tissue damage. However, there is only strong evidence of benefit in tuberculous meningitis, although they are sometimes used with less evidence in spinal block, obstruction of bronchi by lymph nodes, miliary disease with alveolar capillary block, pleural effusion and pericarditis.<sup>315</sup> Prednisolone 1.5–2 mg/kg/d is given for 2 weeks and gradually tailed off over 6 weeks. Higher doses are given by some for meningitis.<sup>298</sup>

In children, knowledge of drug resistance is usually obtained from culture and sensitivity of the contact. If drug resistance is suspected or is likely, four bactericidal drugs, e.g. INH, RIF, PZA and EMB, should be given. If possible, SM should be avoided because of the trauma of daily injections. In drug resistance, at least two drugs to which the mycobacteria are susceptible should be given. For INH resistance RIF, PZA and EMB are given for a 9–12 month course. For multiple drug resistance, e.g. to INH, RIF and SM, four or more drugs are required initially and treatment should continue for 12–24 months.<sup>269,310</sup> Depending on sensitivities, PZA and EMB are given with three or more second line drugs, e.g. ethionamide, ciprofloxacin, cycloserine or parenterally administered drugs, e.g. kanamycin, amikacin or capreomycin. DOT should be considered.

Patients should be seen monthly for the first 2–3 months to make sure of compliance and to monitor any problems with drugs. Chest X-ray should be repeated at 1–2 months, at the end of therapy, and 3 or more months later. Resolution of pulmonary infiltrates may take over a year and lymphadenopathy (intra- or extra-thoracic) 2–3 years. If adequate chemotherapy has been given, there is no need to prolong treatment; if

relapse occurs or the patient stops treatment for a period, the same standard drug regimen should be given, preferably for 9 months' duration. If in doubt about activity of a pulmonary lesion, gastric aspirates or sputum should be obtained for microscopy and culture. Chest X-rays should be repeated every 6–12 months after cessation of therapy until stable.

Children with primary tuberculosis are rarely infectious and sputum is usually non-infectious after 2–3 weeks of chemotherapy and so they may return to school after this period.

## BACTERIAL INFECTIONS: MYCOBACTERIA – ENVIRONMENTAL

Mycobacteria may be divided into those associated with tuberculosis and leprosy and those causing disease associated with the environment, also referred to as nontuberculous, or atypical mycobacteria. The former (including *Mycobacterium leprae*) are highly infectious and are passed from person to person. Environmental mycobacteria, of which there are over 50 species, exist principally as harmless saprophytes in water, soil and vegetation, and also as pathogens in animals such as birds, reptiles and fish. Person-to-person transmission is extremely rare. Environmental mycobacteria generally prefer warm climates and the geographical distribution of the different species is quite variable. Water (fresh or salt) is probably a major vector, e.g. drinking, washing or aquatic sports, or by inhalation of aerosols.<sup>316</sup> The main portals of entry are probably through the skin or mucosa, and by inhalation or ingestion.

## DIAGNOSIS

Environmental mycobacteria may be detected as commensals in sputum or gastric aspirates, swabs from wounds or abscesses, or in inadequately sterilized sputum pots. More definite proof of their pathogenicity is obtained when they are derived from a closed lesion, e.g. by aspiration or resection, or the same strain of mycobacteria is repeatedly isolated. Differentiation between mycobacteria is by their cultural characteristics or by PCR. Histologically, it is usually not possible to differentiate lesions from the granulomata of tuberculosis, although nontuberculous infection is more likely to show 'nonspecific' inflammation with less prominent caseation. Variable numbers of acid-fast bacilli may be seen.

There may be a moderate reaction to the tuberculin test (purified protein derivative, PPD-S), approximately 3–25 mm, or no reaction.<sup>317</sup> Differential intradermal tests with antigens prepared from specific environmental mycobacteria, e.g. *Mycobacterium avium*, *M. intracellulare*, *M. malmoense*, *M. scrofulaceum* or *M. kansasii*, are more likely to produce a larger reaction than that with PPD-S.

The commonest clinical problem due to infection by environmental mycobacteria in children is cervical adenitis. Other conditions include cutaneous infections, rarely pulmonary or otolaryngeal disease, osteitis, disseminated disease and meningitis.<sup>318,319</sup> In adolescents and adults, infection in the presence of pre-existing pulmonary disease (including cystic fibrosis) is the commonest association.

## LYMPHADENITIS

There appears to be a relative if not an absolute increase in incidence of lymphadenitis due to environmental mycobacteria in areas of the world where tuberculosis is now rare, which may be partly due to decline in neonatal BCG vaccination.<sup>320</sup> However, it also occurs in resource limited countries but is under-reported due to lack of facilities to identify environmental mycobacteria.<sup>321</sup> A defect in the type 1 cytokine pathway could be a factor in some cases.<sup>322</sup> Disease usually presents in children aged between 1 and 5 years, and is usually unilateral and cervical. The submandibular group of nodes is most often infected, followed by tonsillar, pre-auricular and anterior cervical groups. Infection of axillary, inguinal and epitrochlear nodes has been described. The area of entry is rarely identified, although occasionally a lesion on the tonsil

Table 28.26 Recommended drugs for tuberculosis

Drug	Children	Daily dose		Thrice weekly dose			Side-effects
		Adolescents		Children	Adolescents		
		< 50 kg	> 50 kg		< 50 kg	> 50 kg	
Isoniazid (INH)	6 mg/kg p.o., i.m., i.v. 15–20 mg/kg (meningitis)	300 mg	300 mg	15 mg/kg (max 900 mg)	15 mg/kg	Max 900 mg	Hepatic enzyme elevation, hepatitis, peripheral neuropathy, hypersensitivity
Rifampicin (RIF)	10 mg/kg p.o., i.v. 15–20 mg/kg (meningitis)	450 mg	600 mg	15 mg/kg (max 600 mg)	15 mg/kg	Max 900 mg	Orange discoloration of secretions and urine (also contact lens), nausea, vomiting, hepatitis, febrile reactions, thrombocytopenia
Pyrazinamide (PZA)	30–35 mg/kg p.o. 40 mg/kg (meningitis)	1.5 g	2.0 g	50 mg/kg	2.0 g	2.5 g	Hepatotoxicity, hyperuricemia, arthralgia, gastrointestinal upset, skin rash
Ethambutol (EMB)	15–20 mg/kg p.o.*	15 mg/kg (max 2.5 g)	15 mg/kg (max 2.5 g)	30 mg/kg	30 mg/kg	Max 2.5 g	Optic neuritis, skin rash
Streptomycin (SM)	15–20 mg/kg i.m.	750 mg	1.0 g	15–20 mg/kg	750 mg	1.0 g	Ototoxicity, nephrotoxicity
Thiacetazone	4 mg/kg p.o.	150 mg	150 mg	Not recommended	Not recommended	Not recommended	Gastrointestinal disturbance, vertigo, visual disturbance, hepatitis, agranulocytosis, exfoliative dermatitis in HIV infection
Ethionamide/ protionamide	15–20 mg/kg p.o. (divided doses)	750 mg	1.0 g	Not recommended	Not recommended	Not recommended	Gastrointestinal disturbance, hepatotoxicity, allergic reactions

\*In children &lt; 5 years old, give 15 mg/kg.

or buccal mucosa is seen. Enlargement of pre-auricular nodes suggests that the eye might be a portal of entry in some cases. Enlargement of nodes occurs over weeks to months. The overlying skin becomes erythematous or purple prior to discharge of the abscess, but is not usually warm unless secondarily infected. It is commonly mistaken for a pyogenic cervical abscess. A sinus may develop and later calcification may occur. Some nodes probably settle spontaneously. Infection by environmental mycobacteria should be considered when a submandibular or pre-auricular node enlarges in a young child from a background of low tuberculous endemicity, in the presence of a normal chest X-ray and a negative or low grade sensitivity to PPD.

The treatment of choice is excision biopsy of the primary group of involved nodes.<sup>317,318,323</sup> Often the lesion is incised when mistaken for a cervical abscess, or it has discharged spontaneously. In these circumstances, as much necrotic material as possible should be removed and later, if necessary, the primary node excised. Fine needle aspiration is helpful for diagnosis, but mycobacterial culture or PCR is required for confirmation.

Chemotherapy is not usually indicated as the disease is local and the usual mycobacteria causing disease, e.g. *M. avium* complex (MAC) and *M. malmoense*, are commonly resistant to standard tuberculosis chemotherapy. However, if surgery is difficult, e.g. involvement of the parotid gland or closeness of the lesion to the facial nerve, limited incision and curettage may be undertaken and, if healing is slow, antimycobacterial therapy commenced. A suggested drug regimen is azithromycin (10 mg/kg) or clarithromycin plus rifabutin (6 mg/kg) daily for 6 months.<sup>317</sup> Occasionally, longer or repeat treatment is required. Azithromycin has the advantage of once daily treatment and high tissue concentration. There are no controlled trials on the value of single versus combined drugs or duration of therapy. Recurrence of disease in another site sometimes occurs and should be treated as usual.

## OTOLARYNGEAL DISEASE

Chronic infection of the middle ear associated with tympanotomy tubes and chronic mastoiditis due to colonization by, particularly, rapidly growing mycobacteria, e.g. *Mycobacterium abscessus* and *Mycobacterium chelonae*, has been described. Debridement with removal of all diseased tissue and in the case of chronic mastoiditis securing maximum ventilation of the cavity is essential. Chemotherapy with appropriate drugs is given for 6 months. Treatment for *M. abscessus* and *M. chelonae* includes parenteral therapy with amikacin and cefoxitin or imipenem for a few weeks, followed by oral clarithromycin and/or ciprofloxacin, depending on sensitivities.<sup>319,324</sup>

## SOFT TISSUE INFECTION

The most common soft tissue infections are 'swimming pool granuloma' and 'fish tank granuloma', both caused by *M. marinum*. Local abscesses may follow infection by *M. fortuitum* or *M. chelonae* at injection sites, trauma or surgery, and often present 3–4 weeks after infection, although the incubation period may be much longer in deep infections. Regional nodes are not usually enlarged. Mycobacteria can usually be detected in the lesions. Management comprises debridement of diseased tissue, with chemotherapy reserved for extensive or deep-seated disease.

'Swimming pool granuloma' commonly affects children bathing in infected water on areas of abrasion such as the knees or elbows. Papules, which may ulcerate, appear on the affected areas; scab formation follows. Spontaneous healing occurs within a few months. If drug therapy is required, a single agent such as co-trimoxazole, clarithromycin, ciprofloxacin, or, for more severe infections, dual therapy with rifampicin plus ethambutol, is given for 3–6 months.

Buruli ulcer derives its name from a district in northern Uganda and is known as Bairnsdale ulcer in Australia where the causative agent (*M. ulcerans*) was originally identified. *M. ulcerans* produces a potent toxin, mycolactone.<sup>325</sup> It occurs in localized places in a number of tropical rain forest areas around swamps and river banks. It is transmitted

through minor skin injury after contact with water, soil or vegetation contaminated probably by water bugs.<sup>325</sup> It starts as a subcutaneous nodule, often on a leg or arm, ulcerates and gradually progresses to a large ulcer with deep, undermined edges. Satellite nodules or ulcers may be present. Perhaps a third of small lesions heal spontaneously. Diagnosis is by detection of acid-fast bacilli, culture, histology and PCR (98–100% sensitivity).<sup>325</sup> Treatment of large ulcers requires wide excision, cleansing with antiseptic such as 0.5% silver nitrate, and immediate skin grafting. Application of heat to maintain the temperature of the ulcer above 40 °C, which inhibits growth of *M. ulcerans*, may be successful, though not practical in resource limited countries. Chemotherapy is given along with surgery to assist healing. A suggested regimen is rifampicin plus streptomycin for at least 2 months. BCG may give some protection.

## PULMONARY DISEASE

Pulmonary disease due to environmental mycobacteria is rare in immunocompetent children. It presents similarly to pulmonary tuberculosis: primary complex, bronchial obstruction, bronchopneumonia or primary progressive disease.<sup>326</sup> The majority of cases are caused by MAC, less often by *M. kansasii* and, in some cases, by other mycobacteria such as *M. fortuitum*. Obstruction of a bronchus should be resected either at bronchoscopy or thoracotomy. Prolonged chemotherapy may be required.

In about 13% of patients with cystic fibrosis, environmental mycobacteria may be recovered from respiratory tract specimens.<sup>327</sup> The decision to treat with chemotherapy depends on a number of indications including: recovery of mycobacteria on serial specimens, reduction in lung function not responding to standard management, changes on chest X-ray compatible with superinfection, and response to chemotherapy for mycobacteria. Choice of chemotherapy depends on species of mycobacteria. Drugs may need to be continued for up to 2 years.<sup>328</sup>

## DISSEMINATED AND EXTRAPULMONARY DISEASE

Disseminated disease is usually associated with severe immunological defects, congenital or AIDS. When bone disease occurs, it is usually disseminated osteomyelitis, but can rarely be multifocal osteomyelitis without an apparent underlying immunodeficiency. Infection of the meninges may also occur. A variety of inherited defects in the IL-12 dependent gamma interferon (IFN-gamma) output pathway are recognized, which increase susceptibility to mycobacteria (especially environmental mycobacteria and BCG) and to Salmonella.<sup>329</sup> Some patients respond to IFN-gamma therapy.

In HIV infection, disseminated disease due to MAC is usually seen in older children with a low CD4 count and advanced disease. Trials are in progress regarding optimal chemotherapy. A suggested regimen is clarithromycin, ethambutol and rifabutin.<sup>330</sup> Other drugs include clofazimine, rifampicin, ciprofloxacin or amikacin.<sup>324,328</sup>

## DRUG THERAPY

Drugs appropriate for environmental mycobacteria are outlined in Table 28.27. In vitro drug sensitivities may not predict clinical response. Duration of treatment and synergy between drug combinations are important factors. In general, neither isoniazid nor pyrazinamide is useful for environmental mycobacteria. Experience with many of the newer drugs is limited in children and it is important to be aware of side-effects, particularly when used in combination, e.g. plasma levels of rifabutin may be increased by clarithromycin and fluconazole with a risk of uveitis.

## PERTUSSIS (WHOOPIING COUGH)

Although theoretically vaccine-preventable, pertussis continues to be a significant health problem throughout the world. There are a number of reasons for this including:

**Table 28.27** Suggested antimicrobials for treating environmental mycobacterial infection

Organism	Drugs
<i>M. avium-intracellulare</i> and <i>M. scrofulaceum</i> (MAIS complex)	Azithromycin/clarithromycin, rifabutin/rifampicin, ethambutol, ciprofloxacin, clofazimine, amikacin
<i>M. malmoense</i>	Rifampicin, ethambutol, ciprofloxacin, clarithromycin
<i>M. kansasii</i>	Rifampicin, ethambutol, ciprofloxacin, clarithromycin
<i>M. marinum</i>	Rifampicin, ethambutol, clarithromycin, TMP-SMZ, ciprofloxacin
<i>M. fortuitum</i>	Amikacin, ceftoxitin, clofazimine,
<i>M. chelonae</i>	clarithromycin, ciprofloxacin,
<i>M. abscessus</i>	imipenem

TMP-SMZ, trimethoprim-sulfamethoxazole.

- Immunization rates are low in some countries.
- The vaccine is not 100% effective and the immunity is transient.
- Because of potential adverse effects of the vaccine in older children and adults, booster vaccinations have rarely been given beyond the age of 5–6 years, although this is changing.
- Because of the transient nature of the immunity, many adults are non-immune and are now the major source of infection, particularly to pre-vaccinated or incompletely vaccinated infants.
- Because of perceived major adverse events from pertussis vaccine, many parents and medical practitioners are wary about giving this vaccine. Further, they will often give an incomplete course of pertussis vaccination if there have been any (even minor) adverse events from earlier vaccinations.
- Infants are born with no passive immunity to pertussis. The non-immune status of neonates means they are highly vulnerable to this disease until vaccination is complete (generally at 6 months). Unfortunately, this is also the age group where the disease is most deadly.

## PATHOGENESIS

Pertussis is a bacterial infection due to a Gram negative coccobacillus, *Bordetella pertussis*. Although this organism is sensitive to antibiotics (particularly macrolides), once the paroxysmal cough is established, antibiotics have little or no effect on the clinical course of the illness, except to render that patient non-infectious to others. Thus, recognition and treatment of index patients to prevent further spread is an important public health measure.

It is ideal if pertussis is diagnosed *before* the development of the paroxysmal coughing phase, as antibiotics in this initial stage of the illness can reduce the severity of the clinical illness. Although recognition in the pre-paroxysmal phase is difficult, diagnosis of index cases and treatment of any household contacts with any respiratory symptoms (particularly young children) with the appropriate antibiotics is warranted. Indeed, in a young unimmunized infant (less than 6 months), contact with a known pertussis case is an absolute indication for immediate prophylactic antibiotics.

## SPREAD

Droplet or aerosol spread is usual, and indirect spread (e.g. via fomites) is unlikely. The disease is highly infectious and over 80% of unvaccinated household contacts of a known case will develop the clinical illness.

## CLINICAL FEATURES

There are several distinct phases of this illness (see [Table 28.28](#)). The initial early 'catarrhal' phase consists of upper respiratory tract symptoms and a nonspecific dry cough. This phase lasts for 7–10 days and is abruptly followed by the paroxysmal cough phase. During the early paroxysmal phase, there are violent spasms of uncontrollable cough with facial flushing. These spasms of cough can persist for several minutes and are classically followed by an inspiratory 'whoop'. Infants often vomit and may develop apnea and cyanosis with these coughing spasms, and a 'whoop' is often absent in this age group. This phase of the illness can persist for up to 3 months.

Between coughing spasms, children are strikingly well. Thus, pertussis is generally diagnosed on the basis of the history, unless a spasm is directly observed. The number of spasms per day is highly variable and generally peaks within the first 2–3 weeks of the illness, before a very gradual reduction in the frequency and severity of spasms.

In adolescents and adults the disease is highly modified, presumably reflecting their partial immune status. Thus, any adult with a troublesome cough which has persisted for 2–3 weeks should be suspected of having whooping cough. Epidemiological studies have repeatedly shown that adults are the major reservoir of *B. pertussis* infection, particularly of young unvaccinated or incompletely vaccinated infants.

## CASE DEFINITION

The current World Health Organization case definition is as follows: *B. pertussis* infection should be suspected if there is severe cough for greater than or equal to 2 weeks (i.e. 'probable' pertussis). If *one* of the following are present *in addition* to the above, the child should be notified and treated:

- Prolonged cough followed by apnea or cyanosis, and in the older child paroxysm followed by vomiting, inspiratory whoop or the presence of subconjunctival hemorrhages;
- exposure to suspected case in the previous 3 weeks;
- epidemic whooping cough in the area;
- a lymphocytosis of 15 000/mm<sup>3</sup> or greater.

## LABORATORY DIAGNOSIS

Confirmation of the diagnosis is an issue. While a positive culture is the gold standard, this lacks sensitivity and false negatives are common. Standardization of other laboratory methods, including PCR and serology, is required to firmly establish their role in diagnosis. Detection of *B. pertussis* by culture or PCR is used for infants and young children who do not mount a good serological response, while serology is more useful in older children and adults. The USA Centers for Disease Control suggest the following as a guide:

- during the first 7 weeks of the cough: culture and PCR;
- cough for 3–4 weeks: PCR and serology;
- cough for more than 4 weeks: serology only.

**Table 28.28** Natural history of pertussis

## EPIDEMIOLOGY

The disease is endemic in most resource rich countries despite widespread immunization programs. In addition to the endemic cases, there are frequent epidemic peaks, which classically occur every 2–5 years. The endemic nature of this disease presumably reflects the large reservoir of adults who develop a modified illness and infect infants and young children. The true incidence of pertussis is difficult to determine because of the problems with accurate clinical diagnosis, the low sensitivity of microbiology, and uncertainty concerning PCR and serological testing methods. As well as lack of recognition, there is almost certainly under-reporting of the condition in resource rich countries.

## MORTALITY/MORBIDITY

The estimated annual burden of disease, as reported by the World Health Organization, is 200 million–400 million infections worldwide, causing 200 000–300 000 deaths.

The quoted mortality in resource rich countries for this disease is approximately 0.3%, and is slightly higher in infants < 6 months old (0.5%). Major complications resulting in prolonged morbidity include hypoxic encephalopathy and subsequent brain damage. Most of the morbidity and virtually all of the mortality is in infants < 6 months of age.

## VACCINATION

Until recently, the standard vaccine used was a whole cell pertussis vaccine, which unfortunately had a reputation for being both relatively ineffective and potentially harmful. As a consequence, vaccination rates for pertussis often fluctuated and most countries observed major increases in the rates of pertussis when vaccine uptake fell or was low.

Because of the widespread perception of a poor risk:benefit ratio with pertussis vaccine, complete coverage of children < 5 years of age fell to < 50% in the UK in the late 1980s, and was associated with major epidemics.

The introduction of acellular vaccines, with high quality studies showing excellent effectiveness and low adverse event rates, has dramatically altered the situation.<sup>331</sup> Most resource rich countries have replaced whole cell vaccine with acellular vaccine, with increased coverage of complete vaccination in young children. However, to control *B. pertussis* infection will require repeated booster vaccinations in adolescents and adults. The introduction of the acellular vaccine, which can be safely given to adolescents and adults, means that eradication is now a real prospect.

## VACCINE EFFICACY

The published data on vaccine effectiveness have been quite variable. For the whole cell vaccine efficacy varied from approximately 35 to 98%. While the whole cell vaccine offered protection against more severe disease, it did not confer long term immunity. Recent studies show that the efficacy of the acellular vaccine has ranged from 85 to 90%, with a much lower incidence of adverse events.

## TREATMENT

In the paroxysmal phase, antibiotics are indicated to prevent the spread of infection. However antibiotics have little or no impact on the child's coughing illness. Although the usual antibiotic is erythromycin for 7–10 days, newer macrolides (e.g. azithromycin) are equally effective and better tolerated.

In young infants with severe and frequent spasms, admission to hospital and close observation is essential. Treatment revolves around experienced, high quality pediatric nursing care. This includes: avoidance of provoking spasms; close observation and treatment of spasms (with oxygen if necessary); minimal handling; and for uncontrollable life-threatening spasms – endotracheal intubation and mechanical ventilation.

## BACTERIAL INFECTIONS: PNEUMOCOCCUS

Pneumococcus (*Streptococcus pneumoniae*) is a common cause of serious disease in children, particularly otitis media, pneumonia and meningitis. It is also a frequent cause of occult bacteremia.<sup>332</sup> *S. pneumoniae* are Gram positive oval cocci. They cause beta hemolysis (a green zone around the colony) on blood agar, and occur in pairs (diplococci) or short chains. Pneumococci can be characterized serologically by the capsular polysaccharides or by molecular biological techniques. More than 90 pneumococcal serotypes have been characterized but only a small number are responsible for the majority of serious, invasive infection.

## EPIDEMIOLOGY

Approximately 50% of healthy children and 8% of adults<sup>333</sup> carry *S. pneumoniae* in the upper respiratory tract and it is thought that spread is mainly by healthy carriers although patient-to-patient and patient-to-doctor transfer has been documented. Children under 2 years have the highest rate of carriage, but why some infants develop disease whereas others remain unaffected is unknown. In resource limited countries, a high proportion of lower respiratory infection in young children is due to *S. pneumoniae*, and pneumococcal meningitis is associated with a high mortality (30–35%). Globally, *S. pneumoniae* is thought to cause over 1 million deaths in children under the age of 5 years.<sup>334</sup> The 'pneumonia season' in late winter and early spring has been attributed to indoor crowding and damage to respiratory mucosal defenses by recent virus infections.

From the nasopharynx, *S. pneumoniae* may reach the lungs or through impaired respiratory mucosa spread to the middle ear or meninges. Bacteremic spread to a variety of sites may occur, notably the joints.<sup>335</sup>

Antibiotics have reduced the severity and mortality of pneumococcal disease but have had little influence on disease incidence. Despite timely administration of appropriate antimicrobial therapy, infants with pneumococcal meningitis remain at considerable risk from neurological sequelae and the pneumococcus is more likely to cause permanent deafness than either the meningococcus or *Haemophilus influenzae*. Recurrent pneumococcal meningitis is occasionally seen when CSF leakage complicates skull fracture. Children with an absent or nonfunctioning spleen, impaired antibody production and HIV infection are at particular risk of serious pneumococcal infection.

## DIAGNOSIS

In pneumococcal pneumonia there is usually tachypnea with grunting, inspiratory retractions, nasal flaring and cyanosis, but physical examination of the chest may be unhelpful and the radiological changes surprisingly few in the early stages of illness. Blood and CSF cultures are helpful in diagnosis. In bacteremic disease, the white blood cell count is often elevated to over  $20 \times 10^9/L$ . Recovery of the pneumococcus from the upper respiratory tract is unhelpful because of the frequency of the carrier state. Pneumococcal antigen detection in CSF, pleural fluid, serum and urine may be useful for rapid diagnosis, especially in children who have received antibiotics prior to culture.

## TREATMENT

A worrying trend is the increasing antimicrobial resistance among *S. pneumoniae* worldwide.<sup>336</sup> There is regional variation in the incidence of resistant organisms and risk factors include recent antimicrobial use. Penicillin remains the drug of choice for infections with penicillin-sensitive organisms and high drug levels may overcome drug resistance if they exceed the minimum inhibitory concentration (MIC) of the organism. It may not be possible, however, to achieve adequate CSF levels, and pneumococcal meningitis due to resistant organisms should not be treated with penicillin. Multiply drug resistant pneumococci can also be resistant to ceftriaxone and cefotaxime so, whilst awaiting sensitivity

results, vancomycin use is recommended (usually in combination with ceftriaxone) if there is a strong clinical suspicion of multiply resistant organisms.

## PREVENTION

### Pneumococcal vaccine

Although pneumococcal vaccines have been available for many years they have had, until recently, limited efficacy in children under 2 years and their use was therefore targeted towards older children with risk factors such as splenectomy.

The older pneumococcal polysaccharide vaccines (PPV) are manufactured using 23 (23-valent) pneumococcal serotypes, do not stimulate T cells, do not induce a boostable memory response and are ineffective in children under 2 years of age.<sup>337</sup>

The pneumococcal conjugate vaccine (PCV) is manufactured by conjugating carrier proteins to capsular polysaccharides from the seven (7 or hepta-valent) or nine (9-valent) commonest pneumococcal serotypes responsible for 80% of invasive disease. These vaccines are T cell dependent and thus are immunogenic in infancy and induce memory so that the immunological response is boostable.<sup>337</sup>

A pivotal, randomized controlled trial of heptavalent PCV in more than 18 000 children given from 2 months of age showed 97.4% protection against invasive pneumococcal disease.<sup>338</sup>

PCV was introduced for routine use in infants and toddlers in the USA in 2000 and since then significant reductions in invasive pneumococcal disease have been seen in vaccinated children.<sup>339-342</sup> Hospitalization rates for all-cause pneumonia in children less than 2 years (the target population) have declined by 39%<sup>343</sup> but the introduction of the vaccine has also been linked with reduced invasive pneumococcal disease in young infants and adults suggesting changes in pneumococcal carriage rates, transmission and herd immunity.<sup>339,344,345</sup> The vaccine also appears effective in children with chronic diseases<sup>342</sup> including HIV infection.<sup>340,346</sup>

PCV was introduced into the UK childhood immunization program in the autumn of 2006 and offered to children age 2, 4 and 13 months (<http://www.immunisation.nhs.uk>).

PPV is recommended as an additional strategy for children aged 2 years or older in whom pneumococcal infection is likely to be more common and/or dangerous:

- asplenia or severe dysfunction of the spleen, e.g. homozygous sickle cell disease and celiac syndrome;
- chronic renal disease or nephrotic syndrome;
- immunodeficiency or immunosuppression from disease or treatment (including HIV infection);
- chronic heart, lung or liver disease;
- diabetes mellitus;
- cochlear implants
- history of invasive pneumococcal disease
- presence of CSF shunt or other condition with risk of CSF leak

*Note:* Where possible, the vaccine should be given 4–6 weeks (but at least 2 weeks) *before* splenectomy and *before* courses of chemotherapy, together with advice about the risk of pneumococcal infection. If this is not possible, as for splenectomy following trauma, the vaccine should be given as soon as possible after recovery and before discharge from hospital. If not given before chemotherapy and/or radiotherapy its use should be delayed for at least 6 months after completion of treatment.

### Chemoprophylaxis

An alternative for children with functional or anatomical asplenia, for those receiving immunosuppressive therapy, or for infants under 2 years, is to give them continuous antibiotic prophylaxis, e.g. phenoxymethyl penicillin.<sup>347</sup>

## EDUCATION

Patients at risk (or their parents) need to be educated about the risks and the importance of seeking medical help at the onset of illness.

A MedicAlert bracelet should be used. A patient card and information sheet for asplenic or hyposplenic patients is available from: Department of Health, PO Box 410, Wetherby LS23 7LL.

## BACTERIAL INFECTIONS: PSEUDOMONAS

### PSEUDOMONAS AERUGINOSA

*Pseudomonas aeruginosa* is an important nosocomial pathogen with innate resistance to many antimicrobial agents and disinfectants. The bacterium grows readily in moist environments including ventilator and incubator humidification systems. Known to pediatricians as a cause of life-limiting respiratory infection in cystic fibrosis, *P. aeruginosa* can infect virtually any part of the body. Infection is usually associated with congenital or acquired immunodeficiency, prematurity, neutropenia or white cell dysfunction, malignant disease and its treatment, transplantation, prolonged instrumentation of body cavities (e.g. tracheostomy, ventricular drainage, bladder catheterization, venous catheterization, peritoneal dialysis) and following puncture wounds. *P. aeruginosa* infections are generally restricted to immunocompromised patients, but severe infections may occur in healthy children and require prompt diagnosis and treatment. The most important *P. aeruginosa* infections in pediatric patients include:

### Septicemia

*P. aeruginosa* is an important cause of septicemia in oncology and neonatal units. However, anti-pseudomonas activity is not usually included in antibiotic protocols to cover presumed sepsis in children with no previous medical disorders. Even when appropriate antibiotic therapy is given, mortality is high. The characteristic necrotic skin lesion, known as ecthyma gangrenosum, is a typical feature of *P. aeruginosa* septicemia and may be useful in diagnosis.

### Meningitis

*P. aeruginosa* meningitis is seen mainly in premature babies and in patients with ventricular drainage catheters or those undergoing intrathecal therapy. It calls for immediate intravenous therapy with a suitable antibiotic, guided by the results of antibiotic sensitivities.

### Ear infection

*P. aeruginosa* is commonly cultured from chronically infected ears (otitis externa) and mastoids, particularly in regular swimmers (swimmers' ear). Occasionally an aggressive and painful infection is produced which is difficult to eradicate and may require surgery.

### Eye infections

*P. aeruginosa* is an important cause of pediatric keratitis following corneal trauma, or secondary to immunosuppression or prematurity. The response to apparently appropriate systemic and topical antibiotic therapy is often disappointing and keratoplasty may be necessary. *P. aeruginosa* also causes orbital cellulitis.

### Urinary tract infection

Urinary tract infection usually follows long term catheterization, but also occurs when chronic infection has impaired local tissue viability. The organism is a common commensal under the prepuce, and this should be suspected as the source of unexpected *Pseudomonas* bacteriuria.

### Respiratory infections

*P. aeruginosa* pneumonia occurs in the presence of the predisposing factors outlined earlier or following prolonged treatment of other bronchopulmonary infections. Chronic airway infections with mucoid variants of *P. aeruginosa* and repeated debilitating exacerbations are a major cause of morbidity and mortality in individuals with cystic fibrosis.

### Osteomyelitis

*Pseudomonas* osteomyelitis is particularly associated with penetrating injuries to the foot through sports shoes such as from stepping on a

nail ('sneaker osteomyelitis'). In this setting or when osteomyelitis fails to respond to antibiotic therapy directed against *Staphylococcus aureus*, *Pseudomonas* should be considered. It is not always possible to isolate the organism from blood cultures, and antibiotic therapy may have to be broadened blindly.

### Skin infections

*Pseudomonas* skin infections are seen where the skin of the foot has become macerated from prolonged immersion or the wearing of rubber footwear. Ecthyma gangrenosum, an aggressive skin infection usually arising in children with one of the predisposing factors already mentioned, produces necrotic ulcerative lesions involving particularly the anogenital and axillary areas, and can be rapidly fatal.<sup>348</sup>

### Management of *Pseudomonas aeruginosa* infections

Treatment of *P. aeruginosa* infections can be difficult if not diagnosed early. The choice of antibiotic therapy should depend on the laboratory sensitivity of the isolate.<sup>349</sup> Many strains are sensitive to broad spectrum penicillins such as ticarcillin, aminoglycosides such as gentamicin, and anti-pseudomonal beta-lactams such as ceftazidime, all of which must be given parentally and usually in combination. Safety concerns over the use of quinolones in pediatric patients have reduced, and agents such as ciprofloxacin can be given orally.

### BURKHOLDERIA (PSEUDOMONAS) CEPACIA COMPLEX

*Pseudomonas cepacia*, now classified as a group of closely related species known as the *Burkholderia cepacia* complex, are important pulmonary and transmissible pathogens in children with cystic fibrosis or chronic granulomatous disease.<sup>350</sup> Outbreaks of nosocomial infection in intensive care units can also occur and usually be traced to contaminated solutions, including disinfectants. In individuals with cystic fibrosis, the *B. cepacia* complex can be aggressive pathogens producing a rapidly fatal necrotizing pneumonia, known as 'cepacia syndrome'.

*B. cepacia* complex species are intrinsically resistant to many antibiotics but may be sensitive to antibiotic combinations containing two or three agents. Of the newer antibiotics, meropenem is the most active agent.

### BURKHOLDERIA (PSEUDOMONAS) PSEUDOMALLEI

*Burkholderia pseudomallei* causes melioidosis, is spread mainly by contaminated monsoon waters and is endemic in tropical areas of south-east Asia and Australia. Pediatric pneumonia is an important feature of melioidosis, but it may also present with multiple metastatic abscesses and 'imitate' other infections. Melioidosis has a high mortality and responds better to intravenous ceftazidime than to conventional therapy with tetracyclines and chloramphenicol.<sup>351</sup>

### OTHER PSEUDOMONAS SPECIES

Numerous species of *Pseudomonas* (e.g. *P. fluorescens* and *P. putida*), some renamed (e.g. *Stenotrophomonas maltophilia* and *Ralstonia pickettii*), are recovered from time to time from clinical microbiology specimens, particularly from immunocompromised or otherwise vulnerable patients.

### PREVENTION OF NOSOCOMIAL PSEUDOMONAS INFECTIONS

In the management of *Pseudomonas* infections, prevention is easier than cure. Thorough drying (and preferably sterilizing) of equipment after cleaning, and scrupulous attention to the manufacturer's instructions for the storage and use of antiseptic solutions are important in curtailing outbreaks of nosocomial infection.

## BACTERIAL INFECTIONS: RELAPSING FEVER

Relapsing fever is a disease caused by *Borrelia* species. It is characterized by sudden onset of fever with recurrent episodes of fever. There are two types of relapsing fever (RF): epidemic or louse-borne relapsing fever (LBRF) and endemic or tick-borne relapsing fever (TBRF).

### EPIDEMIOLOGY

Relapsing fever has a worldwide distribution, though epidemic RF is prevalent in East Africa, particularly Ethiopia and the Sudan. LBRF epidemics usually follow massive movement of people or disasters such as famine, flooding and earthquake.<sup>352,353</sup> Disaster situations cause overcrowding and lapses in personal and domestic hygiene. The seasonality of TBRF infection varies depending on the behavior of the ticks, whereas LBRF peaks in the rainy season, when people tend to crowd. RF affects both sexes equally in children. Infants account for less than 5% of cases.<sup>354</sup>

### ETIOLOGY

LBRF is caused by *B. recurrentis*, while TBRF is caused by various *Borrelia* species in different areas, including *B. duttoni* (East Africa), *B. hispanica* (Spain), *B. persica* (Asia), *B. hermsii* and *B. turicatae* (North America).

### PATHOGENESIS

LBRF is transmitted from person to person by body lice. Man is the only reservoir for *B. recurrentis*. The lice prefer normal body temperature to higher temperatures, so lice leave febrile patients and infect afebrile ones.<sup>355</sup> Lice acquire *Borrelia* while feeding on the blood of an infected person. The ingested *Borrelia* enter the mid-gut of the louse. From the mid-gut, the *Borrelia* penetrate the gut wall, enter the hemolymph, and multiply in the body cavity. They do not reach the salivary glands or the ovaries. Human beings are infected when the infected lice are crushed on the skin and *Borrelia* enter the human body through the skin abrasions or intact skin. The louse can remain infective throughout its life span.

Ticks of the genus *Ornithodoros* are important vectors for the transmission of TBRF. Ticks inhabit rodent burrows, earthen floors and crevices of houses. Ticks get infected while feeding on infected animals, especially rodents. Within a few days the spirochetes enter the salivary glands, coxal glands, central ganglion and Malpighian tubules. Infected ticks transmit *Borrelia* to human beings through bites. An infected tick can transmit *Borrelia* to its offspring, which can also transmit to human beings.

In both types of RF spirochetemia occurs and the spirochetes can be detected in the blood of the patient. The characteristic recurrence of symptoms in RF is due to antigenic changes that result in new clones, and during relapse new antibodies are formed. An important clinical characteristic of RF is a Jarisch-Herxheimer (JHR) reaction following destruction of the spirochetes in the course of the disease or treatment. The cause is unclear, although JHR is associated with raised levels of tumor necrosis factor alpha (TNF-alpha), IL-6 and IL-8.<sup>356,357</sup>

### CLINICAL FEATURES

The incubation period for both LBRF and TBRF is about 7 days, range 4–18 days. The clinical manifestations may be indistinguishable from the common tropical febrile illnesses such as malaria, typhus fever and typhoid fever. Concomitant infection with typhus is not uncommon in LBRF as both are transmitted by lice.

The onset of RF is characterized by sudden onset of high grade fever, shaking chills, dry cough, abdominal pain and headache accompanied by joint pain, back pain, neck pain and myalgia. Some patients have neck stiffness. Hepatomegaly with hepatic tenderness is common and about a third of patients have splenomegaly. Jaundice with dark-colored urine is occasionally seen, with or without hepatic

abnormalities. Hemorrhagic manifestations can include petechial rash, epistaxis and/or hematuria. Neurological abnormalities in TBRF include peripheral neuritis and focal neurological deficits, while patients with severe RF of either type may develop confusion and altered consciousness. Severe cases may develop pneumonia and myocarditis. Myocarditis is usually the cause of death in RF, especially during JHR.

In untreated cases, symptoms disappear in about a week, but tend to recur after 7 or more days. With each relapse the symptoms are milder and shorter in duration. In LBRF the usual number of relapses is 1–2, but for TBRF it is 3 or more.

JHR occurs within a few hours of starting antibiotics in about a third of children and severity varies.<sup>358</sup> JHR has two phases: the chill phase and the flush phase.<sup>359</sup> The chill phase, which begins about an hour after administration of an antibiotic and lasts for 10–30 minutes, causes a rise in heart rate, arterial blood pressure and breathing rate, rigors and anxiety. This is followed by the flush phase, in which the temperature and arterial blood pressure drop and the patient becomes diaphoretic and may become shocked.

## DIAGNOSIS

Diagnosis is based on the identification of *Borrelia* in blood films taken during the febrile period and stained with Wright or Giemsa stains. Detection of spirochetes can be enhanced by staining fixed smears with acridine orange and by dark-field or phase-contrast microscopy of wet-mount preparations. *Borrelia* can be cultivated by inoculation of rodents or in artificial medium. The role of serology in the diagnosis of RF is not well established. The leukocyte count may be normal or elevated, but is low in JHR. The platelet count is often low. Urinalysis often reveals increased leukocytes, red blood cells (RBC) and RBC casts. Blood urea nitrogen is elevated until patients are rehydrated and urine output is increased. Liver transaminases and bilirubin levels may be elevated. Cerebrospinal fluid analysis may reveal pleocytosis in a few patients, but CSF culture is negative.<sup>358</sup>

## TREATMENT

The aim of treatment is to clear spirochetes from blood and tissues and to prevent or control JHR. A wide range of antibiotics is effective. A single dose of an antibiotic often clears the organism from the blood, but it is recommended to continue antibiotics for a couple of days to prevent relapses. Fast destruction of the spirochetes with antibiotics such as tetracycline increases the severity of JHR. Hence, it is recommended to start treatment with less intense destruction of the organisms by using penicillin followed by tetracycline for LBRF. A single dose of benzylpenicillin 400 000 units is given intramuscularly, followed by tetracycline 50 mg/kg/d in 4 divided doses for 2 days for children > 8 years old. Erythromycin or chloramphenicol is an alternative for children less than 9 years old, for whom tetracycline is contraindicated. Penicillin does not eradicate spirochetes from the blood in some patients,<sup>354,360</sup> probably due to poor penetration of penicillin across the blood–brain barrier to clear spirochetes persisting in the cerebral vessels. For TBRF, a 7–10 day course of penicillin is recommended.

It is important to be vigilant for the occurrence of JHR by monitoring vital signs. Keep an IV line open with normal saline to combat shock in case it occurs during JHR. Meptazinol has been claimed to be effective in diminishing the JHR.<sup>361</sup> Recent studies have shown that JHR is associated with increased levels of TNF- $\alpha$ , IL-6 and IL-8; when anti-TNF $\alpha$ -Fab was given 30 minutes before penicillin, plasma levels of IL-6 and IL-8 were reduced and the incidence of JHR decreased.<sup>356,357</sup> However, the place of antibodies against TNF- $\alpha$  in the treatment of JHR has not been well established.

## PREVENTION

The most important measure is avoidance of lice and ticks. Improvement in personal and domestic hygiene is an important step to

prevent breeding of vectors. Insecticides should be used to delouse the body, clothing and dwellings. In epidemics early case identification and treatment will decrease the size of the human reservoir in LBRF.

## PROGNOSIS

In adults, the case fatality rate of LBRF is 3–4% among treated patients<sup>359</sup> and may be as high as 40% among the untreated.<sup>361</sup> In TBRF, the case fatality rate in children admitted to hospital is 8.8% in Tanzania.<sup>362</sup> Among hospital admitted children with LBRF, the case fatality rate is <2%.<sup>354,358</sup> In LBRF, death is associated with adulthood, delay in consultation and presence of vomiting.<sup>363,364</sup>

## BACTERIAL INFECTIONS: SALMONELLOSIS

Salmonellosis is caused by nontyphoidal salmonellae (NTS) which are important causes of infection and disease in children worldwide. A relatively large dose (more than  $10^5$  colony-forming units) of *Salmonella* is usually required to cause infection. Neonates and young infants are at particular risk of infection because of relative achlorhydria and frequent milk feeds that increase gastric pH and because of lack of acquired immunity.

There are important differences between resource rich and resource limited countries regarding epidemiology and clinical presentation of salmonellosis.<sup>365</sup> In industrialized countries, NTS infection is usually food-borne, causing acute gastroenteritis, but extraintestinal disease is rare.<sup>366</sup> In the UK, most reported cases of food poisoning are due to *Salmonella*. These outbreaks are associated with infections contracted abroad and with infected food, especially from poultry, cattle and pigs. Infection may occur from unhygienic handling or inadequate cooking of food, especially of infected frozen meat that has not been allowed to thaw fully or of refrigerated eggs. Intensive farming methods with the addition of antibiotics to feeds have increased the frequency of infected food and added to the growing problem of multidrug resistant *Salmonella*. Intrafamilial spread and spread through institutions is common, and outbreaks at restaurants, parties and picnics are frequently reported. Pet reptiles are also occasional household sources of infection.

In resource limited countries NTS are also an important cause of invasive extraintestinal disease, particularly in tropical Africa during the rainy season.<sup>367</sup> Intensive rearing of food animals is uncommon in this context, but many children live in crowded conditions with poor sanitation and contaminated water sources. Human-to-human infection by chronic carriers and water-borne salmonellosis in sewage are more likely methods of spread in the community. Nosocomial infection is also relatively common.

## PATHOGENESIS

The sites of invasion by salmonellae are usually the ileum and/or the colon. The bacilli can penetrate the mucosa to the lamina propria of the ileum without producing obvious damage to cells and invoke a mainly neutrophil response (as opposed to *S. typhi* which produces a monocytic response). Infection of the ileum results in a watery diarrhea, secretory in nature. Less commonly, invasion of the colon may produce a dysentery-type illness.

Under certain conditions there may be bloodstream invasion, resulting in septicemia or focal infection such as meningitis, osteomyelitis, septic arthritis or empyema. Risk factors for invasive disease include young age, malnutrition, and immunodeficiency including HIV infection. In tropical Africa, an association of invasive NTS disease with malaria and anemia has been reported. Conditions such as hypochlorhydria, hemoglobinopathies especially sickle cell disease, schistosomiasis and malignancy also increase risk of invasive disease.

In sickle cell disease, infarction of the gut may allow salmonellae access to the bloodstream, from where they may invade infarcted areas of bone resulting in osteomyelitis. Also, the impaired opsonization and phagocytic activity in sickle cell disease exacerbates the infection. People

with schistosomiasis may harbor salmonellae within the worm or perhaps the granuloma, which protects them from the body's immune system. There may be prolonged or intermittent fever with joint pains and malaise. Treatment should include appropriate chemotherapy for schistosomiasis and *Salmonella*.

## CLINICAL FEATURES

The incubation period of *Salmonella* enteritis is 12–48 h. Symptoms in essentially healthy individuals include nausea, vomiting, abdominal pains and diarrhea. In mild cases there may only be diarrhea. The diarrhea may be secretory in nature, with frequent high volume, watery stools resulting in hypotonic dehydration. Alternatively, the presence of blood and mucus may indicate colitis. In severe cases, toxic megacolon and perforation can occur.<sup>367</sup> Fever is common and occasionally there may be an enteric fever-type illness. A reactive arthritis may occur and is associated with HLA-B27 histocompatibility antigens. Symptoms usually settle after 5–7 days but loose stools may continue for several weeks.

In infants < 1 year old, especially neonates and infants < 3 months, septicemia with metastatic infections can occur. In systemic salmonellosis, gastrointestinal symptoms may not be prominent and the infection may be diagnosed only by blood culture. Serious consequences of blood invasion in young infants are meningitis, osteomyelitis and failure to thrive. In older infants and children, bacteremia is usually associated with fever or toxemia, but infants < 3 months old may be afebrile.

Studies in sub-Saharan African children have shown that invasive NTS disease is also common in children > 1 year old and is associated with a high mortality.<sup>367,368</sup> The presentation is often a nonspecific febrile illness or with cough, dyspnea or diarrhea. Associated clinical features are anemia, hepatosplenomegaly, malnutrition and malaria parasitemia. Other common presentations of extraintestinal disease include meningitis and septic arthritis.<sup>367</sup> Mortality is reported as 25% for NTS bacteremia and over 50% for NTS meningitis. In contrast, *Salmonella typhi* is the commonest blood isolate in under-5s in the Indian subcontinent, while NTS is relatively uncommon.<sup>369</sup>

## DIAGNOSIS

*Salmonella* culture is more likely from feces than from a rectal swab. In suspected cases, repeat culture may be necessary as excretion of the organisms may be intermittent. Leukocytes are often seen, and red blood cells and mucus may be present. In *Salmonella* colitis, endoscopy may demonstrate a swollen edematous mucosa with mucus and areas of hemorrhage suggesting ulcerative colitis.

In invasive disease, blood, CSF, urine culture and culture of metastatic lesions such as bone will confirm the diagnosis. Blood culture is advised in infants < 3 months of age and immunocompromised children with *Salmonella*-positive stools, irrespective of whether or not there are symptoms of bacteremia. NTS are not fastidious organisms and are usually readily cultured.

## MANAGEMENT

In cases of secretory diarrhea, rehydration and fluid maintenance alone may be necessary. Antibiotics are not indicated for otherwise healthy children with acute NTS gastroenteritis because they do not alter the course of the disease but may prolong excretion in stools and encourage development of multidrug resistance.<sup>370,371</sup> Resistance of NTS to antibiotics relates to their ability to acquire drug resistance from other bacteria in the gut through plasmids and transposons.

Antibiotics are indicated for children with invasive disease. Current preferred first choice is a third generation cephalosporin, cefotaxime or ceftriaxone, or one of the fluoroquinolones, e.g. ciprofloxacin, but multidrug resistance is increasingly common.<sup>366</sup> Treatment for NTS bacteremia should be given for at least 7 days, but longer courses are required for meningitis, osteomyelitis or for children with HIV/AIDS who are at

particular risk of relapse after cessation of antibiotics. The advantages of fluoroquinolones are excellent efficacy and tissue penetration with either parenteral or oral administration, and eradication of intestinal carriage.

Antibiotics are indicated in suspected *Salmonella* enteritis, pending blood culture results, for infants < 3 months of age (particularly febrile infants and neonates), and for immunocompromised children.<sup>372</sup> In prolonged illness, with failure to thrive or in immunocompromised children, intravenous feeding should also be considered before significant weight loss has occurred.

Persistent excretion of *Salmonella* may occur for weeks or some months, especially in young infants. No action is necessary, except for advice regarding hygiene, e.g. when changing nappies and washing the hands of young children. No restriction of activities is necessary, if stools are normal.

## TYPHOID FEVER

In England and Wales, from 1996 to 2006, there were on average 182 reports of *S. typhi*, 177 of *S. paratyphi* A, and 22 reports of *S. paratyphi* B infection per annum, over two thirds of which were contracted abroad, particularly in the Indian subcontinent.<sup>373</sup> *S. paratyphi* C was rare. There has been a recent increase in *S. paratyphi* A consistent with the increase reported in parts of Asia.<sup>374,375</sup> In many resource limited countries, where hygiene and sanitation are poor, typhoid fever is endemic and constitutes a major health problem.<sup>374</sup> It is considered that up to 80% of infections are mild or subclinical and thus hospital statistics grossly underestimate the prevalence. The classical features of typhoid fever are mainly found in school-age children and young adults. When *S. typhi* is isolated from young children the presentation is often atypical.<sup>376</sup>

*S. typhi* only infects humans. Subjects are infectious during the acute phase of the disease and when chronic infection of the biliary system, especially the gallbladder, occurs, persistent excretion of the bacteria in feces results. In patients with structural abnormalities of the urinary tract, such as those resulting from *Schistosoma haematobium* infection, there may be prolonged excretion of *S. typhi*.

## Epidemiology

In technically advanced countries, typhoid fever is usually caused by contamination of food by a carrier. *S. typhi* can survive for long periods in food and can withstand freezing and drying. Outbreaks may occur from infected milk and ice cream, and in institutions a wide variety of foods have been infected when a carrier is involved with preparation. Oysters and shellfish cultivated in contaminated sewage may be infected. In resource limited countries, flies and insects may transmit infection and a contaminated water supply may be the source of an outbreak. Contaminated ice may also be a cause. The infective dose is much smaller than in nontyphoidal salmonellosis.

## Pathogenesis and pathology

After ingestion, the bacilli invade mainly the upper bowel, with minimal inflammation, and pass to the local lymphatics where they are taken up by macrophages. Their easy access through the bowel may be explained by the ability of *S. typhi* to invade the gut without stimulating an acute inflammatory response or recruitment of neutrophils. If the macrophages have not been sensitized by a previous infection they are unable to kill the bacteria, which are then transported within the macrophages to the thoracic duct and thus to the reticuloendothelial system where the uncontained bacilli proliferate in the bone marrow, lymphoid tissue, liver and spleen. At this stage, marrow and blood culture will be positive. The degree of infection depends on the dose and virulence of the organism, the protective effects of gastric juice, and the host's immune response.

Proliferation of bacilli, which is enhanced by bile, continues in the bile ducts and especially the gallbladder, from where large loads of bacteria pass into the gut and may be cultured from a duodenal aspirate. The organisms are taken up by macrophages in Peyer's patches,

particularly those in the ileum. By now, the macrophages have been activated by sensitized lymphocytes and an inflammatory reaction takes place. This results in swelling, necrosis and ulceration of Peyer's patches, which in most cases heal uneventfully. However, erosion of blood vessels may cause intestinal hemorrhage, and extension of the necrosis through the bowel wall may result in perforation. At this stage, which is usually 2–3 weeks after the initial infection, most of the bacteria are intracellular and so blood culture is less often positive, but continuous proliferation in the gallbladder results in shedding of large numbers of bacilli into the gut and stool culture becomes positive. Infection of urine reflects the bacteremia, and a quarter to one third of patients may excrete *S. typhi* during the illness.

Within the body, reaction to the infection continues. Many tissues are affected including the liver, spleen, kidney, heart and lungs. Typhoid nodules, which are foci of macrophages and lymphocytes, can be detected in a number of organs. Cloudy swelling of the liver and kidney occurs and the enlarged spleen is packed with proliferating cells in the sinusoids and pulp. Toxemia is the most likely cause of organ dysfunction, as signs of inflammation are patchy, and is also probably responsible for the mental confusion. Glomerulonephritis and renal failure may occur and are, in some cases, due to immune complex disease.

Rarely, local suppurative infections may develop in bone, joints, lung, kidney and meninges. *S. typhi* osteomyelitis is commonly associated with sickle cell disease.

### Clinical features

The incubation period is around 10–14 days and shorter in those receiving a high infecting dose of the organism. During the first week of illness there are vague influenza-like symptoms, namely fever, malaise, aches and pains and headache. Persistence of fever for over a week should alert one to the diagnosis. At this stage, common symptoms are headache, drowsiness, anorexia, vomiting, abdominal pain, diarrhea and cough; constipation may be a symptom in older children. On examination the temperature is often 39–40 °C and may have a 'swinging' septicemic pattern. Occasionally, the temperature may be normal in moribund children and rise after resuscitation. Signs of toxemia and confusion are common. The respiration rate is often raised and non-localized wheeze and crackles may be heard in the chest. The pulse rate is raised and may be weak in late-diagnosed cases. A bradycardia relative to the level of temperature, seen in some adults, is usually not present in young children. Signs of heart failure may be present, especially if there is anemia and/or myocarditis. The abdomen is mild to moderately distended with vague nonlocalized tenderness. The spleen is enlarged in 20–30% of cases and the liver in a similar proportion. Rates of hepatosplenomegaly vary geographically and according to the duration of the disease. Meningism may be detected. Rose spots, which are pink macules that fade on pressure, may be seen, especially on the trunk. *S. typhi* may be cultured from them. They may appear in successive crops lasting 2–3 days. They have rarely been reported in children with dark skin.

In uncomplicated cases, treatment results in symptomatic improvement within 2 days and the temperature is usually normal within the week. The physical signs resolve in 2–4 weeks but the child may not regain full strength for 1–2 months.

*S. typhi* infection during pregnancy may cause abortion. Though transplacental infection occurs, perinatal infection is commonly due to infection during parturition.

In infants and young children, infection by *S. typhi* may present as a rapid septicemic-type illness with respiratory signs, seizures and meningism. Conversely, presentation may be milder in some infants compared to older children.<sup>376</sup>

In resource limited countries, the presence of nutritional anemia and malnutrition and diseases such as malaria, tuberculosis, sickle cell disease, schistosomiasis and leishmaniasis may complicate the diagnosis. In these diseases, splenomegaly is a common feature. The tendency to anemia in typhoid, which is commonly due to marrow depression, may be exacerbated by the above diseases, and also by glucose-6-phosphate dehydrogenase deficiency and the thalassemias.

The association between *Salmonella* infections and sickle cell disease and schistosomiasis is described in the section Salmonellosis.

### Complications

Perforation of the gut is one of the major complications. It appears to be less common in young children. It is most common in the second to third week of the illness but may occur at any time. If it is observed in hospital, it is often associated with sudden deterioration, hypotension, tachycardia and abdominal rigidity. Sometimes perforation is less dramatic and presents more as an ileus. Occasionally, air is detected under the diaphragm in a child who is not particularly sick. Presumably, the perforation, being small, has sealed off spontaneously. Intestinal hemorrhage may accompany or occur independently of perforation. Other complications include pneumonia, myocarditis, heart failure, glomerulonephritis, renal failure, hepatitis, focal or generalized central nervous system disorders and meningitis. The association between septic osteitis and sickle cell disease has already been mentioned.

### Diagnosis

Blood culture is positive in 70–80% of cases in the first 7–10 days of the illness and in about half this number in the following 2–3 weeks and may still be positive after some weeks of illness. However, prior antibiotics may affect sensitivity, as may the volume of blood taken. For school-children 10–15 ml, and for preschool children 2–4 ml are required to achieve optimal isolation rates.<sup>374</sup> Culture of marrow is more often positive than blood, and both may remain positive despite previous or current antibiotic therapy. Early on, stool culture may be positive in 50% of cases and later in the disease in over 70%. Urine culture may be positive in 25–30% of cases. Thus, the combination of blood, stool and urine cultures should diagnose most untreated cases. Leucocytes, predominantly mononuclear, are usually detected in the stool and there is often some proteinuria.

In resource limited countries where routine blood cultures may not be available the Widal test is commonly relied upon for diagnosis; however, it lacks sensitivity and specificity.<sup>374,375</sup> A high titer of O antibody (> 1:160) or four-fold rise in titer in a child in a non-endemic area who has not had a recent typhoid vaccination (within 1 year) is highly suggestive of typhoid fever. In endemic areas, H antibodies may be raised from previous infections and vaccination also results in a sustained raised H titer. Also, in endemic areas an anamnestic response of O antibody to nontyphoid illnesses may necessitate having a higher diagnostic level during the first week of illness. Conversely, O antibodies may fail to develop and, if present, fail to rise in confirmed typhoid fever. In tropical countries, immunosuppression by malaria may be a factor. Persistence of Vi antibodies may be used as evidence of carrier status, but they may be raised (> 1:5) in only 70% of cases. A number of rapid diagnostic tests are being evaluated. These include tests to detect IgM antibodies against specific *S. typhi* antigens, e.g. Typhidot-M®, Tubex®, a dipstick test and nested PCR.<sup>374,375</sup>

Anemia is common and the white cell count is usually normal or low. There may be neutrophilia in young infants or when bowel perforation or a pyogenic abscess is present. There is usually a decrease in eosinophil count. Thrombocytopenia may be detected, especially in severe cases. The serum bilirubin is usually normal unless there is a hemolytic anemia, but serum transaminases are often raised. Hyponatremia is common.

### Management

Correction and maintenance of fluid and electrolyte balance is important. Blood transfusion may be necessary. Care regarding overhydration is necessary in the presence of anemia, heart failure, nephritis and/or renal failure.

When the organism is known to be sensitive there is little to choose between chloramphenicol, co-trimoxazole and amoxicillin. Unfortunately, because of multidrug resistance (MDR) alternatives are usually required such as fluoroquinolones (ciprofloxacin or ofloxacin), third generation cephalosporins (ceftriaxone or cefotaxime) and for

uncomplicated cases, azithromycin.<sup>374,375,377</sup> However, there are increasing reports of *S. typhi* with reduced susceptibility to fluoroquinolones but fortunately full resistance and resistance to cephalosporins is still rare. Nalidixic acid resistance is commonly used as a marker for resistance to fluoroquinolones but some organisms with reduced susceptibility to fluoroquinolones may be susceptible to nalidixic acid.<sup>378</sup> Also, presumably because of less use of first line drugs in Asia there has been a recent rise in reports of *S. typhi* with sensitivity to chloramphenicol.<sup>374,375</sup> In sub-Saharan Africa, where resistance is generally lower, in many areas chloramphenicol remains the standard drug.

In industrialized countries where most cases of typhoid fever have been contracted abroad, until full sensitivity results are available it should be presumed that *S. typhi* will be multidrug resistant and some cases will have reduced susceptibility to fluoroquinolones. Ceftriaxone 60–80 mg/kg once daily for 7–14 days or until 3 days after defervescence is effective. Fluoroquinolones have the advantage of better tissue penetration, oral administration and eradication of the carrier stage. Relapse rates may be lower than with third generation cephalosporins. If sensitive, ciprofloxacin 25 mg/kg/d intravenously, followed by 30 mg/kg/d orally, is given for 7–14 days. Fluoroquinolones are not licensed for routine use in children, owing to concerns regarding arthropathic effects on weight-bearing joints in juvenile animals. However, short courses of fluoroquinolones appear safe.<sup>379</sup> For MDR isolates with reduced susceptibility to fluoroquinolones, azithromycin (10 mg/kg/d) given for 7–10 days is an alternative.<sup>377</sup> Cefixime (20 mg/kg/d) is also used but may not be effective in treating MDR.<sup>374</sup> In areas where chloramphenicol is still sensitive it is given in a dose of 50–75 mg/kg/d. Therapy needs to be continued for a minimum of 14 days; 21 days significantly reduces the relapse rate. When fever subsides the dose may be reduced to 30 mg/kg.

Corticosteroids may be beneficial in severe cases. A controlled trial of dexamethasone, 3 mg/kg followed by 1 mg/kg every 6 h for 48 h in severely ill patients, produced a significant reduction in mortality.<sup>379</sup> Perforation should be managed surgically, after full resuscitation with correction of electrolyte and fluid imbalance, and blood transfusion if necessary.<sup>380</sup> Procedures will vary according to circumstances and include simple oversewing of the perforation, or resection, especially in those with multiple perforations. Additional antibiotics to cover Gram negative organisms and anaerobes such as gentamicin and metronidazole should be given.

For clearance of infection, three consecutive stools should be cultured at weekly intervals after chemotherapy ceases. With adequate chemotherapy relapse is uncommon. Children may return to school when symptom free; stools do not have to be culture negative. Preschool children and children unable to practice normal hygiene may need to be excluded until clear of infection. Carriage of *S. typhi* for over 3 months indicates that the child may have become a chronic carrier, but this is uncommon in children. It may be associated with defective cell-mediated immunity to *Salmonella*. Ciprofloxacin or another fluoroquinolone should be given for relapse or chronic carriage.

## Prognosis

In the pre-antibiotic era, the mortality rate for typhoid fever for all ages was around 7–20% and in technically advanced countries is now <0.5%. In resource limited countries, the overall mortality in children shows marked geographical variation. This may depend on age and stage of disease on admission, prior administration of antimicrobials, bacterial resistance and management.

## Prevention

Care should be taken in the handling of stools of infected children and attention paid to hygiene, particularly hand washing. Supervision of young and handicapped children is important.

There are two vaccines available for general use: parenteral Vi capsular polysaccharide and oral live attenuated vaccines which use the Ty21a strain. They provide approximately 50–70% protection.<sup>381</sup> A single dose of Vi polysaccharide vaccine is given by intramuscular injection and side-effects are usually only local and mild. There may be

a suboptimal response in children under 2 years (vaccination is not recommended under 12 months). A booster dose is required about every 3 years. The Ty21a vaccine is given for three to four doses on alternate days. At present it is not recommended for children under 6 years. In unexposed children, reinforcement courses need to be given every year and every 3 years where there is repeated exposure.

The development of a Vi conjugate vaccine has the potential for mass immunization of infants and children in low income countries.<sup>382</sup>

## PARATYPHOID FEVER

Paratyphoid fever, due to *S. paratyphi*, is similar to typhoid fever, but is usually milder with a shorter period of fever and a lower frequency of complications and mortality. The incubation period is often shorter and diarrhea is more common. However, in neonates and young infants complications and mortality may be high. It should be managed along the same lines as typhoid fever.

## BACTERIAL INFECTIONS: SHIGELLA (BACILLARY DYSENTERY)

*Shigella* is a global infection that is notorious for disseminating rapidly in settings where there is crowding, inadequate sanitation and insufficient supply of clean water. The spectrum of symptoms ranges from mild watery diarrhea to fulminant bacillary dysentery, characterized by bloody stools, fever, prostration, cramps and tenesmus. The bacillus was first described by Kiyoshi Shiga in Japan in 1898. The organism he described was *Shigella dysenteriae* type 1, also known as the *Shiga bacillus*, the most virulent of all the shigellae.

Shigellae are nonmotile, Gram negative, non-lactose-fermenting rods belonging to the family *Enterobacteriaceae*. The genus *Shigella* is subdivided into four groups, or species: *Shigella dysenteriae* (12 serotypes), *Shigella flexneri* (15 serotypes and subtypes), *Shigella boydii* (18 serotypes) and *Shigella sonnei* (a single serotype). The most common serogroup of *Shigella* circulating in a community appears to be related to the level of industrialization. *S. flexneri* predominates in resource limited countries (~60% of isolates), with *S. sonnei* being the next most common (~15%).<sup>383</sup> In industrialized countries, *S. sonnei* is the most common serogroup (~77%).<sup>383</sup>

## EPIDEMIOLOGY

The major mode of transmission is by fecal–oral contact, and a low infectious inoculum (as few as 10 organisms) renders *Shigella* highly contagious for humans, the only natural host. Persons symptomatic with diarrhea are primarily responsible for transmission. The majority of infections are due to endemic shigellosis which primarily affects children 1–4 years of age. Endemic strains of *Shigella* cause approximately 10% of all diarrheal episodes in resource limited countries and contribute disproportionately compared to other enteric pathogens to adverse outcomes such as persistent diarrhea, malnutrition, and even death. In contrast, *Shigella* causes fewer than 5% of diarrhea episodes among young children in industrialized countries where it generally has a benign outcome. *Shigella* is an important etiologic agent of diarrhea among residents of industrialized countries (including military personnel) who travel to less developed regions of the world and tends to produce a more disabling illness than other etiologic agents.

Outbreaks of shigellosis occur in settings where suboptimal hygiene allows fecal–oral transmission, such as children attending day care and persons residing in custodial institutions. Outbreaks in the child care setting often result in high attack rates (33–73%) and secondary cases in many families. Outbreaks which involve contaminated food and water in addition to direct contact can be quite extensive, involving thousands of people over a brief period of time. When feces are improperly disposed of, flies may transmit infection. In such settings, the simple introduction of fly-traps can effectively diminish the incidence of shigellosis.

One serotype of *S. dysenteriae* (type 1) is uniquely capable of pandemic spread. During the twentieth century, pandemics of *S. dysenteriae* type 1 appeared in Central America, south and south-east Asia and sub-Saharan Africa, primarily affecting populations in areas of political upheaval and natural disaster. Typically these strains are resistant to multiple antibiotics and induce high attack rates and case fatality in all age groups. A tragic example of the potential for devastation occurred among Rwandan refugees who fled into Zaire in 1994. During the first month alone, approximately 20 000 persons died from dysentery caused by a strain of *S. dysenteriae* type 1 that was resistant to all of the commonly used antibiotics.<sup>384</sup>

## PATHOGENESIS AND PATHOLOGY

After oral inoculation, *Shigella* passes to the terminal ileum and colon where it invades and proliferates within enterocytes, produces cell death, incites an inflammatory reaction and induces intestinal fluid secretion. The ensuing cellular destruction and inflammation result in mucosal ulceration and microabscesses. Two *Shigella* enterotoxins (ShETs), designated ShET1 and ShET2, have been incriminated as mediators of the watery diarrhea seen early in the course and may possess other virulence properties. *S. dysenteriae* 1 uniquely produces the highly potent cytotoxin called Shiga toxin which has been implicated in hemolytic uremic syndrome (HUS). The Shiga toxin produced by *S. dysenteriae* 1 has genetic and functional homologies to the Shiga toxins produced by the enterohemorrhagic *Escherichia coli*, and both can cause HUS.

## IMMUNITY

Exposure to wild-type *Shigella* infection confers immunity, at least to the same serotype. This immunity is associated with serum antibody recognizing the O-antigen of the lipopolysaccharide moiety. Cross-protection among *S. flexneri* serotypes and subtypes seems to occur, but there is no evidence to date that immunity is shared among *Shigella* species. Mucosal immunity is also important, as illustrated by the protective effect of breast-feeding on the severity of shigellosis in infants from endemic areas<sup>385</sup> and of passively transferred oral immunoglobulin in preventing experimental shigellosis in subjects.<sup>386</sup> Infection also induces cell-mediated immune responses, but their contribution to clinical protection has not been elucidated.

## CLINICAL FEATURES

Shigellosis typically evolves through several phases. The incubation period is 1–4 days, but may be as long as 8 days with *S. dysenteriae*. First there is fever and other constitutional symptoms such as headache, malaise, anorexia and occasionally vomiting, followed in several hours by watery diarrhea. In a minority of cases, there is progression within hours to days to frank dysentery with frequent small stools containing blood and mucus, accompanied by lower abdominal cramps and rectal tenesmus. A variety of unusual but important extraintestinal manifestations may occur, including seizures (usually fever-associated), encephalopathy and metastatic infections such as meningitis, arthritis, and splenic abscess, infection of the vagina with bloody discharge, corneal infection and urinary tract infection. Hematologic complications include leukemoid reaction and HUS (following *S. dysenteriae* 1).

Most episodes of shigellosis in otherwise healthy persons are self-limited and resolve within 5–7 days without sequelae. Acute life-threatening complications are largely confined to infants and children from resource limited countries, particularly those with underlying malnutrition. Dehydration, electrolyte imbalance and hypoglycemia are the most common metabolic derangements and are associated with a poor outcome. Intestinal complications include toxic megacolon, rectal prolapse from tenesmus, and intestinal perforation. Sepsis is rare and seen mostly when there is malnutrition or immunodeficiency. Persistent diarrhea and malnutrition are the major long term sequelae resulting, at least in part, from a protein-losing enteropathy that follows *Shigella*-induced intestinal

damage. An uncommon late sequel seen primarily in adults is reactive inflammatory arthritis, alone or as part of a constellation of arthritis, conjunctivitis and urethritis known as Reiter syndrome. Persons with HLA-B27 haplotype are predisposed, accounting for about half of the cases.

## DIAGNOSIS

The diagnosis should be suspected in patients with dysentery, febrile diarrhea or close contacts of patients with such symptoms. These symptoms in a child 1–4 years old should trigger the highest suspicion. If the patient presents with fever and diarrhea without macroscopic blood in the stools, the diagnosis of *Shigella* infection may be suggested by the presence of large numbers of leukocytes in the stool. Stool microscopy is also useful for distinguishing enteroinvasive bacterial infection from amebic dysentery or enterohemorrhagic *Escherichia coli* (EHEC). Moreover, EHEC and amebic dysentery are less likely to cause fever, and EHEC typically produces voluminous bloody stools rather than dysentery. On the other hand, bacterial pathogens such as nontyphoidal *Salmonella*, *Campylobacter jejuni*, *Yersinia enterocolitica* and enteroinvasive *E. coli* can cause bloody stools or dysentery accompanied by fecal leukocytes, as can a heavy *Trichuris trichiura* or *Schistosoma mansoni* infection.

Definitive diagnosis of *Shigella* infection is made by culturing the organism from a fresh stool specimen or rectal swab. Areas of fecal mucus are optimal for sampling. *Shigella* survives poorly in stool samples that are left in ambient temperature; therefore, if the sample cannot be promptly plated onto solid media, it should be inoculated into appropriate transport media and refrigerated. Culture of two or more stool specimens before initiation of antibiotic therapy increases the yield. Blood culture should be undertaken in toxic patients, young infants and those who are immunocompromised.

## MANAGEMENT

Careful attention to the patient's fluid and electrolyte balance with correction of deficits and replacement of ongoing losses is a central feature of management. Agents that suppress intestinal motility, such as diphenoxylate, loperamide and opium-containing preparations, should not be given to children, debilitated or immunocompromised patients with known or suspected shigellosis, or to patients infected with antibiotic-resistant strains or with *S. dysenteriae* as they may increase the severity of dysentery by delaying clearance of the organism.

Many controlled clinical trials of patients with shigellosis have demonstrated that appropriate antibiotics significantly decrease the duration of fever, diarrhea, intestinal protein loss, and excretion of the pathogen. Most patients in these studies were infected with either *S. flexneri* or *S. dysenteriae*. The advantages of treating *S. sonnei*, which is usually self-limited, are less clear. Treatment is recommended for patients with severe disease, dysentery or underlying immunosuppression and should be administered empirically while awaiting culture and antibiotic susceptibility results. The major indication for treatment in mild disease is to decrease excretion and eliminate the potential for transmission. For susceptible strains, ampicillin, trimethoprim-sulfamethoxazole, nalidixic acid and pivmecillinam are good choices. Amoxicillin is less effective, presumably because of its rapid absorption and low fecal concentrations. For cases in which susceptibility is unknown or there is resistance to first line agents, a fluoroquinolone (such as ciprofloxacin), azithromycin or parenteral ceftriaxone can be used. The efficacy of ceftriaxone has been attributed to excretion of its active form in the bile; despite in vitro susceptibility, other cephalosporins such as oral cefixime and parenteral cefamandole are inconsistently effective, perhaps due to their lack of intracellular activity. Treatment can be administered orally except in seriously ill patients and is generally given for 5 days.

## PREVENTION

Interruption of transmission by individual hygienic behavior such as hand washing is effective in interrupting outbreaks. Segregation of

ill persons is useful in settings where hygienic practices are difficult to enforce, such as outbreaks occurring in institutions for the mentally handicapped. Antibiotics should not be used to prevent transmission.

Oral live attenuated vaccines and parenteral O-polysaccharide conjugate vaccines have been developed that show promise in early clinical trials, but as yet no effective vaccine is in use.<sup>387</sup> A polyvalent vaccine will be required to cover the *Shigella* serotypes of clinical and epidemiologic importance.

## BACTERIAL INFECTIONS: STAPHYLOCOCCUS

Staphylococci are Gram positive cocci and include the coagulase positive *Staphylococcus aureus* which is responsible for most of the clinical problems. Coagulase negative staphylococci (CNS) include *Staphylococcus saprophyticus*, a cause of urinary tract infection, and *Staphylococcus epidermidis*, a skin commensal, which has become an increasing problem with the use of intravascular and other implantable devices.

### STAPHYLOCOCCUS AUREUS

Staphylococci are relatively resistant to heat and drying, enabling them to survive for some months on a variety of surfaces or in dust. Their pathogenicity depends on various cell wall components, enzymes and toxins. Toxic shock syndrome toxin-1 (TSST-1), for example, is associated with toxic shock, exfoliative toxins A and B (ETA and B) with scalded skin syndrome,<sup>388</sup> and Pantone–Valentine leukocidin (PVL) with abscesses and necrotizing pneumonia.<sup>389</sup> The production of beta-lactamases (penicillinases and cephalosporinases) is of particular clinical relevance, as these enzymes effectively inactivate beta-lactam antibiotics, and agents such as flucloxacillin or clavulanate-potentiated amoxicillin are required to overcome this.

Asymptomatic carriage of *S. aureus* is common, and the organisms can be found in the anterior nares and less often on the skin, particularly the perineum and axillae. This can be a problem in hospitals, where staff and patients can become carriers of resistant staphylococci, and can have serious consequences in obstetric units, burns units and surgical wards. Immunocompromised patients on broad spectrum antibiotics are particularly at risk. Since the 1960s, the prevalence of methicillin resistant strains of *S. aureus* (MRSA) and epidemic MRSA (EMRSA) has increased both in hospital and in the community. Local hospital infection control strategies vary in terms of patient isolation, barrier nursing and 'decontamination programs' with detergent baths and topical use of mupirocin (pseudomonic acid) to the anterior nares. Serious infection can occur with MRSA, and although strains are generally sensitive to vancomycin and teicoplanin, there are now occasional reports of vancomycin-resistant *S. aureus* (VRSA)<sup>390</sup> and vancomycin-intermediate *S. aureus* (VISA).

### Bacteremia and septicemia

Septicemia and bacteremia with *S. aureus* is generally associated with a focus of infection such as osteitis, pneumonia or a severe skin infection and can be associated with intravascular devices such as intravenous cannulae, central lines and prosthetic heart valves. Severe systemic upset with fever is common, and weight loss and anemia can occur with prolonged illness. Staphylococcal bacteremia can progress to endocarditis with risk of damage to previously normal heart valves.

Toxic shock syndrome can be associated with tampon use or with other foci of infection, particularly where the skin integrity is compromised by trauma, surgical wounds, burns, chickenpox, eczema, etc. Symptoms include fever, headache, diarrhea, myalgia and confusion. Clinical features include pyrexia, hypotension, a widespread erythematous rash, particularly on the hands and soles (which later desquamate) and mucosal involvement with conjunctivitis and red, inflamed lips. It is a multisystem disease with frequent renal impairment, hepatitis or thrombocytopenia.

Successful treatment depends on rapid institution of antistaphylococcal therapy and general supportive measures, including surgical drainage or removal of tampon, as indicated (Table 28.29). Eradication of staphylococci from indwelling devices such as central lines is unlikely with antibiotic therapy alone and removal of the infected device is usually required. Staphylococci are generally penicillin resistant and suitable antimicrobial agents include flucloxacillin, second generation cephalosporins, rifampicin and fusidic acid. Clindamycin or erythromycin may be useful in combination with fusidic acid, particularly if there is a history of penicillin allergy or to treat suspected or proven community acquired MRSA infection. Aminoglycosides, such as gentamicin, have antistaphylococcal action and can be used in combination with other antistaphylococcal agents. Vancomycin or teicoplanin is prescribed for more resistant organisms. Usually 2 weeks of therapy is sufficient for uncomplicated bacteremia.

### Skin infection

Intact skin is a powerful barrier against staphylococcal infection and most skin infection is fairly minor resulting in boils, pustules, furunculosis, carbuncles, styes, paronychia and impetigo. Topical therapy with mupirocin or fusidic acid ointment should suffice for the treatment of impetigo. Large abscess formation may require surgical drainage. Children who are prone to recurrent minor staphylococcal skin infections should be investigated for possible nasal carriage as they may benefit from a course of mupirocin applied to the anterior nares, and if necessary other family members may also be treated. In children with recurrent staphylococcal skin infection, consideration should be given to screening for neutrophil abnormalities, although the vast majority of these children are immunologically normal.

Table 28.29 Antimicrobial therapy for *Staphylococcus aureus* infection

Parenteral				
Flucloxacillin or cloxacillin	i.v. or i.m.	1 month to > 12 years	12.5 mg/kg	6-hourly
Fusidic acid	i.v. only	1 month–12 years 12 years	6–7 mg/kg 500 mg	8-hourly Diethanolamine fusidate
Vancomycin (infusion over 60 min, monitor levels)	i.v. only	> 1 month	15 mg/kg/d	
Oral				
Flucloxacillin		1 month–1 year	62.5 mg	6-hourly
		1–4 years	125 mg	6-hourly
		5–12 years	250 mg	6-hourly
		> 12 years	500 mg	6-hourly
Fusidic acid		1 month–1 year	12.5 mg/kg	8-hourly
		1–4 years	250 mg	8-hourly
		5–12 years	250–500 mg*	8-hourly
		> 12 years	500 mg*	8-hourly

\*As sodium salt.

Cellulitis, a more deep-seated, spreading infection of the skin is an indication for systemic antimicrobial therapy. Orbital cellulitis carries risks of cavernous sinus infection and should be treated promptly with high dose intravenous antibiotics.

The scalded skin syndrome is discussed in Chapter 30.

## Gastrointestinal infection

### Food poisoning

Foodstuffs such as cooked meat products, cream, custard and pastry can be a source of staphylococcal food poisoning. The organism may be isolated from the food handlers involved, and often the food is found to have been undercooked and then refrigerated. Symptoms caused by the enterotoxin (which is heat stable) occur 2–5 h after consumption and result in an acute onset of sweating, abdominal pain, diarrhea and vomiting. The symptoms rarely last longer than a few hours but occasionally supportive therapy with intravenous fluids is required. Antibiotics are not helpful.

### Pneumonia, osteitis, meningitis

These staphylococcal infections are discussed in Chapter 12.

## STAPHYLOCOCCUS EPIDERMIDIS

With the increasing use of invasive procedures, this skin commensal has become an important pathogen, particularly in the neonate and in the presence of indwelling catheters and shunts. Children with ventriculoatrial shunts may have bacteremia, and ventriculoperitoneal shunts can lead to peritonitis. In this situation, eradication of infection with antimicrobial therapy may not be possible and relapse is common. Replacement of the infected device or catheter is, therefore, usually required.

Particularly in hospital acquired infection, resistance to many antimicrobial agents is common. Resistance to vancomycin is rare, though, despite its widespread use in this setting.

## BACTERIAL INFECTIONS: STREPTOCOCCUS AND ENTEROCOCCUS

The large family of streptococci can be responsible for a variety of diseases and sequelae. Streptococci are Gram positive cocci, which tend to form chains. There are several classification systems based on serological or molecular biological techniques. A more traditional classification is based on the degree of hemolysis surrounding a colony on blood agar. Hemolysis can be complete (beta hemolysis), partial (alpha hemolysis) or absent (gamma hemolysis).

The beta hemolytic streptococci are responsible for most of the streptococcal disease in humans and are among the most common bacterial infections of childhood. Streptococci belonging to the other two groups are mainly commensals of the pharynx or gastrointestinal tract and tend to be less virulent pathogens.

## THE BETA HEMOLYTIC STREPTOCOCCI

Beta hemolytic streptococci can be further classified into Lancefield groups depending on the serological characterization of the polysaccharide layer of the cell wall. Most human disease is caused by Lancefield group A streptococci (GAS), which include *Streptococcus pyogenes*. GAS can be further categorized into subtypes.

Beta hemolytic streptococci can produce disease by direct tissue invasion or by toxin production. Some strains have a hyaluronic acid capsule which is non-antigenic and has an inhibitory effect on phagocytosis. The cell wall is a complex structure built upon a peptidoglycan matrix. There are a variety of antigenic determinants, including the protein M antigen, which confer further resistance to phagocytosis and may act as a superantigen. Streptococci lacking this antigen are generally avirulent. The T antigens are useful for epidemiological tracing. The polysaccharide layer determines the Lancefield group. Lipoteichoic acid

is a further cell wall component, which influences membrane affinity and adherence to epithelial cells. Virulence also depends on the production of toxins. Several strains can produce the streptococcal pyrogenic exotoxins (SPE) A, B and C, previously known as erythrogenic toxins, which act as a superantigen triggering the rash of scarlet fever and the syndrome of streptococcal toxic shock syndrome. The two streptolysins O and S are responsible for the hemolytic action of streptococci and the estimation of the antistreptolysin O (or ASO) titer can be useful in diagnosing streptococcal infection. Persisting high ASO titers are seen, for example, in rheumatic fever. Other extracellular products, which are possibly involved in spread of infection and the pyogenic process, include DNases, hyaluronidases and streptokinase.

## Epidemiology

GAS are principally carried in the pharynx and asymptomatic carriage occurs in 15–20% of children. Infection is spread by direct contact or droplet spread and outbreaks may occur particularly in dormitory-type accommodation in winter months. Food- or water-borne outbreaks have been reported. There have been changing patterns in streptococcal disease worldwide. Scarlet fever, for example, is less of a clinical concern than previously, although over the last few decades<sup>391</sup> there has been an increase in more severe invasive forms of disease such as necrotizing fasciitis.

## Immunity

In view of the antigenic variety of the streptococcal strains, repeated streptococcal infection is possible. A child who has suffered from scarlet fever and developed immunity to the SPEs should be protected against further attacks of the syndrome.

## Clinical features

The usual focus for GAS infection is the throat, and infection generally presents with symptoms and signs of acute tonsillitis. In children up to the age of 5 years the illness may be less specific. The incubation period is 2–4 days and the child usually complains of a sore throat and headache, is febrile and may have cervical lymphadenopathy. The pharynx may appear mildly inflamed or a more severe form of exudative pharyngitis may be present. Clinical discrimination from viral infection is not usually possible and uncomplicated carriage is always a possibility when streptococci are isolated from the throat swab. Classically, after 10 days of illness, a rise in the ASO titer will be apparent. Tonsillitis, otitis media, mastoiditis, sinusitis and the much rarer GAS pneumonia, impetigo or pyoderma, empyema, meningitis and septicemia are described elsewhere. Scarlet fever and erysipelas are unique to streptococcal infection.

## Scarlet fever

Scarlet fever is caused by infection with an SPE producing strain of GAS. The usual portal of entry is via the pharynx and the syndrome classically follows acute streptococcal tonsillitis. However, the streptococci may gain access via broken skin following pyoderma, minor cuts, burns, surgical wounds or chickenpox infection.

## Clinical features

The incubation period is usually 2–4 days and the illness may be of variable severity with sudden onset fever, headache, vomiting, sore throat and refusal to eat. In the past, severe illness was more common and delirium a frequent feature. The erythematous rash appears some 2 or 3 days after the onset of illness and classically is first seen in the axillae and groins with blanching on pressure (Figs 28.26 and 28.27). Within 24 h the rash spreads to the trunk and limbs. The face may be flushed and circumoral pallor is a common feature. Pastia's sign – linear petechiae in the flexures – may be helpful diagnostically. After a week or so, desquamation usually occurs starting on the face, then the trunk and limbs. Initially the tongue appears swollen with a yellowish white coating and prominent papillae. This is known as the 'white strawberry' tongue, which later becomes the 'red strawberry' tongue as the coating disappears.

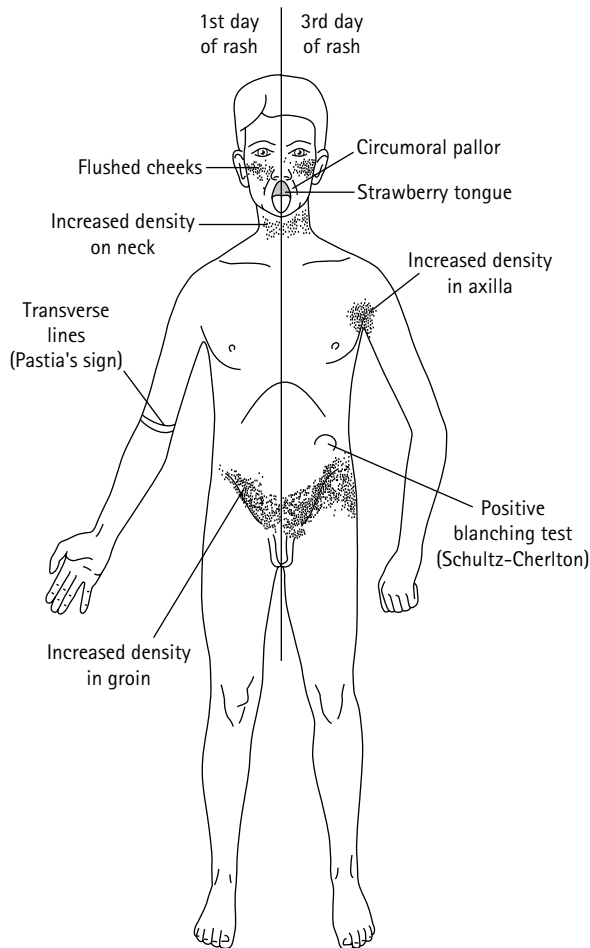

Fig. 28.26 The distribution and the development of rash in scarlet fever.

Untreated, the illness runs its course within 10 days or less. A high fever and tachycardia are common.

Albuminuria is a common finding and a polymorphonuclear leukocytosis is usual.

Since the availability of antibiotic therapy, serious complications are rare. Immediate complications include cervical lymphadenitis with more rarely abscess formation necessitating surgical drainage. Acute otitis media may develop and without treatment further complications including mastoiditis, meningitis or cerebral abscess may ensue. Involvement of the paranasal sinuses can lead to suppurative sinusitis. Other recognized local complications include peritonsillar cellulitis or abscess formation, laryngitis and retropharyngeal abscess.

Rarely, bacteremic spread can lead to metastatic foci of infection, and bronchopneumonia is a further complication, which may lead to empyema or suppurative pericarditis.

Fig. 28.27 The development of scarlet fever.

The later complications, occurring about 2–3 weeks after the onset of illness, include rheumatic fever, acute glomerulonephritis and erythema nodosum. Early antibiotic therapy should prevent such complications.

**Differential diagnosis**

Where acute tonsillitis is present the diagnosis is usually straightforward. With milder or subclinical pharyngitis the diagnosis may be less apparent and confused with other exanthemata. Measles is recognized by the prodromal catarrhal symptoms, diarrhea, conjunctivitis, the presence of Koplik spots and the different character and distribution of the rash. In rubella, the diffuse rash contrasting with the mild illness and the presence of predominantly occipital cervical lymphadenopathy are distinguishing features. Generalized lymphadenopathy with splenomegaly is often present in infectious mononucleosis; the blood film examination may reveal atypical mononuclear cells and Epstein–Barr virus (EBV) serology is positive. Other viral exanthemata run a shorter course and usually have leukopenia rather than polymorphonuclear leukocytosis.

Kawasaki syndrome may be difficult to differentiate. The rash, oral and peripheral changes are similar. The cervical lymphadenopathy of Kawasaki syndrome may be characteristically unilateral and matted, and the episcleritis with limbal sparing of Kawasaki syndrome is not usually seen in scarlet fever. In clinical practice, failure of a child with suspected scarlet fever to respond to antibiotics should arouse suspicion of Kawasaki syndrome.

A very similar rash may be seen with staphylococcal toxic shock syndrome but there is often an obvious focus of staphylococcal infection and the rash tends to be more severe on the palms and soles.

Drug rashes, particularly following antibiotic usage, can be scarlatiniform (scarlet fever-like). The other features of disease are not usually present, however, and the rash fades with the cessation of therapy.

**Prevention and treatment**

The main aim of antimicrobial therapy is to eradicate the infection and thereby prevent the sequelae of local suppurative disease or later rheumatic fever and post-streptococcal glomerulonephritis (Table 28.30). Penicillin is the drug of choice for the treatment of GAS. In severe cases intravenous or intramuscular administration of benzylpenicillin may be required initially. In milder cases, oral phenoxymethylpenicillin for 10 days is usually sufficient. Erythromycin is a suitable alternative in cases of penicillin allergy. Ampicillin and amoxicillin should be avoided, as if mistakenly given in infectious mononucleosis they can cause a severe rash and constitutional upset.

It is unusual to get multiple cases of scarlet fever in a family, although uncomplicated streptococcal throat infection may develop in other children.

**Erysipelas**

Erysipelas is a skin infection caused by any of the GAS, which can enter the skin through trivial wounds or abrasions. Children of all ages are susceptible and recurrent attacks often involving the same site can occur. Children with congenital lymphedema appear to be more at risk.

**Clinical features**

The illness may present with fever, malaise, vomiting and anorexia or the symptoms may be confined to the affected skin or occasionally the mucous membranes. A small erythematous patch may develop into a much larger area of affected skin, which becomes red, hot, painful, indurated and well demarcated by a raised edge. In infants, the periumbilical region is a common site, whereas in older children the extremities or the face are sites of predilection and both cheeks may be involved in a butterfly type of distribution. Facial erysipelas must be differentiated from the violaceous cellulitis caused by *Haemophilus influenzae* type b infection or the slapped cheek appearance of parvovirus B19 infection. Resolution of erysipelas starts centrally and may be followed by desquamation.

Table 28.30 Antimicrobial therapy for *Streptococcus pyogenes* infection

<i>Parenteral</i>				
Benzylpenicillin	i.m.	1–12 months	15 mg/kg	6-hourly
		1–4 years	150 mg	6-hourly
		5–12 years	300–600 mg	6-hourly
		> 12 years	600 mg–1.2 g	6-hourly
Erythromycin	i.v.	All ages	25–50 mg/kg	4–6-hourly
	i.v. only	1 month–12 years	8–12 mg/kg	6-hourly
<i>Oral</i>				
Phenoxyethylpenicillin		< 1 year	62.5 mg	6-hourly
		1–4 years	125 mg	6-hourly
		5–12 years	250 mg	6-hourly
		> 12 years	500 mg	6-hourly
Erythromycin		1 month–1 year	125 mg	6-hourly
		2–8 years	250 mg	6-hourly
		> 8 years	500 mg	6-hourly

Blood cultures are frequently negative but after 10 days of illness there may be a rise in the ASO titer.

Erysipelas responds quickly to penicillin or erythromycin. It may be difficult to differentiate erysipelas from other soft tissue infection such as cellulitis, the more deep-seated infection caused mainly by staphylococcal infection, and in cases where doubt exists, antistaphylococcal antimicrobial therapy should also be prescribed, e.g. flucloxacillin.

### Streptococcal pyoderma

Although most impetiginous lesions are caused by staphylococcal infection, localized purulent streptococcal infection of the skin (streptococcal impetigo or pyoderma) may result from secondary infection of wounds or burns. In children, particularly in the age range 2–5 years and living in tropical or subtropical climates, it mainly involves the lower limbs and may follow intradermal inoculation of streptococci by minor trauma or insect bites. Multiple lesions are common and begin as small papules, becoming vesicular with surrounding erythema. Pustule formation occurs and the lesions then enlarge and break down with formation of thick crusts. Systemic upset is not common but regional lymphadenitis is usually present. Ten days of penicillin therapy is advised although there appears much less risk of rheumatic fever with this type of infection.

Lymphangitis, characterized by red, linear streaks leading to the enlarged regional lymph nodes, may follow very minor skin infection or inoculation with streptococci. It may accompany cellulitis.

### *Streptococcus agalactiae* (group B streptococcus)

*Streptococcus agalactiae*, or group B streptococcus (GBS), is a beta hemolytic streptococcus belonging to Lancefield group B, and is a major cause of neonatal infections, both early and late.

### VIRIDANS GROUP STREPTOCOCCI

Viridans streptococci are usually alpha hemolytic but can be non-hemolytic. They are generally oropharyngeal commensals, and include *Streptococcus mutans*, *S. salivarius*, *S. sanguis* and *S. mitis* groups and three streptococci formerly known as the *Streptococcus milleri* group (*S. anginosus*, *S. constellatus* and *S. intermedius*). Even minor dental procedures can be complicated by a transient bacteremia, which is of no clinical consequence except for children with cardiac disease, either congenital heart disease, such as patent ductus arteriosus or bicuspid aortic valves, or acquired, such as rheumatic heart disease. Infective endocarditis is a risk in such cases. Regular dental care with additional antibiotic prophylaxis for dental procedures is advised for children who have a history of rheumatic fever or congenital heart disease.

### ENTEROCOCCI

Enterococci are commensals of the intestinal tract. They can cause urinary tract infection, particularly in cases of structural urinary tract abnormality or neurological dysfunction of the bladder such as in children with lumbar or sacral myelomeningocele. *Enterococcus faecalis* and *E. faecium* are the major pathogens of the 18 types of enterococci seen in humans. *E. faecalis* can cause infective endocarditis and has emerged as a major cause of bacteremia in hospitalized patients. Enterococci are often penicillin resistant, and determination of the antibiotic sensitivity is important. In endocarditis, combinations of antimicrobial chemotherapy are advised, such as the synergistic combination of amoxicillin and an aminoglycoside such as gentamicin. Vancomycin is an alternative, but this treatment is threatened by the emergence of vancomycin resistant enterococci (VRE). Fortunately, few of these isolates appear clinically relevant and the organisms are often no longer evident after cessation of vancomycin or removal of infected lines and devices. There are concerns that VRE may cause more clinical problems in the future and drugs with activity against vancomycin resistant *Enterococcus faecium* include linezolid and quinupristin/dalfopristin.<sup>392</sup>

### BACTERIAL INFECTIONS: TETANUS

Despite the availability of an effective active vaccination since 1923, tetanus remains a major health problem in resource limited countries and is still encountered in resource rich countries. At least 1 million cases require hospital treatment worldwide each year and there are approximately 400 000 deaths.<sup>393</sup> There are approximately 800 000 tetanus deaths each year, of which approximately 400 000 are due to neonatal tetanus.<sup>393</sup> Approximately 12–15 cases are reported per year in the UK and between 40 and 60 cases per year in the USA.<sup>393</sup>

### ETIOLOGY

Tetanus is caused by a toxin released following infection with *Clostridium tetani*, a Gram positive, spore forming, obligate anaerobic bacillus. Tetanus typically follows deep penetrating wounds where anaerobic bacterial growth is facilitated. The most common portals of infection are wounds on the lower limbs, postpartum or postabortion infections of the uterus, nonsterile intramuscular injections and compound fractures. Minor trauma can lead to disease and in up to 30% of cases no portal of entry is apparent.<sup>393</sup>

### EPIDEMIOLOGY AND PATHOGENESIS

*Clostridium tetani* is a ubiquitous inhabitant of the intestinal tract of many animals and commonly found in soil. The toxin binds to

gangliosides on peripheral nerves, and the toxin is internalized. It is then moved by retrograde axonal transport to the central nervous system. The toxin prevents release of the inhibitory neurotransmitter (GABA) into the synaptic cleft. The alpha motor neurones are therefore under no inhibitory control and undergo sustained excitatory discharge causing the characteristic motor spasms of tetanus.

## PREVENTION

Tetanus toxoid is produced by formaldehyde treatment of the toxin, its immunogenicity improved by absorption with aluminum hydroxide.<sup>394</sup> In the UK and USA it is administered to children between 2 and 6 months old (3 doses at 4–8 week intervals) with boosters at 15 months in the USA and at 4 years. A further dose is recommended in both the USA and UK within 5–10 years. In order to maintain adequate levels of protection, five additional booster doses should be administered to ensure life-long protection.<sup>394</sup> Minor reactions to the tetanus toxoid are estimated to be 1 in 50 000 injections. Severe reactions such as the Guillain–Barré syndrome and acute relapsing polyneuropathy are rare. Neonatal tetanus can be prevented by immunization of women during pregnancy.<sup>395</sup> Two or three doses of absorbed toxin should be given with the last dose at least one month prior to delivery. There is no evidence of congenital anomalies associated with tetanus toxin administered during pregnancy.<sup>395</sup> Maternal HIV and also malaria infection may limit the transfer of protective maternal antibodies. Passive immunization with human or equine tetanus immunoglobulin shortens the course and may reduce the severity of tetanus. The equine form, widely available throughout resource limited countries, has a higher incidence of anaphylactic reactions. In established cases, patients should receive 500–1000 IU/kg of equine antitoxin or 5000–8000 IU of human antitetanus immunoglobulin intravenously or intramuscularly. For prophylaxis 1500–3000 IU equine or 250–500 IU human antitetanus immunoglobulin should be given. Passive immunization should be administered as soon as possible after the injury; once the toxin is bound and internalized it will have no effect. In addition to passive immunization, active vaccination needs to be administered to all patients.

## CLINICAL FEATURES

The incubation period (the time from inoculation to the first symptom) can be as short as 48 h or as long as many months after inoculation with *Clostridium tetani*. The period of onset is the time between the first symptom and the start of spasms. These periods are important in determining the prognosis: the shorter the incubation period or period of onset, the more severe the disease. Trismus (lockjaw), the inability to open the mouth fully owing to rigidity of the masseters, is often the first symptom. Generalized tetanus is the most common form of the disease, and presents with pain, headache, stiffness, rigidity, opisthotonus and spasms which can lead to laryngeal obstruction. These may be induced by minor stimuli such as noise or touch, or by simple medical and nursing procedures such as intravenous and intramuscular injections, suction or catheterization. The spasms are excruciatingly painful and may be uncontrollable leading to respiratory arrest and death. Spasms are most prominent in the first 2 weeks; autonomic disturbance usually starts some days after spasms and reaches a peak during the second week of the disease. Rigidity may last beyond the duration of both spasms and autonomic disturbance. Severe rigidity and muscle spasm necessitates paralysis for prolonged periods in severe tetanus.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis is a clinical one, relatively easy to make in areas where tetanus is seen frequently, but often delayed in resource rich countries where cases are less common. The differential includes tetany, strychnine poisoning, drug induced dystonic reactions, rabies and orofacial infection. In neonates the differential diagnosis includes hypocalcemia, hypoglycemia, meningitis and meningoencephalitis, and seizures.

## TREATMENT

In patients with a deep wound, thorough debridement and toilet are critical to reduce the anaerobic conditions that the bacteria thrive in. Common complications in tetanus are those of prolonged periods in intensive care. Secondary infections are a frequent complication, most commonly associated with the lower respiratory tract, urinary catheterization and wound sepsis. Gram negative organisms, particularly *Klebsiella* and *Pseudomonas*, are common. Meticulous mouth care, chest physiotherapy and regular tracheal suction are essential to prevent atelectasis, lobar collapse and pneumonia, particularly as salivation and bronchial secretions are greatly increased in severe tetanus. Adequate sedation is mandatory before such interventions in patients at risk of uncontrolled spasms or autonomic disturbance and the balance between physiotherapy and sedation may be difficult to achieve. Energy demands in tetanus may be very high due to muscular contractions, excessive sweating and sepsis.

## SPECIFIC TREATMENT

Penicillin is the standard antibiotic therapy for tetanus. The dose is 100 000–200 000 IU/kg/d intramuscularly or intravenously for 7–10 days. Metronidazole is a safe and effective alternative. Autonomic disturbance with sustained labile hypertension, tachycardia, vasoconstriction and sweating is common in severe cases. Profound bradycardia and hypotension may occur and may be recurrent or preterminal events. Diazepam has a wide margin of safety and a rapid onset of action, and is a sedative, an anticonvulsant and a muscle relaxant. However, it has a long cumulative half-life. Invariably, in the doses required to achieve adequate control of spasms, respiratory depression, coma and medullary depression are common. Magnesium sulfate has been used to reduce autonomic disturbance and help to control spasms.<sup>396</sup> There is very little information on follow-up of patients after tetanus; enuresis, mental retardation and growth delay have all been reported after neonatal tetanus.

## PROGNOSIS

The prognosis in tetanus remains serious despite the best available treatment. Globally the mortality rate in neonatal infection is approximately 60%.<sup>397</sup> Older children and adults have a mortality rate of 10–30% depending on the availability of basic intensive care facilities.<sup>393</sup>

## BACTERIAL INFECTIONS: TULAREMIA

### ETIOLOGY

This disease derives its name from Tulare, a county in California, where it was first discovered amongst ground squirrels by McCoy in 1911. It is caused by a small, intracellular, nonmotile Gram negative coccobacillus, *Francisella tularensis*, that commonly causes disease in wild animals such as rabbits, hares, squirrels, foxes, rats and deer. There are four subspecies of the organism that are serologically identical but differ in biochemical properties and virulence.<sup>398</sup> *E. tularensis* subsp. *tularensis* represents over 90% of the isolates from North America and is highly virulent in man and rabbits.<sup>399</sup> It is usually recovered from rodents and arthropods. *F. tularensis* subsp. *holartica*, the type most commonly found in Europe and Asia, is less virulent in man and rabbits.<sup>400</sup> It is usually isolated from aquatic animals. The other two subspecies have only rarely been associated with disease in humans.

### EPIDEMIOLOGY

The organism can be isolated from a wide variety of wild mammals, from domestic animals such as sheep, cattle and cats, and from the arthropods that bite these animals such as ticks, fleas and deer flies. Human infection occurs after a bite from an infected arthropod, by contact with an infected animal, by ingestion of a diseased animal or

contaminated water, or by inhalation of infected secretions. Humans are highly susceptible to the organism, with fewer than 50 organisms required for infection. Tularemia occurs throughout the northern hemisphere, with large outbreaks reported in North America, the southern part of the former Soviet Republic, and northern Scandinavia. In the eastern part of the continental USA it occurs mostly in winter, related to the rabbit hunting season, whereas in the states west of the Mississippi River it occurs in summer when there is a preponderance of ticks. Human case-to-case contact has not been documented, though care must be taken in dressing discharging wounds. Tularemia is extremely infectious for laboratory workers, who must take exceptional care in the handling of infected material or cultures. Its high attack rate and virulence after inhalation has caused its frequent citation as a possible agent for bioterrorism.<sup>401</sup>

## PATHOLOGY

There is a local lesion at the portal of entry and, at times, disseminated lesions throughout the body. Entry is usually through the skin, but may be via the conjunctiva, the respiratory tract or rarely the gastrointestinal tract. Dissemination occurs via the lymphatics or blood, and lesions may be found in the regional lymph nodes and in many other parts of the body. The local lesion is a painful, erythematous papule often with central ulceration and regional lymph node enlargement. The lesions are granulomatous, much like the lesions of miliary tuberculosis, but the center of the lesions is often necrotic and consists of polymorphonuclear leukocytes.

## CLINICAL FEATURES

The incubation period ranges from 1 to 21 days but most cases occur 3–5 days after exposure. The severity of the disease depends on the route of entry, the subspecies involved, and the host's immune response. Children usually show more constitutional upset and less respiratory involvement than adults. Most frequently there is an abrupt onset of high fever, headache and malaise with or without regional adenopathy, chest X-ray changes, vomiting, and a cutaneous lesion at the site of entry. Sterile pyuria is also common. Rarely there may be pericarditis, osteomyelitis, meningitis, splenic abscesses or thrombophlebitis. Before antibiotics, reported mortality ranged from 7 to 30%. Six clinical syndromes have been described which occur according to the portal of entry. Most common is the *ulceroglandular syndrome* characterized by a primary painful maculopapular lesion at the point of skin entry with subsequent ulceration and slow healing. This is associated with painful, acutely inflamed regional lymph nodes that may ulcerate and proceed to abscess formation. Other forms of the disease include *typhoidal* tularemia, with high fever and hepatosplenomegaly, *pulmonary* tularemia, with pneumonia, pleuritis and hilar adenopathy, *ocular* tularemia, in which the eyelids become edematous and painful, *oropharyngeal* tularemia, in which the tonsils are covered by a pseudomembrane, and a *glandular* form in which no portal of entry can be identified.<sup>402</sup>

## DIAGNOSIS

The circumstances of the disease onset, especially a history of bite or scratch or exposure to wild animals, should readily suggest the diagnosis in endemic areas. There is a significant risk to laboratory personnel when handling specimens so the laboratory should be informed if tularemia is suspected. Serology is the usual means of establishing the diagnosis: a four-fold or greater rise in serum agglutination titer to *F. tularensis* is evident after the second week of illness. Nonspecific, low titer cross-reactions may occur to *Brucella*, *Proteus* and *Yersinia* species. The organism can be cultured from infected sites on special media or by rodent inoculation, but this should be attempted only by personnel vaccinated against the organism.

PCR-based methods may be used to distinguish subspecies,<sup>398</sup> but are not routinely available.

The differential diagnosis depends on the presentation, but includes causes of skin lesions with regional adenopathy such as cat-scratch disease, causes of prolonged fever including brucellosis and salmonellosis (especially typhoid), and causes of atypical pneumonia.

## TREATMENT

Streptomycin is the historical drug of choice for treatment of severe tularemia. However, as it is not widely available, gentamicin is an effective alternative although treatment failures have been reported.<sup>403</sup> Chloramphenicol should be added for tularemic meningitis. Options for outpatient therapy of older children include tetracyclines or the quinolones, although relapses have been reported after completion of therapy with both drugs.<sup>404</sup> Treatment is usually for 6–10 days, the duration depending on the severity of the illness.

## PREVENTION

In endemic areas, opportunities for arthropod bites should be minimized by wearing protective clothing and regular tick inspections. Prevention also involves avoidance of contact with infected or potentially infected animals and insect vectors, adequate cooking of potentially infected meat and the boiling of water from springs and streams.

In the USA, a live attenuated vaccine is available for those repeatedly exposed to the organism such as laboratory technicians.<sup>405</sup>

## BACTERIAL INFECTIONS: YERSINIOSIS AND PLAGUE

### YERSINIOSIS<sup>406,407</sup>

Yersiniosis is caused by two species of enteric bacteria, *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*. A wide spectrum of clinical manifestations occurs, including acute watery diarrhea, mesenteric adenitis, extraintestinal infection and bacteremia. Postinfectious sequelae such as arthritis or erythema nodosum are also common.

### Microbiology and pathogenesis

*Yersinia* spp. are facultative anaerobic Gram negative coccobacilli which grow well on bile containing media. There are three human pathogens within the genus, *Y. pseudotuberculosis*, *Y. enterocolitica* and *Y. pestis*. Over 50 serogroups of *Y. enterocolitica* have been described. *Yersinia* infections occur through invasion of the gastrointestinal tract via a membrane protein, invasins, which binds to a cell surface ligand. Multiplication may occur within intestinal epithelial cells and Peyer's patches, with the potential for systemic spread.

### Epidemiology

*Yersinia enterocolitica* infection occurs globally but is most common in temperate regions. Yersiniosis is a zoonotic infection but usually causes food-borne illnesses. The organism can be found in the gastrointestinal tract of a number of domestic and livestock animals. Infection of humans usually occurs after eating or drinking contaminated food or water; incompletely cooked pork is a major risk factor.<sup>408</sup> Infection may also occur by person-to-person or direct animal-to-person contact. Most infections are sporadic but a number of specific outbreaks due to contaminated food or water have occurred. Infants and young children are more susceptible to infection with *Y. enterocolitica* than adults.

Infection with *Y. pseudotuberculosis* is less common, apart from in Japan. Infection results from contact with both sylvatic and domestic animals and a number of birds. It usually affects patients aged between 5 and 20 years.

## CLINICAL FEATURES<sup>409</sup>

The incubation period for acute yersiniosis is 3–7 days. *Y. enterocolitica* infection most commonly presents as acute gastroenteritis in young children with diarrhea, fever and abdominal pain, clinically indistinguishable from *Salmonella* or *Campylobacter* infection. Stools contain mucus, leukocytes and red blood cells. Patients may be symptomatic for up to 3 weeks and remain infectious over this period, due to shedding of organisms in the feces. Rare complications include diffuse ulceration of the small intestine and colon, perforation, intussusception and toxic megacolon.

*Y. enterocolitica* infection in older children most commonly causes mesenteric adenitis and terminal ileitis; this is also the most common manifestation of *Y. pseudotuberculosis* infection. The presentation mimics appendicitis. Diarrhea is unusual and the infection is usually self-limiting. Ultrasound and/or CT may help by demonstrating a normal appendix and enlarged mesenteric nodes. The differential diagnosis includes acute appendicitis or terminal ileal disease such as Crohn's or tuberculosis.

*Y. enterocolitica* bacteremia is rare and usually occurs in patients with other chronic medical conditions or immunosuppression. There is also a strong association with iron overload syndromes. Case fatality rates for *Y. enterocolitica* bacteremia range from 7.5 to 25%, but may reach 50% in patients with iron overload. Focal *Y. enterocolitica* infection can occur as a complication of bacteremia or occasionally in the absence of detectable bacteremia. *Y. pseudotuberculosis* bacteremia is much less common, but is also associated with chronic illness. Case fatality rates are extremely high in the immunocompromised population. In Japan, *Y. pseudotuberculosis* infection has been associated with renal failure in young children.

Secondary, immunologically mediated, postinfective complications may occur in up to 30% of patients following *Yersinia* infection. A reactive asymmetrical large joint polyarthropathy or erythema nodosum are the most common manifestations, occurring 1–2 weeks after the acute presentation. There is a strong association with the possession of HLA B27. Reiter syndrome, glomerulonephritis and myocarditis have also been described. Synovial fluid culture is normally sterile. Joint symptoms of reactive polyarthritides may last for several months.

## Diagnosis

Definitive diagnosis of yersiniosis is by culture of the organism from stool, lymph nodes or blood. Isolation from stool may be optimized by using cold enrichment or cefsulodin–Irgasan–novobiocin (CIN) agar. High titers of *Yersinia* antibodies in a previously healthy individual are suggestive of infection but four-fold rises in titer are rarely found. Interpretation of serology is also complicated by low titers following yersiniosis in infants or immunocompromised patients, a high background prevalence of positive serology in some populations and cross-reactivity with *Brucella*, *Rickettsia* and *Salmonella* spp. Cultures are often negative by the time of appearance of postinfective symptoms.

*Y. pseudotuberculosis* may be found in sterile site samples, but is rarely isolated from stool. Serology is often the only mode of diagnosis available; antigens cross-react with those of *Y. enterocolitica*.

## Treatment

Antimicrobial treatment does not shorten the course or severity of enterocolitis and is not indicated in uncomplicated cases. Localized infection, systemic disease or enterocolitis in an immunocompromised patient should be treated. *Y. enterocolitica* is resistant to most penicillins and first generation cephalosporins: amoxicillin–clavulanate combinations are also unsuitable due to variable minimum inhibitory concentrations. Aminoglycosides, chloramphenicol, tetracycline, co-trimoxazole and fluoroquinolones have been most effective in clinical practice: third generation cephalosporins may also be effective.<sup>410</sup> *Y. pseudotuberculosis* is sensitive to ampicillin and cephalosporins in addition to the drugs already discussed.

## PLAGUE<sup>411,412</sup>

### Epidemiology and pathogenesis

Plague is a zoonosis caused by *Yersinia pestis*. It occurs globally; approximately 2000 cases of plague are reported annually. Over 90% of cases occur in Africa, with current epidemics in the Democratic Republic of Congo and Madagascar; major active foci also exist in other parts of Africa, the Western USA, China and south-east Asia. Mammals, particularly rodents, act as host reservoirs. Fleas feed upon diseased hosts and organisms multiply within the midgut of the flea before being transmitted to humans or other mammals when the flea bites and regurgitates a blood meal. Human infection can also be acquired from direct contact with wild rodents or their predators (including cats), and person-to-person spread can occasionally occur in epidemics. Most human plague cases currently occur in rural settings with transmission from wild animals; epidemics in human settlements occur when domestic rat species become infected. Plague is a potential bioterrorism agent and this has led to an increased interest in the disease.

### Clinical features

There are three main clinical forms of plague. *Bubonic* plague is most common. Bacteria multiply in regional lymph nodes following a flea bite, culminating 2–8 days later in systemic symptoms, fever, headache and malaise. Regional lymph nodes enlarge and become extremely tender with swelling and inflammation around the nodes: the bubo. Occasionally, pustules, eschars or papules occur at the site of flea bites. Most individuals develop a transient secondary bacteremia: in some this leads to septicemic or pneumonic plague.

Patients with *septicemic* plague present with Gram negative septicemic shock and may develop complications such as renal failure or DIC. Septicemic plague occasionally occurs in the absence of buboes; this presentation is more common in children.

*Pneumonic* plague is usually a complication of bacteremia and presents with cough, fever and hemoptysis: the chest X-ray may show bronchopneumonia, consolidation or cavitation. Large numbers of bacteria may be exhaled with the potential for respiratory spread to cause primary pneumonic plague.

### Diagnosis

The patient's symptoms and an appropriate exposure history may lead to a clinical diagnosis of plague. Leukocytosis is common and liver function tests may be abnormal. *Yersinia pestis* may be demonstrated on smears from blood, bubo fluid or CSF: fluorescent antibody techniques increase the sensitivity. Definitive diagnosis depends upon culture of the organism, which grows readily on standard media. A rapid diagnostic test that detects plague antigens in blood has been developed and has helped considerably in field conditions, allowing confirmation of diagnosis within 15 minutes.<sup>412</sup> Serological tests are useful in retrospective diagnosis of plague.

### Treatment

Case fatality rates may reach 30–50% in untreated plague. Streptomycin is the traditional drug of choice; gentamicin or doxycycline has been shown to be equally effective, with response rates of around 95%.<sup>413</sup> Seven days' therapy is required to prevent relapse: clinical improvement normally occurs within 3 days. Fluoroquinolones may also be effective, particularly for the rare strains with high level multidrug resistance, although clinical experience is limited. Ciprofloxacin is also indicated as prophylaxis for contacts of pneumonic plague.

### Prevention

Plague vaccines are only usually administered to individuals at high risk in laboratories or field control teams: their efficacy against pneumonic plague is limited and frequent boosting is necessary. A number of new vaccines are being developed. Public education, reducing flea bites and rodent exposure, and avoidance of sick or dead animals are all measures that can help avoid infection.

## INFECTIONS DUE TO VIRUSES AND ALLIED ORGANISMS

### USE OF THE VIROLOGY LABORATORY BY THE CLINICIAN

#### VIROLOGY SPECIMEN COLLECTION AND TRANSPORT

When virus infection is suspected, it is important for the pediatrician to take a careful medical history and perform a thorough medical examination of the patient to decide the most likely viral pathogens causing an infection. The possible diagnoses should be discussed with the clinical virologist, so that appropriate specimens are collected and laboratory tests ordered. It is important to collect specimens for viruses as early as possible in the illness after the onset of symptom. Swabs and tissue specimens for viral culture should be placed in viral transport media, i.e. buffered media containing protein and antibiotics. The presence of antibiotics in viral transport media makes these specimens unsuitable for bacterial or fungal cultures. Separate swabs and specimens need to be collected if bacterial or fungal cultures are also required. Liquid samples such as CSF, bronchoalveolar lavage fluid or urine can be sent in clean sterile containers without transport media. Blood for virological tests should be sent in a tube containing an anticoagulant. Both heparin and EDTA are suitable for specimens for viral culture or antigen detection, but citrate should not be used. Heparin should not be used if polymerase chain reaction (PCR) testing of blood is to be performed, as it inhibits the reaction. All specimens for virological testing should be kept cold on ice after collection and during transport. Transport to the laboratory should be prompt and if there is a delay in transport the specimen should be frozen, preferably at  $-70^{\circ}\text{C}$  rather than  $-20^{\circ}\text{C}$ , as this temperature often reduces virus viability. Most swabs are suitable for collection of specimens, e.g. cotton, Dacron, polyester and rayon, but calcium alginate may inactivate some viruses and inhibit PCR reactions. Swabs should have a metal or plastic shaft, as wood shafts can be toxic to cell cultures.

#### METHODS OF VIRUS DETECTION

There are five approaches to virus identification:

1. Sending patient material for direct examination by electron microscope.
2. Culturing body fluid or tissue for viruses.
3. Detecting viral antigen in clinical specimens.
4. Using PCR and nucleic acid probes to detect genomic material.
5. Identifying postinfection antiviral antibody by serological methods.

#### LABORATORY DIAGNOSIS OF VIRAL INFECTION

##### Respiratory viruses

Historically, cell culture techniques have allowed the detection of a wide range of viral pathogens which cause respiratory infections and also detect dual or mixed infections. However, traditional cell culture techniques are usually slow and often do not provide a diagnosis until the patient is recovering or has been discharged from hospital.

To enhance the clinical utility of viral diagnosis in respiratory infections, most laboratories now use virus specific fluorescent antibodies for direct identification of viruses in cells collected from the respiratory tract via nasopharyngeal aspirates, swabbing or bronchoalveolar lavages. There are now commercially available tools with monoclonal antibodies which are run simultaneously and can detect respiratory syncytial virus (RSV), influenza A, influenza B, parainfluenza viruses 1–3 and the adenovirus group. In addition these antibodies can be used to detect viruses in culture and decrease the culture time from 10–14 days to 3–5 days, thus improving the clinical utility of this test.<sup>414</sup> More recently molecular diagnosis using polymerase reverse transcription and polymerase chain reaction (RT-PCR) has increased the sensitivity of detection, but at a significantly increased cost.<sup>415</sup>

Rapid identification of respiratory viruses is important in health care, because it permits timely and appropriate cohorting (isolation) of patients to prevent nosocomial spread of disease and allows for prompt and appropriate clinical management, i.e. stopping unnecessary antibiotic therapy and commencing specific antiviral therapy for influenza or RSV if indicated.

##### Childhood exanthems

It is unusual to require laboratory diagnosis of common childhood exanthems such as measles, mumps and rubella and chickenpox, unless there is very severe or atypical disease.<sup>416</sup> Viral culture may be performed in these situations, but serological testing is used more commonly, with detection of IgM being most commonly performed by enzyme linked immunosorbent assay (ELISA) or immunofluorescence (IF) assay.

##### Enterovirus infection

Enteroviruses, now with more than 101 recognized members, are a common cause of many clinical syndromes including mild febrile illness, upper respiratory tract infections, viral pneumonia, exanthems, enanthems, myocarditis, pericarditis, aseptic meningitis, encephalitis and acute flaccid paralysis. Enterovirus infections are more prevalent in summer and early autumn in temperate climates, but can occur all year round. Enteroviruses are transmitted by the fecal–oral route; they replicate in the gastrointestinal tract, where they rarely cause gastrointestinal symptoms, but can cause diseases in other tissues or organs throughout the body.<sup>417</sup> During the acute illness, enteroviruses are excreted from the oropharynx for several days and continue to be excreted in the feces for several weeks. Most enteroviruses can be grown in tissue culture and usually take 4–8 days to detect. However, more recently PCR detection of enteroviruses has enabled more rapid diagnosis of enterovirus meningitis and encephalitis.

##### Gastrointestinal infection

Most viruses which cause diarrheal illnesses are not detectable by cell culture. Historically, viral gastrointestinal pathogens have been detected using electron microscopy, which is still used today. More commonly rotavirus, adenovirus or norovirus antigens are detected by immunological methods using ELISA, membrane enzyme immunoassay or latex agglutination. Potentially, PCR technology could be used to detect these viruses, but is not routinely available at present.

##### Arboviruses

Arboviruses (*arthropod-borne viruses*) include the alphaviruses and flaviviruses. These viruses are all transmitted by the bite of a hematophagous arthropod which transmits the virus to humans. As these viruses are transmitted by arthropods they occur seasonally, i.e. in the warm weather when arthropods are much more active and also are limited to specific geographic regions consistent with the distribution of the transmitting arthropod. Arboviruses are responsible for a significant amount of viral disease globally, e.g. dengue, yellow fever, Japanese encephalitis and West Nile virus.<sup>418</sup> Arbovirus infections may be asymptomatic. Clinical illnesses include mild febrile illness, acute hepatitis, viral arthritis, rash, hemorrhagic shock and encephalitis. Diagnosis of arbovirus infection is commonly performed by serology, commonly using ELISA technology to detect IgG and IgM antibodies.

##### Herpesviruses

The herpesviruses are a very large and diverse group of DNA viruses, of which eight have been recognized as the cause of infections in humans. Herpes simplex virus (HSV) types 1 and 2, cytomegalovirus (CMV), and varicella zoster virus (VZV) can be cultured from most sites by conventional cell culture or culture fluorescence. However, human herpes virus 6 (HHV-6), and HHV-7, HHV-8<sup>419</sup> and Epstein–Barr virus (EBV) cannot be cultivated. Diagnosis of central nervous system infections by HSV, CMV or VZV is now commonly done using PCR. Viral culture, while slower, can be performed. HSV and VZV can be detected in scrapings from vesicular skin lesions, using immunofluorescent antibody staining

or PCR detection of a cell smear taken from the base of the vesicle. These assays are quite sensitive and specific.

Diagnosis of CMV infection in organ donors or recipients, neonates and pregnant women is usually performed using serology. Detection of IgM antibodies in the absence of IgG antibodies indicates acute infection in neonates and pregnant women while the presence of IgG antibodies indicates past infection in organ donors and recipients. The isolation of CMV from the urine and saliva of neonates in the first week of life is diagnostic of congenital CMV infection.

CMV infection and reactivation can cause significant disease in immunosuppressed patients, such as solid organ recipients, bone marrow transplant recipients, patients receiving chemotherapy and HIV positive patients. Culture for CMV alone is not adequate in these situations, as CMV shedding is quite frequent in immunosuppressed patients without the development of disease. The diagnosis of CMV disease in immunosuppressed patients is achieved by the detection of CMV in a biopsy of the affected organ. Detection of CMV in biopsy tissues can be achieved using histological evidence of CMV inclusions, evidence of CMV antigen, usually detected by immunoperoxidase antibody staining of tissue sections, or detection of CMV by culture or PCR. As tissue biopsies are very invasive, the detection of CMV viral load in blood as a surrogate marker for CMV disease or as an indicator for risk of development of CMV disease has become the standard of care. The usual method for detecting CMV in blood is a CMV antigenemia assay in infected leukocytes, using monoclonal antibody to the CMV late protein, pp65. By using a fluorescent label, CMV-infected cells can be counted using a microscope and the number per high power field determined, giving a relatively quantitative result. These assays can also be used to monitor the efficacy of CMV antiviral therapy in the prevention and treatment of CMV disease. More recently, detection of CMV DNA in blood using a quantitative PCR assay has been used.<sup>420</sup> Qualitative CMV PCR detection is adequate for the diagnosis of CMV retinitis by detection of CMV in aqueous or vitreous humor.

Serological methods are used for the diagnosis of primary EBV infection, whereas molecular methods are used to diagnose EBV-associated lymphoma of the brain and post-transplant lymphoproliferative disease. Diagnosis of acute EBV infection is performed with an EBV viral capsid antigen (VCA) IgM ELISA assay. Past infection of EBV can be determined by detecting IgG antibodies to VCA or Epstein-Barr virus nuclear antigen (EBNA). VCA IgG appears within one week of acute infection while EBNA IgG appears 1–2 months after acute infection. Quantitation of EBV DNA in serum can be used to monitor patients at risk for EBV associated lymphoproliferation; however, currently there are no established threshold levels of EBV DNA which indicate risk of disease.<sup>421</sup> These assays are most useful when run as serial assays to determine increases or decreases in EBV viral load in response to alterations in immunosuppression.

## Hepatitis viruses

The hepatitis viruses are a group of unrelated DNA and RNA viruses that cause liver disease as the major clinical manifestation. Diagnosis of these infections is usually with serological techniques. More recently, quantitation of hepatitis B virus DNA and hepatitis C virus RNA has been developed to aid in monitoring antiviral therapeutic responses.

## Human immunodeficiency virus infection

Human immunodeficiency virus (HIV) infection in infants greater than 18 months of age is confirmed with a positive HIV antibody test. The diagnosis of vertical HIV infection in an infant less than 18 months is achieved by culture of HIV or detection of HIV DNA in blood. Both these assays have a sensitivity of approximately 80% and are the current 'gold standard'. More recently, detection of HIV RNA (viral load assays) has been used. If using this assay, one has to be careful of the possibility of false positive results. Using these methods, greater than 90% of vertically infected HIV infants will be identified by 6 months of age.

## Polyomaviruses

The human polyomaviruses, BK virus and JC virus, infect the majority of the population but remain latent in the kidneys after primary infec-

tion. Reactivation can occur when there is T cell immunodeficiency. BK viraemia in bone marrow transplant patients is associated with hemorrhagic cystitis. JC virus causes progressive multifocal leukoencephalopathy (PML), seen primarily in AIDS patients.

Detection of BK virus can be achieved by cytologic examination of exfoliated urinary epithelial cells or by PCR detection of BK virus DNA in the urine or blood. JC virus is detected by PCR detection of DNA in CSE.<sup>422</sup> Alternatively, a brain biopsy of a patient suspected of PML may indicate histopathological changes consistent with the diagnosis of PML.

## New viruses

More recently, newly discovered respiratory viruses have caused significant illness globally. In 2001, human metapneumovirus was discovered as a cause of bronchiolitis in infants and young children, clinically indistinguishable from that caused by RSV.<sup>423</sup> In 2003, the agent of severe acute respiratory syndrome (SARS), a coronavirus, was associated with a global outbreak of respiratory illness associated with high mortality.<sup>424</sup> There are ongoing concerns regarding pandemic avian influenza virus (H5) which has been spreading around the world both in avian populations and to a much lesser extent in humans since it was first recognized in Hong Kong in 1977. All three of these agents can be identified using molecular technology and PCR assays.

## ANTIVIRAL SUSCEPTIBILITY TESTING

Antiviral therapy is now available for the management of many viral infections, including HIV, HSV-1 and 2, CMV, VZV, influenza A and B, RSV, hepatitis B virus and hepatitis C virus. It is anticipated that resistant viruses will invariably occur and increase in prevalence with increased use of antiviral agents. Antiviral resistance is defined as a decrease in susceptibility to an antiviral agent established by *in vitro* testing and confirmed by genetic analysis of the viral genome and biochemical analysis of the altered enzyme. Clinical failure of antiviral therapy may not always be due to antiviral resistance and consideration must be given to the patient's immunological status, the pharmacokinetic properties of the drug in a given patient, and patient compliance. Antiviral resistance is more likely to occur with long term or recurrent administration of intermittent or suboptimal therapy.

Laboratory assays to detect the viral susceptibility to an agent can be either phenotypic or genotypic assays. Phenotypic assays require growth of the virus *in vitro* in the presence of the drug and establishment of the concentration of antiviral agent resulting in 50% and 90% inhibition of growth. These assays have not been standardized or correlated with therapeutic success, as they have for antibacterial susceptibility testing, and are not routinely available.

On the other hand, genotypic assays which detect genetic mutations known to confer antiviral resistance are more widely available, especially in the management of HIV infected patients and the selection of anti-HIV therapeutic agents. The major limitation of genotypic assays is that they can only detect resistance caused by known mutations and will not detect new resistance mechanisms.

## HIV INFECTION

### EPIDEMIOLOGY

The first cases of pediatric acquired immune deficiency syndrome (AIDS) were described in 1982 and the causative agent, HIV, was first isolated in 1983. Since then, a large amount has been learnt about the disease and for resource-rich countries and even increasingly in resource-limited settings, antiretroviral therapies (ART) have had a major impact in reducing morbidity and mortality in HIV infected adults<sup>425</sup> and children,<sup>426</sup> as well as dramatically reducing transmission from mother to child.<sup>427,428</sup> However, the global HIV epidemic has continued, with an estimated 40 million people living with HIV worldwide in 2006 (Fig. 28.28). Whilst the global prevalence (proportion of the population living with HIV) appears to have plateaued, the total number of people

Fig. 28.28 (a) Adults and children estimated to be living with HIV/AIDS as of end 2001. (b) Children (< 15 years) estimated to be living with HIV/AIDS as of end 2001.

infected continues to rise with population growth and prolonged life expectancy from ART. About 95% of people infected with HIV live in resource-limited settings, with Africa continuing to bear the brunt of the epidemic (approximately 65% of global HIV infections), although incidence rates appear to have peaked in several African countries, and may even be falling in some countries (e.g. Kenya). Women are disproportionately affected by HIV, and HIV seroprevalence is over 20% among pregnant women in many sub-Saharan African countries. Because over 95% of paediatric infections are acquired from mother to child, this has major implications for HIV infection in children. In Africa, where almost 90% of the world's infected children live, HIV has reversed gains in child survival and has lowered life expectancy. In addition, large numbers of children have been orphaned. By the end of 2006, UNAIDS estimated that there were over 12 million children under 18 years of age in Africa who had lost their mother or both parents to AIDS,<sup>429</sup> placing enormous strains on communities already devastated by the social and economic impact of so many young adults prematurely dying.

The global HIV epidemic continues to grow outside Africa. Over half of the world's population lives in the Asia/Pacific region and in 2006 an estimated 8.3 million people were infected with HIV. Two thirds live in India, which now has the largest number of HIV infected persons of any single country.<sup>429</sup> Seroprevalence rates in pregnant women are over 1% in many states. The epidemic in Eastern Europe and Central Asia has seen a twenty-fold increase in the number of people living with HIV in under a decade; estimated at 1.5 million in 2006, the majority live in the Russian Federation and the Ukraine, where adult prevalence rates are

above 1%. While intravenous drug use is a major risk factor, increasing reports of new sexually transmitted infections suggest HIV is spreading into the general population.<sup>429</sup> Increasing availability of surveillance data from China provides estimates that at least 650 000 people are living with HIV, with highest prevalence rates seen in injecting drug users and sex workers.

Even in Western countries, prevention efforts appear to be stalling. Available information indicates that the number of newly infected people is no lower in 2006 compared with previous years, with 720 000 adults and children estimated to have acquired HIV in Western and Central Europe and 1.2 million in North America.<sup>429</sup> Overall HIV prevalence has risen in both regions, because ART is resulting in HIV infected individuals living longer, and also likely as a result of more people coming forward for testing (including in particular, pregnant women). Thousands of infections are still occurring through unsafe sex between men, where complacency may be attributed to the fact that in the age of ART, HIV is seen as a treatable if not curable disease. However, it is also true that transmission rates of HIV are likely to be lower from persons on highly active ART (HAART) who will have lower plasma concentrations of the virus.<sup>430</sup> In the USA, there remain an estimated 25% of persons with HIV who have not been diagnosed, this proportion being higher in black African populations where HIV is now the leading cause of death in African American women aged between 25 and 34 years.<sup>429</sup> The proportion of persons with undiagnosed HIV is higher (around one third) in the UK. These persons are more likely to transmit HIV to their sexual partners as they are less likely to use barrier contraception and are not on HAART and therefore have higher levels of plasma viremia.

It is estimated that around 43% of transmission occurs around the time of seroconversion and thus generally before the infected person knows he or she has HIV infection.

By the end of 2006 there were an estimated 2.3 million children < 15 years old living with HIV infection worldwide, of whom 540 000 were newly infected and 360 000 died during 2006 alone; 87% live in sub-Saharan Africa.<sup>429</sup> Although contributing less than 1% of children infected with HIV worldwide, there are currently around 11 000 children living with HIV in North America and about 4000 in Western and central Europe, of whom over 1100 live in the UK and Ireland ([www.chipscohort.org](http://www.chipscohort.org)).<sup>429</sup> With dramatic decreases in transmission rates from mother to child in resource rich countries, new pediatric infections amongst babies usually occur only in countries where antenatal screening is not comprehensive and/or interventions to reduce mother-to-child transmission (MTCT) are not widely offered. Recent cases of MTCT in UK have been reported in infants of women with a negative HIV antibody test in early pregnancy who subsequently seroconvert during pregnancy or breast-feeding.<sup>431</sup> It is not surprising that pediatric infections in many countries of the north are increasingly in migrants from countries with a high prevalence of HIV infection. In the UK, over 75% of seropositive newborns are delivered to mothers born in sub-Saharan Africa, and whereas prior to 2000 approximately one third of HIV infected children were themselves born overseas, this proportion increased to around two thirds after 2003.<sup>432</sup> Similar patterns are being observed in many countries in Europe.<sup>433</sup>

Romania has the largest number of HIV infected children in Europe.<sup>429</sup> The majority belong to a cohort of children who were uniquely infected with HIV through contaminated blood products and needles in the late 1980s. Although many have died, there remain a considerable number of these children who are now teenagers in Romania. Maternal seroprevalence in Romania is about 0.3% in cities such as Costansa, on the Black Sea.

### Surveillance for pediatric HIV infection

Unlinked anonymous monitoring of HIV through testing dried blood spots (Guthrie cards) collected on all newborns in many countries for metabolic screening, or antenatal bloods, can provide an unbiased estimate of the prevalence of HIV infection among women having live babies. This is a useful method of providing information about the extent of heterosexually acquired HIV infection in a population, particularly if monitoring is undertaken longitudinally. This might be done continuously or, if resources are scarce, it can be done intermittently (e.g. for 3 months each year). It is possible, while preserving full anonymity, to retain demographic information (e.g. mother's country of birth) which can then determine HIV seroprevalence among particular groups within a community as was done in North London, showing low HIV prevalence among women coming from Asian communities in

1998.<sup>434</sup> Data from anonymous serosurveys have also been combined with non-named confidential register data on HIV in pregnancy in order to provide an indication of the proportion of pregnancies being identified before or during pregnancy.<sup>435</sup> This can be a useful way to audit antenatal testing policy and provide local feedback to care providers (see below).

HIV antibody testing of Guthrie cards is being undertaken in the UK and covers approximately 70% of live births. In 2004, the HIV antenatal seroprevalence was 0.44% in Greater London and 0.11% in the rest of England, but women of sub-Saharan origin had a rate of 2.2%, over 30 times the rate of 0.07% in women born in the UK<sup>436</sup> (Fig. 28.29). Maternal seroprevalence rates in England and Scotland have risen from 0.16% in 2000 to 0.27% in 2004,<sup>436</sup> and this rise may in part reflect an increasing desire for HIV infected women on HAART and clinically well to have children, in the knowledge that the risk of MTCT with appropriate intervention is very low. In London in 2004, three quarters of seropositive newborns were delivered to mothers born in sub-Saharan Africa, and similar patterns are being observed in European countries such as France and Belgium. In Scotland, Ireland and southern Europe a higher proportion of seropositive children are still born to women with injecting drug use (IDU) as a risk factor, but here too the proportion of women acquiring HIV from heterosexual transmission is increasing.

Of 1441 children reported to the National Study of HIV in Pregnancy and Childhood (NSHPC) by June 2006, over 1300 are currently known to be living with HIV in the UK and Ireland. Over two thirds reside in London and were born to women who acquired HIV in sub-Saharan Africa. With dispersal of refugees to other cities in the UK, this is changing. Similarly, whereas the majority of HIV infected children in Scotland and Ireland are still white children born to mothers with IDU as a risk factor for acquiring HIV, this is changing and increasing numbers of mothers of more recently diagnosed HIV infected children acquired the disease through heterosexual contact, often abroad. Follow-up of infected children is being coordinated, along with follow-up of children in Europe participating in clinical trials [Paediatric European Network for Treatment of AIDS (PENTA)], through the Collaborative HIV in Paediatric Study (CHIPS) cohort which has over 1100 children in follow-up from over 40 centers and is coordinated through the MRC Clinical Trials Unit in London in collaboration with the Institute of Child Health (ICH) ([www.chipscohort.ac.uk](http://www.chipscohort.ac.uk), [www.pentatrials.org](http://www.pentatrials.org)).<sup>432</sup>

With the advent of HAART, children with HIV are living longer and the average age of the cohort of infected children in the UK and Ireland is now around 8.5 years, with 12% being 15 years of age or older, and over 100 having transferred to adult clinics.<sup>432</sup> As children with HIV survive into adolescence they face many similar issues to other young people with chronic disease such as delayed growth, development and puberty and adherence to and the long term side-effects of drug therapy. However, these young people have the additional issues

Fig. 28.29 Trends in prevalence of HIV infection in pregnant women by area of residence: 1989–2000.

of negotiating adolescence with a stigmatizing sexually transmissible disease. Many will also have lost a parent or will have to care for a sick family member. The complex medical, psychological and social needs of these young people require multidisciplinary team involvement with close liaison with adult colleagues when transitioning young people to adult services.<sup>437</sup>

### MOTHER-TO-CHILD TRANSMISSION OF HIV

Mother-to-child transmission (MTCT) of HIV can occur during pregnancy, labor or breast-feeding.<sup>438</sup> In the absence of breast-feeding, approximately two thirds of transmission occurs around the time of delivery. In Europe and the USA, the rate of MTCT in the absence of breast-feeding prior to the advent of interventions was around 15–20%, compared with around 30–40% in Africa. Most of this difference is due to breast-feeding, which accounts for about one third of transmission in Africa.<sup>439</sup> Factors independently affecting the rate of transmission include the mother's clinical status, HIV viral load and CD4 cell count, particularly at the time of delivery, prematurity, factors around delivery such as duration of rupture of membranes and mode of delivery<sup>438,440</sup> (Table 28.31).

In the last 10 years, rates of MTCT in resource rich countries have fallen dramatically to 2% or less with strategies including use of antiretroviral therapy, elective Cesarean section (CS) and refraining from breast-feeding.<sup>427,441</sup> Unfortunately in most resource limited settings, despite increased availability of at least some interventions to reduce MTCT, only about 10% of women are diagnosed in pregnancy and therefore have access to such interventions.<sup>429</sup>

### Antiretroviral therapy to reduce MTCT

In 1995, the first placebo-controlled trial (the ACTG 076 trial) of zidovudine (ZDV) monotherapy, given to the mother antenatally from a median of 26 weeks by continuous intravenous infusion during labor, and then orally to the infant from birth for 6 weeks, resulted in a 67% reduction in MTCT in non-breast-feeding US and French HIV infected women compared with placebo.<sup>442</sup> This trial was followed by non-randomized studies to document the effect of ZDV monotherapy on MTCT in the clinical setting<sup>427,441,443</sup> and of non-randomized studies of double<sup>444</sup> and triple antiretroviral therapy. The results showed that ZDV was highly effective in reducing MTCT and, compared with historical controls, the use of double therapy was superior to monotherapy.<sup>444</sup> With triple therapy, MTCT rates below 1% are achievable among women with undetectable HIV viral load at delivery.<sup>445</sup> Cohort studies have documented reductions in MTCT over calendar time with increasing use of triple HAART in pregnancy (Fig. 28.30).<sup>428</sup>

The importance of low maternal plasma HIV viral load around the time of delivery in reducing the risk of MTCT has been demonstrated in subsequent trials.<sup>446</sup> However, it is not the only important factor and it is clear that ART reduces MTCT both by decreasing maternal viral load and by providing pre- and post-exposure prophylaxis to the infant. In an individual patient meta-analysis of women with low HIV RNA of <10000 copies/ml, the transmission rate was reduced from 10% to

Fig. 28.30 Estimated vertical transmission rate (95% CI) in UK over time in non-breast-feeding women.

(From Duong et al 1999<sup>428</sup>)

only 1% by the use of ZDV alone, which has only a minimal effect on maternal viral load (reduction by only about 0.3 log copies/ml).<sup>447</sup> This suggests that post-exposure prophylaxis to the fetus is also important, a factor borne out by the large impact on transmission of giving long acting nevirapine (NVP) to women during labor and to the baby.<sup>448</sup> Even if a woman has not received ART during pregnancy or delivery, ART given to the baby as soon as possible after birth is likely to have an effect on transmission. Guidelines for giving ART to pregnant women to reduce MTCT are available and are regularly updated.<sup>449,450</sup>

Trials have been conducted comparing different components of the ACTG 076 regimen and also evaluating other antiretroviral drugs. Most have taken place in resource-limited settings where an important goal was also to refine, simplify and reduce the costs of the initial ZDV regimen used in the ACTG 076 trial. A trial of ZDV monotherapy in non-breast-feeding women in Thailand showed that a 50% reduction of MTCT was possible by giving ZDV from 36 weeks' gestation, oral ZDV during labor and for 2 weeks to the baby.<sup>451</sup> However, another trial from Thailand emphasized that starting ART at 28 weeks added benefit compared with starting at 36 weeks,<sup>452</sup> suggesting that some in utero transmission may be prevented by ART. It is also true that if starting ART is left until 36 weeks, some women will go into premature labor having received minimal or no pre-labor ART.

Intrapartum ART alone does not appear to be useful<sup>453</sup> if given without postpartum prophylaxis to the baby. In HIVNET 012 undertaken in Uganda, a single 200 mg oral dose of NVP, given to the mother in labor, followed by a single oral dose of 2 mg/kg to the infant at 48 h (total cost US\$4), led to a 40% reduction in MTCT at 16 weeks compared with intrapartum and neonatal (for 1 week) oral ZDV.<sup>448</sup> Follow-up to 18 months has shown continued efficacy of around 40% despite breast-feeding for an average of 9 months. However, probably due to its long plasma half-life,<sup>454</sup> nevirapine resistance rates of up to 75% in mothers and 46% in infants after single dose exposure have been reported.<sup>455,456</sup> As ART becomes increasingly available worldwide the therapeutic implications of NVP resistance for mothers and infants infected despite NVP are of increasing concern.<sup>457,458</sup> Methods to reduce rates of nevirapine resistance include the use of short course combination therapy to protect the nevirapine 'tail'. In the Treatment Option Study (TOPS) significantly reduced rates of NVP resistance were seen in women who received either 4 or 7 days of Combivir with single dose nevirapine (SD-NVP) when compared to women who received SD-NVP alone.<sup>459,460</sup> In a study from Malawi, infants who received SD-NVP plus AZT had lower rates of NVP resistance at 6–8 weeks of age than infants who received SD-NVP or mothers who had peripartum SD-NVP alone. Similar rates of MTCT were seen in all groups.<sup>461</sup> For those women who develop NVP resistance there are some data suggesting that these mutations fade over time. Women who had received peripartum SD-NVP had higher rates of virological failure when commencing subsequent NVP-based HAART than women who had received a placebo but only if they started HAART within 6 months of delivery.<sup>462</sup> Whether archived NVP mutations will continue to impact on the longer term response to subsequent

Table 28.31 Factors associated with mother-to-child transmission (MTCT) of HIV

- Without interventions, the rate of MTCT was 15–20% in Europe, and 25–40% in Africa
- Most MTCT occurs around the time of delivery
- Increased risk is associated with:
  - late stage maternal disease
  - high maternal plasma viremia
  - prolonged rupture of membranes
  - invasive obstetric procedures
  - prematurity
  - breast-feeding

NNRTI-based regimens requires further follow-up. The balance between preventing transmission of HIV to infants whilst minimizing impact on maternal health and future HAART options is a complex issue requiring continuing research, during which time NVP continues to have a role in the prevention of MTCT in resource poor settings.

### **Reducing MTCT in well resourced settings**

Whilst randomized controlled trials of HAART are lacking, in a European cohort HAART was associated with a fall in transmission from 11.5% to 1.2%, with a greater reduction (0.25% versus 1.92% respectively) if started prior to pregnancy compared to during pregnancy.<sup>463</sup> Prior to 2004, women commencing HAART in pregnancy would typically receive NVP with two nucleoside reverse transcriptase inhibitors (NRTIs), often ZDV and 3TC. Following reports of fatal fulminant hepatitis in pregnant women with good CD4 counts receiving NVP-based HAART, nevirapine is no longer recommended for pregnant women with good CD4 counts (> 250 cell/uL) who are taking ART for the prevention of MTCT. Alternate regimens based on a protease inhibitor are used. NVP monotherapy is not recommended because of concerns about the development of resistance to all non-nucleoside reverse transcriptase inhibitor (NNRTI) drugs.

### **Problems with ART to reduce MTCT**

#### **Maternal pre-eclampsia and premature labor**

Advances in the development of pharmaceutical interventions to reduce HIV MTCT are not without complications. Analysis of a Spanish cohort of HIV positive women delivering between 1985 and 2003 showed a marked reduction in MTCT but an increased risk of fetal death or pre-eclampsia with any form of HAART taken pre-pregnancy.<sup>464</sup> A European study found an increased risk of prematurity associated with combination therapy commenced before the pregnancy (OR 2.6, 95% CI 1.43–4.75),<sup>465</sup> but a US cohort reported similar rates of prematurity of 17% but no significant difference between mothers who had received ART and those who had not.<sup>466</sup> It is speculated that immune reconstitution due to ART may play a part in adverse pregnancy outcome.

#### **Neonatal toxicity**

In a French study of ZDV + 3TC, concerns were first raised about a possible link between mitochondrial dysfunction in HIV uninfected children and perinatal exposure to NRTIs.<sup>467</sup> This complication is also known to occur rarely in HIV infected individuals taking NRTIs. Retrospective analysis of other large cohort data failed to reveal other definitive cases.<sup>468</sup> Neonatal anemia, and neutropenia have been reported in uninfected infants perinatally exposed to NRTIs, but they rarely require transfusion and respond to discontinuing the NRTIs, although a small negative effect on hematopoiesis has been seen up to 18 months of age.<sup>469</sup> Although concerns about the potential carcinogenicity and reproductive effects of ART as well as mitochondrial toxicity remain, current evidence suggests that the benefit of ART in dramatically reducing MTCT far outweighs potential harm. Many countries are now setting up long term surveillance to follow all children born to HIV infected mothers, whether exposed or not to ARTs in utero. In the UK, the CHART study, the National Study of HIV in Pregnancy conducted at the ICH, assesses the long term health and development of ART-exposed children.

### **Effect of mode of delivery on MTCT**

Several cohort studies have shown that factors around delivery contribute importantly to MTCT. In a meta-analysis of 15 large studies, including more than 5000 mother-child pairs from the USA and Europe, it was estimated that each hour longer in labor with ruptured membranes was associated with a 2% increase in the risk of MTCT.<sup>470</sup> A meta-analysis of these studies, a randomized European trial, and a European controlled trial, showed that among more than 8000 women the risk of transmission was 50% lower for babies delivered by elective CS prior to membrane rupture, compared with vaginal or emergency CS delivery.<sup>471,472</sup> Subsequent cohorts have shown that reduction of MTCT to around 2% is possible with ZDV, elective CS delivery and with not

breast-feeding.<sup>428,442</sup> The question of how much additional reduction to transmission may occur if elective CS delivery is undertaken in women on HAART with undetectable HIV RNA viral load around the time of delivery is unclear<sup>473</sup> and is unlikely to be answered from controlled trials. However, as the risk is very low, most guidelines suggest that the women can undergo a normal vaginal delivery in this situation, but that membranes should not be ruptured prematurely, and invasive interventions during labor or delivery (e.g. use of scalp electrodes and instrumental delivery) should be avoided.<sup>449,450</sup> Increasingly, women on HAART with undetectable plasma viral loads are choosing vaginal delivery. This may be of particular importance for women returning to areas of the world where elective CS is not readily available for subsequent pregnancies.

### **Breast-feeding**

HIV can be transmitted through breast milk.<sup>474,475</sup> Most transmission appears to occur early, and factors including HIV viral content in colostrum, immaturity of the infant gastrointestinal tract in the neonatal period, and the contribution of breast and nipple complications (e.g. mastitis and bleeding nipples which may increase the amount of virus in breast milk) all play a role. Breast milk transmission continues, however, throughout the duration of breast-feeding, posing extremely difficult dilemmas for policy in parts of the world where alternatives to breast-feeding are expensive, unsafe and culturally unacceptable, but where HIV prevalence is high.<sup>476</sup>

The current recommendation is that infants should continue to be breast-fed where infectious diseases and malnutrition are the main cause of infant mortality, because artificial feeding substantially increases the risk of illness and death.<sup>476</sup> Evidence suggests that mixed feeding is associated with a higher risk of transmission and therefore it has been recommended that women in these areas exclusively breast-feed for 4–6 months (which is anyway advocated for all women) and then wean as quickly as possible. After this time, the benefits of breast-feeding may be outweighed by the risk of HIV infection.<sup>477</sup> This strategy is likely to be more feasible than exclusive formula feeding, which in many settings is likely to increase infant mortality from other infections, to be socially unacceptable and unaffordable and risk a 'spill-over effect' on non-HIV infected mothers. Where infants of HIV infected mothers can be ensured uninterrupted access to nutritionally adequate, safely prepared breast milk substitutes, they are at less risk of illness and death from non-HIV related illness and their mothers should be encouraged not to breast-feed. Hopefully, larger prospective studies will help clarify the effects of exclusive breast-feeding followed by early weaning after short course anti-retroviral therapy on HIV transmission rates, and the morbidity and mortality of HIV infected and uninfected babies. The risk of transmission through breast-feeding in mothers with an undetectable plasma viral load on suppressive HAART is being assessed in studies in Africa.<sup>478</sup>

### **Other interventions to reduce MTCT**

Other interventions that have been explored to reduce MTCT include trials of cleansing the birth canal and vitamin A supplementation during pregnancy. The rationale for the former is that the maximum risk of exposure appears to be around the time of delivery and, therefore, cleaning with chlorhexidine might reduce vertical transmission. However, clinical trials have failed to show significant reduction of MTCT with this approach.<sup>479</sup>

Observational studies suggested that low vitamin A levels were associated with increased MTCT.<sup>480</sup> Randomized trials have, however, failed to show a significant impact of supplementation with vitamin A on prevention of MTCT.<sup>481</sup>

## **ANTENATAL TESTING**

### **In resource rich countries**

The case for offering antenatal HIV testing is overwhelming. A recommendation that HIV testing should be offered to all women in pregnancy has been successfully implemented in most well resourced countries. In

the UK, the universal offer of HIV testing during the antenatal period was endorsed in 1999 after an economic analysis showed that a universal offer policy was cost effective throughout the UK provided that a high uptake of testing was achieved.<sup>482</sup>

Statistical analysis of unlinked anonymous seroprevalence data with reported infections suggests that in 2004, 90% of infected women living in the UK were diagnosed prior to delivery and were therefore able to take up interventions to reduce MTCT. In most European countries and in the USA, a marked decrease in infected babies reflects the high proportion of pregnant women receiving appropriate care to reduce MTCT. However, a few infants continue to present with severe *Pneumocystis jiroveci*, previously called *P. carinii* pneumonia (PCP), and cytomegalovirus (CMV) infection<sup>483</sup> as a result of perinatal transmission of HIV from mothers who are unaware of their own HIV infection or from mothers who have seroconverted in pregnancy or during breast-feeding.<sup>431</sup> Discussions are underway in the UK to determine whether a second HIV antibody test in the later stages of pregnancy would be feasible and cost effective in further reducing the risk of MTCT.

### In resource limited countries

In low income countries, ART to prevent MTCT is only one strand of a much more complex mesh of issues surrounding the prevention of vertical transmission.<sup>484</sup> With the available tools and knowledge that we have already, there is a strong argument for putting resources into providing antenatal diagnosis and the appropriate perinatal interventions. This undoubtedly requires a huge input of resources into the development of sustainable infrastructures in situations where antenatal care may currently be rudimentary.

Understandably, concerns have been raised that, rather than putting scarce resources into a 'magic bullet' of ART to pregnant women, efforts should be concentrated on the more difficult issue of preventing women getting infected in the first place. In sub-Saharan Africa pilot projects offering antenatal screening and intervention have been established since 2001, but the scaling up of these services has been disappointing, with less than 10% of infected pregnant women in sub-Saharan Africa offered intervention to prevent MTCT in 2006.<sup>429</sup> Preventing HIV infection in women will require both behavioral and biomedical interventions such as microbicides, several of which are currently being evaluated in phase III trials.

### ETIOLOGY AND PATHOGENESIS

HIV is a retrovirus. Transmission occurs through sexual intercourse, via infected blood and blood products and by transmission from mother to child. Many of the clinical features of HIV can be ascribed to profound immune suppression, because HIV infects cells of the immune system and ultimately destroys them. An understanding of the way it does this is helpful in interpreting tests used in monitoring the disease and helps explain the difficulties in developing a vaccine for HIV.

The virus predominantly infects a subset of the thymus-derived lymphocytes carrying the surface molecule CD4, which binds the glycoprotein on the envelope of HIV called gp120. CD4 is also present on many monocytes and macrophages and on Langerhans' cells of the skin and dendritic cells of many other tissues. HIV also requires co-receptors to enter cells. Two of these, termed CCR5 and CXCR4, are of particular importance. These co-receptors are members of a family of receptors, expressed on the cells of lymphocytes, dendritic cells and cells of the rectal, vaginal and cervical mucosa, that function as receptors for chemokines that orchestrate the migration and differentiation of leukocytes during immune responses. Virus strains able to infect primary macrophages (R5 tropic viruses) use CCR5 as a co-receptor and these are detected early in infection, suggesting they are important for transmission. Further evidence for this comes from studies showing that individuals homozygous for a 32 pair deletion of CCR5 show increased resistance to being infected by HIV.<sup>485,486</sup> Both R5 and strains infecting T cells use CXCR4 as a co-receptor (T or X4 viruses) and they arise during the course of infection.

CD8 cytotoxic lymphocytes (CTL) capable of killing HIV infected targets develop early in primary HIV infection and are very important in the initial control of viremia.<sup>487,488</sup> Among CD8 cells, rapid expansion of strong T cell responses to multiple viral epitopes has been shown to be associated with better control of viremia following primary infection in adults. CD8 T cells kill infected cells and produce CD8 T cell antiviral factor (CAF) which inhibits viral replication. The breadth and strength of the CTL responses are determined by the degree of CD4 specific helper response, which may be determined by the level of HIV viremia and by genetic host factors. In adults who fail to control viral load, CTL responses are narrower and less marked. Because HIV replication is very rapid and errors occur in reverse transcription, these mutants can evade CTL response (escape mutants), i.e. the viral epitope mutates to 'escape' control by the CTL. Children surviving with perinatally acquired HIV have been shown to have more robust HIV-1-specific CD8 responses than was previously thought, comparable in magnitude and breadth to those of adults<sup>489</sup> and, as in adult studies, infants and children with unsuppressed viral loads had poorer CTL responses.<sup>490</sup>

In infants in whom the immune system is immature, the viral load rises over the first weeks after primary infection around the time of birth, and stays high throughout infancy. It then falls in the absence of therapy over the next 3–5 years (Fig. 28.31)<sup>491,492</sup> to reach a 'set point' which is much later after primary infection than in adults (set point at about 6 months). Unlike adults, infants have a highly active thymus which may 'work' to replenish CD4 cells destroyed by the virus. While this may appear to be advantageous, recent work has suggested these new thymic cells may quickly become infected with HIV and possibly delay reduction in HIV viremia in children on ART.<sup>493</sup>

As viremia starts to decline in adults, HIV antibody production increases. Detection of HIV antibodies is the principal way of making the diagnosis in adults and older children, as antibodies persist usually until death.

Polyclonal activation of B cells also occurs, resulting in high immunoglobulin levels in most children commencing during infancy, although infants with rapid disease progression may rarely be hypogammaglobulinemic. This polyclonal increase in immunoglobulin is in many cases nonfunctional, while antigen-specific antibody production is reduced, resulting in increased susceptibility to bacterial infections.

There are reports of both adults and children being exposed to HIV and remaining uninfected; these individuals have detectable HIV-specific CTL. In addition, individuals with strong CTL responses may have delayed disease progression (long term nonprogressors); the latter has also been associated with certain HLA type 1 alleles.<sup>494</sup>

The CD4 cell plays a central role in orchestrating the immune system, and their destruction by HIV accounts for much of the immunosuppressive

Fig. 28.31 Log<sub>10</sub> HIV-1 RNA plotted against age in untreated HIV infected children (fitted line and 95% CI). (From Gibb et al 1998<sup>492</sup>)

effect of the virus. Following fusion into CD4 and other cells, viral core material enters the host cell and the genetic material encoded in RNA is converted to DNA by reverse transcriptase. This DNA 'provirus' is then integrated into the host genome. HIV replicates at an enormous rate with  $>10^6$  particles being produced daily.<sup>495</sup> In addition, turnover of infected replicating CD4 cells is high, occurring approximately every 1.5 days. CD4 damage occurs both directly and through mechanisms resulting in apoptosis of infected cells. The exact role of both mechanisms is still debated. HIV in resting memory and long-lived cells both in the immune system and in other tissues remains latent for long periods of time and is largely responsible for persistence of the virus despite the ability of HAART to decrease virus to undetectable levels in plasma. In 1996, with the advent of HAART, there was great hope that the half-life of long-lived cells might be in the order of only a few years and that HIV eradication might be possible. Sadly this is not the case, and modeling exercises estimate the half-life of these long-lived infected cells to be around 70 years.<sup>496</sup> If HAART is stopped, even after plasma viral load has been undetectable for several years, HIV viral load rises again within 1–2 weeks, typically returning to the 'set point' seen prior to initiation of HAART. The virus also has a remarkable ability to mutate and develop resistance to antiretroviral drugs, as seen following single dose nevirapine exposure (see above). Mutant virus may remain in latent cells for many years but re-emerge if that drug is re-started in an individual.

### Monitoring with CD4 and HIV RNA viral load

The most widely used markers for predicting disease progression in children, as in adults, are the CD4 cell count (or percentage) and viral load as measured by HIV-1 RNA in plasma.

Absolute CD4 counts are higher in young children than in adults and there is great within- and between-individual variability. CD4 percentages vary less with age, although they are still higher at very young ages as can be seen from percentile charts constructed from uninfected children born to HIV positive mothers (Fig. 28.32).<sup>497</sup> By around 4–5 years of age, the CD4 cell count number and range has fallen to nearer adult values. In children with HIV infection, as in adults, absolute lymphocyte counts and CD4 cell counts decrease with progression of the disease. Analyses of combined individual longitudinal data in untreated children prior to the advent of ART (HIV Paediatric Prognostic Markers Collaborative Study) have provided guidance for thresholds of CD4%, CD4 count and total lymphocyte counts (TLC) associated with a marked increase in disease progression at different ages.<sup>498–500</sup> These have formed the basis for new WHO guidelines<sup>501</sup>; clinicians can use a risk calculator (available on <http://www.hppmcs.org/>) to estimate risk of progression in an untreated child according to age and CD4% count or TLC level. Most pediatricians use CD4% up until the age of around 5 years when increasing account should be taken of the total CD4 count. Of particular note, in very young children, no marker is very good at predicting

Fig. 28.32 CD4 lymphocyte counts in uninfected children by age: 3rd, 5th, 10th, 25th, 50th, 75th, 90th, 95th and 97th centiles. Created from data collected by the European Collaborative Study using the methods of Wade & Ades (1994).<sup>497</sup>

disease progression. Whereas, in adults, a CD4 cell count below 200 cells/mm<sup>3</sup> is a useful predictor of risk of developing *Pneumocystis carinii* (*P. jirovecii*) pneumonia (PCP) and is therefore used to determine the time to start prophylaxis against this disease, during infancy even CD4 percentage is of limited predictive value.<sup>502</sup> After infancy, a CD4% greater than 25% is considered evidence of minimal immunosuppression, 15–25% moderate, and  $<15\%$  severe immunosuppression and these form the basis of the Centers for Disease Control (CDC) immunological classification of HIV in children.<sup>503,504</sup> The Revised WHO Clinical Staging and Immunological Classification of HIV/AIDS (2006) incorporates age-related immune classification from infancy through to adulthood.<sup>501</sup> Importantly, for the individual child the rate of fall of CD4% and at older ages of CD4 cell counts are of importance and should be taken into account when making decisions about when to start antiretroviral therapy. Further analyses of HPPMCS data are ongoing to try to define this more accurately.

Viral load as measured by plasma HIV RNA is an independent predictor of HIV progression in adults after the 'set point' has been reached. Several different assays are available in kit form with quality control (Roche, Chiron and NASBA). The Roche PCR version 1.5 and Chiron assays are widely used and include additional primers to ensure accuracy when measuring viral load in persons with different subtypes of HIV (e.g. subtype B is the most common virus subtype in white North Americans and Europeans but subtypes A, C and D are common in Africans). It is important to be aware that assay variability may be as high as 0.7 log and that results need to be interpreted on a log scale. Repeating results is advisable if treatment decisions are being taken based on viral load results; in general viral load is less predictive of disease progression than CD4% or count and used less to make decisions about starting therapy.<sup>498</sup> All assays are less precise at values above 750 000 copies/ml but all assays are more robust at low levels down to a cut-off of 50 copies/ml. In infants, HIV RNA is very high after infection around the time of birth and remains much higher (often 1 million copies/ml or more) than observed in adults for the first 2 years of life, gradually reducing by an average of about one log over the first 5 years of life in the absence of antiretroviral therapy (Fig. 28.33).<sup>492,495</sup>

### LABORATORY DIAGNOSIS OF HIV

Enzyme linked immunosorbent assays (ELISA) for measuring HIV antibody are highly sensitive and specific for diagnosing HIV in adults and in children over 18 months of age. However, because of transplacental transfer of maternal antibody, all babies born to HIV infected women will have antibodies at birth which take a median of 10 months and a maximum of 18 months to clear. Other techniques, directed at viral components rather than the host immune response, are therefore required to diagnose HIV in young infants.

In Western countries, early diagnosis of HIV in infants has been improved significantly by polymerase chain reaction (PCR) techniques for detecting proviral DNA and RNA. Using these techniques, HIV infection can be definitively diagnosed in about 90% of infected infants by age 1 month and in virtually all by 3 months. HIV proviral DNA PCR is the preferred method for initial diagnosis. In a meta-analysis, 38% (90% CI = 29–46%) of infected children had positive PCR DNA tests by age 48 h, rapidly increasing in the second week with 93% of infected children (90% CI = 76–97%) testing positive by 2 weeks of age.<sup>505</sup>

HIV RNA tests may be more sensitive than DNA PCR for diagnosis, but limited data suggest lower specificity, immediately after birth. However, they may be alternatives if proviral DNA tests are not available and give additional information about the degree of viremia. Culture of HIV is time consuming and expensive and is no longer routinely undertaken. The detection of p24 antigen, both standard and immune-complex dissociated, although highly specific, is not as sensitive as DNA PCR. Nevertheless, detection of acid or heat dissociated p24 antigen by ELISA is considerably cheaper than PCR tests and is also technically less demanding, making it more promising as a diagnostic tool for resource limited settings; it is highly specific but less sensitive than proviral DNA.

Fig. 28.33 Change in log<sup>10</sup> RNA after starting ART in the PENTA 5 trial. (From PENTA 2002<sup>535</sup>)

Another laboratory clue that a child may have HIV infection is the presence of polyclonal hypergammaglobulinemia, which in the presence of CD4 lymphopenia should lead to a high suspicion of HIV infection.

In the last 5 years, there has been increased focus on developing cheaper ways of detecting early infection in infants. Although still outside the reach of most countries' budgets, early diagnosis using DNA PCR techniques is now available in many parts of South Africa and is being introduced into countries such as Uganda. Updated WHO guidelines recommend that treatment of symptomatic infants can start in the absence of a definitive diagnosis.<sup>501</sup> Early detection of infection among babies born to mothers who have received PMTCT is more problematic because, with reduced transmission rates, many babies have to be tested to detect a single infected baby. The issues of testing during breast-feeding also require attention; the WHO recommends that testing might be focused around timing of immunizations, and in women who wean at 6 months according to guidelines, after cessation of breast-feeding.<sup>501</sup> Debate continues about the best time to test if only one test per infant is available. However, unless it is undertaken early, it is clear that infected babies will die before there is time for diagnosis to occur.

### CLINICAL ASPECTS IN WELL RESOURCED SETTINGS

HIV infected babies generally appear normal at birth, with birth weight in the normal range. Clinically one cannot usually detect any signs that a baby has HIV in the first days of life. Signs and symptoms develop over the first few weeks and most children have evidence of infection before 12 months of age. Anecdotally, axillary lymphadenopathy may be an early sign that a baby is infected. However, there is a wide spectrum and some infected children may not present to medical attention for several years, with a smaller number remaining asymptomatic into adolescence.

HIV can present with a spectrum of signs and symptoms in children. This is reflected in both the four-stage CDC classification<sup>504</sup> and more recently in the revised four-stage WHO classification system for children<sup>501</sup> (Table 28.32), and important differences between adults and children are summarized in Table 28.33. In the absence of antiretroviral

therapy or prophylaxis against PCP (see below), disease progression is faster than in adults, even in well resourced settings. Cohort studies reported in the early 1990s that 15–20% of children progressed to an AIDS-defining illness by 12 months of age.<sup>506–508</sup> Over half of this subset of perinatally infected children presented with PCP at around 3–6 months of age in the absence of using prophylactic co-trimoxazole. Data from prospective cohorts in Europe in the early 1990s reported overall survival rates in children on either no ART or only ZDV monotherapy of around 70% by 6 years and 50% by 9 years of age.<sup>506–508</sup>

Children with HIV infection frequently present with nonspecific signs and symptoms that are common in general pediatrics. The most usual clinical features associated with HIV infection include persistent generalized lymphadenopathy (particularly axillary), hepatosplenomegaly, chronic or recurrent diarrhea, prolonged or recurrent oral or diaper candidiasis, fever, recurrent otitis or sinusitis and chest infections. Children may also present with a picture of idiopathic thrombocytopenic purpura with no other signs and may be more prone to developing eczema, extensive molluscum, and recurrent allergic iritis and rhinitis. A typical and quite specific presentation is non-tender bilateral parotid enlargement, which may be associated with generalized cervical lymphadenopathy and X-ray appearances of lymphocytic interstitial pneumonitis (LIP) with hilar lymphadenopathy (see below). Such children often also have allergic rhinitis, tonsillar and/or adenoid enlargement and may present with sleep apnea. Herpes zoster (shingles) in childhood is uncommon and suggests a defect in cellular immunity justifying an HIV test in the absence of other explanations.

Persistent or recurrent oral candidiasis after the neonatal period, abnormal neurological signs, failure to thrive and poor growth in association with HIV are all indications of increasing immune deficiency and a poorer outcome. Conversely, thrombocytopenia does not indicate a poor prognosis and bilateral parotitis, lymphadenopathy and LIP (see below) are often associated with a relatively good prognosis. Details of the main AIDS (CDC stage C) presenting conditions are described below. Although the development of these conditions, along with immunological stage 3 disease, has been shown to be predictive of a poor outcome, the prognosis varies. For example, conditions such as recurrent

Table 28.32 Revised WHO clinical and immunological staging in adults and children with established HIV infection

HIV-associated symptoms	WHO clinical stage
Asymptomatic	1
Mild symptoms	2
Advanced symptoms	3
Severe symptoms	4

Severe	< 25	< 20	< 15	< 200 or < 15%

WHO Case Definitions of HIV For Surveillance and Revised Clinical Staging and Immunological Classification of HIV-Related Disease in Children:  
 WHO clinical staging of HIV/AIDS for children with confirmed HIV infection

*Clinical stage 1*

Asymptomatic

Persistent generalized lymphadenopathy

*Clinical stage 2*

Unexplained persistent hepatosplenomegaly

Papular pruritic eruptions

Extensive wart virus infection

Extensive molluscum contagiosum

Fungal nail infections

Recurrent oral ulcerations

Unexplained persistent parotid enlargement

Lineal gingival erythema

Herpes zoster

Recurrent or chronic upper respiratory tract infections (otitis media, otorrhea, sinusitis or tonsillitis)

*Clinical stage 3*

Unexplained moderate malnutrition not adequately responding to standard therapy

Unexplained persistent diarrhea (14 days or longer)

Unexplained persistent fever (above 37.5°C intermittent or constant, for longer than one month)

Persistent oral candidiasis (after first 6–8 weeks of life)

Oral hairy leukoplakia

Acute necrotizing ulcerative gingivitis or periodontitis

Lymph node tuberculosis

Pulmonary tuberculosis

Severe recurrent bacterial pneumonia

Symptomatic lymphoid interstitial pneumonitis

Chronic HIV-associated lung disease including bronchiectasis

Unexplained anemia (< 8 g/dl), neutropenia (< 0.5 × 10<sup>9</sup>/L) and/or chronic thrombocytopenia (< 50 × 10<sup>9</sup>/L)

Unexplained refers to where the condition is not explained by other causes

*Clinical stage 4*

Unexplained severe wasting, stunting or severe malnutrition not responding to standard therapy

*Pneumocystis carinii* pneumonia (PCP)

Recurrent severe bacterial infections (such as empyema, pyomyositis, bone or joint infection or meningitis but excluding pneumonia)

Chronic herpes simplex infection (orolabial, genital or anorectal of more than one month's duration or visceral at any site)

Esophageal candidiasis (or candidiasis of trachea, bronchi or lungs)

Extrapulmonary tuberculosis

Kaposi sarcoma

Cytomegalovirus infection (retinitis or infection of other organs with onset at age older than one month)

Central nervous system toxoplasmosis

HIV encephalopathy

Extrapulmonary cryptococcosis including meningitis

Disseminated nontuberculous mycobacterial infection

Progressive multifocal leukoencephalopathy

Chronic cryptosporidiosis

Chronic isosporiasis

Disseminated endemic mycosis (extrapulmonary histoplasmosis or coccidioidomycosis)

Cerebral or B cell non-Hodgkin lymphoma

Symptomatic HIV-associated nephropathy

Symptomatic HIV-associated cardiomyopathy

Table 28.33 Differences compared with adults

- Faster rate of disease progression, especially in infants (PCP and CMV)
- Lymphoid interstitial pneumonitis and parotitis common
- More bacterial infections
- Encephalopathy presents differently
- Growth failure occurs as well as wasting
- Kaposi sarcoma rare outside endemic areas
- Different immunology – developing immune system in uninfected children
- Higher numbers and more variation of CD4 cells
- Decline to adult values in mid-childhood
- CD4% is less variable and so is used in children under 5 years
- Different pattern of HIV RNA – decline of HIV viral load up to 5 years

CMV, cytomegalovirus; PCP, *Pneumocystis carinii* pneumonia.

bacterial infections were generally associated with a better prognosis in resource rich settings than HIV encephalopathy. According to the CDC disease classification, stage B disease includes a wide range of conditions with different predictive values.<sup>504</sup>

## Infections

The T and B cell abnormalities resulting from HIV infection result in increased susceptibility to a wide range of organisms including fungi, mycobacteria, bacteria, protozoa and viruses. All infections occur at much higher rates than among HIV negative children, although rates of infection and hospital admissions for children on HAART are significantly lower than those reported in the pre-HAART era.<sup>426</sup> A recent analysis of children participating in clinical trials in the USA compared the incidence of infections in the era pre (n = 3331) and post HAART (n = 2767). The incidence rates of associated infections fell significantly following the introduction of HAART: bacterial pneumonia from 11/100 to 2.15/100 child years, herpes zoster from 2.9/100 to 1.11/100 child years and *Mycobacterium avium intracellulare* complex (MAIC) from 1.8 to less than 0.5/100 child years. Incidence rates of PCP, common in infants not on prophylaxis, fell from 1.3 to less than 0.5/100 child years.<sup>509</sup>

## Opportunistic infections

Opportunistic infections, apart from PCP and primary disseminated CMV disease to which infants with rapidly progressive disease are particularly susceptible during the first 6 months of life, are usually a late complication of HIV infection and result from severe immunosuppression. The most common are esophageal candidiasis, multidermatomal varicella zoster, disseminated *Mycobacterium avium* complex (MAC), CMV infections, cryptosporidiosis, and more rarely, toxoplasmosis.<sup>510</sup> MAC should be considered in any child with advanced disease and unexplained fevers, weight loss and abdominal discomfort.

## PCP infection (also termed *Pneumocystis jiroveci* pneumonia) and CMV

These infections are mentioned in greater detail as they present early, particularly in previously undiagnosed HIV infected babies, have a high mortality even in the era of HAART, and present differently in infants compared with older children and adults.

Among HIV infected babies who have not received PCP prophylaxis, PCP is a common first AIDS indicator disease, occurring most frequently in the first 6 months of life, with reported survival rates of only 38–62%.<sup>483,511,512</sup> CMV is often isolated at the time of PCP diagnosis from HIV infected adults and infants.<sup>483,512</sup> Between 1989 and 1999, PCP was the commonest AIDS defining diagnosis, occurring in 68% of reported infected infants born in the UK and Ireland.<sup>512</sup> In almost all, the mother was unaware of her HIV diagnosis before the child developed PCP.

PCP in infants with HIV infection should be treated with high dose co-trimoxazole (trimethoprim–sulfamethoxazole). An increased rate of reactions to co-trimoxazole has been reported with HIV infection in

children, although interestingly this appears to be less common in black Africans.<sup>483,513</sup> Alternative therapies include pentamidine or atovaquone, both of which may also be used for prophylaxis against PCP (see below). As well as supportive treatment including ventilation, high dose steroids are recommended for PCP and in a few reports have been shown to improve outcome in children as well as adults with PCP.<sup>483</sup> However, concerns have been expressed about the use of steroids in infants dually infected with PCP and CMV.<sup>483,512</sup> In infants, CMV is a primary infection and corticosteroids could adversely affect the course of CMV disease. Infants with PCP should be investigated for CMV viremia and retinitis. Anti-CMV therapy should be strongly considered in infants with PCP who receive adjuvant corticosteroids until CMV co-infection has been excluded.

Babies presenting with multisite CMV disease may have retinitis, which should be actively sought. An association between CMV infection and HIV disease severity and progression has been hypothesized in children.<sup>514</sup>

## Bacterial infections

Recurrent bacterial infections occur frequently in children with HIV infection, and include pneumonia, septicemia, meningitis, cellulitis, osteomyelitis, septic arthritis and skin and lymph node abscesses. The common causative organisms are similar to those seen in children with hypogammaglobulinemia and include pneumococci, non-typhi salmonellae, staphylococci, streptococci and *Haemophilus influenzae*, reflecting the B cell defect that accompanies destruction of the CD4 cells.

As noted above, despite the presence of hypergammaglobulinemia due to dysregulated polyclonal B cell activation, specific antibody responses are frequently absent either following infections or following immunizations, particularly in children with low CD4 counts. Studies of antibody levels following immunization with *H. influenzae* type b vaccine showed reduced levels in children with HIV infection compared with uninfected children, particularly in children with more progressive disease; in addition, antibody levels were not sustained.<sup>515</sup> Abnormal antibody function and avidity probably also play a role in the increased susceptibility to bacterial infections.

## Lymphoid interstitial pneumonitis

Lymphoid interstitial pneumonitis (LIP) is characterized by multiple foci of proliferating lymphocytes in the lung interstitium and occurs in about 20–30% of vertically infected children, but is rare in adults or in children infected with HIV later in childhood. The cause of LIP is not clear. It may be an abnormal response to primary Epstein–Barr virus (EBV) infection or to HIV infection. Parotitis, prominent lymphadenopathy and very high immunoglobulin levels are frequently associated. It usually develops during the second year of life (and therefore should not be confused with PCP which is more commonly seen in infants under 6 months of age) and the child may have no clinical signs but persistent bilateral reticulonodular shadowing on chest X-ray. Alternatively in older children, clinical features may include chronic hypoxia and recurrent respiratory bacterial and viral infections with or without features of bronchospasm.<sup>516</sup>

The differential diagnosis includes other causes of interstitial pneumonitis including infection with *Mycobacterium tuberculosis*, which can be difficult to distinguish radiologically from LIP. Clinically, a child with bilateral infiltrates due to TB would be highly symptomatic, as opposed to LIP which may be clinically silent. A presumptive diagnosis of LIP is often made on clinical and radiological grounds, because definitive diagnosis requires lung biopsy. The symptoms and signs of LIP respond to antiretroviral therapy, although steroids were used in severe cases before the advent of HAART. Chest infections should be treated promptly and, where present, bronchospasm responds to bronchodilators. Without therapy clinical and radiological features may progress over time with increasing immunodeficiency. Older children diagnosed late may already have chronic lung disease such as bronchiectasis and present with a picture similar to cystic fibrosis (CF). Even with HAART, these children will continue to require treatment, similar to those with CF, for recurrent chest infections, including antibiotic prophylaxis, regular physiotherapy and nutritional support.

## HIV encephalopathy

Encephalopathy due to effects of HIV infection on the central nervous system is seen most frequently in the subgroup of infants with rapid disease progression. The most common neurological manifestations are hypertonic diplegia, developmental delay (particularly affecting motor skills and expressive language) or acquired microcephaly. Cranial imaging studies may show basal ganglia calcification and cerebral atrophy and MRI scans may show evidence of white matter damage. Seizures are not usually a feature of HIV encephalopathy, which does not tend to affect the gray matter. In older children, presentation is more similar to that observed in HIV dementia in adults and may include behavioral change and memory loss.

HAART has reduced the incidence and prevalence of HIV encephalopathy and may arrest the progression of HIV encephalopathy in affected infants.<sup>517</sup> However, despite effective immune reconstitution on HAART, a proportion will have persistent motor and neurocognitive impairment requiring timely referral to child development services.<sup>518,519</sup>

## Failure to thrive

Failure to thrive is a hallmark of HIV infection and is multifactorial in origin. In children, there is growth failure in addition to wasting. Failure to gain weight in adults has been related most closely to decreased intake and the same is probably true for children.

## Malignancy

HIV infection greatly increases the risk of non-Hodgkin lymphoma (NHL) and Kaposi sarcoma (KS) in children and adults and is associated with more modest increases for other non-AIDS-defining malignancies.<sup>520</sup> The incidence of lymphoma has been estimated to be about 1000-fold higher in HIV infected children compared with the normal population.<sup>521</sup> In HIV infected adults, HAART has been shown to substantially reduce the risk of NHL and KS but not other non-AIDS-defining cancers.<sup>522</sup> Recently a similar response to HAART has been reported in pediatric cohorts.<sup>523</sup> Success of treatment for lymphoma often depends on the state of immunosuppression; response to standard chemotherapy may be good and has improved in the era of HAART. Decisions such as whether to stop HAART therapy during chemotherapy need to be made on an individual basis taking account of the stage of HIV disease, ability of the patient to tolerate both ART and chemotherapy, as well as consideration of possible drug interactions. Patients with refractory or relapsed disease with good immunology may now be considered for autologous bone marrow transplantation.<sup>524</sup>

Kaposi sarcoma (KS) is associated with human herpes virus 8 (HHV8) and is uncommon in children except for those from endemic areas for the disease in Africa. As in adults, cutaneous KS may regress with HAART alone but systemic disease may require additional treatment with liposomal daunorubicin. Cases have been reported of KS in both mother and child, suggesting MTCT of HHV8 may be responsible.<sup>525</sup>

## CLINICAL ASPECTS IN RESOURCE LIMITED SETTINGS

The clinical aspects of HIV are similar in resource limited settings but several aspects differ. First, disease progression is much faster; about half of all infected children die in the first 2–3 years of life.<sup>506,526</sup> Second, background malnutrition and infections (including tuberculosis and bacterial infections) are common and may make it more difficult to distinguish HIV infected from uninfected children clinically. The revised four-stage WHO classification has been shown to have predictive value.<sup>501,513</sup>

## MANAGEMENT

### Testing for HIV

Recognizing HIV infection requires considering the diagnosis in children presenting with a wide range of pediatric conditions. All health professionals need to be able to hold a sensitive pre-test discussion with caregivers explaining the benefit of early diagnosis and the implications of a positive result for the family, including the fact that it will almost always indicate that the mother is HIV infected. To do this, there needs to

be communication and collaboration with adult colleagues, and where HIV infection is rare in children, involvement of adult counselors and health advisors as and when appropriate (see below), in line with the English Sexual Health and HIV Strategy published in July 2001.<sup>527</sup>

If a child is being adopted or entering long term foster care, consideration should be given to testing for HIV, hepatitis B and C; ideally maternal consent should be sought, to enable the mother to seek appropriate help for herself if any blood-borne viruses are detected, but if this is not possible, then the wishes of the adopting parents and welfare of the child should be of prime consideration.

## Antiretroviral therapy

A detailed description of the many aspects of ART is beyond the scope of this chapter. This is a rapidly moving field with new drugs continually becoming available, and specialist input is required to manage children on ART. Guidelines for ART have been produced for adults<sup>528,529</sup> and children<sup>530,531</sup> and are regularly updated.

There are 20 drugs belonging to four different classes now available for treatment of HIV infection in adults; 15 have approval for pediatric use (Table 28.34). Two new drug classes, the integrase inhibitors and the CCR5 inhibitors, are currently entering phase 2/3 clinical trials in adults. In children, there is some lag in availability of drugs, particularly in the youngest children because of difficulties with development of appropriate formulations and undertaking of sufficient pharmacokinetic studies to assure correct dosing. The issue of formulations for older children who can take and prefer solid formulations but for whom only adult dosages exist means that in general simplification of HAART is more difficult for children. Fixed dose combination therapies for children with appropriate ratios and doses of drugs for children of different ages are urgently needed in resource limited settings where liquid formulations are particularly impractical because of logistics and cost.<sup>532</sup> However, with respect to licensing antiretroviral drugs for children, increasingly research is being undertaken in parallel in children, to ensure that pharmacokinetic and tolerability data are available in a timely manner. In addition to pharmaceutical company studies, there are two networks coordinating independent clinical trials in HIV infected children – the PACTG (now being replaced by IMPAACT) in the USA and the Paediatric European Network for Treatment of AIDS (PENTA, <http://www.ctu.mrc.ac.uk/penta/trials.htm>) in Europe. Both networks undertake trials addressing questions about management of ART in children (e.g. what to start with, when to switch, the value of

resistance testing, whether HAART can be interrupted, etc.) as well as trials of specific drugs and drug combinations.

Combination ART has turned HIV into a treatable chronic disease of childhood. Until the mid-1990s, only one drug was available – zidovudine [ZDV, azidothymidine (AZT)]. Dual therapy was introduced in 1996/1997, followed by triple (HAART) therapy in 1997/1998 which has led to marked and sustained reductions in disease progression and mortality in HIV infected children in Europe, North America and Africa.<sup>426,432,533,534</sup> Eradication of HIV is not possible with current drugs, and even after virus has been suppressed below the level of detectability in plasma (<5 copies/mm<sup>3</sup> using highly sensitive HIV-1 RNA PCR) for several years in newly infected adults, HIV-1 RNA viral load rises promptly within 1–2 weeks after stopping therapy. Most children on HAART remain clinically very well, thriving normally, and are asymptomatic. However, the complexity of lifetime administration of ART should not be underestimated. With increasing numbers of drugs available, yet limited options for sequencing drugs within classes because of development of cross-resistance, it is important that expert consideration is given to when to start treatment, how best to sequence HAART regimens, and how the whole family (other family members will often be on HAART as well) receives cohesive medical (generally outpatient) management, which is facilitated by attendance at a ‘family-based’ clinic (see below).

### Monitoring HAART

As discussed above, CD4 cell count or percentage and HIV-1 RNA viral load in plasma are useful predictors of disease progression, although much less so in infants than in older children and adults. In addition, they are used as surrogate markers for evaluating response to HAART, both as endpoints in clinical trials and for individual management of patients in clinical practice. In well resourced settings the usual aim of HAART is to suppress the plasma HIV-1 viral load rapidly below the lower limit of detection, typically <50 copies/ml, and maintain it there for as long as possible with restoration of immune function. Within one month of commencing HAART in children, the plasma HIV-1 RNA viral load decreases substantially (Fig. 28.33)<sup>535</sup> and the CD4 lymphocyte count starts to increase. There are differences between adults and children of differing ages in both RNA and CD4 cell response to therapy.<sup>536</sup> Infants with very high HIV-1 RNA viral load may take a longer time to reach an undetectable viral load,<sup>537</sup> possibly because children are starting from a higher viral load than adults. This higher baseline viral load seen in children may be one of the reasons that children have been reported to achieve an undetectable HIV RNA viral load less commonly. However, it is also the case that attaining this goal has improved over time.<sup>432</sup>

Children’s immune systems may also respond differently to HAART, due mainly to the fact that children have a much more active thymus than adults. Whereas in adults expansion of the CD45RO (memory cells) predominates, in children expansion is mainly of the CD45RA+ naive T cells which appear to be derived newly from the thymus.<sup>538</sup> Thus immune restoration in children may be more achievable than in adults, and studies are ongoing to evaluate further the quality of immune responses in children treated with HAART.

Most guidelines suggest that after starting HAART, children should have HIV-1 RNA viral load measured after one month and then both CD4 and viral load should be measured at 3 months to ensure that viral load is decreasing further and the CD4 cell count is starting to rise. Further measurements should be undertaken 3-monthly. Some centers perform tests more frequently, although the benefits of more intense monitoring have not been evaluated in clinical trials. Weight gain and growth are also important<sup>539</sup>; growth has been shown to be a sensitive marker of response to ART in HIV infected children, with significant differences reported in trials comparing different regimens, and reflecting HIV RNA response.<sup>535</sup> In resource limited countries with the advent of generic ART and cheaper drugs, and where the value of monitoring is being questioned because of cost, growth monitoring in children starting HAART may be a useful marker of response.

The goal of ART may vary according to the setting. Ideally, it is to achieve full virological suppression of HIV-1, restoration of both numbers and function of the immune system, and restoration of full growth and development for HIV infected children. This has to be balanced against the potential short and long term toxicity of ART and the effect of taking long term therapy on quality of life for the child and family. Frequently, and particularly in children, immunological and clinical responses to ART are good, but adherence issues and attention to maintaining adequate doses as a child grows<sup>540</sup> are vital to increase the proportion of children attaining undetectable viral load towards the near 100% figure observed in some adult cohorts. Where viral load is not fully suppressed, there is an increased likelihood of selection of resistant viral populations limiting future treatment options. A small number of heavily pretreated children and adolescents with multidrug resistant HIV (MDR HIV) have triple class HIV-1 associated resistance mutations and are awaiting drugs in development for future treatment options.<sup>541</sup>

### When to start HAART

The PENTA 1 trial is the only trial addressing the issue of when to start ART in children, and, as in adults, showed no benefit from early therapy with ZDV monotherapy beyond about 6 months, due to the emergence of resistance.<sup>542</sup> There are no trials in children addressing the question of when to start triple combination therapy. When HAART initially became available, guidelines based on a ‘hit hard, hit early’ approach recommended starting early in the disease course. Subsequently, the development of cumulative adverse effects of long term HAART, as well as evidence of reasonable restoration of the immune system even when CD4 cell counts are low in adults and children, has resulted in adult guidelines being amended to start ART later in the disease course.<sup>528,529</sup> Guidelines for adults in the USA previously recommended starting therapy at a CD4 count <500 cells/mm<sup>3</sup> but subsequently became more conservative and in line with UK guidelines recommend starting all patients at CD4 cell count <200 cells/mm<sup>3</sup> and considering HAART for those between 200 and 350 cells/mm<sup>3</sup>.<sup>528,529</sup> In the last year, the pendulum has again started to swing towards earlier treatment, after the large SMART trial was stopped when it showed small but significant reduced incidence of disease progression in adults on ART even with high CD4 cell counts.<sup>543</sup> The question of conducting a large long term ‘when to start HAART’ trial which might also include older children is again being discussed.

In children, US guidelines have recommended starting HAART during infancy in all infected infants. In Europe, opinions are more divided but increasingly HAART is started either based on CD4% of <35% or presence of any symptoms. Any infected infant not started on ART requires very close monitoring.<sup>544</sup> Highly encouraging results have been reported with three or more drug combinations in selected, infected infants, which demonstrate that complete viral suppression and maintenance of normal immune development can be achieved and sustained for at least 3 years.<sup>545</sup> However, there are concerns about the lack of HIV specific immune responses seen,<sup>545</sup> and the problems of resistance and toxicity in those whose regimens fail.<sup>546</sup> Nonetheless, these successes in infants treated early with HAART, as well as studies of adults treated during primary infection, have provided a rationale for early aggressive therapy of infants supported by recent studies suggesting an improved immune response to ART commenced in infancy.<sup>546,547</sup>

In infancy, viral load and CD4 cell counts are less predictive of outcome, and the anxiety this engenders tends to push towards starting HAART early as it can be difficult to distinguish the infant who will progress rapidly from the infant who remains asymptomatic for several years. However, the problem of inadequately defined pharmacokinetics for many drugs in infancy (and in particular, the PI class of drugs, such as nelfinavir in infants<sup>548</sup>) and the likely adverse consequences of early prolonged therapy, particularly the long term adverse metabolic effects of lipid abnormalities (PI class of drugs) and mitochondrial effects (nucleoside analogue class) are deterrents to such an approach. Despite these uncertainties many pediatricians continue to start all infants diagnosed under 6 months of age on HAART.

A number of factors need to be taken into account when starting ART in children (Table 28.35). Education of families, taking account of drugs other family members may be taking, as well as due care in choosing a regimen which the family can adhere to are important considerations. Considerable support is required to enable families to sustain high levels of adherence long term. Frequency of dosing has been a major development and once daily regimens are now feasible for children with well established once daily pharmacokinetics for drugs such as lamivudine and abacavir that were previously given twice daily.<sup>550-552</sup>

There is some evidence that adherence may be poorer among asymptomatic children who have never been ill. This disadvantage needs to be weighed against avoiding children becoming seriously ill before starting ART. Educating parents and carers about following CD4 and viral load as predictors of progression at monitoring visits is important to ensure that a consensus between health professionals and the family is achieved about the right time to start therapy. Viral load and CD4% can fluctuate, and at least two or three values should be obtained. Time spent on preparing and educating the family before commencing ART is always important. For children under 12 years the 'PENTA Calculator' (<http://www.ctu.mrc.ac.uk/penta/>) can be a useful tool in decision making and help parents and carers to further understand the risk of disease progression.

Older children presenting for the first time are a selected group who do not have rapid disease progression. For these children it is reasonable to monitor CD4 counts and only offer treatment if counts are declining steadily below 20% or counts are between 200 and 350 as in adults (Table 28.35).<sup>501</sup> There is no consensus level of viral load above which treatment should be started in children.

**Which ART to start**

When starting HAART, most prescribers would initiate triple therapy with two NRTI drugs and one PI or one NNRTI. Intensive induction with quadruple combination therapy, sparing at least one class of drugs, reducing to a maintenance regimen of three drugs when the plasma viral load is well maintained at undetectable levels is another possible option and has been used in infants with extremely high levels of plasma viremia in some centers. The PI drugs are difficult to formulate into palatable suspensions for children compared with the NRTIs and NNRTIs. No large randomized clinical trials in children or adults provide evidence to conclude that PI-containing or PI-sparing regimens have greater long term clinical efficacy. This question and when to switch therapy is being addressed in a randomized controlled trial of children in Europe and the US starting therapy randomized to either PI- or NNRTI-based HAART (PENPACT 1 trial; [www.pentatrials.org](http://www.pentatrials.org)).

Data from the UK and Ireland CHIPS cohort show that most children start HAART with a triple regimen and over time there has been a shift from a PI- to an NNRTI-based regimen.<sup>426</sup> NVP is the main NNRTI in young children, but efavirenz is increasingly being used in children over 3 years. The main PI was nelfinavir, but increasingly this is being replaced by ritonavir boosted lopinavir (Kaletra). NRTI fixed drug combination tablets are increasing being made available in adult doses to reduce pill burden and ease adherence, thereby potentially improving response to therapy. Combivir (ZDV+3TC), Trizivir (ZDV+3TC+ABC), Kivexa (3TC+ABC) and Truvada (TDF+FTC) are available, the latter two formulations administered once daily. However, no combination liquid formulations are available. Use of crushed whole or half tablets requires care as some pills (e.g. Combivir) have these drugs unevenly distributed through the tablet. Fixed drug combinations containing an NNRTI with

**Table 28.35** WHO recommendations for initiating ART in HIV-infected infants and children according to clinical stage and availability of immunological markers<sup>549</sup>

WHO pediatric stage	Availability of CD4 cell measurements	Age-specific treatment recommendation	
		≤ 11 months	≥ 12 months
4	CD4	Treat all	
3	No CD4	Treat all	
	CD4	Treat all	Treat all, CD4-guided in those children with TB, LIP, OHL, thrombocytopenia
2	No CD4	Treat all <sup>c</sup>	
	CD4		CD4-guided
1	No CD4	TLC-guided	
	CD4		CD4-guided
	No CD4	Do not treat	

WHO age-specific recommendations for starting ART on immunological markers				
Immunological marker	Age-specific recommendation to initiate ART			
	< 11 months	12–35 months	36–59 months	> 5 years
%CD4	< 25%	< 20%	< 15%	< 15%
CD4 count	< 1500 cells/mm <sup>3</sup>	< 750 cells/mm <sup>3</sup>	< 350 cells/mm <sup>3</sup>	< 200 cells/mm <sup>3</sup>
WHO TLC criteria for severe HIV immunodeficiency requiring initiation of ART; suggested for use in infants and children with clinical stage 2 and where CD4 measurement is not available				
Immunological marker	Age-specific recommendation to initiate ART			
	< 11 months	12–35 months	36–59 months	> 5 years
TLC	< 4000 cells/mm <sup>3</sup>	< 3000 cells/mm <sup>3</sup>	< 2500 cells/mm <sup>3</sup>	< 2000 cells/mm <sup>3</sup>

**What HAART to start?**  
 Either: 2 NRTI + 1 PI (PI: NFV or lopinavir/r)  
 plus NRTI combinations: ZDV + ddI; ZDV + 3TC; ddI + d4T, d4T + 3TC; 3TC + ABC  
 Or: EFV + 2 NRTI (if over 3 years)  
 NVP + 2 NRTI (all ages)  
 Or: 3 NRTI: ZDV + 3TC + abacavir

two NRTIs are already available as generic formulations in resource limited countries, and a combined once daily pill of efavirenz, emtricitabine and tenofovir is available for adults and can be used for older adolescents in well resourced settings.

There is considerable inter- and intra-patient variation in drug levels achieved even when using standard ART doses for size. The role of therapeutic drug monitoring (TDM) has not been clearly defined in pediatrics but is frequently used in many centers. A randomized controlled trial assessing the impact of differing levels of TDM compared to no TDM (PENTA 14) was recently halted due to low levels of recruitment. TDM is definitely indicated where there is the possibility of drug interactions and can provide additional information regarding individual pharmacokinetics, absorption and adherence.

### Adherence

It has become very clear from adult and pediatric studies that adherence is one of the principal determinants of both the degree and duration of virological suppression.<sup>553</sup> In one study, children whose caregivers reported no missed doses in the previous week were more likely to have an undetectable viral load (50% versus 24%).<sup>554</sup> The reasons for non-adherence are complex and multifactorial. Adherence is difficult to assess in the clinic. No pediatric intervention studies aimed at improving adherence have been conducted. Outpatient attendance and adherence are poorer in adolescents and young adults, increasing their risk of virological failure and the evolution of resistance.<sup>555</sup>

### Changing therapy

Virological failure requires investigation into the potency of the regimen, including checking that the child is on the correct dose (which may be higher than the recommended dose in drug packet inserts)<sup>548,550</sup> and that the child has not outgrown their dose, checking for possible pharmacokinetic interactions with other drugs or food, and checking on adherence. These should all be done before switching therapy. A recent study demonstrated that children were frequently underdosed with antiretrovirals, a continuing issue for growing infants and children whose dosing is calculated on weight or surface area.<sup>540</sup> The level of viremia in children that should prompt a switch in therapy is the subject of an ongoing trial discussed above. Adult guidelines recommend switch consideration for sustained viral rebound, defined as two plasma viral loads at least one month apart > 400 copies/mm<sup>3</sup>, for patients whose viral loads have previously been undetectable.<sup>528,529</sup> Occasionally, despite virological failure, families and doctors may wish to continue the current regimen when the child is clinically and immunologically stable, and there is not an obvious easy palatable regimen to switch to. However this may lead to accumulation of resistance mutations and therefore fewer options for subsequent therapy. The choice of the new regimen will depend on the prior ART history, drug toxicity, availability of new drugs/formulations and adherence, and may be guided by resistance testing.

### Resistance

Resistance testing is recommended for treatment of naive adults prior to initiation of HAART as transmitted resistance is well recognized and has also been reported in infants following mother-to-child transmission.<sup>556</sup> As the availability of ART increases worldwide, baseline resistance testing may be considered for children if there is any uncertainty regarding ART exposure either for the child directly or the mother prior to or during pregnancy or breast-feeding.<sup>530</sup> Resistance testing is increasingly routinely performed in children on HAART with virological failure, although virological or immunological benefit was not demonstrated in a recently published pediatric trial with long term follow-up<sup>557</sup> and results from short term adult studies are conflicting. Further validation of resistance testing is difficult as, like TDM, it has increasingly become part of standard care.

### Toxicity

Children on HAART are now surviving into adult life, but as the length of exposure to HAART grows, the long term side-effects are becoming

increasingly apparent. Lipodystrophy (LD) is defined as abnormality in lipid metabolism resulting in dyslipidemia (high lipids) and body changes characterized by truncal obesity alongside disfiguring loss of fat on the face and in the periphery. A European cross-sectional study reported fat redistribution in a quarter of children. Increased risk was associated with more advanced disease, female gender, use of protease inhibitors and of stavudine, which are similar risk factors to adults.<sup>558,559</sup> However, studies are hampered by the lack of a standard definition of LD in the growing child, and many reports are clearly subjective although efforts are being made to standardize assessments.<sup>560</sup> Hyperlipidemia is being increasingly reported but there is uncertainty as to the level of hyperlipidemia that should precipitate a treatment switch or addition of lipid lowering drugs. Insulin resistance resulting in hyperglycemia and occasionally exogenous insulin dependence is seen in adults and occasionally in pediatric cohorts and has been associated with length of time on PI-based HAART.<sup>561</sup> Adult cohorts have reported an increase in cardiovascular events when compared to the general population. HIV itself has a pro-inflammatory effect on the endothelium but coupled with the metabolic complications described above, concern is growing about the cardiovascular risk in adult life for children with perinatally acquired HIV infection.<sup>562</sup>

A high prevalence of bone demineralization has been reported in children in association with HIV infection and HAART, raising concerns of risk of progression to osteopenia and osteoporosis in early adult life. The optimum management strategy is currently unclear and requires further consideration.<sup>563,564</sup> Mitochondrial toxicity, at least in part due to the inhibition of DNA polymerase by nucleoside analogues, has rarely been associated with severe, even fatal, lactic acidosis in children on HAART.<sup>565</sup> Asymptomatic hyperlactatemia occurs more frequently but may be temporary and current evidence does not support routine lactate measurements for children on HAART.<sup>566</sup> Unexplained nausea, vomiting, fatigue and/or neurological deterioration in a child on HAART should prompt assessment of lactic acid status and consideration of mitochondrial toxicity.

As toxicity associated with long term continuous ART becomes more apparent, strategies to reduce ART exposure, including structured treatment interruptions (STI) and immune therapies, are being evaluated in children and adults. Recent trials of STIs in adults have been halted early due to an excess of clinical adverse events in patients off treatment, although overall absolute risk of events in the SMART trial was small.<sup>543</sup> Interim analysis of a pilot European pediatric trial (PENTA 11) was satisfactory. The argument prevailed that STI in children has a compelling rationale and may be safer because of a more active immune system: the trial is continuing, with a parallel trial also continuing in Botswana. The cost/benefit for children may be different to adults as they potentially face a lifetime of ART with its cumulative toxicities.

### Prophylaxis against opportunistic infections Co-trimoxazole prophylaxis for prevention of PCP

There is good evidence from randomized trials in adults with HIV that co-trimoxazole is very effective at preventing PCP and this is the drug of choice. Dapsone or inhaled pentamidine can be used in the event of hypersensitivity to co-trimoxazole but they are less efficacious. The evidence for efficacy of co-trimoxazole in preventing PCP in infants with HIV is indirect, and comes from studies showing decreased PCP after the introduction of guidelines recommending starting all babies on co-trimoxazole.<sup>567,568</sup>

The MTCT rates are now so low in Europe and the USA that, coupled with the ability to exclude HIV infection by 3 months of age, the need for PCP prophylaxis has decreased and can be restricted to babies born to mothers who do not take interventions in pregnancy to reduce MTCT, or have a high risk of MTCT (e.g. because of detectable HIV RNA viral load at delivery) or babies where the mother is reluctant for the baby to be tested early in life.<sup>449</sup> Prophylaxis can be stopped once it has been established that the baby is uninfected. Infected infants should continue prophylaxis throughout the first year of life, as CD4 counts are unreliable indicators of PCP risk. Thereafter, it is not unreasonable to stop prophylaxis unless the CD4 count is under 15%.

Guidelines for PCP prophylaxis in adults permit discontinuation of both primary and secondary PCP prophylaxis when the CD4 cell count is above 200 cells/ $\mu$ L for greater than 3 months in response to HAART. Although evidence is more limited in pediatric populations, most practitioners consider discontinuation of primary and secondary prophylaxis when the CD4 count has increased above 200 cells/ $\mu$ L or 15% on HAART,<sup>568</sup> and the majority of children on HAART in the UK are not on PCP prophylaxis. A prospective study in children over 2 years in the US supported the safe withdrawal of OI and PCP prophylaxis following immune reconstitution in response to HAART.<sup>569</sup> In all children, whether or not they are on HAART, guidelines recommend restarting co-trimoxazole when the CD4% falls below 15% or 200 cells/ $\mu$ L.

### Prophylaxis against other infections

Co-trimoxazole has also been shown, in a large placebo controlled trial of Zambian HIV infected children aged 1–14 years (mean age 4.5 years), to reduce mortality by 43%.<sup>513</sup> The efficacy was maintained over a period of 18 months and occurred despite high background prevalence of *S. pneumoniae* and non-typhi *Salmonella* species with resistance to co-trimoxazole. The trial also showed a reduction in hospital admissions and use of antibiotics in the arm treated with active drug. Although most causes of death and hospital admissions were presumptive diagnoses, it appeared that reduction in bacterial lung infections was the most likely mode of action and PCP was not observed in nasopharyngeal aspirates.<sup>534</sup> Updated WHO guidelines recommend that all HIV infected children in resource limited settings continue to receive co-trimoxazole prophylaxis while awaiting HAART.<sup>501</sup> The question about continued benefit of co-trimoxazole prophylaxis in the presence of HAART requires further evaluation.

In well resourced countries, as a result of advances in antiretroviral therapy, there has been a shift in focus from diagnosing and managing opportunistic infections to restoring and maintaining cellular immunity with HAART and thereby preventing opportunistic infections.

HIV infected children who are contacts of individuals with open pulmonary TB should be carefully assessed, bearing in mind skin testing is frequently unhelpful because of anergy. If there is no evidence of infection, prophylactic isoniazid for 6 months, or isoniazid plus rifampicin for 3 months is recommended. Prophylaxis against *Mycobacterium avium-intracellulare* in children is not recommended because of adverse reactions and the potential for resistance and breakthrough on single agents such as rifabutin.

Primary prophylaxis against CMV is not recommended. With respect to secondary prophylaxis following CMV infection, infants who have had CMV usually reconstitute their immune systems very well, obviating the need for secondary prophylaxis.

For most other established opportunistic infections, such as cryptosporidiosis for which there were few useful therapeutic options, the best treatment is HAART, which should be started as soon as possible if a child presents initially with HIV infection and an acute opportunistic infection. Immune reconstitution disease, which may occur particularly in severely immunocompromised children, may make opportunistic infection symptoms worse initially. Some individuals with immune reconstitution disease may require steroids in addition to HAART and specific therapy for opportunistic infections.

### Immunizations

Children with HIV infection should be immunized according to normal schedules with both live and killed vaccines. The exception is that BCG is not advised for children with HIV infection in low prevalence areas because of the risk of dissemination. However, it should be given in areas of high TB prevalence and this, in the author's view, should include babies born to African women in the UK who have a high rate of TB and may also return to Africa either to live or to visit. In line with current UK vaccination schedules, inactivated polio vaccine (IPV) is to be preferred to live oral polio vaccine because of theoretical concerns about paralytic poliomyelitis in contacts of children excreting live virus. Pneumococcal polysaccharide vaccine has been recommended for HIV

infected children over 2 years of age, but a trial of its use in adults with HIV in Africa showed no benefit. Conjugate pneumococcal vaccine should be given to children under 2, in line with national UK guidelines. Annual influenza vaccination is also recommended. All children with HIV should be screened for hepatitis A, B and C co-infection; hepatitis A and B vaccination should be offered to those who are susceptible to infection.

The efficacy of all vaccines is improved among children who have immune reconstitution following ART. Children immunized before starting ART in whom responses are inadequate should be revaccinated.

Passive immunization of symptomatic children with CD4% < 15% is recommended if they are in contact with varicella zoster virus (VZV) and are either VZV naive or have no detectable specific antibodies to VZV. Varicella zoster immunoglobulin (VZIG) ideally should be given within 72 h of contact. VZIG may prolong the incubation period to 28 days, so clinicians need to consider isolating these patients at clinic visits. Similarly, normal human immunoglobulin should be given for susceptible symptomatic children in contact with measles. The role of oral aciclovir in preventing VZV infection following contact has not yet been ascertained but it is used by some pediatricians.

Regular intravenous immunoglobulin infusions (400 mg/kg every 28 days) should only be given to children with recurrent bacterial infections despite good compliance with HAART and co-trimoxazole prophylaxis, or those with proven hypogammaglobulinemia. Higher doses may be useful in the management of thrombocytopenia (0.5–1.0 g/dose every day, for 3–5 days). However, in the era of HAART, the number of children requiring such therapy should be minimal.

### Supportive care

Unlike most other severe chronic diseases of children, HIV simultaneously affects family members including the parents and other siblings. The parents' own health, their social isolation and feelings of guilt compound the difficulties of caring for a sick child. An effective well coordinated multidisciplinary team is required to address the changing needs of infected children and their caregivers. Continuity of care needs to be developed between inpatient and outpatient services, local referring hospitals and the community. Ideally adults and children should be treated in family based units.<sup>570</sup> All too often parents will ignore their own health needs because they put their children first.

The work of the multidisciplinary team has increasingly shifted towards ways of helping families achieve long term adherence to HAART. As children survive longer, meeting the needs of adolescents and planning transition to adult clinics is placing new demands on services. The decision as to who should be informed should be tailored individually. Families may need help in explaining the diagnosis to older children. This needs to be undertaken at the child's pace, and is frequently most effectively achieved in gradual steps. It is not mandatory to tell staff at schools, as universal precautions should be employed for all children with injuries. The risk of transmission from casual contacts in school or daycare settings is virtually zero. Ensuring that adolescents are well informed and responsible before they become sexually active is a priority and pediatric family clinics in London are setting up specific adolescent clinics with their adult colleagues. Peer support for adolescents is important to help young people with HIV come to terms and live with their disease.

The multidisciplinary team should include a dietician, as nutritional problems and growth faltering are not uncommon even in the era of HAART and particularly in children with chronic lung disease. Balanced supplements are sometimes required and enteral feeding through gastrostomy tubes may be necessary. Gastrostomy tubes have been used with success to allow unpalatable medicines to be given, particularly in children on multiple therapies such as in TB co-infection, those with neurological impairment, or in children who have failed first/second line therapy due to poor adherence. In addition, dietary and exercise advice is increasingly needed to prevent and treat obesity in HIV infected children on HAART.

Pain management is important in late stage disease. Complementary therapies frequently used in adults with late disease, such as aromatherapy,

may be useful and require evaluation. With the continuing success of HAART, there are currently very few children in industrialized countries needing palliative or terminal care. However a small number of children and adolescents in Europe and more in the USA have multidrug resistant virus and urgently require novel therapies.

Prevention remains the top priority in managing HIV infection in children. Reducing national perinatal transmission rates to below 2% is an achievable target that can only be realized if HIV infected mothers can be identified prenatally and offered appropriate interventions. Antenatal detection rates in most European countries and the USA have reached high levels for several years and continued effort by health professionals, public health planners and community organizations is essential.

## EXANTHEMATA

### MEASLES (MORBILLI AND RUBEOLA)

Measles is a viral disease of high infectivity, which presents with an acute catarrhal illness, fever, and characteristic Koplik spots on the buccal mucous membranes followed by a distinctive maculopapular rash. There is a high incidence of serious complications of the respiratory and nervous systems. In large cities and towns, measles is most likely to occur in infants and preschool children, but in rural and less crowded urban areas the principal incidence is between the ages of 5 and 10 years. Measles is extremely rare under 3–4 months of age, because of protective maternal antibody, but authenticated cases have occurred.

In some countries measles outbreaks have shown a characteristic biennial periodicity but such a pattern is by no means universal and the introduction of active immunization has altered the natural epidemiology of the disease.

### Mortality

In resource limited countries, where malnutrition is common, measles may have a mortality as high as 25% and produce serious complications.<sup>571</sup> Children are at increased risk of dying for a year after their measles due to impaired cellular immunity. Inhibition of macrophage production of interleukin-12, a cytokine important for driving cell mediated immunity, by binding of measles virus to CD46, a cellular protein that regulates complement, is thought to be partly responsible for this immunosuppression.<sup>572</sup> Measles can cause devastating outbreaks when the virus is introduced into naive populations such as on remote islands. Although the morbidity and mortality are lower in highly immunized, industrialized countries, outbreaks can still occur if a population of unimmunized children, usually preschool, is allowed to develop. In more exposed communities, measles is now comparatively mild and its morbidity and mortality lower, although occasional deaths still occur in the UK. Children who contract measles when in remission from acute leukemia or who have other conditions in which immunity is compromised are at particular risk.

### Etiology

Measles virus is an RNA virus of the paramyxovirus family, genus *Morbillivirus*, and morphologically resembles the parainfluenza viruses. It is usually transmitted by droplet infection from the respiratory tract of a case before, or close to, the onset of the rash. Entry mainly occurs through the respiratory tract, but infection through the intact conjunctiva has been postulated. Clinically significant antigenic variation has not been described. An attack is usually followed by life-long immunity and there is little or no authenticated evidence of second attacks of measles except in individuals with severe immunological defects. Subclinical infection can probably occur but is rare.

### Clinical features

Measles has an incubation period of 8–14 days. A mild illness may occur at the time of infection but most cases develop a prodromal illness some 3–5 days before the eruptive stage. The main features of this

illness are pronounced catarrh, characterized by a constantly running nose, conjunctivitis and a harsh dry cough. Fever and irritability are usually present and there may be a fleeting scarlatiniform or morbilliform rash. Koplik spots, the most pathognomonic sign of measles, appear during this stage and are seen as small, grayish white lesions on the buccal mucosa close to the posterior molar teeth; they are usually quite numerous but may be scanty or occasionally cover the entire lining of the cheek. They can be difficult to demonstrate and the angle of the inspecting light is critical; having faded, they are replaced by a dry, matte appearance on the mucosa, which has a ground-glass-like surface.

The true rash of measles (Fig. 28.34)<sup>573</sup> starts behind the ears and along the hairline. Fever, which will have lessened at the end of the prodromal period, may now rise again to 39–40 °C (Fig. 28.35),<sup>573</sup> and the eruption spreads rapidly to involve the face. The lesions are maculopapular in character and of a dusky hue. Over the next two days the eruption spreads downwards and becomes generalized; marked confluence of the spots develops and this gives a blotchy appearance.

The extent and severity of the rash shows wide variation. In some, especially the younger cases, the eruption may be unusually sparse and modification by maternal antibody has been suggested. There is frequently some degree of hemorrhage or diapedesis into the rash giving it a purpuric quality and subsequent skin staining. This should not be confused with the rare, and usually fatal, hemorrhagic measles in which extensive bleeding occurs into the skin and from the mucous membranes. In the immunocompromised child, the rash occasionally does not develop.

Fading of the rash can be surprisingly rapid but it usually disappears quite slowly, beginning to fade on the third day in the order of

Fig. 28.34 The distribution and the development of rash in measles. (From Krugman & Ward 1968<sup>573</sup>)

Fig. 28.35 The development of measles. (From Krugman Et Ward 1968<sup>573</sup>)

appearance; the rash may be largely gone from the face and upper trunk by the fourth day though persisting on the lower extremities. After a further 3–4 days a brownish staining appears, probably due to capillary hemorrhage and, on occasions, this staining can be very intense. In severe cases, a fine desquamation may occur at the site of the rash, but this does not usually involve the hands and feet like scarlet fever.

## Complications

### Respiratory

Measles virus always attacks the respiratory tract causing some degree of laryngotracheobronchitis. An element of bronchitis is universal and can be severe, extending even to bronchiolitis; the latter can be complicated by acute mediastinal emphysema. Croup may be prominent. Viral damage may denude the respiratory tract of its protective lining and allow the aspiration of bacteria. Bronchopneumonia may result and the severity will depend on the nature of the aspirated material. Staphylococcal pneumonia can be life threatening.

In a few instances measles virus involvement of the respiratory tract may spread to the lung parenchyma, giving rise to the condition known as giant cell pneumonia. This complication may be prolonged and is often fatal, and the illness may be accompanied by little or no rash. It is usually found in association with underlying disease such as HIV infection, leukemia, or other immune deficiency with impaired T cell function. In view of its atypical nature, this illness is often undiagnosed during life and the true diagnosis is made as a result of autopsy findings.

### Ophthalmic

Some degree of conjunctivitis and keratitis occurs in every case of measles. It is typically exudative, nonpurulent and nonfollicular and can be characterized by Koplik spots. When pseudomembranes or corneal ulcers occur they are the result of secondary bacterial infection. Optic neuritis and retinitis are associated with measles encephalitis.

### Ear

Involvement of the middle ear used to be commonplace and could result in suppurative otitis media, chronic perforation or mastoiditis. The lessening severity of measles and prompt antibiotic treatment has reduced the incidence of these complications to a low level.

### Gastrointestinal tract

Severe oral inflammation due to secondary infection by bacteria, *Treponema vincentii*, or thrush can occur but cancrum oris is only likely to be seen where malnutrition is rife. Cancrum oris (noma) is a gangrenous form of stomatitis that commences with a dusky red spot on the inside and outside of the cheek. This rapidly spreads to form a sloughing gangrene of the gums and jaws and in extreme cases teeth

may be shed. The breath develops a peculiarly foul odor and death can supervene.

Gastroenteritis is common in measles in non-industrialized countries and can be prolonged; it probably results from direct viral involvement of the gut with or without superinfection with organisms such as *Cryptosporidium*. Appendicitis can occur in measles though abdominal pain is more commonly due to associated mesenteric adenitis.

Enlargement of the spleen is more frequently encountered in measles than is generally realized.

### CNS

Measles, with its pronounced constitutional upset and high fever, is often complicated by febrile convulsions. These are most commonly encountered at the start of the eruptive stage and either settle spontaneously or in response to simple sedation; they should not be assumed to be indicative of encephalitis.

True postinfectious encephalomyelitis occurs in from 1 in 1000 to 1 in 5000 cases of measles and has a mortality of about 10% and leaves about 15% with neurological residua. It normally presents after 7–14 days, when the rash is subsiding, but can commence earlier in the disease and rarely even before the rash. Drowsiness, fits, a recrudescence of fever, focal neurological signs and progressive coma suggest that severe cerebral involvement is occurring. In some cases the process may arrest at this juncture and be followed by rapid improvement; in others there is a steady deterioration and death. Between these extremes there are patients in whom recovery is slow and permanent cerebral damage likely.

Rarely subacute sclerosing panencephalitis (SSPE) may complicate measles infection, though not apparently measles immunization. In SSPE, measles virus becomes latent in the cerebrum following primary infection and is then reactivated, usually 5–10 years later, by some unknown stimulus. An alternate hypothesis suggests that a partially immune individual is reinfected by measles which then provokes this unique form of encephalitis. It is more common in children in whom primary measles occurs before 1 year of age.

### Others

Uncomplicated measles tends to produce leukopenia, and significant thrombocytopenia is occasionally encountered. Epistaxis is a common and occasionally troublesome feature.

There is a traditional but unconfirmed belief that measles may activate or predispose to tuberculosis. Diagnostic difficulty is provided by the fact that measles may suppress the Mantoux reaction for several weeks.

## Diagnosis

Provided the medical attendant is consulted at its inception, measles can be diagnosed on clinical grounds with a fair degree of accuracy. Immunofluorescence can be used to detect measles virus antigen in respiratory secretions if rapid diagnosis is needed. Difficulties can arise when an opinion is required later in the disease.

Neutralizing, complement-fixing and hemagglutination-inhibiting antibodies to measles develop during the illness and appropriate serological tests can confirm their presence. Detection of measles IgM on a single specimen is the simplest method for diagnosis. Measles IgM can be detected from 3 days after the onset of the rash for about a month. Sensitivity rates, however, vary according to the type of assay used and the time after the onset of the rash, with the hemagglutination-inhibiting antibodies assay being the most sensitive and complement fixation the least (87% and 37% of cases, respectively, 3 days after the onset of the eruptive phase).<sup>574</sup> The demonstration of a significant rise (four-fold or greater) in antibody titer to measles virus confirms the clinical diagnosis. The hemagglutination-inhibition and complement fixation tests are usually employed, on account of the ease and rapidity with which they can be performed.

Measles virus can be isolated in primary tissue cultures of human kidney, human amnion or monkey kidney, and several other tissue culture systems have been used. The growth rate of measles virus in tissue

culture is relatively slow and serological tests will often yield a positive result before the virus has been isolated and identified. During the late prodromal stage of the illness virus can be recovered from the nasopharynx, urine, conjunctival secretions and blood. By the second day of the rash, virus isolation becomes more difficult, though the urine may continue to contain virus for a further 2 days. In the immunocompromised child, there may be prolonged shedding of measles from the sites after the initial infection.<sup>575</sup>

In SSPE, measles antibody in high titer is demonstrable in the serum many years after a typical attack of measles. Antibody may also be detected in the CSF and the ratio of this antibody to that in the serum may be of diagnostic significance. Brain biopsy can confirm the diagnosis of SSPE where facilities for electron microscopy and immunofluorescence are available.

### Differential diagnosis

Kawasaki disease can cause a morbilliform rash with fever, conjunctivitis and lymphadenopathy and can be quite difficult to distinguish clinically from measles. The milder illness of rubella with its pinker rash and selective involvement of the suboccipital glands is usually distinguishable. The rash of infectious mononucleosis can cause confusion but its other clinical and laboratory features usually lead to the correct interpretation. Enteroviral infections associated with a rash are usually more transient and lack the catarrhal involvement. Influenza virus infections, both A and B, can occasionally cause a morbilliform rash with respiratory symptoms and fever. In roseola infantum, the rash is very like measles, but as it appears the fever falls and the child is well, in contrast to measles. Scarlet fever and drug eruptions have readily distinguishing features.

### Treatment

There are currently no antiviral agents available with demonstrated efficacy *in vivo* against measles virus. Ribavirin has been shown to inhibit measles virus replication *in vitro*, and there are anecdotal reports of its use either intravenously or by aerosol to treat severe pneumonitis or encephalitis in the immunocompromised child.<sup>576</sup> However, this treatment remains experimental in the absence of data from a randomized controlled trial.

Amongst the earliest complications that may require treatment are croup and febrile convulsions. These are managed symptomatically (see Chs 20 and 22).

Secondary bacterial infection, superimposed on viral damage to the respiratory tract, will require treatment. Staphylococcal pneumonia is the most feared complication, and if bacterial pneumonia is suspected antistaphylococcal antibiotics should be used. Prophylactic antibiotics are unnecessary, as confirmed by a recent systematic review on the subject.<sup>577</sup>

Mastoiditis should not occur if adequate treatment of otitis media is given early, but if it does occur surgical drainage is required. Any sign of secondary infection of the conjunctiva should be treated with appropriate antibiotics, and chloramphenicol eye ointment smeared on to the lids often proves efficacious.

It is rare for gastroenteritis to be so severe as to cause fluid and electrolyte depletion but where this occurs appropriate measures require to be taken. True appendicitis can present in the course of measles.

Postinfectious encephalitis requires intensive supportive treatment, including anticonvulsants for seizures. The use of corticosteroids remains controversial, but many clinicians feel such therapy warrants trial in severe cases whose progress is unsatisfactory.

### Preventive measures

#### Quarantine

Because this disease is highly infectious and the maximum infectivity is before the rash appears, quarantine measures are frequently ineffective. However, any child who is suffering from a severe, debilitating disease should be protected from exposure whenever possible. In the hospital setting, appropriate quarantine measures should be in place for up to

4 days after the onset of the rash while the child is infectious via the respiratory route. The immunocompromised child with measles should be placed on respiratory isolation for the duration of the illness.

#### Passive immunization

Passive immunization has been used as post-exposure prophylaxis against measles for many years, although the evidence for it is sparse. Normal human immunoglobulin (gamma globulin) is used (0.2 ml/kg intramuscularly for normal children, 0.5 ml/kg for immunocompromised children, maximum dose 15 ml). The use of passive immunization is particularly important when immunocompromised children, for whom active immunization is contraindicated, are exposed to measles.

#### Active immunization

In the early years of measles vaccines, an inactivated measles vaccine was used which not only failed to protect against infection but resulted in the children developing severe, atypical illness with giant cell pneumonitis when exposed to wild-type virus.

Live, attenuated measles vaccines are highly protective and have very few side-effects. Where they have been used to immunize whole populations, acute measles, encephalitis and subacute sclerosing panencephalitis have virtually disappeared. In countries where immunization rates are relatively low, there are many cases of acute encephalitis, with several children each year dying or handicapped as a result.<sup>578</sup> Measles vaccine is readily inhibited by maternal antibody and may be ineffective if given before 1 year of age. If it is wished to protect a child exposed to measles who has no contraindications to immunization and is over 1 year old, then measles vaccine is preferable to passive immunization. Many countries now give measles vaccine in conjunction with mumps and rubella vaccines (MMR) in the second year of life, and a second dose may be given at school entry or at 12–14 years old. The only contraindication to measles vaccine is immune deficiency (including high dose but not low dose steroids). Anaphylactic egg allergy is no longer considered to be a contraindication.<sup>579</sup> HIV infection is not a contraindication unless the patient is severely immunocompromised; on the contrary, as they are at high risk from wild-type measles virus, every attempt should be made to immunize HIV positive children against measles. Measles continues to be a significant public health concern despite an effective vaccine. Recent outbreaks in countries such as the USA<sup>580</sup> and UK<sup>581</sup> where endemic infection was considered to be virtually eliminated have highlighted the need for sustained high vaccination coverage in areas where wild-type virus no longer circulates. There is also concern that infants, who are at greater risk of severe disease, are becoming susceptible to measles earlier in their first year due to declining levels of maternal antibody.<sup>580</sup>

### RUBELLA (GERMAN MEASLES)

Postnatal rubella is characterized by its mild nature and relative freedom from complications. Some of the original accounts of the disease emanated from Germany and because of this and a certain similarity to measles, the name of German measles became a popular, if ill-conceived, descriptive title.

#### Etiology

Rubella virus is an RNA virus of the *Togaviridae* family. It was first cultured and identified as recently as 1962. Since then it has proved possible to grow it quite readily on suitable tissue cultures, a factor that has considerably enhanced our knowledge of the disease. Transmission is primarily through droplet spread of infected nasopharyngeal secretions from a few days before to up to 14 days after the onset of the rash.

#### Incidence

The true incidence of rubella is difficult to assess as infection is subclinical in a sizable proportion of cases. Even the clinical illness itself has no pathognomonic features, a point that is substantiated in surveys where rubella antibody levels correlate poorly with the history of previously

suspected infection. By early adult life as many as 90% of city dwellers may show serological evidence of previous rubella but the figure can be much lower in rural communities. Rubella is less common in preschool children than, for example, measles and in one survey less than 10% of children under 2 years showed evidence of previous infection, though this figure had risen to 25% between the ages of 2 and 5 years. By 12 years of age, 80% had antibody, suggesting the bulk of infection occurs between 6 and 12 years of age.

**Clinical features**

Rubella has an incubation period of 14–21 days, with an average of 17 days. In children it is rare to have a significant prodromal illness and the first indication of rubella infection is the appearance of a rash over the face (Fig. 28.36).<sup>573</sup> This soon spreads to cover the trunk and later the limbs. The basic lesions are fine, pink macules which, originally discrete, can soon coalesce over the face and trunk. The rash usually disappears within 2–3 days but may persist for as long as 5 days. Occasionally it has a duration measured in hours and in this instance can be readily missed. A biphasic type of rash, with complete regression in between, has been described and a small area of the eruption may persist on the medial aspect of the thighs after the main rash has subsided. Small purpuric spots sometimes appear on the soft palate but have no diagnostic significance, as other infections are associated with a similar enanthem.

Lymph node enlargement is an important feature of the disease. It may appear as much as a week before the rash, though usually just before, and may persist for some time after the eruption has faded. The cervical, postauricular and suboccipital glands are most commonly involved, can be tender and are sometimes unassociated with any rash.

In adolescents and adults, especially female, prodromal symptoms are more likely and include malaise, headache, stickiness of the eyes,

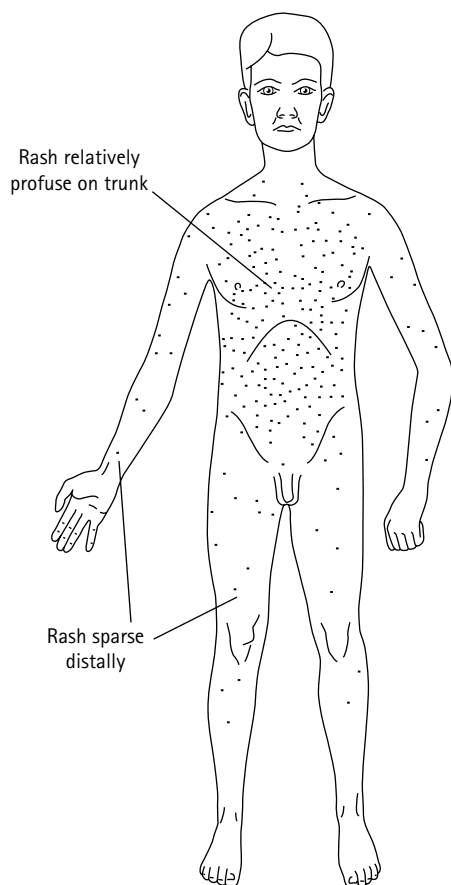

Fig. 28.36 The distribution and development of rash in rubella. (From Krugman & Ward 1968<sup>573</sup>)

conjunctivitis and fever. In children the temperature rarely rises above 37.1–37.4°C but in adults it can attain 39.5–40.0°C (Fig. 28.37).<sup>573</sup>

The clinical stigmata of congenital rubella are described in Chapter 12.

**Complications**

In general, complications are unusual though a higher incidence is encountered in certain epidemics and some seem age or gender dependent.

Polyarthrititis may be a sequel of rubella. It usually commences when the rash has subsided, is more common after florid eruptions and occurs in adults, especially women, rather than in children. The small joints of the hands and the wrist joints are most often involved but the large joints can also be attacked. The condition usually resolves within 2 weeks.

Postinfectious encephalitis, myelitis and polyradiculitis may follow an attack of rubella and have a similar pathology to these syndromes when they occur after other infections. However, in rubella they appear to have a better prognosis.

Thrombocytopenia is quite common in the course of the illness and may become clinically manifest as purpura. Epistaxis, hematuria and melena can also develop. Some cases of so-called ‘idiopathic thrombocytopenic purpura’ can be shown by laboratory tests to have resulted from subclinical rubella infection. Leukopenia is frequently found at the height of the illness and there may be an increase in plasma or Turk cells.

**Diagnosis**

Owing to the lack of pathognomonic features, one cannot rely on a clinical diagnosis of rubella and, whenever confirmation is important, laboratory tests (in the form of appropriate serological studies) should be used.

A serological diagnosis depends on the demonstration of a significant rise in antibody titer (four-fold or greater) when a sample of serum collected at the onset of the illness and a further sample taken 2–3 weeks later are compared.

Antibodies to rubella virus may be detected by hemagglutination-inhibition, neutralization, complement-fixation or radial hemolysis test. Nowadays, the hemagglutination test is generally preferred, owing to its reliability and the ease with which it can be performed.

Following infection both neutralizing and hemagglutination-inhibition antibodies persist, at a variable titer, for a long time whereas complement-fixation antibodies disappear more rapidly.

Virus may be recovered with relative ease from the nasopharynx during the last week of the incubation period and for up to 2 weeks thereafter. It is less readily isolated from the urine and blood. However, many laboratories do not offer viral culture for rubella.

Fig. 28.37 The development of rubella. (From Krugman & Ward 1968<sup>573</sup>)

### Differential diagnosis

Rubella may be confused with many common exanthemata and other skin eruptions. Differentiation from measles, glandular fever and drug eruptions does not present great difficulty but scarlet fever can cause confusion. Enteroviral infections accompanied by a rash, especially those associated with ECHO virus infection, provide the greatest diagnostic challenge. The presence of the herald patch, the distribution over the trunk and the complete well-being of the patient help to distinguish pityriasis rosea.

Resort to laboratory tests is always desirable when doubt exists in regard to a suspicious rash in a pregnant woman or her contacts.

### Treatment

There is no specific treatment for rubella. A rapid recovery is to be expected. Prodromal symptoms rarely cause trouble but analgesics may be needed when polyarthritides occurs. Neurological complications are managed along the usual lines for such conditions.

### Prevention

As a general rule, preventive measures are unnecessary in view of the mild nature of the disease. However, the situation is quite different in the case of women in early pregnancy, and attempts to prevent rubella were traditionally made using intramuscular normal human immunoglobulin. Evaluation of this procedure proved difficult, but laboratory-confirmed cases of rubella occurred despite immunoglobulin. Attenuated live rubella vaccines are now widely used and in general stimulate reasonable antibody levels. Opinions differ as to how they are best employed. Some recommend they are given to girls around puberty and non-immune pregnant women postpartum (selective immunization) while others believe children of both sexes should be given the vaccine in early childhood, usually in conjunction with measles and mumps vaccine as MMR, in an attempt to reduce the pool of infection in the community (universal immunization). Although terminations of pregnancy are frequently performed on pregnant women who have been inadvertently immunized there have been no cases of congenital rubella syndrome caused by the vaccine.

### ERYTHEMA INFECTIONOSUM (FIFTH DISEASE, SLAPPED CHEEK DISEASE)

This disease may occur at any time of year, but outbreaks in primary school children are classically in the winter and spring. Joint involvement may occur. Children with shortened red cell survival can develop profound anemia (aplastic crises), including children with endemic malaria,<sup>582</sup> and sickle cell disease.<sup>583</sup> Infection during pregnancy can lead to hydrops fetalis.

### Etiology

Erythema infectiosum is caused by parvovirus B19 (human parvovirus), a small, single-stranded DNA virus. Spread is by droplet infection, although as the virus can be seen in plasma during infections, it could be transmitted by blood products. Erythrocyte precursors are particularly susceptible to the virus, causing a mild fall in hemoglobin (of about 1 g/dl) in normal individuals but profound anemia in those whose red cell survival is already shortened.

### Clinical features

B19 infection may be asymptomatic or may cause a mild febrile illness with rash. In children the first sign of infection is usually marked erythema of the cheeks or slapped cheek appearance often with relative circumpallor (Fig. 28.38). In volunteer studies, however, there is an initial febrile episode with headache, chills, myalgia and malaise associated with viremia and the rash appears about 7 days later (Fig. 28.39). Then 1–4 days after the slapped cheeks an itchy, erythematous, maculopapular rash develops on the trunk and limbs. As the rash on the limbs clears it leaves a lacy, reticular pattern. The rash may fluctuate over the next 1–3 weeks and a hot bath, for example, may lead to recrudescence of an evanescent rash.

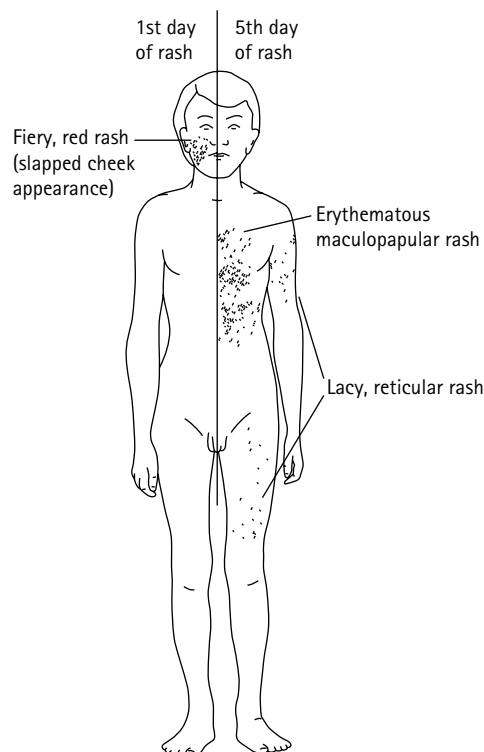

Fig. 28.38 The distribution and development of rash in erythema infectiosum (fifth disease).

### Complications

Arthritis or arthralgia is more common in adults, but certainly can occur in children. It usually appears 1–6 days after the rash but there may be no history of rash at all. Arthritis is characteristically transient and asymmetrical, affecting wrists, knees, ankles, elbows and fingers, though it may persist for weeks or even months.

Children with a shortened red cell survival, such as those with sickle cell anemia, thalassemia major, hereditary spherocytosis or other hemolytic anemias, may have severe aplastic crises with hemoglobin levels falling as low as 1–2 g/dl and no reticulocytes.

Children with malignancy, particularly acute leukemia, or with HIV infection may develop prolonged anemia from chronic parvovirus B19 infection.

Infection during pregnancy can result in hydrops fetalis due to fetal anemia, which may be fatal, but no congenital syndrome has been described in babies of infected mothers who delivered at term.<sup>584</sup>

Fig. 28.39 The development of erythema infectiosum (fifth disease).

Encephalitis with or without neurological sequelae has rarely been reported after clinical erythema infectiosum, but it is not certain that this is a true complication of B19 infection.

## Diagnosis

Erythema infectiosum may closely mimic rubella, and the two diseases can circulate concurrently. The slapped cheek appearance with circum-oral pallor can be mistaken for scarlet fever.

The diagnosis can be made serologically by demonstrating parvovirus B19-specific IgM on an acute serum sample, although it is always better to get a paired sample in case there is a late rise in antibody. The virus can be detected by electron microscopy or PCR of plasma of patients with aplastic crises. This is particularly important in patients with sickle cell disease in whom severe anemia might be due to sequestration or pneumococcal sepsis. DNA probes and PCR have been used to detect the viral genome in stillbirths with hydrops fetalis and to demonstrate persisting antigen in children with leukemia and chronic anemia.

## Treatment

There is no specific treatment. Isolation of patients is unnecessary since they are no longer infectious when the rash appears.

Arthritis may require salicylates or nonsteroidal anti-inflammatory agents. Children with aplastic crises may require blood transfusion until the red cell aplasia resolves spontaneously after 1–2 weeks.

## ROSEOLA INFANTUM (SIXTH DISEASE, EXANTHEM SUBITUM, THREE DAY FEVER)

Roseola infantum is a common disease of infancy, characterized by fever and the appearance of an erythematous maculopapular rash as the fever defervesces. It may be confused with measles clinically. It is generally benign.

## Etiology

Human herpesvirus 6 (HHV-6) is the main causative agent of roseola. <sup>585,586</sup> HHV-7 is responsible for most clinical cases of roseola infantum which are HHV-6 negative. <sup>587</sup> These double-stranded DNA viruses are members of the herpesvirus family, and as such, persist for the life of the host with frequent asymptomatic reactivation. There are two variant strains of HHV-6: type A and type B. Most of the primary infections in childhood are due to type B infection, and nearly 80% of children acquire HHV-6 by 2 years of age. <sup>588</sup> Primary HHV-6 infection is usually symptomatic and often results in presentation for medical evaluation. <sup>588</sup>

## Clinical features

The illness starts abruptly with fever and some anorexia and irritability although in general the child appears relatively well. Mild cough, coryza, diarrhea and vomiting rarely occur. The pyrexia of 38.9–40.6 °C persists for 3–5 days, then falls precipitously as the rash appears (Fig. 28.40). <sup>573</sup> The rash is erythematous, with discrete macular or maculopapular

Fig. 28.40 The development of exanthem subitum. (From Krugman & Ward 1968<sup>573</sup>)

lesions, and starts on the trunk and neck, sometimes spreading to the face and limbs. It lasts 1–2 days. Cervical lymphadenopathy is common and may sometimes be prominent: the suboccipital, posterior cervical and posterior auricular nodes are most commonly involved. There is no characteristic enanthem, although there may be pharyngitis, small exudate follicular tonsillar lesions, or small ulcers on the soft palate, tonsils and uvula.

For the first day or two of fever the white count is often elevated with a neutrophil leukocytosis, but then may fall as low as 3000/uL ( $3 \times 10^9/L$ ) predominantly lymphocytes with an absolute neutropenia.

A number of clinical syndromes (bone marrow suppression, pneumonia, hepatitis, encephalitis) have been associated with reactivation of HHV-6 in the immunocompromised, although a causal link has been difficult to prove. <sup>586</sup>

## Complications

Convulsions may occur in association with roseola. <sup>589</sup> These are usually febrile convulsions but encephalitis has rarely been described, sometimes with severe residua such as hemiparesis or mental retardation. Rarely thrombocytopenic purpura may occur following roseola. <sup>586</sup>

## Diagnosis

The diagnosis of roseola infantum is primarily clinical, although it can now be confirmed serologically. PCR assays to detect HHV-6 DNA are available, but cannot distinguish an acute infection from reactivation. The characteristic fever chart and discrete rash that does not become confluent distinguish roseola from other childhood exanthemata including measles. The rash may be confused with a drug rash if antibiotics have been given and a vaccine reaction may cause confusion if the illness comes on soon after immunization.

## Treatment

There is no specific treatment. There are anecdotal reports of treatment of HHV-6 infection in immunocompromised children with ganciclovir, but there is no evidence to support efficacy from clinical trials. Antipyretics may lessen the risk of convulsions, but if these occur, encephalitis should be considered and the child treated appropriately.

## HERPESVIRUSES

### CHICKENPOX (VARICELLA)

Chickenpox is a common and highly infectious disease caused by varicella zoster virus (VZV). In general, chickenpox is relatively benign and has a virtually worldwide distribution. However, chickenpox is not endemic in some isolated areas and if introduced to such a community a more serious disease may occur. It can also prove severe and even fatal in neonates, when contracted by a patient on immunosuppressive drugs and rarely in previously healthy children and adults. <sup>590</sup>

Immunity following chickenpox is usually life-long and second primary attacks are rare. Like all herpesviruses, however, the virus can remain latent and recur years later, in the case of VZV, in the form of zoster (shingles).

## Etiology

Chickenpox is transmitted from person to person by direct contact, droplet or airborne spread; infection can also arise through articles recently contaminated by an infected person. Viral entry is through the upper respiratory tract mucosa or via the conjunctiva. Infectivity is maximal during the prodromal period 1–2 days before the eruption of the rash and has completely waned by the time the eruption becomes crusted. In the immunocompromised, infectivity may continue after crusting has occurred if new lesions continue to develop.

The causative agent, VZV, is a large DNA herpesvirus. The virus is highly specific for humans and is very difficult to grow in culture in the laboratory.

## Clinical features

Chickenpox is predominantly a disease of childhood and usually occurs between 2 and 8 years of age. Cases may occur in infancy. Peripartum intrauterine infection can lead to varicella neonatorum (see below) which, untreated, has a mortality up to 20%. Postnatal infection can cause classical chickenpox of a lesser severity occurring only in babies whose mothers have not had chickenpox.

Following an incubation period of 10–28 days, usually around 16 days, the disease starts with mild malaise and fever (Fig. 28.41).<sup>573</sup> In children prodromal symptoms may be absent and the illness begins with a rash. Older children and adults have more definite prodromata and symptoms include malaise, fever, headache, sore throat and backache.

The rash (Fig. 28.42)<sup>573</sup> commences as a crop of macules, which within hours pass through a papular stage to become vesicular; the vesicles persist

Fig. 28.41 The development of chickenpox. (From Krugman & Ward 1968<sup>573</sup>)

Fig. 28.42 The distribution of rash in chickenpox. (From Krugman & Ward 1968<sup>573</sup>)

for 3–4 days, becoming pustular and finally forming a crust. The spots are superficial and the vesicles may be round, oval, elliptical or irregular in shape; they are often surrounded by a red areola. The rash is usually mild in children vaccinated against varicella with the Oka vaccine and may be atypical (maculopapular with few or no vesicles).<sup>591</sup>

Evolution of the rash occurs by a series of crops, and lesions at different stages may be seen. The trunk is principally involved but spots also appear over the face, scalp and the proximal parts of the limbs. Lesions tend to be more abundant on covered rather than exposed parts of the body.

In mild cases the entire eruption may consist of a few spots; less often, the rash is almost generalized, extending to the distal parts of the limbs including the soles and palms. By the time of vesiculation there is often an intense pruritus. In some patients crusts can be very tenacious and 2–3 weeks may elapse before their separation is complete.

An enanthem is usually found and presents as vesiculation over the palate, tongue or buccal mucous membranes; the conjunctivae and vagina may be similarly affected.

## Hemorrhagic chickenpox

In this there is usually a marked constitutional disturbance and high fever. Extensive bleeding into the vesicles develops and the lesions become black; areas of ecchymosis can appear on otherwise uninvolved skin. Bleeding may occur from mucous membranes and present as hematuria or melena. Both children and adults may contract this form of chickenpox and it has been particularly reported in patients receiving corticosteroids or cytotoxic drugs suggesting the importance of cell mediated immunity as well as antibody in recovery from infection. It can be associated with profound thrombocytopenia (purpura fulminans) and is often fatal.

## Varicella gangrenosa

This form of the disease usually results from severe secondary bacterial infection (usually due to group A streptococci) of the vesicles which may extend down to muscle. These lesions are slow to heal and can leave considerable scarring. Occasionally this form of varicella appears to start ab initio before any apparent secondary infection.

## Varicella neonatorum

If the maternal rash appears less than 7 days before delivery or up to 2 days after delivery there is a risk that the baby will receive a large inoculum of virus without maternal antibody. Such babies are at very high risk of disseminated disease with death from pneumonitis, and should be protected at birth by giving zoster immune globulin (ZIG) (reviewed in Heuchan & Isaacs 2001<sup>592</sup>). Since this does not always protect them,<sup>593</sup> families of these infants should be informed of the risk of severe disease and early treatment with acycloguanosine (aciclovir) commenced promptly if symptoms develop. Babies whose mother's rash develops 7 days or more before or 3 days or more after delivery are at low risk. Postnatally acquired chickenpox is nearly always mild although if the mother has not had chickenpox the use of ZIG should be considered for a neonate exposed to the virus.

## Varicella bullosa

Bullous varicella may occur in children, the lesions developing into large bullae with a positive Nikolsky sign. It is due to superinfection with a toxin-producing *Staphylococcus aureus*, and the prognosis for full recovery without scarring is excellent. Treatment is with antistaphylococcal antibiotics.

## Complications

### Sepsis

Secondary skin infection is the commonest complication. Abscesses may form locally or in regional lymph nodes. Cellulitis, erysipelas and scarlet fever can also develop. Bacteremic spread may give rise to pneumonia, osteomyelitis and septic arthritis. Common infecting organisms include group A streptococci and *S. aureus*.

### Neurological

Postinfectious encephalitis can occur and usually starts as the rash reaches maturity. The most common manifestation is a pure cerebellar ataxia with an excellent prognosis. Complete recovery is virtually invariable, usually rapidly, though it may rarely take some weeks. Acute disseminated encephalomyelitis (ADEM) is a more sinister but rarer form of post varicella encephalitis with cerebral demyelination giving rise to long tract signs, cranial nerve lesions, convulsions, etc. Examination of the CSF may show a mild lymphocytic pleocytosis and slight elevation of the protein content. About 10% of cases of Reye syndrome occur secondary to chickenpox. Transverse myelitis, acute infantile hemiplegia and Guillain-Barré syndrome have been described complicating varicella.

### Pneumonitis

Pneumonitis is usually seen in adults and immunocompromised children (and varicella neonatorum) and may present with acute respiratory distress or hemoptysis; diffuse nodular infiltration is seen on X-ray of the chest. The diagnosis is often obscure until the typical exanthem develops. Some cases die and, in those who recover, miliary calcification may be seen in the lung fields some years later.

In normal children, pneumonia complicating chickenpox is most likely to be bacterial, due to *S. pneumoniae*, group A streptococcus or occasionally *S. aureus*.

### Others

Myocarditis, pericarditis, endocarditis, hepatitis and glomerulonephritis have rarely been reported. Appendicitis may also occur and can present before the eruptive phase; this sometimes leads to cross infection in pediatric surgical wards. Keratitis and conjunctivitis are rare and usually benign. Arthritis may mimic septic arthritis but the latter should always be excluded by examination of the joint fluid because septic arthritis can complicate chickenpox. If ampicillin is prescribed a drug eruption may occur as with EBV infection, probably as a result of drug-hapten interaction.

### Congenital varicella

If the mother contracts chickenpox up to 20 weeks' gestation, there is about a 2% risk of the baby developing congenital varicella syndrome with cicatricial scarring of the limbs, cortical atrophy, hypoplasia of limbs, digital defects, retinitis or cataracts. Maternal chickenpox in the second 20 weeks of gestation may result in an inapparent primary infection in the fetus, and causes shingles in the first years of life in about 1% of exposed children.

### Diagnosis

The clinical course of varicella and the nature of the rash are usually typical and a firm clinical diagnosis can be made. Rapid diagnosis can be by direct immunofluorescence (DEA) of cells scraped from the base of a vesicle and placed directly on a slide. DFA can also be performed on respiratory secretions obtained by nasopharyngeal aspirate or bronchoalveolar lavage for the diagnosis of infection in the immunocompromised.

VZV can be isolated from vesicle fluid collected during the first 3 or 4 days of the rash, but rarely from other sites. Tissue culture for varicella is not widely available. Detection of VZV DNA in body fluids or tissues by PCR is a sensitive technique that may be helpful in the diagnosis of VZV infection in the immunocompromised child.

A number of serological assays are available for diagnosis of past VZV infection that vary in their sensitivity. These have application in deciding if an exposed individual needs passive immunoprophylaxis. They can also be used to make a retrospective diagnosis of VZV infection if a significant rise in varicella IgG has occurred during the illness. In this setting, it is necessary to test two sera – an acute sample collected within a day or two of the onset of the illness and a convalescent sample collected 2 or 3 weeks later.

### Differential diagnosis

Chickenpox can be confused with impetigo, scabies, dermatitis herpetiformis, eczema herpeticum or vaccinatum and erythema multiforme.

In most of these the absence of the typical, centripetal distribution and cropping of varicella helps in the differentiation.

### Treatment

#### General

No treatment is usually required and bed rest is probably unnecessary except in ill patients. Simple analgesics will control prodromal symptoms where these are troublesome. Aspirin should not be given because of the risk of Reye syndrome. Calamine lotion will normally soothe pruritus; if not, an antihistamine should be tried. If the enanthem is unusually severe careful oral toilet is needed and lesions on the conjunctiva should be protected from secondary infection. Treatment with aciclovir is indicated if infection develops in immunosuppressed cases, and in any patient with severe disease.

#### Sepsis

In convalescence, simple antiseptics should control superficial skin infection. More severe sepsis will require appropriate antibacterial chemotherapy, which should be guided by swabbing of the affected lesions and by cultures of the blood and of any pus. Flucloxacillin will adequately treat hemolytic streptococcal infection or staphylococcal infection until culture results are available.

#### Encephalitis

No specific treatment is available for the neurological complications and the usual supportive measures will be employed. Some clinicians favor the use of corticosteroids in severe cases despite the unhappy association of chickenpox with these drugs. It is argued that the encephalitis is of allergic origin and that by this stage of the illness there is sufficient antibody response to prevent further dissemination of the virus. In practice no serious untoward effects have been reported where steroids have been used in this condition although it is difficult to assess how much this therapy contributes to any recovery. Similarly the role of aciclovir in treating varicella encephalitis is unclear.

#### Others

Cases of severe varicella pneumonitis and profound thrombocytopenia have also been treated with aciclovir and corticosteroid drugs but an accurate evaluation of their benefit is impossible. Appendicitis should be treated surgically.

### Prevention

The live attenuated Oka strain varicella vaccine is available in some countries for use in healthy children over 12 months of age or adults who have not had varicella. It has been shown to be highly effective (approximately 85% of children) in preventing clinical disease post exposure.<sup>594</sup> However, clinical disease in vaccinated persons is contagious and can sustain transmission, prompting the question of whether a two-dose regimen is required to prevent transmission during outbreaks. The Oka vaccine has been shown to be safe in solid organ transplant recipients post transplantation,<sup>595</sup> and in HIV infected children with CD4+ T cell counts  $\geq 200$  cells/ $\mu$ l (or 15%).<sup>596</sup>

The infectivity of chickenpox is such that the strictest isolation measures may fail to prevent its spread. In the community, it is usual practice to isolate a child from school or day care until the rash has become crusted. In the hospital setting, a child with active chickenpox should be quarantined in respiratory isolation while the rash remains vesicular.

#### Postexposure prophylaxis

In the case of patients who are receiving corticosteroid drugs or cytotoxic drugs, every effort should be made to prevent exposure to chickenpox and herpes zoster for reasons already described. If such exposure should occur then hyperimmune chickenpox gamma globulin (ZIG) has been shown to modify severity even if it does not always prevent the disease, and should be given. The use of ZIG in neonates has already been discussed. Chemoprophylaxis with aciclovir after exposure to VZV reduced the likelihood of clinical disease in a few small case control studies,<sup>597-599</sup>

but has not been assessed in a properly evaluated randomized controlled trial and is not routinely advocated.<sup>600</sup> Postexposure immunization with the Oka VZV vaccine has been shown to protect against or modify chickenpox in nonrandomized cohort studies.<sup>601</sup> It is thought to be most effective if given within 5 days of exposure.

## HERPES ZOSTER (ZOSTER: SHINGLES)

The clinical relationship between chickenpox and herpes zoster has long been recognized. The virus causing the two syndromes is identical, and is referred to as the varicella zoster virus (VZV). Non-immune persons may develop chickenpox when exposed to herpes zoster but the converse rarely occurs. The inoculation of children with virus obtained from zoster patients has resulted in clinical chickenpox which has then spread to other children as chickenpox.

Following an attack of varicella, the virus survives in a latent form in the sensory root ganglia of the cord and brain, a situation with similarities to latent infection by HSV. After an interval of many years, but sometimes earlier, the virus becomes activated by local precipitating factors or by some depression of protective immunological mechanisms. Virus then spreads along the sensory root in question; adjacent motor areas of the cord, or other parts of the cerebrum, may become involved. A degree of systemic spread can also occur which provokes a modified form of chickenpox. Such modification may result from the antigenic stimulus provided by the reactivated virus, and the very high antibody levels found early in the course of herpes zoster support this impression.

Patients who develop zoster are usually elderly, but the disease does occur in children and younger adults. In young children, pain is much less marked than in adults, and zoster is not suggestive of immune deficiency or malignancy. There is often a history of maternal varicella during pregnancy or early neonatal varicella; it is thought that varicella at a time of relatively poor immunity is more likely to result in childhood zoster. In a few instances, primary infection by VZV appears to provoke zoster rather than chickenpox; the explanation is not known. On occasion zoster may also occur simultaneously with a primary attack of chickenpox.

For reasons alluded to above, zoster is seen quite frequently in persons suffering from leukemia or other malignant disease and can follow radiotherapy.

### Clinical features

Zoster may start with constitutional disturbance or progressive pain over a particular dermatome, although in children zoster may be pain free. Clusters of macules and papules appear on the skin overlying the dermatome, rarely crossing the midline. These soon vesiculate and the vesicles formed may be larger than in chickenpox and tend to coalesce. Extensive crusting follows, which slowly separates to expose a raw, ulcerated area. This will bleed readily and is susceptible to secondary infection. Healing is slow, vitiligo may develop after months or years and the involved skin is often anesthetic. Enlargement of the regional lymph nodes is very common.

Acute pain tends to subside as crusting sets in, but extreme irritation and neuralgia may persist for months and even years (post-herpetic neuralgia). In children the illness tends to be much milder, pain is mild or absent and recovery is considerably quicker.

Thoracic segments are most commonly involved in the community, but zoster of the trigeminal nerve, and usually of the ophthalmic division, is the commonest variety seen in hospital.

*Geniculate herpes* is of special interest and is frequently misdiagnosed; in this form of zoster, vesicles appear on the meatus and pinna of the ear. Pain may be experienced in the throat, in or behind the ear, and taste may be lost over the anterior two thirds of the tongue. Facial paralysis, sometimes permanent, may result. This condition is sometimes referred to as the *Ramsay Hunt* syndrome. A modified generalized rash over the trunk and face is seen in many cases provided examination is sufficiently diligent. Other features include involvement of the adjacent motor root with resultant paralysis, which can be permanent, and meningitis, encephalitis or myelitis can be encountered.

Occasionally zoster occurs without any accompanying rash, the so-called 'zoster sine herpete'.

### Diagnosis

Prior to the appearance of the skin eruption diagnosis is difficult in children, in whom zoster is rather unexpected. Diagnoses such as pleurisy or fibrositis may be made but the difficulties are quickly resolved when the classical rash, along the line of a nerve, makes its appearance. If it is in a distribution that looks dermatomal, HSV infection may sometimes be mistaken for zoster. Laboratory tests are referred to in the section on chickenpox.

### Treatment

The illness is usually mild in children and simple analgesics such as paracetamol will usually control pain. Relief may follow the application of a dusting powder of zinc oxide or the use of cold sprays.

Ophthalmic zoster requires special care because of the danger to the eyes. Topical or systemic antivirals may be needed for ophthalmic VZV. Consultation with an ophthalmologist is advisable.

In some instances, particularly severe zoster may show a dramatic response to treatment by corticosteroid drugs. However, their general use is not advised and they are best avoided in zoster affecting the eye and wherever any underlying immunological defect may be present. Aciclovir may be needed for immunocompromised children or those with severe zoster.

High doses of the live attenuated Oka vaccine (known as the 'zoster vaccine') have been shown to reduce disease incidence and severity in the elderly,<sup>602</sup> but the vaccine has not been evaluated for use in children or young adults.

### Prognosis

This is usually good. Post-herpetic neuralgia is uncommon in children. Certain paralyses can prove permanent and impairment of vision has followed ophthalmic zoster. Such complications are more commonly found in adult cases.

## HERPES SIMPLEX VIRUS

Primary infection by *Herpesvirus hominis* (HSV) usually occurs in early childhood and is generally subclinical. However, in a small percentage of children it may produce a variable clinical illness, the main features of which include localized vesiculation on some part of the body and a sharp constitutional reaction. Some children avoid infection altogether and may reach adolescence or adult life with no immunity to this virus. This is more likely to occur when they have been brought up in rural, as opposed to urban, areas and, as with many other viral infections, an attack in adult life can often be more severe.

An interesting feature of this virus is its ability to persist in a latent form once the primary infection, whether clinical or subclinical, has subsided. In some people, the virus becomes reactivated by certain non-specific stimuli at various times in their lives and the resultant clinical manifestations tend to differ from those seen with primary infection. Reactivation of HSV with asymptomatic shedding or, less commonly, clinical disease is a common event after the initial infection.<sup>603</sup>

### Etiology

HSV is a DNA virus surrounded by a membrane and is approximately 150–180 nm in diameter. There are two strains, HSV types 1 and 2. HSV type 2 primarily infects the genital tracts of adults, and infection in the pregnant woman near term can result in serious infection in the newborn infant. HSV type 1 is primarily oral, although type 2 can cause oral disease and type 1 can infect the genitalia.

### Clinical features

A variety of different syndromes may result from primary infection by HSV beyond the neonatal period. Neonatal HSV disease is discussed in Chapter 12.

### ***Acute herpetic gingivostomatitis (ulcerative stomatitis)***

This, the commonest manifestation, commences with a sharp constitutional reaction with high fever, malaise, anorexia and irritability. The patient, usually a young child, has difficulty feeding due to pain in the mouth. Inspection, often hampered by severe discomfort, reveals marked swelling and inflammation of the gums which may bleed at the merest touch. Deeper inspection will reveal the typical shallow ulcers, white in color, on such sites as the tongue, palate, gums, buccal mucosa and tonsils. In mild cases, the ulcers are few; in more severe examples there may be a contiguous sheet of ulcers involving all the sites mentioned. Saliva tends to flow from the mouth and satellite lesions form down the chin or cheek where the child dribbles. Considerable swelling of the face and neck may accompany or even precede the appearance of lesions and cause diagnostic confusion. Mild cases subside rapidly but the worst may take up to 2 weeks before the local lesions disappear. Younger children may implant the virus onto other sites such as the sucked finger or perineal region, where vesiculation will develop. The isolation of HSV2 from an oropharyngeal lesion in a child prior to puberty should raise the question of sexual abuse.

### ***Perineal herpes (acute herpetic vulvovaginitis)***

This is a less common primary manifestation, though it may be underdiagnosed in view of confusion with severe napkin and other eruptions in the same area. It is diagnosed far more often in girls, though primary perineal herpes sometimes occurs in boys. Some degree of constitutional upset will again herald the infection, to be followed by painful vesiculation over the perineum, which may extend into the vagina in girls. Lesions close to the external urethral orifice may cause difficulties with micturition and regional adenitis may develop. The lesions usually subside without scarring despite the likelihood of secondary infection. Reactivation occurs over the buttocks, thighs or perineum.

### ***Traumatic herpetic infection***

The intact skin appears relatively resistant to this virus but primary infection may arise over the site of abrasions and burns. An interesting variety is the herpetic whitlow of the finger which is sometimes seen in nurses who contract the infection by virus entering such lesions as needle puncture wounds or the abrasions that can result from opening glass phials – lesions that are common on the nurse's hand. Here again there may be a marked constitutional upset and regional lymphadenitis.

### ***Acute herpetic keratoconjunctivitis***

Primary herpetic infection of the eye is a serious presentation of this infection though relatively rare. The majority of cases are due to HSV1, although HSV2 eye disease may occur as a consequence of neonatal infection. Normally only one eye is involved and cases present with constitutional upset and pain. Marked reddening and edema appear on the affected conjunctiva, the cornea becomes hazy and the eye will usually close. Vesicles appear around the lids and a purulent discharge often occurs. So long as the infection remains superficial the condition will usually subside without complications in 10–14 days. Deeper involvement may give rise to keratitis disciformis, hypopyon keratitis or iridocyclitis, all of which may be followed by scarring; however, these are more commonly encountered in recurrent herpetic infection. Recurrent herpetic keratitis has been shown to be an immune-mediated phenomenon.<sup>604</sup>

### ***Kaposi varicelliform eruption (KVE) or eczema herpeticum***

Children with eczema are prone to superinfection of the involved skin by a number of organisms including HSV. The disease starts with a particularly sharp constitutional upset and vesicles then appear on the skin and are most intense at the eczematous areas. An experienced observer may readily recognize the condition; more often the true diagnosis is unappreciated and extensive secondary infection accompanied by a marked serosanguinous discharge will develop. Further crops of vesicles may appear and the child's condition may deteriorate further. The most severe cases may be fatal without aciclovir therapy. In the remainder there is a slow recovery over a period of 3–4 weeks.

### ***Primary herpetic meningoencephalitis***

Previously considered an infrequent infection, modern virological techniques have shown that herpetic meningoencephalitis is more common than was believed. The signs of CNS involvement may appear shortly after a primary lesion at some other site but there is usually no clinical evidence to indicate the basic etiological agent. Cases may present as mild forms of aseptic meningitis or as a rapidly fatal form of encephalitis principally involving the temporal lobes. Recently, a genetic etiology for HSV encephalitis was demonstrated in two children with autosomal recessive deficiency in the intracellular protein UNC-93B, resulting in impaired cellular type I interferon responses.<sup>605</sup>

### **Clinical features: recurrent herpes**

Exacerbations of latent HSV infection may be provoked by a variety of nonspecific stimuli which include upper respiratory infections, any febrile illness, gastrointestinal upsets, overexposure to sunlight and emotional upsets. Drugs and certain foods have also been incriminated.

Whatever the excitant, recurrent herpes presents as a crop of tiny vesicles which are sometimes painful and after a few days will dry up to form a scab. They may erupt on almost any part of the skin or on the mucous membranes of the mouth, conjunctivae or genitalia. The most usual site is on the skin around the nose and mouth (cold sores). Exacerbations tend to recur at the same site in any particular individual. Recurrent herpes gives rise to little or no constitutional upset or fever but the excitant, such as lobar pneumonia, may do so.

### **Diagnosis**

The clinical features are often diagnostic in themselves but resort to laboratory aid is of help in certain instances. The procedures most commonly employed are:

1. growth of the virus in tissue culture;
2. demonstration of viral antigens in the material by a fluorescent antibody technique;
3. detection of HSV DNA in CSF or other bodily secretion or tissue by PCR.

Other procedures that may be employed are:

4. demonstration under the electron microscope of herpesvirus particles in material taken from a lesion;
5. antibody estimations on acute and convalescent serum samples to show specific IgM or a significant rise in IgG during a suspected primary infection;
6. histological evidence of intranuclear inclusions and giant cells.

### ***Primary herpes***

The oral lesions of primary herpetic gingivostomatitis may be confused with a variety of conditions such as thrush, tonsillitis, Vincent's stomatitis, agranulocytosis and leukemia. Careful clinical and laboratory studies readily differentiate most of these but herpangina, due to infection by coxsackie viruses group A, can cause genuine confusion; however, gingivitis does not normally accompany herpangina, but is common in herpetic infections. Virus studies may be needed in difficult cases. Herpetic vulvovaginitis is readily confused with amoniacal dermatitis which has been secondarily infected. Impetigo of the vulva is usually accompanied by involvement elsewhere. Kaposi varicelliform eruption (eczema herpeticum) may be confused with bacterial superinfection of eczema, with eczema vaccinatum and occasionally with varicella. Herpetic meningoencephalitis is difficult to diagnose on clinical grounds; usually virological studies are required to make a conclusive diagnosis.

### ***Recurrent herpes***

Recurrent herpes produces a fairly precise diagnostic picture, but on occasion can resemble herpes zoster. The absence of pain, lack of a definable neurological distribution and differing nature of the vesicles should differentiate these conditions.

### **Treatment**

As a rule, primary oral herpetic infections do not require other than supportive treatment. Children with severe gingivostomatitis may

have feeding difficulties due to pain, and careful coaxing will be needed to ensure adequate hydration; cleansing of the mouth is also difficult on account of this pain. Irritating acidic fluids should be avoided and diet restricted to cold, bland drinks during the most acute phase. Superinfection by *Candida* may occur but this usually responds to treatment by the local application of nystatin suspension; secondary bacterial infection rarely warrants any antibiotic therapy though this may be required in herpetic vulvovaginitis. Intravenous aciclovir should be reserved for children requiring hospital admission for intravenous rehydration.

Eye involvement is best managed by an experienced ophthalmologist. Herpetic infections are amongst the few viral diseases in which highly successful treatment by antiviral agents has been reported; topical 5-iodo-2-deoxyuridine (IDU) or aciclovir are effective in herpetic eye infections.<sup>606</sup> Intravenous aciclovir is the treatment of choice for herpes simplex encephalitis, for KVE and for any manifestations of HSV disease in a neonate.

## CYTOMEGALOVIRUS INFECTIONS

Cytomegalovirus (CMV) is a DNA virus of the herpesvirus group and as such, after the primary infection, causes latent infection with frequent subclinical reactivations for the life of the host. It is ubiquitous in the community, and in the immunocompetent host usually results in asymptomatic infection. CMV infection of the fetus and newborn (congenital and perinatal CMV infection) is discussed in Chapter 12. CMV can cause life-threatening disease in immunocompromised patients with HIV infection, or post solid organ or bone marrow transplantation, either after a primary infection or when a latent infection becomes reactivated.

### Clinical features

In immunocompetent older children and adults, CMV infection is usually asymptomatic. On occasion, it may present with fever, cough, headaches and pains in the back and limbs. The clinical picture is one of infectious mononucleosis, with lymphadenopathy, hepatosplenomegaly and sometimes jaundice. Examination of the peripheral blood reveals the presence of atypical lymphocytes, and there is a varying degree of derangement in liver function tests. Hemolytic anemia can occur, and cold agglutinins, cryoglobulins and antinuclear factor may be present. Ampicillin may cause a rash as in EBV infection. CMV may produce a pneumonitis but this is usually seen in premature neonates with postnatally acquired infection or in children suffering from underlying diseases such as chronic hepatic disorders, leukemia and other malignancies.

A febrile illness with features suggesting infectious mononucleosis may also be encountered in patients who have recently undergone open heart surgery or organ transplantation and investigation of obscure postoperative illness in such cases should include tests for CMV infection. In patients with immune deficiency, particularly AIDS patients, CMV may cause pneumonitis, hepatitis, encephalitis or myelitis, severe retinitis and colitis. HIV infected children who acquire CMV during the first 4 years of life have been shown to have a more rapid progression to AIDS than those who remain CMV negative.<sup>607</sup> CMV is a frequent cause of hepatitis, pneumonitis or graft rejection in solid organ transplant recipients and is associated with increased rates of co-infection with other opportunistic pathogens in these individuals. The virus is usually acquired from the donor organ or blood products, although reactivation of latent host CMV may also occur.

### Laboratory diagnosis

Histological lesions due to CMV infection are characterized by large cells containing intranuclear and cytoplasmic inclusion bodies. The inclusion-containing cells may be widely disseminated.

Rapid viral diagnosis using DNA probes or by early immunofluorescence testing of tissue cultures (so-called 'shell vial cultures') or detection of the CMV pp65 antigen in blood is particularly useful in

the management of suspected CMV infection in immunocompromised patients.

A clinical diagnosis may be confirmed by:

1. isolation of the virus from urine, peripheral blood mononuclear cells, or other secretions;
2. demonstration of a significant rise in antibody titer during the illness;
3. the presence of typical histological lesions in a biopsy specimen, e.g. liver;
4. typical inclusion bodies in cell deposits of fresh urine.

With improved virological techniques, efforts should always be made to grow CMV when infection is suspected. Suitable specimens are fresh urine samples and saliva swabs but these specimens must be delivered to the laboratory with minimum delay as the virus easily loses its infectivity. Isolation of the agent is usually carried out in tissue cultures of human fibroblasts.

Quantification of the amount of CMV DNA or antigen in blood or other secretions to monitor recurrence and allow early pre-emptive therapy in the immunocompromised child is currently being evaluated.<sup>608</sup>

### Differential diagnosis

CMV infections acquired in later life may mimic a variety of febrile states but infectious mononucleosis is the most likely condition to cause confusion. Where jaundice occurs, infectious hepatitis, serum hepatitis and leptospirosis require exclusion.

### Prevention

Blood products from CMV antibody negative donors should always be given to preterm neonates and immunocompromised patients, particularly post-transplant or HIV infected patients. Alternatively, as the virus is cell associated, filtration or freezing of the donor blood to remove white cells also reduces the risk of acquired CMV infection.

Passive immunoprophylaxis of transplant patients with immunoglobulin is partially successful in reducing the risk of CMV infection. Seropositive CMV patients may reactivate when immunosuppressed, and interferon but not aciclovir reduces this risk.

### Treatment

Ganciclovir, a derivative of aciclovir, has been successfully used to treat immunocompromised patients with CMV retinitis, enteritis and pneumonitis.<sup>609</sup> In adult patients, 70–80% cease excretion of CMV within a week, with the exception of marrow transplant patients with CMV pneumonitis, of whom somewhat fewer respond. However, relapse occurs in about half when ganciclovir is stopped, it causes significant marrow suppression, and the drug is incorporated into the host genome. Milder CMV disease can be treated with oral valganciclovir.

Foscarnet causes less marrow suppression, although transient renal impairment may occur. There are few controlled data on its use in CMV infections in childhood. Cidofovir is another antiviral agent with activity against CMV. Its main use is in CMV retinitis or prophylaxis in the organ transplant population.

Prophylaxis with oral antiviral agents in solid organ transplant recipients to prevent CMV disease has been recently demonstrated to be successful in a meta-analysis.<sup>610</sup>

### Prognosis

Congenital CMV infection has a variable outcome. Normal individuals who contract CMV infection rarely suffer any sequelae, but in immunocompromised patients, blindness due to retinitis, graft rejection and death from pneumonitis, hepatitis and disseminated CMV infection or opportunistic infection may occur.

## EPSTEIN–BARR VIRUS

EBV is the cause of infectious mononucleosis or glandular fever, a disease primarily of older children, adolescents and young adults. An almost

identical syndrome can be caused by CMV and *Toxoplasma gondii* as well as EBV. An anginose form of glandular fever primarily affecting the tonsils is seen in younger children under 5 years of age. EBV is a DNA virus and like the other herpesviruses can persist in a latent state and reactivate. It has a worldwide distribution, is potentially oncogenic and has been linked with nasopharyngeal carcinoma, Burkitt lymphoma and other lymphomas, particularly in immunocompromised patients. It can also cause lymphoproliferative syndromes post transplant or in the HIV infected individual.

## Etiology and epidemiology

Primary infection of the lymphoid tissue of the nasopharynx may be asymptomatic or may lead to symptomatic infection of lymph nodes. Humans are the only source of EBV, transmission is by the respiratory route and the virus is of low infectivity, usually requiring intimate oral contact. The 'kissing disease' refers to its spread among adolescents and young adults by this route. Epidemics are unusual. The virus persists in the nasopharynx and the uterine cervix. The virus primarily infects B lymphocytes but the atypical mononuclear cells seen in the blood film are activated T lymphocytes.

## Clinical features

The anginose form of glandular fever is characterized by fever and sore throat with moderate or marked cervical lymphadenopathy. The tonsils are red and inflamed and there is often exudative folliculitis with white exudate. Other lymph nodes and spleen are rarely enlarged and the clinical picture is not readily distinguishable from acute streptococcal tonsillitis, except that EBV is more likely to cause palatal petechiae.

Glandular fever often starts insidiously with malaise, anorexia and fever, and sore throat is usually a prominent symptom. Occasionally the patient merely has malaise and fever for 1–3 weeks with chills and sweats (febrile form of infectious mononucleosis) and presents with pyrexia of unknown origin. Generally, however, there is marked enlargement of posterior and anterior cervical lymph nodes, and the suboccipital, postauricular, axillary, epitrochlear and inguinal nodes may also be enlarged (glandular form). The tonsils may be inflamed with exudate and rarely this can be sufficient to impair swallowing and even breathing. Splenomegaly is usual and hepatomegaly may also be present, sometimes with jaundice.

Skin eruptions occur in about 10–15% of cases. Most common is a widespread maculopapular rash but morbilliform, scarlatiniform, purpuric and urticarial rashes may occur. Ampicillin (or amoxicillin) causes a particularly florid, confluent maculopapular rash in EBV infection, and the ampicillin rash may be seen less commonly in conjunction with other herpesvirus infections, such as CMV and chickenpox.

In Duncan syndrome, or X-linked lymphoproliferative disease, affected males are unable to control EBV infection and develop generalized lymphadenopathy and hepatosplenomegaly which persists and is rapidly fatal. These patients usually have persistently high levels of IgG antibodies to the viral capsid antigen (VCA).

EBV may be responsible for the lymphoid interstitial pneumonitis that can occur in children with HIV infection, since the EBV genome has been demonstrated in lung biopsy specimens from these patients. It can also cause CNS and other lymphomas in patients with HIV infection.

## Complications

Threatened obstruction of the airway may occur in the severe anginose variety, especially when there is secondary edema in the neck. Neurological complications include aseptic meningitis, cranial nerve palsies (including Bell's palsy), encephalomyelitis, transverse myelitis and Guillain-Barré syndrome. Cardiac involvement may present as myocarditis or as transient arrhythmias. Other complications include pneumonitis, orchitis, rupture of the spleen, hemolytic anemia, thrombocytopenic purpura and various ocular manifestations; hepatic involvement has been referred to previously. A prolonged illness with fatigue and relapses over many months has occasionally been described in children, in association

with raised EBV antibodies. Chronic EBV infection is not a common cause of the 'chronic fatigue syndrome' or myalgic encephalopathy (ME).

EBV is thought to be the cause of Burkitt lymphoma and of nasopharyngeal carcinoma, in both of which tumors the EBV genome can consistently be demonstrated.

## Diagnosis

Five main points arise in the diagnosis of glandular fever: a suggestive clinical picture, typical changes in the peripheral blood, a positive heterophile antibody test, IgM antibody to EBV, and certain nonspecific changes in other laboratory tests.

### Blood changes

Most important is the presence of large, atypical mononuclear cells which have an irregular nucleus, whose cytoplasm contains vacuoles, and which have characteristic pale staining of the cellular cytoplasm. Often there is a leukocytosis of  $10\text{--}20 \times 10^9$  cells/L and sometimes the predominant cells are initially polymorphonuclear. However, atypical monocytes and lymphocytes soon appear, or may be present from the outset, and these can represent from 5 to 50% of the total leukocyte count. Other changes in the blood include occasional leukopenia and rare instances of profound thrombocytopenia and transient autoimmune hemolytic anemia.

### Heterophile antibody test (Paul-Bunnell reaction)

There is massive B cell activation in acute EBV infection resulting in an outpouring of nonspecific antibodies. Sheep red cell agglutinins (heterophile antibodies) develop frequently by the second week of infectious mononucleosis, but occasionally not for 2 or 3 weeks, so an early negative test should be repeated.

Sheep red cell agglutinins are not specific for infectious mononucleosis and may occur in other conditions. However, by means of absorption tests using guinea pig kidney and ox erythrocytes the specificity of the test may be increased. The following are the salient features:

1. Antibodies present in infectious mononucleosis are not absorbed by guinea pig kidney but are absorbed by ox erythrocytes.
2. Antibodies found in normal serum are not absorbed by ox erythrocytes but they are absorbed by guinea pig kidney.
3. Antibodies found in serum sickness are absorbed by both guinea pig kidney and ox erythrocytes.

Agglutinins to horse erythrocytes may also be present in the serum of a patient suffering from infectious mononucleosis and in many laboratories a test based on the agglutination of horse erythrocytes is in use. This is the basis of the rapid slide test, the 'Monospot' test. This test may sometimes be negative early in the disease and if EBV is suspected should be repeated. The test is unreliable under 5 years of age, owing to false negative results.

### EBV antibody tests

The presence of specific EBV anti-VCA IgM antibody indicates a recent or current infection, whereas the presence of IgG antibodies to the VCA or nuclear antigen (EBNA) merely indicates an infection with EBV some time in the past. Only a small proportion of affected patients show a rise in IgG to VCA, so the IgM test is preferred to show acute infection.

### Nonspecific laboratory tests

In well over half the cases some derangement of liver function tests will be found. Most often there is a mild or moderate rise in the serum alanine aminotransferase (AAT) or glutamic pyruvate transaminase (SGPT) level but the alkaline phosphatase and serum bilirubin levels may also rise. Usually these changes are transient but in cases with clinical evidence of hepatic involvement the derangement in liver function tests is more marked.

On occasion, a false positive Wassermann reaction occurs in infectious mononucleosis. High antistreptolysin 'O' titers may be found, probably due to an anamnestic reaction.

The detection of EBV DNA by PCR or in situ hybridization in saliva or tissue of an immunocompromised child may indicate a lymphoproliferative syndrome.

### Differential diagnosis

Infectious mononucleosis may be diagnosed too readily. Young children with mild fever and lymph node enlargement in the neck are more likely to have a respiratory viral infection.

Cases that present with fever and little else may be confused with influenza, brucellosis or typhoid; those with a sore throat need to be differentiated from streptococcal or other viral tonsillitis, diphtheria, agranulocytosis and leukemia. Glandular enlargement may be mistaken for toxoplasmosis, CMV infection or reticulosis, and the icteric form of the disease has to be distinguished from infectious hepatitis, leptospirosis and, occasionally, from obstructive liver disease.

The skin eruption of glandular fever has produced confusion with measles, rubella, secondary syphilis, Kawasaki disease and drug rashes.

### Treatment

There is no specific treatment. Aciclovir has virtually no in vivo activity against EBV. The disease tends to be mild in children, but simple analgesics may be required to ease pain and gargles to soothe the sore throat. There is increasing evidence that antibiotics can do more harm than good, as toxic skin eruptions appear to follow their use, and ampicillin is especially incriminated in this direction. However, in cases where significant secondary infection is fully substantiated, antibiotics may need to be employed. Corticosteroids can have a dramatic, symptomatic effect but should be reserved for cases where edema of the airway is severe or where life-threatening complications such as thrombocytopenic purpura or severe neurological involvement are encountered. Reduction of immunosuppression or bone marrow transplantation may be of value in the management of EBV lymphoproliferative diseases.<sup>611</sup>

### Prognosis

The prognosis is good and children recover more quickly than adults, though some cases run a protracted course and patients may take months to recover their full health. Death is rare and usually results from rupture of the spleen or severe neurological involvement. Recurrences in the immediate convalescent phase can occur but are usually short-lived.

## VIRAL AND ALLIED INFECTIONS OF THE RESPIRATORY TRACT

Infections of the respiratory tract are frequent and ubiquitous. They are the most common cause of illness in almost any age group and have a predilection for the extremes of life. Agents that are capable of attacking one part or another of the respiratory tract include viruses, rickettsiae, mycoplasmas and fungi.

Respiratory infection frequently results from a combination of different organisms because, once the initial assault has damaged the defensive mechanisms within the air passages, secondary infection is readily superimposed. This often renders it difficult to prove the primary cause. Nevertheless, detailed studies on the etiology of acute respiratory tract infection indicate that up to 85% of such disease may be initiated by a virus.

In the ensuing account a description is given of the various viruses and allied organisms which play a significant role in the production of infective respiratory disease.

### INFLUENZA

Influenza is an acute infectious disease of variable severity with an emphasis on general illness rather than on symptoms arising from the respiratory tract. It tends to occur in pandemic form every few years. In most instances the disease is a benign condition, but it may have a devastating effect in some normal children. Disease is often more severe with an increased mortality in immunosuppressed patients or those with chronic cardiorespiratory disease.

### Etiology

Influenza viruses are RNA viruses of the orthomyxovirus family. There are three antigenic types: A, B and C. Infection by type C is relatively uncommon, results in mild or inapparent illness and does not produce epidemics. Type B virus produces significant illness, followed by reasonably effective immunity. Outbreaks or small epidemics may occur, especially in schoolchildren, but are often of a localized nature. Some variation in antigenicity of type B virus occurs and outbreaks appear sporadically at intervals of 3–6 years.

Most clinical, virological and epidemiological interest is focused upon type A viruses, as these produce the most noteworthy outbreaks or epidemics and, when major new variants emerge, pandemics. Pandemics have usually been identified by titles that reflect the suspected geographical origin, as in 'Asian flu' or 'Hong Kong flu'. The World Health Organization has devised a more definitive classification of influenza viruses which reflects the nature of mutation more precisely.<sup>612</sup> Influenza strains that cross the species barrier pose an increasing pandemic threat as shown by the recently identified avian influenza A strain (H5N1).<sup>613</sup>

Structurally, influenza viruses comprise a central core of ribonucleoprotein with a covering envelope. From this envelope spikes containing hemagglutinins project and between these spikes are mushroom-shaped protrusions composed of neuraminidase.

Each basic type of influenza (A, B or C) has its own distinctive ribonucleoprotein consisting of the S or soluble antigen. Protein antigens on the viral surface are related to hemagglutinins (the H antigens) and to neuraminidases (the N antigens). In the case of type A viruses minor changes may occur year by year, producing what is known as antigenic drift. However, at intervals usually exceeding a decade, major changes take place producing antigenic shift. The virtually new type A virus that emerges as a result of antigenic shift has thus acquired the potential to produce a pandemic.

Strain designation of influenza viruses is, therefore, based on the following points:

1. identification of the S antigen – that is, whether the virus is type A, B or C;
2. the host origin – when isolated initially from man, no specific identification is recorded but, if from an animal source, a suitable suffix is appended;
3. the geographical origin;
4. the strain number and the subtype of the hemagglutinin and neuraminidase identified;
5. the year of isolation.

Without an appreciation of the relatively complex antigenic structure and its variation, an understanding of the epidemiology of influenza is difficult.<sup>614</sup> Furthermore, effective vaccination requires using vaccines whose antigenic components accurately reflect the strain of influenza virus prevalent at the time of use.

### Epidemiology

Man is the principal reservoir of infection and the disease is transmitted by direct contact, through droplet infection and by articles that have been freshly soiled with discharges from the nose or throat of infected persons. Infectivity appears to persist for 4–5 days after the clinical onset of the disease. Occasional cases originate from animals, e.g. pigs or chickens. In view of the high infectivity of influenza and the rapidity of modern travel, an epidemic can soon develop pandemic proportions. Human infection with avian influenza A strain (H5N1) was initially described in Vietnam, but the virus has now been isolated from individuals in most parts of the world.<sup>613</sup> It infects humans in contact with diseased birds and is associated with high mortality rates due to respiratory failure. At the current time, only low levels of human to human transmission of H5N1 have been shown to occur, but an increase in transmission efficiency via this route could result in a major world pandemic.

### Pathogenesis

Influenza infection causes necrosis of ciliated respiratory epithelium and this commences in the nose and spreads downwards to the trachea and bronchi. Edema and leukocyte infiltration follow causing

pharyngitis, tracheitis and bronchitis; in severe cases considerable exudation of blood and edema fluid may occur and enter the alveoli with resultant pneumonia.

Primary respiratory damage from influenza virus may in itself produce a severe illness, but secondary bacterial infection is more often the cause of fatal pneumonia; organisms such as *Staphylococcus aureus* and *Klebsiella pneumoniae* are particularly dangerous in this context.

### Clinical features

The incubation period of influenza is short and ranges from 1 to 3 days. In children over 5 years of age there is a sudden onset of fever, headache and shivering, with pains in the limbs and back. Anorexia, listlessness and malaise may also be experienced and in some instances, particularly in children, nausea and vomiting may be unduly pronounced. Abdominal pain ('gastric flu') can be a prominent symptom. A dry, painful cough, discomfort in the throat, hoarseness and nasal discharge are usual.

The temperature may reach 39–40 °C, but apart from signs of pharyngitis, objective physical findings are few and in uncomplicated cases clinical and radiographic examination of the chest is usually clear. Leukopenia will be found in uncomplicated cases and the ESR becomes moderately elevated.

The illness usually runs a short course and is followed by rapid improvement. Some patients experience a period of mental and physical lethargy in convalescence but seriously complicated cases are rarely seen outside epidemics.

In younger children and infants influenza A typically causes high fever (over 39 °C) and upper respiratory tract infection with coryza, cough, irritability and pharyngitis. Otitis media, laryngotracheitis, bronchitis, bronchiolitis indistinguishable from that due to RSV, and pneumonia may all occur. Vomiting and diarrhea are frequent in infants. Febrile convulsions are frequent, as are fleeting erythematous rashes, which can be morbilliform. Despite these manifestations, a recent large scale epidemiological study in the USA confirmed that a significant burden of influenza disease in infants and young children goes unrecognized.<sup>615</sup> The risk of severe lower respiratory tract involvement is greater in immunocompromised children, and in children with neurological and neuromuscular disease.<sup>616</sup>

In neonates the picture is nonspecific, with apneic episodes, lethargy, poor feeding and impaired circulation. Outbreaks may occur in neonatal units.

### Diagnosis

At epidemic times, a clinical diagnosis of influenza has a high likelihood of being correct, but such a diagnosis in a sporadic case can often be incorrect. Other respiratory viral infections and some quite unconnected diseases may present with a similar clinical picture and a specific diagnosis depends on definitive laboratory tests.

Virological confirmation of influenza can be established by serological studies or by demonstrating the presence of influenza virus. The latter can be isolated from pharyngeal swabs, nasal swabs or throat washing during the acute stage of the illness and can be grown in the amniotic cavity of chick embryos or in tissue cultures. Influenza may be isolated in monkey kidney tissue cultures. During epidemics, immunofluorescence using an antiserum to the epidemic strain to test nasopharyngeal secretions can be used for rapid diagnosis. Complement-fixation, neutralization and hemagglutination-inhibition tests are available for the serological study of antibody responses to infection with influenza. In all these tests it is desirable to show a significant (four-fold or greater) rise in antibody titer during the illness.

### Complications

Viral complications such as myocarditis, polyneuritis, encephalitis and psychosis are rarely seen in childhood cases. Secondary bacterial infection of the respiratory tract is more likely and pneumonia, otitis media and purulent sinusitis may occur. Death can result from severe overwhelming infection by influenza virus itself, though a fatal outcome is

more likely to result from secondary bacterial infection. Acute myositis may be severe, particularly affecting the calves, with a raised serum creatine phosphokinase (CPK). Reye syndrome has sometimes followed influenza infection.

### Treatment

In mild cases this is essentially symptomatic. Bed rest is advisable and pain will be eased by simple analgesics such as paracetamol (acetaminophen). Troublesome cough may respond to codeine or similar preparations. Bacterial complications may require antibiotic treatment, whenever possible guided by appropriate laboratory studies. Amantadine and rimantadine have been successfully used to treat severe infection in immunocompromised children or those with underlying chronic illnesses. The neuraminidase inhibitors are a new class of antiviral agents that have been shown to be effective in the treatment of severe influenza in high risk patients.<sup>617,618</sup> Zanamivir is an inhaled preparation, and oseltamivir is an oral preparation. Their use in childhood disease is still under evaluation.

### Prophylaxis

The extreme infectivity of influenza renders such measures as isolation and quarantine virtually ineffective. There is evidence that killed virus vaccine can significantly reduce the incidence of influenza, although the sudden emergence of a fresh influenza A mutant may render it impossible to produce the specific vaccine in time to influence an outbreak. Annual influenza vaccination should be considered for the child over 6 months with chronic pulmonary, circulatory or neuromuscular disorders, or with chronic renal disease or diabetes mellitus, or with immunosuppression (including HIV infection). Postexposure prophylaxis with amantadine or the neuraminidase inhibitors has been shown to be effective in preventing illness in adults and children.

In the USA, annual influenza vaccination is now recommended for all children aged 6–59 months, using either a trivalent inactivated influenza vaccine or a live attenuated vaccine.<sup>619</sup> Previously unvaccinated children under 9 years should receive two doses the first year.<sup>619</sup> In other countries, including the UK and Australia, annual influenza vaccination is recommended for children at high risk of severe influenza.

## PARAINFLUENZA VIRUS INFECTIONS

The parainfluenza viruses are RNA viruses of the *Paramyxovirus* group. They are more closely related to mumps and Newcastle disease viruses than to influenza.

Four antigenic varieties, called 1, 2, 3 and 4, are recognized, although type 4 has no known role in causing disease in humans. Types 1, 2 and 3 have frequently been isolated from cases of acute laryngotracheobronchitis (croup), bronchitis, bronchiolitis and pneumonia in infants and children, and less often from rhinitis and pharyngitis. They are undoubtedly the commonest cause of acute laryngotracheobronchitis, in which other viruses such as influenza A, RSV and ECHO viruses play a lesser role.

Serological studies indicate that infection, especially with type 3, is common in preschool children. Type 3 infection is endemic and occurs at any time of the year. Type 1 infection tends to occur in summer or autumn outbreaks every second year while type 2 outbreaks are less predictable.

### Laboratory diagnosis

Parainfluenza viruses can be isolated from nasal and pharyngeal swabs. The viruses are relatively labile so these swabs should be placed in virus transport medium and delivered to the laboratory with minimum delay. Antigen detection by immunofluorescence or ELISA is increasingly available. Serological diagnosis is rarely helpful, other than in epidemiological studies, because of heterotypic antibody rises among the three types and related viruses, particularly mumps.

### Treatment

There is no specific treatment available. Symptomatic treatment of laryngotracheobronchitis with steroids or adrenaline (epinephrine) for

severe airways obstruction may be indicated. Ribavirin has been used to suppress infection in immunocompromised hosts.

A live attenuated parainfluenza type 3 vaccine is currently in clinical trial in young infants.<sup>620</sup>

## RESPIRATORY SYNCYTIAL VIRUS INFECTIONS

Respiratory syncytial virus (RSV), first identified in 1956, is now recognized to be amongst the most important agents causing respiratory infection in infants and young children worldwide. RSV is an RNA paramyxovirus. The virus grows well in many tissue cultures. In contrast to members of the myxovirus group, to which it shows some resemblance, RSV has no hemagglutinins so does not cause hemagglutination, but produces a fusion protein which causes *in vitro* and *in vivo* fusion of cells to form syncytia. Only two antigenic strains of RSV have been described.

### Clinical features

RSV has been found in association with several clinical syndromes including mild upper respiratory tract infection, croup, bronchitis, bronchiolitis and pneumonia. Its principal association is with acute bronchiolitis in infants below 1 year of age. Epidemics of RSV infection occur annually in late autumn and winter in temperate climates. Outbreaks are mainly found in urban communities. In tropical climates there is not such a clear-cut annual epidemic. Nosocomial infections can be a major problem in hospitals.

Bronchiolitis is described elsewhere and although infection by influenza viruses, parainfluenza viruses, human metapneumovirus, mycoplasmas, adenoviruses and rhinoviruses may produce a similar picture, few clinical respiratory syndromes have so close an etiological association as bronchiolitis and RSV infection.

Neither maternal nor acquired antibody protects absolutely against RSV, so RSV can infect neonates. Reinfections throughout childhood are common, but successively milder. Preterm infants with symptomatic RSV bronchiolitis appear to have worse lung function at follow-up.<sup>621</sup> High RSV viral load is associated with more severe disease.<sup>622</sup> Toddler-age children may develop bronchitis or pneumonia, school-age children more commonly develop otitis media, while adults get a severe cold with sore throat. Infants with mutations in the Toll-like receptor 4 (TLR4) gene complex involved in the innate immune response to RSV are especially prone to severe disease.<sup>623</sup>

### Laboratory diagnosis

The ideal specimen is a nasopharyngeal aspirate of mucus. Rapid viral diagnosis by immunofluorescence (or ELISA) has greatly aided the management of infants with bronchiolitis. The virus can be isolated successfully in various tissue culture systems, but as it is relatively unstable it is recommended that the specimen should be inoculated directly into the cultures without previous freezing. If the specimen has to be stored for a few hours it should be kept in virus transport medium at 4 °C.

Serology can be used in children over 6 months of age, usually by complement-fixation test on paired sera. Under this age there is often no IgG response.

### Treatment

Treatment is primarily supportive with supplemental oxygen and/or fluids. Nebulized ribavirin may be indicated in proven severe RSV infection in infants at high risk, particularly those with pre-existing cardiopulmonary disease or immune deficiency.<sup>624-626</sup>

### Prevention

Two agents have recently become available for the prevention of RSV in high risk infants (those born prematurely < 35 weeks' gestation, or those with underlying chronic lung disease, cardiac disease or immunosuppression). RSV intravenous immunoglobulin (RSV-IVIG) from pooled donors is administered intravenously, and palivizumab is a mouse monoclonal antibody to the RSV protein that is given intramuscularly. Both are given monthly during the RSV season and have been shown to

significantly reduce the number of cases of hospitalized RSV bronchiolitis in at-risk groups,<sup>627-629</sup> but are expensive. The cost effectiveness of these agents in the UK has been questioned based on local data.<sup>630</sup>

## HUMAN METAPNEUMOVIRUS

Human metapneumovirus (MPV) is an RNA virus that was discovered in 2001 in the respiratory isolates of young children.<sup>631</sup> It has been found to be a cause of respiratory illness in all age groups.<sup>631-634</sup> It is a member of the *Paramyxoviridae* family and has four major genotypes that fall into two antigenic subgroups (A and B). Humans are the only source of infection and transmission is thought to occur through contact with infected secretions. Infection occurs in yearly epidemics, peaking in late winter to spring.<sup>632-634</sup> Co-infection with other viral pathogens is common. Seroprevalence studies suggest that virtually all children have been exposed to MPV by the age of 5.<sup>631</sup>

### Clinical features

The clinical features of MPV are similar to those of RSV.<sup>630,631,633</sup> It causes respiratory illnesses of both upper and lower respiratory tract, including bronchiolitis in infants and croup. Disease in normal hosts is usually mild, although MPV can occasionally cause severe pneumonitis. Preterm infants and children with underlying pulmonary or cardiac disorders or with immunodeficiency are at risk of severe disease from MPV, although RSV is a more common pathogen in this group.<sup>635</sup> Immunocompromised children may have persistent shedding of MPV.<sup>636</sup> Severe disease in children with HIV infection is usually associated with pneumococcal superinfection.<sup>637</sup> Like RSV, recurrent infections occur throughout life.

### Laboratory diagnosis

There are currently no commercially available tests for the diagnosis of MPV. MPV can be isolated by culture of respiratory secretions, and MPV viral nucleic acid can be detected by RT-PCR in reference or research laboratories.<sup>632,634</sup>

### Treatment

Treatment is supportive with supplemental oxygen and attention to hydration as required.

### Prevention

Control of nosocomial MPV infection requires contact precautions, with particular attention to hand washing after contact with infected respiratory secretions.

## ADENOVIRUSES

The first isolation of an adenovirus took place in 1953 from fragmented human adenoids grown in tissue culture, hence the name. Subsequently a number of different strains, chiefly types 1, 2, 5 and 6, were isolated from cultures of tonsils and adenoids. Outbreaks due to these agents have been encountered in children at boarding schools, at summer camps and amongst those attending communal swimming pools. Outbreaks in adults mainly involve military recruits. The nature of the clinical illness produced shows considerable variation and overlap but some relatively specific syndromes are included.

Adenoviruses are DNA viruses. They are relatively stable to changes in temperature and pH. They are widespread in nature and have been isolated from monkeys, pigs, dogs, birds and cattle, as well as from man. They may persist for weeks or even months in the upper respiratory tract.

### Clinical features

Adenovirus infections are principally diseases of childhood, occurring mostly in children under 5 years old. Certain adenovirus types show a pronounced age association. Immunocompromised hosts are at risk of severe disease from adenovirus.<sup>638</sup>

Amongst syndromes recognized to be associated with adenoviral infection are the following:

### **Acute febrile pharyngitis**

This syndrome has a high endemic rate in infants and young children and mainly results from infection by types 1, 2 and 5. It can also occur in epidemic form when type 3 is usually involved.

### **Pharyngoconjunctival fever (PCF)**

Most commonly associated with infection by type 3, and less frequently with types 7A and 14, this syndrome can also follow infection by types 1, 2, 5 and 6. Epidemics occur in children, some associated with swimming pools. Symptoms include sore throat, headache, myalgia, eye discomfort, abdominal pain and back stiffness. Examination often reveals pharyngitis and unilateral or bilateral follicular conjunctivitis.

### **Acute respiratory disease (ARD)**

Uncommon in children, ARD is usually found in military recruits. It is most commonly due to infection by types 4 and 7, less often by types 3 and 14. The main clinical features include pharyngitis, cough, hoarseness and chest pain.

### **Viral pneumonia in infants**

Adenoviruses may cause severe pneumonia, and outbreaks have been reported in hospital nurseries. Types 3, 7 and 21 have caused the most severe, sometimes fatal, cases. Infection may disseminate (see below) or may result in bronchiolitis obliterans, bronchiectasis or unilateral hyperlucent lung. In immunocompetent infants hospitalized with severe adenovirus infection, disease severity correlates with serum LDH and oxygen saturation at admission.<sup>639</sup>

### **Ocular syndromes**

Two specific ocular syndromes are associated with adenovirus infection. The first is called *epidemic keratoconjunctivitis* and is associated with type 8 infection; the second, *follicular conjunctivitis*, usually results from infection by type 3 and may expand into the fuller syndrome of pharyngoconjunctival fever.

### **Disseminated disease**

Adenovirus types 7 and 21 are particularly prone to cause pneumonia and disseminate to involve the liver (hepatitis), heart (myocarditis or pericarditis) and CNS (meningitis or encephalitis). This is more likely in immunocompromised patients.

### **Gastroenteritis**

Noncultivable enteric adenoviruses (types 40 and 41), seen on electron microscopy of feces, have been associated with gastroenteritis.<sup>640</sup>

### **Laboratory diagnosis**

Adenoviruses can be grown in a wide range of tissue cultures. These viruses are relatively stable and can readily be isolated from throat swabs and feces. In respiratory disease, a pharyngeal swab should be sent to the laboratory in virus transport media. Growth may be slow, so cultures should be incubated for at least 3 weeks before being regarded as negative.

Serological evidence of infection is by detecting complement-fixing antibodies to adenoviruses in acute and convalescent serum samples. Antigen detection by immunoassays and detection of viral DNA by PCR in body fluids may aid in diagnosis of adenovirus infection in the immunocompromised.

### **Treatment**

Treatment is largely supportive. The new antiviral agent, cidofovir, has been used with some success in the treatment of severe adenoviral infections in children post bone marrow transplantation.<sup>641</sup>

## **MUMPS (EPIDEMIC PAROTITIS)**

To mump is an old English word meaning to mope. Mumps is an acute infectious disease characterized by nonsuppurative enlargement of the salivary glands, particularly the parotids. It results from infection by mumps virus, one of the myxoviruses, and is associated with an unusually

diverse range of complications. Infection may be inapparent in as many as 30% of cases and the illness may present with a complication and no history of preceding salivary gland involvement.

### **Epidemiology and etiology**

Mumps is an endemic disease of urban communities which occasionally occurs in epidemic proportions, especially in certain closed communities. Spread is by droplet infection or from recently contaminated articles and close contact is required. The relatively high incidence in adults bears witness to the comparatively low infectivity of the disease, though when mumps is introduced into a naive community, a serious and widespread outbreak may follow. There have been recent outbreaks of mumps in young adults in the UK.<sup>642</sup>

The responsible agent is an RNA virus. Man appears to be the only reservoir and the portal of entry is through the mouth or nose. Infectivity may extend from several days before the illness to several days after the first sign of salivary gland involvement. Virus has been isolated from the blood in the prodromal stage and from the urine up to 14 days after the commencement of clinical illness. It is not clear whether spread to the salivary glands occurs locally or through the bloodstream.

### **Clinical features**

The main incidence occurs between 5 and 15 years of age; mumps is relatively uncommon in younger children and in adults over 30 years.

The incubation period is between 14 and 21 days and the illness may commence with malaise, fever, headache and anorexia; these prodromal symptoms may be absent. Salivary gland involvement commences 1–2 days later and the parotid glands are the most frequently affected. Pain develops around the ear and a swelling appears which extends forwards from the lobe of the ear, downwards over the angle of the jaw and backwards behind the pinna, which is usually pushed outwards. The swelling may be so trivial as to escape casual inspection or be very marked and exquisitely tender. Often only one parotid is involved initially, followed, in 75% of cases, by swelling of the other parotid 1–5 days later. Less often simultaneous and synchronous swelling of both parotids occurs.

Submandibular salivary gland involvement can easily be overlooked as the soft tissues under the jaw readily absorb such swelling, unless it is particularly marked, and it is often the concomitant swelling of the parotids that directs attention to it. Sublingual involvement is much less common but is extremely painful and can be seen readily beneath the upturned tongue.

In addition to salivary gland involvement, the orifice of Stensen's duct may be swollen and the mouth rather dry. Fever is present in the majority of cases, may reach 40 °C and persist for up to a week; in fact, cases without salivary gland involvement may present as examples of unexplained fever and recover without the true diagnosis being appreciated, though in others the later development of a typical pattern of complications may indicate mumps to be the cause.

There may be some degree of leukopenia in mumps though certain complications, such as meningitis and pancreatitis, may provoke a leukocytosis.

### **Complications**

Complications are common and varied.

#### **CNS**

Aseptic meningitis is the commonest complication and may present before, coincidentally with, or after, the illness. The CSF will show a lymphocytic pleocytosis and the count may exceed 1000 cells/μl. The protein content may be moderately raised and the glucose level is usually normal. However, the latter is occasionally decreased in mumps meningitis and where no salivary gland enlargement occurs to indicate the diagnosis, confusion with tuberculous meningitis has occurred. Other less common complications include postinfectious encephalitis, myelitis and polyradiculitis. Although usually unilateral, bilateral nerve deafness, often complete, can also occur, as may transient facial paralysis. The virus

is easily isolated from the CSF of patients with mumps meningitis, which is generally benign. The postinfectious encephalitis is, however, more severe; although complete recovery is usual, neurological sequelae and even death may occur. Virus can be grown from the CSF, but an immune-mediated mechanism is more likely to contribute to pathogenesis.

### Orchitis

Orchitis may occur in 20% of postpubertal males and in younger children can occasionally occur in an undescended testicle. The involvement is usually unilateral but even after severe orchitis, sterility is rare, and males with orchitis should be firmly reassured of the good prognosis.

### Pancreatitis

A significant degree of pancreatitis is rare and this complication is over-diagnosed. Salivary gland enlargement by itself raises the serum amylase level but when the pancreas is significantly involved intense pain will occur with rigidity of the abdominal wall and there is often a marked leukocytosis.

### Other complications

These include oophoritis, mastitis, bartholinitis, myocarditis, hepatitis, thyroiditis and thrombocytopenic purpura. An occasional case of diabetes mellitus has also been reported following mumps.

### Laboratory diagnosis

Viral confirmation of mumps depends on isolation of the virus or the demonstration of a significant rise in antibody titer during the illness.

Mumps virus can be cultured from saliva swabs and urine during the acute illness and from the CSF in cases complicated by meningitis.

Serological tests are readily available to demonstrate a significant rise in antibody titer during the illness and the complement-fixation test is most commonly employed. In this test, two specific antigens, soluble (S) and viral (V), are often used. In general, antibody to S antigen rises earlier in the illness than antibody to V antigen, but whereas S antibody may only persist for a few months, the V antibody is present for a very long period. Hemagglutination-inhibition and virus neutralization tests are also of help where available.

### Differential diagnosis

In children, the differential diagnosis is more limited than in adults as in the latter one may encounter more diseases that involve the salivary glands. Conditions that cause lymph node enlargement produce most confusion but careful clinical examination should resolve the difficulty. Pyogenic submandibular abscesses and glandular fever can prove more perplexing and in these instances the blood picture and serum amylase estimations can be helpful. Suppurative parotitis may be considered where there is overlying inflammation and where pus can be expressed from the appropriate salivary duct. Recurrent parotitis is quite common in children. It is not due to repeated attacks of mumps. Sometimes an underlying allergic disorder, sialectasis or duct calculi may be found. Other conditions which may require exclusion are tumors, Mikulicz syndrome, uveoparotid fever in sarcoidosis, HIV infection, tuberculosis and dental conditions.

### Treatment

There is no specific treatment. Pain may be relieved by simple analgesics and the application of heat to the glands can prove soothing. The mouth should be kept clean and a fluid diet is needed until swelling subsides. Neurological complications are managed along customary lines though the diagnostic lumbar puncture in mumps meningitis often produces dramatic relief of headache. In orchitis the testes should be supported and ice bags may ease the discomfort; there is no evidence that corticosteroid drugs, stilbestrol or incision of the tunica albuginea significantly alter the course of this complication.

### Prognosis

This is generally good and a fatal outcome exceedingly rare, although permanent brain damage and deafness have been described. Sterility

is most unlikely. One attack of mumps appears to provide life-long immunity.

### Prevention

Injections of human anti-mumps immunoglobulin have been used prophylactically and appear beneficial if given sufficiently early in the incubation period. Live vaccines are safe and produce a good antibody response with long immunity though the duration has not been fully substantiated. They can be used to immunize contacts, and are incorporated into the MMR vaccine for routine immunization in many countries.

## COXSACKIE AND ECHO VIRUS INFECTIONS

Respiratory illness in association with these enteroviruses is usually mild.

Certain coxsackie viruses produce specific respiratory syndromes. Some group A serotypes can cause herpangina and certain group B viruses are the agents responsible for causing pleurodynia (Bornholm disease). Agents from both groups of coxsackie viruses have been found in association with mild febrile respiratory disease and one strain, coxsackie A21 (Coe virus), has been recovered with particular frequency from outbreaks in young servicemen.

ECHO viruses are not usually regarded as respiratory pathogens, but they have been found in the throat or feces during upper respiratory disease. Amongst serotypes isolated in these circumstances are ECHO viruses types 6, 11, 19 and 20.

The laboratory diagnosis of infections due to coxsackie and ECHO viruses is described in the section specifically devoted to these agents.

## RHINOVIRUS INFECTIONS

Rhinoviruses are the main cause of the common cold. There are many serologically distinct types. They belong to the large group of picornaviruses, meaning small RNA viruses, but unlike coxsackie and ECHO viruses they are acid labile at pH 3.

The common cold is probably the most ubiquitous infection in man and the illness tends to be more severe in children than in adults, with an acute catarrhal inflammation involving the nose, nasopharynx and accessory sinuses. The onset is usually abrupt and is accompanied by a copious watery discharge, which may later turn mucopurulent even in the absence of bacterial superinfection. Little or no fever occurs and constitutional symptoms are mild.

Apart from their ability to produce the common cold, rhinoviruses have been found in association with acute wheezing episodes in children and with pneumonia.<sup>643</sup>

### Laboratory diagnosis

Nasopharyngeal aspirates in virus transport medium, nose swab or throat swab collected during the acute stage of the respiratory illness should be sent to the laboratory for the isolation of rhinoviruses. Serology is generally unhelpful. ELISA and PCR for rhinovirus have been developed but are not widely available.

## CORONAVIRUSES AND SARS

Human coronaviruses (HCV) are probably almost as frequent a cause of colds and acute upper respiratory tract infections as rhinovirus infections.<sup>644</sup> Coronaviruses have also been associated with wheeze and pneumonia.<sup>645</sup> The exact frequency of HCV infections has been difficult to ascertain because coronaviruses are difficult to grow and can often only be isolated in tracheal organ cultures. The diagnosis can be made by ELISA on respiratory secretions or serologically by detecting antibody to one of the two main serotypes, 229E and OC-43. PCR is not widely available.

During 2002–2003, there was an acute outbreak of a severe atypical pneumonia, originally in China and Hong Kong, that did not respond

to routine antimicrobial therapies.<sup>646,647</sup> The disease was labeled severe acute respiratory distress syndrome (or SARS). Commonly known viruses and bacteria were not isolated and eventually a novel coronavirus, SARS-CoV, was confirmed to be the causal agent.<sup>648,649</sup> The syndrome was characterized by fever of 38 °C or more, respiratory symptoms (cough, dyspnea), myalgia and marked infiltrates on chest X-ray which were often out of proportion to the degree of symptoms. Most patients did not experience upper respiratory tract symptoms. Gastrointestinal symptoms were present in 10% of patients. Severe disease was associated with deranged liver function enzymes, thrombocytopenia and leukopenia, and respiratory failure, and was associated with high mortality. Infected children < 12 years of age experienced only mild disease and rarely progressed to respiratory failure or death.<sup>648,649</sup>

Transmission of SARS-CoV is by contact with respiratory secretions, although urine, stool and blood can also be a source of infection. Infected individuals are most contagious during the second week of the illness. In the 2003 outbreak, high rates of human to human transmission were reported in exposed health care workers.<sup>648,649</sup> Routine diagnostic tests are not available for SARS-CoV, and the diagnosis is usually made by the combination of known exposure, clinical features and failure to isolate other pathogens. The virus is difficult to isolate in cell culture. Research laboratories have confirmed the infection by molecular techniques, serology or by immuno-electron microscopy. Although severe SARS has been treated with steroids, ribavirin and interferon alfa, there is no antiviral agent with proven efficacy against this virus.<sup>648,649</sup>

## REOVIRUS INFECTIONS

In 1954, a new group of respiratory-entero or reovirus agents was recognized. It had originally been thought to belong to the ECHO virus group. Since then three distinct types (1, 2 and 3) have been serologically differentiated though they share a common complement-fixing antigen.

Following these preliminary investigations reoviruses have been isolated from many different animal hosts in widely separated areas. These viruses have also been recovered from rectal and throat swabs taken from children suffering from mild respiratory disease, diarrhea, and occasionally fatal pneumonia.

A recent seroprevalence study in the USA suggests that reovirus infections are common during early childhood.<sup>650</sup> However, the exact role of reoviruses in producing human disease is largely undetermined. The family Reoviridae also includes the rotaviruses, which are associated with gastroenteritis.

### Laboratory diagnosis

Reoviruses can be isolated from pharyngeal swabs and nasal secretions, but are more commonly recovered from feces.

Acute and convalescent samples of serum are required for hemagglutination-inhibiting antibody titer estimations; a four-fold, or greater, rise in titer during the illness is evidence of infection with a reovirus.

Rotaviruses are difficult to culture and diagnosis depends on electron microscopic examination or ELISA tests on feces.

## CHLAMYDOPHILA PSITTACI (PSITTACOSIS)

Psittacosis is a zoonosis contracted from birds or objects they have contaminated. It was originally considered that infection could only result from birds of the psittacine group (psittacosis) but it is now appreciated that infection may arise from many other birds, both wild and domesticated (ornithosis), and animals such as sheep and goats.

*Chlamydia* (formerly *Chlamydia*) *psittaci*, the causative organism, is antigenically and genetically distinct from the genus *Chlamydia* in which it was previously grouped.<sup>651</sup> This obligate intracellular organism appears to occupy an intermediate position between viruses and rickettsiae and shows sensitivity only to certain antibiotics.

### Clinical features

The presentation is usually with high fever, chills, headache, myalgia, chest pain, anorexia and fatigue. A dry cough may become productive

and fine crackles may be heard. The pulse may be relatively slow. Contact with a sick bird is suggestive, but there may be no history of bird or animal contact. Chest radiography may show perihilar infiltrates, atelectasis or even consolidation. Children and adolescents seem less susceptible to psittacosis than adults. However, this may merely reflect the fact that less specific illness is produced in the young and the diagnosis may therefore be overlooked.

### Laboratory diagnosis

A clinical diagnosis of psittacosis can be confirmed by serological tests. Treatment can suppress antibody responses. The estimation of complement-fixing antibodies in acute and convalescent samples of serum is a reliable and popular test which avoids the hazards involved in the isolation of a highly infectious agent but does not distinguish between other species of *Chlamydia* or *Chlamydia*. The acute serum sample should be collected as early in the illness as possible and a convalescent sample taken about 2 weeks after the onset of the illness. It is often worthwhile examining a third sample of serum obtained after a further 2 weeks. A four-fold, or greater, rise in antibody titer during the illness is indicative of infection with a member of the psittacosis-lymphogranuloma venereum group of agents.

The psittacosis agent can be isolated from blood in the early stages of the illness and later from pleural fluid and infected tissues by reference laboratories where appropriate controls are enforced to prevent infection in personnel.

Sensitive immunoassays for *C. psittaci* are available in some reference laboratories.<sup>652</sup>

### Prognosis

Spontaneous recovery is to be expected, but where the diagnosis is confirmed during the clinical illness, tetracycline (except in children less than 8 years old) or erythromycin may reduce symptoms and hasten convalescence.

## CHLAMYDOPHILA PNEUMONIAE

*C. pneumoniae* is closely related to *C. psittaci*, and cross-reacts with it in complement-fixation serological tests. Infection can be subclinical or result in mild to moderate respiratory illnesses. The prodrome may include a sore throat, and there is often a protracted cough persisting up to 6 weeks with a biphasic course.<sup>653</sup> Serological surveys suggest it is a not uncommon cause of pneumonia in children, particularly in resource limited countries. Treatment is as for psittacosis.

## CHLAMYDIA TRACHOMATIS

*C. trachomatis*, acquired by passage through an infected birth canal, can cause a pneumonitis usually at 3–11 weeks of age. There may be a history of maternal vaginal discharge and the infant may have had conjunctivitis. The infant is afebrile with a characteristic staccato cough. There are often crackles and wheezes on auscultation. About half the infants have otitis media with a pearly white tympanic membrane. The radiographic appearance is of diffuse pulmonary infiltrates with peribronchial thickening and focal consolidation. Definitive diagnosis is by culturing *C. trachomatis* or detecting antigen in a nasopharyngeal aspirate or conjunctival swab, or by detecting specific IgM by immunofluorescence. PCR and other nucleic amplification techniques can be used to detect *C. trachomatis* DNA in genital swabs or urine from the mother. They can also be used on conjunctival swabs from the infant, but the test has not proved sensitive when performed on infants' pharyngeal specimens. Presumptive evidence can be obtained by demonstrating characteristic inclusions on conjunctival scrapings if there is active conjunctivitis. Treatment of conjunctivitis is with erythromycin 40 mg/kg/d 6-hourly for 14 days. Parents should be alerted of the signs of infantile hypertrophic pyloric stenosis, which is associated with erythromycin use in infants < 6 weeks of age, although the link has not been proven to be causal.<sup>653</sup>

Chlamydia pneumoniae can be treated with erythromycin as before or with azithromycin 20 mg/kg orally once daily for 3 days. The parents should also be treated.

### MYCOPLASMA PNEUMONIAE

*Mycoplasma pneumoniae* is a common cause of atypical pneumonia in childhood but can also cause a variety of clinical syndromes. It is not a virus but a pleuropneumonia-like organism (PPLO) that lacks a cell wall and belongs to the distinctive genus of mycoplasmas.

#### Clinical features

*M. pneumoniae* may give rise to inapparent infection, mild upper respiratory tract infection, bronchitis, bronchiolitis, bronchopneumonia and bullous myringitis both in adults and children. Epidemics occur every 3–4 years. *M. pneumoniae* may have an etiological role in some cases of Stevens–Johnson syndrome and can also cause myocarditis, pericarditis, arthritis and encephalitis. When it causes pneumonia, the radiological appearance may be of bilateral, diffuse reticular infiltrates or of consolidation, including lobar consolidation. Small pleural effusions can occur.

#### Laboratory diagnosis

Isolation of *M. pneumoniae* from sputum, throat washings or pharyngeal swabs is possible, but the agent grows slowly.

For serological studies, acute and convalescent samples of serum should be collected. Various serological tests are available, but the complement-fixation test appears popular and reliable. A single high titer of IgG antibodies to *M. pneumoniae* on an acute serum sample may be helpful, since there is often a fairly long history of illness. Detection of *M. pneumoniae* IgM by immunofluorescence does not distinguish an acute infection from one in the recent past, as the antibody may persist for many months.

Cold agglutinins are present in the serum in many cases and may be useful in acute management, although their detection is not specific for *Mycoplasma* infection.

#### Treatment

Mild respiratory illnesses caused by *Mycoplasma* are usually self limiting and do not require treatment. Pneumonia caused by *M. pneumoniae*, where a diagnosis is made during the active stage of illness, can be treated with tetracycline (25–50 mg/kg/day) or doxycycline (2.5 mg/kg up to 100 mg twice daily) in children over 8 years old, or with erythromycin (30–50 mg/kg/day) or with one of the newer macrolides such as clarithromycin or azithromycin in younger children. There is no evidence that antimicrobial treatment alters the course of nonrespiratory forms of *Mycoplasma* disease.

### VIRAL INFECTIONS OF THE CNS (INCLUDING MENINGITIS, ENCEPHALITIS, MYELITIS AND POLYNEURITIS)

See Chapter 22 (Infectious and inflammatory disorders of the CNS).

#### LYMPHOCYTIC CHORIOMENINGITIS

Lymphocytic choriomeningitis (LCM) virus was first recognized in 1934, and is classified as a member of the Arenavirus group. It occurs in mice.

Sporadic cases and small outbreaks of LCM aseptic meningitis in man have been reported in Europe and the USA, in circumscribed areas where infected mouse colonies have been shown to exist.<sup>654</sup> Although originally suspected to be a common cause of aseptic meningitis, it is now known to have a very small role except in these endemic areas.

#### Clinical features

The incubation period of LCM lies between 7 and 14 days. Any age group may contract the disease, if in contact with the relevant infected

mouse colonies. The clinical picture and the abnormalities in the CSF are identical with those found in other types of viral meningitis and etiological diagnosis can only be made by laboratory studies. LCM can also cause mild respiratory illness and occasionally pneumonia. Orchitis, myopericarditis, arthritis or alopecia may rarely occur. The prognosis is usually excellent, although an occasional fatality has been reported in infants. No specific treatment is indicated. Control of infected mouse colonies should be undertaken by expert rodent exterminators.

#### Laboratory diagnosis

LCM virus can be isolated from blood in the initial febrile phase of the illness, and from CSF after the onset of meningitis. The virus can be propagated in young mice and in various tissue cultures.

Complement-fixing and neutralizing antibodies appear in the patient's serum following infection and a serological diagnosis can be made by demonstrating a significant rise in antibody titer during the illness. The antibodies tend to be produced rather late in the illness, so the convalescent serum sample for complement-fixing antibodies should be collected about the third week of the illness and that for neutralizing antibodies about 6 weeks after the onset of the disease.

### RABIES (HYDROPHOBIA)

Rabies, the most feared of all zoonoses, has been a recognized disease of man since early times.<sup>655</sup> Spread to man may occur from a wide variety of warm-blooded animals which demonstrate variable susceptibility. Although this susceptibility is extremely high in such animals as foxes, jackals and wolves, it is only moderate in others including the dog. However, as man has a closer association with domestic animals, such as the dog, they provide a greater risk to him. In any particular geographical area, enzootic or epizootic infection may predominate in only one or two species of wild animal. In Central and South America the dominant animal is the vampire bat, in Russia the wolf, in North America the bat and skunk, and in Europe the fox.

Certain areas of the world are currently free of rabies including New Zealand, certain Pacific islands, parts of Scandinavia and the UK. In an attempt to retain this position, the movement of animals is governed by strict regulations including compulsory quarantine of animals, but such measures can be severely stretched. Enzootic rabies was eradicated from the UK in 1922, but fears exist that the current epizootic form amongst foxes in Europe, which has spread rapidly westwards over recent years, may result in the reintroduction of rabies.

Infection can follow the licking of abraded skin or mucosa by an infected animal as well as by a bite. Airborne infection from bats to man can also occur in caves where they are roosting. In most instances suspicion will arise that the animal concerned is rabid, especially where the furious form of the disease occurs. Should the less dramatic, dumb form occur, however, the true nature of the illness is not so readily suspected.

#### Clinical features

The incubation period may be as short as 10 days or as long as 7 years, but is usually between 1 and 3 months. Wounds on the hands, forearm and neck are especially dangerous and in them, or where there is extensive biting at any site, the incubation period may be shortened. Age may also be a factor, and cases in young children tend to have a shorter incubation period.

The onset of clinical illness is heralded by a prodromal period of 2–7 days. Indefinite sensory changes may be experienced at the site of the bite, together with such nonspecific features as slight fever, headache, malaise, nausea and sore throat. Paresis and paralysis then develop and the muscles of deglutition go into spasm at any attempt to swallow (hence the term hydrophobia). Increasing depression and anxiety become apparent and the patient may become very withdrawn.

The disease may now enter a stage of excitement (furious rabies) with alternating manic activity and calm. The patient will remain lucid but fearful and the spasms in the throat become more violent. Cranial nerve palsies may develop and generalized convulsions become

frequent. Death follows in virtually every case, from either cardiac or respiratory arrest. Less often the picture is not so florid and a progressive ascending paralysis occurs, giving rise to the so-called 'dumb' form of the disease.

### Clinical diagnosis

A classical case, following a significant bite, provides a clearly recognizable clinical picture. Otherwise, forms of viral encephalitis, bulbar poliomyelitis, hysteria and tetanus may produce similar features and cause diagnostic confusion. Encephalitis can occur following antirabies vaccination with the old vaccines and produce a similar picture to that of rabies itself, but this has not been recorded following the human diploid cell vaccine.

### Laboratory diagnosis

Rabies virus is probably not a single antigenic species and four rabies-related viruses are recognized. These agents have a marked predilection for nervous tissue but multiply in other organs such as the salivary glands. Within the nervous system the main pathological process is an encephalomyelitis leading to the development of inclusion bodies, particularly within the hippocampus. These inclusions are known as Negri bodies.

During life, the laboratory diagnosis of rabies depends on testing such specimens as saliva, CSF and conjunctival secretions by animal inoculation and immunofluorescent techniques. Viral antigens may be detected in skin biopsies. The rapidly fatal outcome, and the confusion which serum or vaccine can introduce, may render serological tests unhelpful.

If the suspected animal is available, it should be sacrificed and the brain examined for rabies virus antigens by hybridization techniques.

After death, specimens of brain tissue should be inoculated intracerebrally into mice. The specimens should also be subjected to rabies immunofluorescent tests and examined for Negri bodies. These tests should yield results within 1–2 days. However, if they are inconclusive, the results of mouse inoculation must be awaited, and it may take up to 3 weeks to declare this test negative.

### Treatment

The treatment of clinical rabies is largely symptomatic, but intensive supportive therapy including artificial ventilation has been employed and at least two cases of proven rabies have survived following such measures. Appropriate steps must be taken to avoid possible spread to the attendants and to the immediate environment.

### Postexposure prophylaxis

**Local treatment of the wound.** This can prove highly beneficial and should not be overlooked or delayed. Ideally wounds should be thoroughly cleansed using a 20% soap solution and after washing any residual soap away with water, a 0.1% quaternary ammonium compound such as cetrimide should be applied. Alternatives include 40–70% alcohol or tincture and aqueous solutions of iodine. Should none of these agents be immediately available, extensive cleansing with clean water should be used as early as possible and the chemical agents employed when practicable. Primary suturing of the wounds should be avoided and human rabies immunoglobulin (HRIG) should be infiltrated into the tissue beneath the wound. If there is any suspicion of exposure to tetanus, tetanus prophylaxis should be instituted.

**Special systemic treatment.** The aim of prophylaxis by vaccination is to induce a rapid antibody response which may prevent clinical disease developing. The human diploid vaccines are safe and highly effective. The site and frequency of injections for postexposure prophylaxis will depend on the vaccine used. If the human diploid cell vaccine is used, vaccination should commence as soon as possible after the incident and injections should be given by deep subcutaneous or intramuscular injection on days 0, 3, 7, 14 and 28. As antibodies do not develop for some days, immunoprophylaxis with HRIG should be given intramuscularly as well as infiltrating the wound<sup>656</sup> of those not previously immunized,

ideally within 24 hours. Treatment may be discontinued if the suspect dog or cat remains healthy after observation for 5 days. Other animals may require longer observation.

### Pre-exposure prophylaxis

Prophylaxis by the human diploid cell rabies vaccine may be used for those at high risk of contracting rabies, e.g. laboratory staff or veterinary staff in endemic areas. Immunization is not routinely recommended for those visiting endemic areas.

## NEURODEGENERATIVE VIRUS DISEASES

### Subacute sclerosing panencephalitis (SSPE)

See Chapter 22 (Infectious and inflammatory disorders of the CNS).

### Rubella panencephalitis

See Chapter 22 (Infectious and inflammatory disorders of the CNS).

### Progressive multifocal leukoencephalopathy

This disease is a demyelinating disease caused by infection of astrocytes and oligodendrocytes with one of two papovaviruses, JC virus or simian virus 40 (SV40). The more common of the two to cause disease, JC, is named after the initials of the first affected patient, a 38-year-old man with Hodgkin disease who developed progressive multifocal leukoencephalopathy.

All cases have been in patients who are immunosuppressed, e.g. post renal transplant, have a malignant lymphoproliferative disorder or have a chronic disease such as tuberculosis or sarcoidosis. All areas of the brain and spinal cord may be affected. The usual presentation is early dementia with confusion, impaired cerebation and labile affect. Focal weakness often progresses to hemiparesis and later to bilateral long tract signs. Blindness, aphasia and ataxia are usual, with death occurring in less than 6 months. Detection of JC viral nucleic acid in the CSF by PCR analysis may be helpful in making the diagnosis of progressive multifocal leukoencephalopathy, but the sensitivity of the assay varies widely between laboratories.

## PRION DISEASES: TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES

The transmissible spongiform encephalopathies (TSE) of man are a rare, neurodegenerative, fatal group of disorders in which there is progressive degeneration of neurones with demyelination and gliosis of gray matter, causing a spongiform appearance of the brain, and the accumulation of a rare protein or prion (proteinaceous infectious agent). Their existence was first postulated by Pruisner in his analysis of the pathogenesis of scrapie in sheep.<sup>657</sup> Prions are thought to cause neuronal dysfunction and pathology when an alpha helical protease-sensitive form of the prion converts to a protease-resistant protein form associated with a structural predominance of beta sheet. Human TSE disorders include Creutzfeldt–Jakob disease (CJD), variant-Creutzfeldt–Jakob disease (v-CJD), Gerstmann–Straussler–Scheinker disease, kuru and fatal familial insomnia.<sup>658</sup> They closely resemble two animal diseases, scrapie and transmissible mink encephalopathy.

Kuru was the first TSE to be identified over 40 years ago. It was initially thought to be caused by a slow virus. In kuru, the cerebellum is most affected, and the disease is characterized by a progressive ataxia with a shivering tremor (the word 'kuru' means shivering). The incubation period is up to 20 years. It was acquired by the women and children of the Fore tribe in New Guinea who ate the brains of dead kinsfolk.

CJD is a progressive dementia with varying neurological features. Myoclonus, ataxic tremor, spasticity and parkinsonian features have all been described. CJD is sometimes familial. Cases have occurred in children who received human growth hormone from human pituitary extracts unwittingly infected with the agent and through brain and eye surgery.

The TSE of most relevance to pediatricians is v-CJD. It was first identified in the UK in 1996,<sup>659</sup> and there is evidence to suggest it is linked to exposure to tissues from cattle infected with bovine spongiform encephalopathy (BSE),<sup>660,661</sup> although the route of infection and indeed much about the natural history of this disease remains unclear despite analysis of the dietary history of people with v-CJD.<sup>662</sup> There appears to be a genetic component to the disease, as all patients identified to date are homozygous for methionine at codon 129 of the 'PRNP' gene.<sup>658</sup> v-CJD is distinguished from CJD by a younger age at onset and some distinguishing clinical features such as a psychiatric presentation, altered pain sensation and the absence of the periodic electroencephalographic complexes seen in CJD. Neurological signs such as ataxia and myoclonus occur later in the illness than in CJD. Amyloid plaques and bilateral, increased thalamic densities may be seen on MRI.

## Treatment

No specific treatment for prion diseases is available. Supportive therapy is indicated for the sequelae of the neurodegeneration.

## INFECTIONS DUE TO ENTEROVIRUSES

### Poliomyelitis (infantile paralysis, acute anterior poliomyelitis)

Poliomyelitis has been a disease of man for many centuries, but has become more virulent since the late nineteenth century.

In the great majority of infected people, poliomyelitis is a harmless subclinical event; nevertheless, severe epidemics can arise with remarkable rapidity and the mortality and morbidity that result demonstrate that the fear in which the disease is held is well founded.

### Epidemiology

Man appears to be the main reservoir of polioviruses in nature, although the great apes can also develop poliomyelitis. In temperate climates, epidemics occur in summer months. The large epidemics of the early 1950s were associated with a higher attack rate and greater severity in older children and young adults in countries with a high standard of living. A possible explanation was that improved hygiene standards led to a diminished rate of subclinical infection in infancy. In countries where vaccination rates are low, poliomyelitis is still primarily a disease of infants and young children.

The Expanded Program of Immunization of the World Health Organization, having as one of its goals global eradication of polio, has led to a steady decline in the world incidence of poliomyelitis since 1973, and a 95% decline in cases worldwide.<sup>663</sup> Intense wild-type poliovirus activity is now limited to the Indian subcontinent and sub-Saharan Africa.<sup>663</sup> In the rest of the world there are rare cases of vaccine-associated paralytic poliomyelitis attributable to the oral poliovirus vaccine.

### Etiology

There are three strains, polioviruses types 1, 2 and 3, which show little antigenic overlap. They are particularly small RNA viruses. Poliovirus type 1 has been associated with most of the major epidemics and shows the greatest propensity to cause paralytic forms of the disease, whereas type 2 causes sporadic cases or small outbreaks with a low incidence of paralysis; type 3 occupies an intermediate position. Clinical severity is increased by age and pregnancy. Excessive muscular activity in a recently infected person makes a paralytic form of the disease more probable as do intramuscular injections into the limbs and other minor, traumatic procedures. Recent tonsillectomy predisposes to bulbar poliomyelitis and corticosteroid drugs can have an adverse effect. Antibody is clearly important as there is a higher incidence in patients with antibody deficiency.

The disease is spread by direct contact with infected persons through pharyngeal secretions and feces. Infectivity is probably maximal early, and oral-oral spread may be more common than fecal-oral spread.

Rarely paralytic poliomyelitis may result from oral vaccine strains which revert to virulence.

### Pathogenesis and pathology

Polioviruses enter the body via the oral route and multiply in the tonsillopharyngeal tissues and intestinal wall. The virus passes to regional lymph nodes. Infectivity of the pharyngeal secretions disappears rapidly, but there is continued excretion into the bowel and polioviruses can be isolated from the feces for weeks and sometimes months.

The viruses probably pass to the bloodstream from the infected lymph nodes and can be isolated from the blood on occasion. The mode of passage thereafter to the nervous system is not fully understood.

In man, the pathological lesions in the CNS are mainly found in the anterior horns of the spinal cord but the posterior horns and intermediate columns may be involved. The essential lesion is neuronal damage, and though some neurones will die, others may recover. Meningitis occurs, and in some cases there is an extensive encephalitis involving motor cells in the medulla and pons, the vestibular nuclei and the motor and premotor areas of the cerebral cortex. Sometimes the lesions are concentrated in the medulla with little damage at lower levels in the cord.

### Clinical features

Poliomyelitis is highly infectious and has an incubation period of 1–3 weeks. Most people infected will have an inapparent illness, which can only be demonstrated by retrospective serological surveys or by examination of contacts in the course of an actual epidemic. Paralytic disease virtually only occurs in unimmunized children or adults, as the virus still circulates in the community.

**The minor illness.** People infected by polioviruses may respond with a mild, insignificant illness whose features may include fever, anorexia, headache, lassitude and gastroenteritic symptoms. The title of 'abortive poliomyelitis' was sometimes used to describe this condition, now more commonly referred to as the minor illness.

**The major illness (nonparalytic or preparalytic poliomyelitis).** The major illness may immediately follow the minor or there may be a short gap of apparent recovery. Occasionally the minor illness does not occur.

In the preparalytic stage of the major illness, the symptoms simulate those of aseptic meningitis with neck stiffness and a positive Kernig sign. The patient has headache, vomiting, malaise, fever, and may develop pain and stiffness in the neck and back. Patients may also complain of an aching pain and spasm in the limbs.

Lumbar puncture normally shows a mild CSF pleocytosis (either polymorphonuclear or lymphocytic) and slight to moderate elevation of the protein content.

A variable percentage of cases presenting with this picture will gradually improve over the ensuing 7–10 days and thereafter make an uninterrupted recovery (nonparalytic poliomyelitis). Others, unfortunately, proceed to paralysis, starting some 2–3 days later. Occasionally, paralysis comes on earlier or the preparalytic stage is absent.

**Paralytic poliomyelitis. Spinal paralysis.** The cervical and lumbar segments of the cord are most frequently involved and patchy, asymmetric paralysis in the limbs results. This may be trivial and can be confined to part of one muscle group when it is easily overlooked. Unilateral involvement of the dorsiflexors of the feet, of the quadriceps or of the deltoids is a common finding. The paralysis is of lower motor neurone type.

**Spinal respiratory paralysis.** This form is usually associated with rapid, severe limb paralysis, and neuronal damage may then extend through the central part of the cord. Paralysis of the abdominal muscles may show itself by a weak cough. Lower intercostal involvement may be symptomless to the patient at rest and only evident to the examiner. Eventually such signs as tachypnea, tachycardia, cyanosis, a rising blood pressure and mental confusion will become apparent. In some instances, the signs of increasing ventilatory failure are difficult to distinguish from those of bulbar involvement or encephalitis, which can be present simultaneously.

*Bulbar poliomyelitis.* This form may be seen with unusual frequency in some epidemics and can be associated with recent tonsillectomy. Difficulty in swallowing is the cardinal sign and the subject is unable to clear mucus and saliva from the throat. There is a reluctance on the part of the patient to breathe deeply, in case secretions become aspirated into the lung. Such symptoms arise from pharyngeal involvement and further spread may cause weakness of the flexors of the neck, facial paralysis, external ocular palsies and, occasionally, true laryngeal paralysis. Extension to the respiratory center, with totally irregular breathing and periods of apnea, has a grave prognosis and involvement of the circulatory center will result in circulatory collapse and an irregular, rapid pulse. Involvement of these vital centers is usually fatal.

**Vaccine associated paralytic poliomyelitis (VAPP).** The World Health Organization defines VAPP as 'acute flaccid paralysis in a vaccine recipient 7 to 30 days after receiving oral polio vaccine, with no sensory or cognitive loss and with paralysis still present 60 days after the onset of symptoms'.<sup>664</sup> It occurs in about one case in every 750 000 first doses distributed,<sup>665</sup> and has led to reintroduction of the inactivated Salk vaccine into the routine immunization schedule in many industrialized countries including the USA, the UK and Australia.

### Laboratory diagnosis

Isolation of poliovirus from the patient is the method of choice. Polioviruses grow well in a variety of tissue cultures, and if specimens are collected early in the illness, successful virus isolation is not difficult. Virus may be recovered from throat swabs early and from the feces for several weeks after the onset. CSF should be cultured for polioviruses but, unlike coxsackie and ECHO viruses, these are found infrequently.

Acute and convalescent samples of serum should be obtained and tested for a significant rise in antibody titer during the illness; tests for both complement-fixing and neutralizing antibodies are available.

### Differential diagnosis

Paralytic poliomyelitis may be confused with a variety of disorders including Guillain-Barré syndrome, botulism, localized paralysis following specific infections such as mumps or infectious mononucleosis, paralytic episodes in sickle cell disease, myasthenia gravis and familial periodic paralysis.

Particular forms of poliomyelitis can be specially confusing, such as isolated facial paralysis which may mimic Bell's palsy, and bulbar paralysis which can be mistaken for tetanus. Pseudoparalysis may be found in acute rheumatism, osteomyelitis, fractures, scurvy, congenital syphilis and hysteria.

A true poliomyelitis-like illness can follow infection by other enteroviruses such as coxsackie, ECHO viruses and enterovirus type 71. Wherever possible, the diagnosis of any case of clinical poliomyelitis should be supported by virus isolation and positive serological tests.

### Complications, course and prognosis

**Nonparalytic poliomyelitis.** There are no complications of nonparalytic forms of poliomyelitis. However, unsuspected paralysis may be detected in cases of this type once they become mobilized and this is particularly seen in the back muscles, the strength of which is difficult to assess whilst the patient remains in bed.

**Spinal paralytic poliomyelitis.** Some recovery may occur in the first 4 weeks following paralysis. Improvement thereafter is much slower. In muscles where the neuronal supply has been severely affected, permanent paralysis with extremely rapid wasting will result.

**Spinal respiratory paralysis.** At the height of the illness in this group, various cardiac irregularities and even cardiac failure may occur, secondary to the respiratory complications or as a direct effect of the virus on the myocardium.

Major complications include pneumonia, hypertension, urinary retention and constipation. Renal calculi are not uncommon.

**Bulbar poliomyelitis.** This form of poliomyelitis is of great seriousness if it spreads to the vital centers in the medulla. However, in those cases without involvement of these centers there is remarkably full and quite

rapid recovery of the cranial nerves. Involvement of the diaphragm may be permanent.

**Late effects (post-polio syndrome).** People with paralytic polio may develop new symptoms many years later, characterized by pain in muscles, weakness, fasciculation, breathlessness and problems with speech and swallowing. The mechanism is unknown.

### Treatment

**Spinal paralysis.** The mainstay of therapy is physiotherapy, emphasizing passive movement, and hydrotherapy if available. Paralytic limbs should be supported and splinting may prevent contractures.

Patients may remain fecal excretors of poliovirus for several weeks and infection control precautions must be used.

In children, lack of growth in severely paralyzed limbs may lead to significant shortening, and skilled orthopedic advice is needed in such instances.

**Spinal respiratory paralysis.** Ventilatory support may be required and a constant watch for the incipient onset of respiratory insufficiency must be maintained. Late diagnosis may cause hypoxia and increased neuronal damage. Where respiratory paralysis is marked, ventilation is best achieved by the use of intermittent positive pressure ventilation combined with tracheostomy.

**Bulbar poliomyelitis.** Mild cases whose major defect is inability to swallow can often be managed conservatively with nasogastric tube feeding and suction of secretions. These patients often do well and undergo spontaneous recovery in 2–3 weeks. More severe cases require tracheostomy. Even in severe cases the prognosis is good and the tracheostomy can often be closed within a few weeks.

### Prevention

Virtually all cases of paralytic poliomyelitis occur in children who have not been immunized. Poliomyelitis outbreaks are unlikely to occur in a community where a high level of protection by immunization is maintained. Active immunization can be produced by either killed virus vaccines (Salk type) or live attenuated virus vaccines (Sabin type). The former require to be given by injection and the latter by the oral route. A full primary course of either type involves three doses with a booster. In general, Sabin type vaccines result in higher humoral antibody levels, are easy and painless to administer and also produce local immunity in the gut. Children with immune deficiency are at increased risk of paralytic polio and should be immunized with the killed vaccine. Children with HIV infection can receive either live or killed vaccines, but if there is a relative at home with AIDS who might be infected by the vaccine virus, Salk (killed) vaccine should be given.

### Non-polio enterovirus infections

The coxsackie and ECHO viruses, nonclassified enteroviruses and polioviruses are called enteroviruses and are classified with rhinoviruses into a larger group known as the picornaviruses (pico = small, RNA viruses). The agents in this group have a similarity in size, a similar nucleic acid core (RNA) and other common physical and chemical properties. Clinical and epidemiological studies show that the coxsackie and ECHO viruses are widely distributed in man and can cause a considerable variety of clinical syndromes. However, they have not demonstrated the same propensity to produce such large and serious epidemics as polioviruses.

### Coxsackie virus infections

The existence of this group of viruses became apparent in 1948 when unidentifiable, filterable agents were isolated from the feces of two children in whom a clinical diagnosis of paralytic poliomyelitis had been suspected. These children resided in Coxsackie in New York State and the large group of similar viruses subsequently identified has been named after this town. At the present time there are approximately 30 different varieties of coxsackie viruses and these have been classified into two groups, known as A and B; 24 of the strains have been allocated to group A and the remaining 6 to group B.

Some, but not all, viruses of the coxsackie groups may be grown on suitable tissue cultures but all produce a characteristic histopathological effect when injected into suckling mice.

### **Coxsackie group A virus diseases**

**Relationship of group A viruses to disease.** Viruses of this group may be isolated from a variable percentage of healthy individuals; as a result their isolation from a sick patient must not necessarily be construed as a diagnostic event.

**Herpangina.** This is one of the most clearly defined clinical syndromes caused by infection with coxsackie A viruses. It is most commonly seen in infants and children, though it can occur in adults. The onset is characterized by fever, anorexia and pain in the throat; other features include headache, abdominal pain and myalgia. Infection will normally derive from another human and the agent may be transmitted from nasal secretions as well as from the feces. The incubation period lies between 3 and 5 days and fecal infectivity may last for several weeks.

Local examination of the mouth will usually reveal hyperemia of the pharynx and characteristic papulovesicular lesions, approximately 1–2 mm in diameter and surrounded by an erythematous ring. Most commonly the lesions are present over the tonsillar pillars, soft palate and uvula, although the tongue may be involved. It is rare to find more than five to six lesions and these soon enlarge and form shallow ulcers. The illness will usually subside within a week and few complications are found in children. Second attacks may result from infection by different antigenic strains. The clinical picture is highly suggestive, but laboratory studies are required for full confirmation, and at least nine different group A viruses are known to produce this syndrome.

**CNS involvement.** Aseptic meningitis is the most common clinical manifestation and may result from infection by several different coxsackie A virus strains. As with other types of viral meningitis, young children are most likely to be involved and the incidence is rather higher in boys. There is no characteristic clinical picture that differentiates this from other causes of viral meningitis, although in a few instances one of the more specific syndromes associated with group A infection may be present simultaneously. On occasion non-polio enterovirus infection may be associated with paralytic disease that is clinically indistinguishable from poliomyelitis. Coxsackie virus A7 is the most frequently implicated, but other strains such as A9 have also been involved. Severe and fatal encephalitis has been described in a small number of cases of coxsackie A virus infection.

**Hand, foot and mouth disease.** Most cases of hand, foot and mouth disease are due to infection with coxsackie virus A16, but other coxsackie viruses (usually A5 and A10), ECHO viruses and enterovirus 71 have all caused cases or outbreaks.

Hand, foot and mouth disease usually presents with little or no constitutional upset. Reluctance to feed may be an early sign in babies. Examination of the mouth often shows mild ulceration of the tongue and pearly white vesicles, sometimes surrounded by a red halo, and further examination shows lesions on the palms and soles. The lesions are mainly found over the ventral surface of the fingers and toes and have a characteristic distribution along the sides of the feet. Some children also have a maculopapular rash over the buttocks which may extend on to the thighs and mimic Henoch–Schönlein purpura. Fever is rarely marked and there is little associated lymphadenopathy.

A fully developed case is extraordinarily characteristic and once seen is readily recognized thereafter. The mouth lesions can be confused with herpetic gingivostomatitis and herpangina as the peripheral lesions are painless and may be overlooked. An occasional case has been confused with scabies.

Outbreaks of this syndrome are usually small and tend to occur in the summer months. Subclinical infection of family contacts can be demonstrated by the isolation of viruses and the prognosis is excellent.

The association between HFM disease caused by enterovirus type 71 and brainstem encephalitis is described below.

**Miscellaneous coxsackie A virus infections.** Coxsackie A viruses have been isolated from children suffering from a febrile illness with a rash, from cases of pharyngitis and from cases of benign pericarditis. They have also been associated with mild undifferentiated respiratory tract infection, especially coxsackie A21 virus (previously known as Coe virus), with acute febrile lymphadenitis, gastroenteritis, tracheobronchitis and pleurodynia.

**Laboratory diagnosis.** The isolation of most coxsackie group A viruses is not difficult provided suitable specimens are sent to the laboratory. Suitable specimens include vesicle fluid, throat swabs, feces and CSF, depending on the clinical syndrome under investigation. Serological tests on acute and convalescent serum samples can be carried out, but owing to the large number of serotypes this is not a practical procedure unless an agent has been isolated. The coxsackie virus complement-fixation test frequently employed cross-reacts with all enteroviruses and is not very sensitive. Detection of viral RNA by PCR is now generally available and more sensitive than culture.

### **Coxsackie group B virus diseases**

**Bornholm disease or epidemic pleurodynia.** This disease, first recognized clinically over a century ago, results from infection with certain group B coxsackie viruses. Children and young adults are usually involved and more severe cases occur in the latter.

After an incubation period of 2–4 days, the illness commences in a nonspecific manner with fever, malaise and headache. However, the characteristic pain will soon follow. This is principally experienced over the lower chest and may be associated with acute dyspnea. A clinical diagnosis of pleurisy can be made, even if no friction rub is audible and X-ray of the chest is clear. Pain may also be felt lower down the trunk and this may spread over the abdomen and simulate an acute surgical condition. Palpation over the affected muscles may reveal exquisite tenderness and this can have a band-like distribution suggestive of a neurological disorder or shingles.

In many instances the illness subsides within a few days but it may run a relapsing course and last for as long as 3–4 weeks. Several members of a family may be attacked in quick succession and show a wide variation in the severity.

Bornholm disease requires to be differentiated from pleurisy and pneumonia. Acute appendicitis and cholecystitis have been mimicked by an abdominal presentation but milder varieties, without significant pain, can be confused with influenza. In general, there is no significant leukocytosis and this may be helpful in the differentiation of pyogenic infection.

Outbreaks are small and often confined to family units. However, an epidemic can be more widespread and in these instances the correct clinical diagnosis may be made with reasonable accuracy. Nevertheless, full confirmation requires detailed virological assessment.

**CNS involvement.** All six group B coxsackie viruses can cause *aseptic meningitis*. The age incidence is similar to that encountered in aseptic meningitis due to other viruses. Clinical differentiation from other possible causes is impossible, although pleurodynia is an occasional accompaniment. Severe and fatal encephalitis has been described in only a small number of cases, as has mild paralytic disease.

**Neonatal or infant coxsackie B virus myocarditis.** Coxsackie viruses B1–5 can all cause myocarditis, but types B3 and B4 most frequently. The illness usually commences within the first 2 weeks of life though older babies have been involved. Most neonatal cases are probably caused by vertical spread from an infected mother, and a maternal history of respiratory or gastrointestinal illness is common. Nursery outbreaks can also occur.

**Clinical features** (see Ch. 21). The presentation can be abrupt or more insidious. Presenting symptoms include feeding difficulties, lethargy, fever, cyanosis, respiratory distress and shock. Cardiomegaly, tachycardia, hepatomegaly and electrocardiographic changes soon appear. Involvement may not be confined to the cardiovascular system. In up to one third of cases, there are central nervous signs such as convulsions, neck stiffness, and coma with CSF changes.

The prognosis is poor, and up to 75% of cases die in spite of intensive therapy. At autopsy an intense inflammatory infiltration and necrosis is found in the myocardium and changes may also be found in the liver, pancreas, suprarenal glands, bone marrow and CNS.

**Differential diagnosis.** Myocarditis is difficult to diagnose in a neonate. Most cases are initially considered to be some form of acute respiratory disorder (e.g. respiratory distress syndrome), other overwhelming infections or congenital heart disease.

**Treatment.** Infants with this condition require intensive nursing in hospital. Oxygen, diuretics and inotropes may be required. The heart is often very sensitive to digoxin and low doses may be needed if used.

**Pericarditis and myocarditis due to coxsackie B viruses in older children.** Acute pericarditis in older children and adults is a syndrome where the causative role of coxsackie B viruses (types B1–5) is well established. Less often, myocarditis may also occur in these age groups but, unlike infection in neonates, the prognosis is generally good. Clinical recovery is quite rapid and although the electrocardiographic changes can take some months to resolve, recovery seems complete and there is little evidence of any permanent cardiac damage. Rare cases of myocarditis are fulminant and fatal.

**Miscellaneous coxsackie B virus infections.** Group B coxsackie viruses can be associated with mild respiratory tract illness, febrile illness with an exanthem and orchitis. They are also reputed to cause endocardial fibroelastosis, the infection of the fetus occurring in utero.

**Laboratory diagnosis.** The six types of coxsackie group B viruses can be readily isolated in the laboratory either in tissue cultures or suckling mice. Virus can be grown from throat swabs, feces, CSF and in some cases from other organs, e.g. myocardium and testis. Acute and convalescent samples of serum should be sent to the laboratory so that, if present, a significant rise in antibody titer during the illness can be shown. Serological tests may be of special value if a coxsackie group B virus has been isolated as in this instance the sera need only be tested for an antibody rise against this specific isolate. In all cases it is advisable to try to isolate a virus from the patient as early in the illness as possible. Detection of viral RNA by PCR is available in many laboratories.

## ECHO virus infections

Agents of this group are named after the initial letters of their original name, enteric cytopathogenic human orphan viruses. There are some 30 distinctive serotypes and their association with aseptic meningitis, encephalitis and paralytic diseases is well documented. They may also cause respiratory tract infections, gastroenteritis, myocarditis and exanthemata of a rather nonspecific character. Subclinical infection with this group is common. Infections may be sporadic or occur in moderate sized epidemics.

A number of different types of ECHO viruses have been associated with each of the various clinical syndromes that this group may cause and most types have been found in association with more than one syndrome. A few of the identified types have not, as yet, been found in association with obvious disease. In general, infection by this group of agents is relatively benign and, except in neonates, few fatalities have been described. They spread in a fashion similar to polioviruses and coxsackie viruses.

### Clinical syndromes

A considerable number of different ECHO virus types can cause *aseptic meningitis*, which may be sporadic or in epidemics. In general, the prognosis is good and in many instances the cases are clinically indistinguishable from those produced by other viral infections. However, in some there is a rash and where this is seen in a reasonable proportion of cases in any outbreak of aseptic meningitis, it often indicates that an ECHO virus is responsible.

Sporadic cases of *poliomyelitis-like illness* with paralysis have been reported in association with confirmed ECHO virus infection. The paralysis is usually mild and reversible, but permanent residual paralysis can occur. Cases of *encephalitis* due to ECHO viruses have also been reported,

occasionally fatal. Children with antibody deficiency can get chronic ECHO virus encephalitis and/or myositis.

*Mild upper respiratory illness* has been found in association with a few ECHO viruses, particularly types 11, 19 and 20. ECHO viruses 5, 11, 14, 18, 19 and 20 have been associated with gastroenteritis in infants and young children.

ECHO viruses have been isolated in association with sporadic cases of pleurodynia, pericarditis and myocarditis. However, as these agents may be cultured from many otherwise healthy people their etiological relationship should not necessarily be assumed.

Where rashes do occur as a result of ECHO virus infection they tend to be of a fine, maculopapular character, have a widespread distribution and fade rapidly. Generally there is no classical distribution or typical enanthem, although lesions may be papular, arranged in lines and located peripherally, the so-called 'papular acro-located syndrome' (PALS).

Neonatal ECHO virus infection can disseminate and cause massive hepatic necrosis, disseminated intravascular coagulation, bleeding and usually death. Such severe cases are acquired vertically (from the mother) and a maternal history of peripartum illness with diarrhea or abdominal pain is common. Although nursery outbreaks may occur, most horizontally acquired or nosocomial cases are relatively mild, although occasionally complicated by meningitis and myocarditis.

### Laboratory diagnosis

The ECHO viruses can be readily isolated in tissue culture, or enteroviral RNA can be detected by reverse-transcriptase PCR. Specimens usually required by the laboratory are CSF, throat swabs and feces depending on the clinical manifestations of the illness. Serology is not sufficiently sensitive to be useful clinically.

## Enteroviruses types 68–71

In addition to the spectrum of symptoms outlined above, this group of enteroviruses is also associated with specific syndromes. Enterovirus type 70 has been isolated from patients with acute hemorrhagic conjunctivitis. Enterovirus type 71 (EV71) is associated with hand, foot and mouth syndrome. In Australia, Malaysia, Taiwan and Japan, outbreaks of EV71-associated hand, foot and mouth disease in children have been followed by severe neurological symptoms such as brain-stem encephalitis often with neurogenic pulmonary edema, and by Guillain-Barré syndrome, acute transverse myelitis, cerebellar ataxia, opsomyoclonus, benign intracranial hypertension and febrile convulsions.

### Treatment

No specific therapy is available. In a small, uncontrolled case series, the antiviral agent pleconaril was used in severe enteroviral infection in infants and immunocompromised children.<sup>666</sup> However, efficacy data from randomized controlled trials are as yet unavailable. Intravenous immunoglobulin and interferon have been used to treat chronic enteroviral infection in immunodeficient children. None of these agents is reportedly effective against EV71-associated disease.

## VIRUSES AND THE GASTROINTESTINAL TRACT

Many viral agents may inhabit the intestinal tract without producing obvious clinical illness. As a result, when such agents are cultured in the presence of gastrointestinal symptoms, their etiological role is difficult to establish. Nevertheless epidemiological studies in the recent past seemed to indicate that some agents, such as certain ECHO viruses, may be involved in outbreaks of diarrhea in infants. The picture has, however, changed in the last few years as a wide variety of new viral agents has been discovered by electron microscopy of feces. Notable amongst these are *rotaviruses* and *noroviruses*, including *Norwalk virus*.

## GASTROENTERITIS

Viruses associated with gastroenteritis include rotaviruses, noroviruses including Norwalk, caliciviruses, coronaviruses, astroviruses, adenoviruses, stool parvoviruses and enteroviruses. The role of rotaviruses and Norwalk virus is most clearly established, but other viruses can cause limited cases or outbreaks of infantile diarrhea.

*Rotaviruses* were initially found on electron microscopy of duodenal biopsies taken from children with diarrhea in Australia in 1973. Since then these agents have been found to be common worldwide and their presence may be detected by a variety of methods. Several different human types have been identified as well as many animal varieties. Species specificity appears incomplete.

Between 1 and 7 days after infection, but usually within 2 days, the affected child starts to vomit and develops a low grade fever. Watery diarrhea soon follows and, although mucus may be seen in the stools, blood is rarely present. The vomiting stops after 1–2 days, but diarrhea persists even if intravenous fluids are started with no oral intake. Nonspecific respiratory symptoms may occur and, although the illness terminates in about 5–7 days, virus may be found in the stool for up to 10 days.

The peak age of attack is between 6 and 24 months of age, mainly from 9 to 12 months. There is a slight male preponderance. Asymptomatic cases may be found in older members of the household. Neonatal infection occurs and has been associated with a clinical picture resembling necrotizing enterocolitis. However, neonatal infection is often subclinical, perhaps due to the presence of maternal antibody. It is suggested that breast-feeding can be protective.

Up to 50% of hospitalized cases of infantile gastroenteritis and a lower proportion of community cases are caused by rotaviruses.<sup>667</sup> Transmission is by the fecal–oral route. In temperate climates it is mainly a winter disease, although cases can occur throughout the year. Serological surveys show that up to 90% of children aged 3 years or over possess antibody to rotaviruses, and surveys in the adult population show figures of up to 70%.

Treatment of gastroenteritis due to rotavirus infection is along standard lines. Fatalities are rare in industrialized countries and usually in otherwise debilitated children. A variety of complications have been found but the role of rotaviruses in their production is not firmly established.

A tetravalent rotavirus vaccine was licensed in the USA in 1998 and introduced into the routine schedule. It was then voluntarily withdrawn from the market in 1999, due to a possible rare association with intussusception that was detected in post-licensing surveillance.<sup>668</sup> New rotavirus vaccines are safe and effective and have not been associated with intussusception.

The *Norwalk virus*, which was first discovered in 1972, and other caliciviruses are also known to produce gastroenteritis. Outbreaks have usually occurred in older children with secondary cases in adults, some involving schoolchildren and their teachers. These agents, first discovered in the USA and certain Far Eastern countries, are now found on a worldwide basis. After an incubation period of some 2 days the illness starts with nausea and vomiting. Diarrhea, abdominal cramps and fever follow in about half of those involved but symptoms usually abate within a day or so. Treatment is purely symptomatic.

Enteric adenoviruses are the second most important cause of viral diarrhea of infancy, in terms of hospitalization, and often cause prolonged diarrhea with or without vomiting. Astroviruses rarely result in hospital admission but can cause winter vomiting and may cause rare outbreaks in hospitals.

## INTUSSUSCEPTION

Intussusception involves the invagination of a portion of the intestine into an adjacent portion. A study found *adenovirus infection* in 34% of Vietnamese and 40% of Australian children with intussusception, but no association with rotavirus, other enteric pathogens or oral polio vaccine.<sup>669</sup> It is thought that adenovirus infection causes inflammation

of the Peyer's patches that acts as a focus for the intussusception. Adenoviruses have also been isolated from regional lymph glands in children with mesenteric adenitis and, as this condition is considered to be associated with the development of intussusception, the possible etiological role seems strengthened.

The association between intussusception and a live attenuated rotavirus vaccine, although not with wild-type rotavirus infection, is further evidence that intussusception may follow virus infections of the gastrointestinal tract.

## OTHER CONDITIONS

Attempts to establish an association between viral infection and appendicitis have not proved very rewarding. Pancreatitis is a recognized complication of mumps and has occasionally been found in association with infection by coxsackie viruses.

## LABORATORY DIAGNOSIS

In general, the main pathogens responsible for viral gastroenteritis, rotavirus, enteric adenoviruses, caliciviruses and astroviruses cannot be readily isolated by culture.<sup>670</sup> Although these agents may be demonstrated in stools by negative staining electron microscopy this has largely been replaced by enzyme immunoassays or PCR for rotavirus and enteric adenoviruses.

## OCULAR DISEASES CAUSED BY VIRUSES AND ALLIED ORGANISMS

It is now recognized that viral and chlamydial infections of the eye constitute a larger proportion of ocular disease than was formerly appreciated. In part this stems from the enormous advances in viral technology but many ocular diseases are now recognized to have a viral basis because chemotherapy has cleared secondary bacterial infection and revealed the true, underlying viral pathogenesis.

In most instances viral infection of the eye presents as part of a systemic infection which may manifest itself by direct tissue invasion or indirectly through neural involvement, as in the viral encephalitides. Examples of viruses that may act this way are CMV and HSV in the congenitally infected or immunocompromised. However, some viral infections seem to involve the eye selectively, including certain adenoviral infections, trachoma, inclusion conjunctivitis and acute hemorrhagic conjunctivitis.

## ADENOVIRUS INFECTIONS OF THE EYE

Two main ocular syndromes are associated with adenovirus infection – *pharyngoconjunctival fever* and *epidemic keratoconjunctivitis*.

### Pharyngoconjunctival fever

Pharyngoconjunctival fever may result from infection by several types of adenoviruses, most commonly type 3. Clinically it may present as unilateral or bilateral follicular conjunctivitis, often with fever, pharyngitis and mild preauricular lymphadenopathy. The conjunctivitis shows follicular hypertrophy and a mild transient keratitis sometimes develops.

Children are most often affected and cases may occur sporadically or in epidemics, sometimes associated with swimming pools.

### Epidemic keratoconjunctivitis

This disease presents as an acute keratoconjunctivitis with follicular hypertrophy of the conjunctiva and marked preauricular lymphadenopathy. A distinctive keratitis then develops and about a third of the cases have pseudomembranes.

Large epidemics may occur and adults are involved rather than children. Infection is usually due to adenovirus type 8 and spread may occur

through ocular instruments, infected eye-droppers and contaminated solutions used in hospitals, first aid stations and surgeries. Complete recovery usually occurs but permanent impairment of vision can occasionally result.

### Laboratory diagnosis

Ocular infection with an adenovirus can be confirmed by culture or PCR. Swabs or scrapings in virus transport medium should be sent to the laboratory for virus isolation. The adenoviruses are not difficult to grow.

## TRACHOMA AND INCLUSION CONJUNCTIVITIS (see Ch. 12)

*Chlamydia* have properties intermediate between viruses and bacteria, and show sensitivity to certain antibiotics. *Chlamydia trachomatis* is the cause of trachoma, inclusion conjunctivitis, afebrile pneumonitis and lymphogranuloma venereum.

### Trachoma

Trachoma is a specific form of keratoconjunctivitis that first involves the upper tarsal follicles. Later upper limbal changes appear followed by pannus formation and the development of Herbert's peripheral pits. The disease is mainly encountered in tropical areas where water is scarce. In such areas there is often a very high incidence. Permanent scarring and blindness may occur, especially where adequate facilities for treatment are not available.

All ages are affected, but the disease is especially common in children and is often associated with secondary infection. Theories to explain the spread have included person-to-person contact, infection through fomites and dissemination by flies.

### Treatment

Among drugs which may be used are sulfonamides, tetracycline and less often erythromycin. Opinions differ as to the efficacy and mode of treatment. However, where topical therapy is conscientiously applied over a period of several weeks or even months, a good response can be anticipated. Some advocate supplementation by oral therapy.

### Inclusion conjunctivitis

This condition is caused by certain strains of *Chlamydia trachomatis* that may reside in the genital tract and produce cervicitis or urethritis. There is a danger of spread to infants during their passage through the birth canal, resulting in inclusion blennorrhoea. Older children and adults may contract inclusion conjunctivitis from swimming pools contaminated by urine or genital tract discharge.

Treatment of inclusion conjunctivitis is also by sulfonamides or topical broad spectrum antibiotics. However, the response is quicker than in trachoma and treatment need not be so prolonged. The prognosis is also better and permanent scarring does not occur. Neonates with inclusion conjunctivitis should be treated with oral erythromycin 10 mg/kg/dose 6-hourly for 14 days because of the risk of progression to afebrile pneumonitis.

### Laboratory diagnosis

The agents are situated in the epithelial cells of the conjunctiva, and for successful culture epithelial scrapings or eye swabs in special transport medium should be sent to the laboratory. Cultural methods consist of inoculation of suitable tissue cultures and then, after incubation, examination under the microscope for typical inclusion bodies. Direct microscopy on Giemsa-stained smears may reveal typical inclusions. ELISA antigen detection tests and PCR that avoid the need for culture and give a rapid diagnosis are increasingly being used.

## ENTEROVIRUS 70 (ACUTE HEMORRHAGIC CONJUNCTIVITIS)

This condition is caused by enterovirus type 70, which has been isolated from the conjunctiva of affected patients. Extensive outbreaks have been

reported from Africa, Pakistan, India and South America. The disease appears to have an incubation period of about 24 hours and to be highly contagious in unhygienic and crowded conditions. The infection is of sudden onset with swelling, congestion, watering and pain in the eye. The most characteristic sign is subconjunctival hemorrhage of varying intensity, which may sometimes be accompanied by corneal keratitis. The disease is not influenced by antibiotics and symptoms usually subside within 1–2 weeks.

### Laboratory diagnosis

Conjunctival scrapings or swabs should be sent to the laboratory where suitable tissue cultures can be used to isolate the causative agent.

## VIRAL INFECTION OF THE LIVER

Acute inflammation of the liver may be caused by a number of viruses including hepatitis viruses A to E, CMV, adenoviruses, picornaviruses, HSV, EBV and the viruses of diseases such as yellow fever and rubella.

### HEPATITIS A VIRUS INFECTION OR INFECTIOUS HEPATITIS (EPIDEMIC HEPATITIS, EPIDEMIC JAUNDICE OR CATARRHAL JAUNDICE)

This disease has an incubation period of 15–50 days (average 30 days) and is mainly found in young children. It is also quite common in older children and young adults but the attack rate declines with increasing age though a higher proportion of severe and complicated cases may be found in these older age groups. Pregnant women may contract a particularly severe form.

Infectious hepatitis occurs worldwide and epidemic periodicity varies greatly in different communities. The responsible agent, hepatitis A virus, is present in both blood and feces at the peak of the illness and persists in the feces for a relatively short time. Susceptible human volunteers have been fed filtered fecal extracts and virus could be found in the feces of those who developed jaundice from 14 to 26 days before the onset of icterus and for over a week thereafter. Furthermore, although at least two thirds of the recipients displayed no clinical evidence of hepatitis, subclinical evidence of infection was found on serial examination by appropriate liver function tests. This indicates a ratio of 1:2 for clinical, as opposed to subclinical, infection and this impression is further substantiated by epidemiological studies in naturally occurring epidemics.

Although infectious hepatitis is mainly transmitted by the fecal–oral route through contamination of food and water, transmission may also occur from blood, urine, nasopharyngeal secretions and saliva. Large epidemics usually occur in institutions and closed communities and, in some of these, infection of a communal water supply has been responsible. Prevention of waterborne outbreaks of this type is difficult, although carefully controlled super-chlorination may be effective. Outbreaks have also followed the ingestion of raw oysters and raw clams infected by sewage. Infection may also result from the use of imperfectly sterilized instruments, syringes and needles that have been contaminated by infected blood or blood products.

The diagnosis, differential diagnosis and detailed treatment of infectious hepatitis are referred to elsewhere (Ch. 19). Complement-fixation tests, immune-adherence hemagglutination, ELISA and radioimmunoassay can be used to detect specific IgM and IgG antibody to hepatitis A virus. The presence of specific IgM antibody indicates a recent infection with hepatitis A virus. In the majority of childhood cases the illness is mild and treatment need not extend beyond simple bed rest and a moderate period of convalescence.

Mortality amongst otherwise healthy, well-nourished individuals is as low as 0.1–0.2% but can rise to 2 or 3% in the poorly nourished. Death may either be early from fulminating hepatitis leading to acute hepatocellular failure or occur considerably later from chronic liver damage.

## Prevention

Killed vaccines are safe and effective,<sup>671</sup> and indicated for older children and adults at long term risk. Human normal immunoglobulin is effective prophylaxis and should be given to adult and child contacts of index cases and to people traveling for short periods to areas with poor sanitation.

## HEPATITIS B (SERUM HEPATITIS, AUSTRALIA ANTIGEN-POSITIVE HEPATITIS)

Hepatitis B is enormously important. Worldwide, there are about 200 million chronic carriers of hepatitis B virus (HBV), which is one of the most important causes of liver cirrhosis and hepatoma. HBV can be transmitted either vertically (mother to child) or horizontally (from an infectious contact). Infection is endemic in some parts of the world, notably South East Asia where carriage rates may exceed 15%. About half of all carriers will die liver-related deaths.

The incubation period is 60–160 days, much longer than hepatitis A. Virus antigen can be detected in the blood up to 3 months before jaundice occurs and often for many years after clinical recovery. The virus is mainly transmitted via infected blood and is highly infectious, far more so than HIV. Infected blood transfusions, needle sharing by intravenous drug abusers, tattooing and ritual scarification are all well-documented means of spread. The virus can be sexually transmitted and the incidence is high in many homosexual communities. Vertical spread is common and is thought to be mainly peripartum rather than transplacental, thus being largely preventable by intervention immediately after birth. Most vertically infected babies become chronic carriers. About a quarter to a third of asymptomatic HBV carriers remain infectious and go on to develop liver fibrosis<sup>672</sup> or carcinoma (hepatoma).<sup>673,674</sup> The virus is also found in breast milk, although breast-feeding has not been shown to be a clear risk factor for transmission. Clinical features of hepatitis B infection are discussed elsewhere.

## Etiology

In 1965, geneticists investigating inherited variations in human plasma proteins discovered an unusual protein antigen in the serum of an Australian aborigine. This antigen, originally called Australia antigen (Au), and now hepatitis B surface antigen (HBs), was found to be associated with hepatitis of long incubation. On electron microscopy of serum three particles are identifiable. Dane particles, 42 nm in diameter, are complete virus comprising an inner core containing double-stranded HBV DNA within a core antigen (HBc) and surrounded by an outer coat of surface antigen (HBs). A further antigen, the e antigen, a component of the inner core, may also be seen (Fig. 28.43). The detection of e antigen in the absence of e antibody correlates with high infectivity. Subjects may be:

1. HBs antigen positive, with no e antigen or e antibody detected – these will be mainly chronic carriers;
2. HBe antigen positive, but e antibody negative – usually also HBs positive – are highly infectious: usually suggests recent, active infection, but can be chronic HBe Ag positive carriers;

Fig. 28.43 Diagrammatic representation of electron microscopic appearance of hepatitis B virus.

3. HBe antibody positive – recovery phase, much less infectious.

Tests commonly used to detect the presence of HBV antigens and antibodies include hemagglutination tests and ELISA tests, which are often used to screen sera for surface antigen (HBs), and radioimmunoassays which are more sensitive.

Detection of HBs antibody indicates either recovery from acute HBV infection or a response to immunization. Presence of HBc IgM antibody indicates acute HBV infection, while HBc IgG antibody is detected following infection but not immunization (which uses only surface antigen).

## Prevention

In many countries, blood or blood product donations are routinely screened for surface antigen (HBs) and antenatal screening of all pregnant women or those from high risk groups allows intervention to prevent vertical transmission. Great care should be taken when handling blood and excreta from HBV positive patients because of the high infectivity, although any person doing so should have been immunized.

Passive immunization with specific immunoglobulin is given for accidental contamination with infected blood, e.g. in the laboratory or from a syringe and needle from a drug abuser. It reduces vertical transmission if given to infected mothers in the first 72 h (ideally < 12 h) after birth.<sup>675</sup> There appears to be no additional benefit by giving further doses of HBV immunoglobulin beyond the newborn period.<sup>675</sup>

Recombinant DNA hepatitis B vaccines are now widely available. All health care personnel likely to come into contact with HBV positive patients (e.g. doctors, dentists, nurses, midwives, students, laboratory staff) should receive a course of three doses of the vaccine.

Babies of mothers who are in the above risk groups 1 (HBs positive) and 2 (HBe antigen positive) are at high risk of becoming chronic carriers without intervention. Indeed this will be the case in up to 90% of babies of HBe antigen positive mothers. Such babies should receive both passive HBV specific immunoglobulin and be actively immunized with hepatitis B vaccine, which provides additional protection against vertical transmission over HBV immunoglobulin alone.<sup>675</sup> Babies of mothers in group 3 (HBe antibody positive) are at lower risk but may rarely develop acute hepatitis, and there is a risk of later horizontal transmission from the mother or an infected sibling. They should therefore be immunized and many would feel they should also receive specific immunoglobulin.

Many countries are now advocating universal neonatal hepatitis B immunization.

## Treatment

Pegylated interferon alpha and lamivudine have been used in the treatment of chronic hepatitis B disease in adults, and shown to be effective at reducing HBV viral load and inducing HbeAg seroconversion in some patients.<sup>676,677</sup> Lamivudine has been given to HBV infected women in the last weeks of pregnancy to reduce the risk of vertical transmission with variable success.<sup>678</sup> The use of these agents for the treatment of chronic HBV infection in children has also been reported in small case series,<sup>679</sup> but the efficacy of these therapies has not been fully evaluated.

## HEPATITIS C (TRANSFUSION-ASSOCIATED NON-A, NON-B HEPATITIS)

Hepatitis C virus is a small single-stranded RNA virus that is a member of the flavivirus family. It is the cause of the great majority of transfusion-associated hepatitis.

The structure of hepatitis C virus (HCV) was determined by molecular biology techniques in 1988. There are multiple HCV genotypes and subtypes, each of which carries a different long term prognosis. Serological tests have been developed to screen blood products, and PCR testing for the presence of viral nucleic acid is widely available. The virus is extremely difficult to grow.

HCV has an incubation period of around 30–60 days. Transmission is mainly via blood transfusion or by needle sharing between intravenous drug abusers. Screening of donated blood for the presence of hepatitis C antibodies has greatly reduced the risk from blood transfusion. HCV

is more resistant to inactivation than HBV or HIV, and blood products such as intravenous immunoglobulin have occasionally transmitted HCV despite viral inactivation steps.

Vertical transmission from mother to fetus occurs in about 5% of pregnancies, and is thought to occur antenatally or perinatally almost exclusively in the setting of high maternal viral load in the serum. Maternal co-infection with HIV is associated with a higher risk of transmission.<sup>680</sup> Other risk factors have been poorly defined. As yet unconfirmed associations include prolonged rupture of membranes, and invasive fetal monitoring<sup>681</sup> and female sex of the infant.<sup>682</sup> Elective Cesarean section does not confer protection from vertical transmission.<sup>682</sup> HCV RNA and antibody have been detected in breast milk,<sup>683</sup> although breast-feeding has not been shown to be associated with transmission to the infant by hepatitis C positive women.<sup>684</sup> Nevertheless, a theoretical risk remains and the decision of a hepatitis C positive woman whether to breast-feed should be made on an individual basis. The diagnosis of perinatally acquired HCV is usually based on the detection of HCV antibody and/or HCV RNA by PCR. The presence of maternal antibody makes interpretation of serological assays difficult in children less than 18 months. At 12 months, up to 10% of uninfected children remain HCV seropositive, but this figure has dropped to 0.1% by 18 months.<sup>685</sup> PCR for HCV RNA is sensitive over 1 month of age and is specific, but the test is expensive. Any positive PCR test should be repeated to exclude false positive results, and because of the possibility of viral clearance.<sup>685</sup>

Childhood HCV infection is largely asymptomatic,<sup>686</sup> but a high proportion of those infected with HCV become chronic carriers and may progress to cirrhosis. A large cohort study from Italy of HCV infected children has shown a shift in the dominant HCV genotype from genotypes 1 and 2, associated with poorer response to therapy and reduced viral clearance, to genotypes 3 and 4, with genotype 3 associated with a better prognosis.<sup>687</sup> Nevertheless, it is estimated that childhood HCV disease will have an important economic impact on direct medical costs in the next decade, as the burden of pediatric HCV infection increases.<sup>688</sup> Interferon alfa therapy alone or with ribavirin is effective in reducing viral replication in around 40% of adult chronic carriers, although half of these responders will relapse when interferon is stopped. Experience with the use of these agents in HCV infected children is increasing. Treatment may be considered for the child with severe hepatitis C induced liver disease, which should be managed by a pediatric hepatologist.<sup>689</sup>

Children with hepatitis C infection should be immunized against hepatitis A and hepatitis B to protect against further insults to the liver.

### DELTA AGENT (HEPATITIS D)

The delta agent is a defective RNA virus which requires HBV for its own synthesis. This is one of the most important examples of viral co-infection described. The delta agent was detected by immunofluorescence studies of liver cell nuclei of chronic HBV carriers. Delta antigen and antibody are detected by radioimmunoassay or ELISA and have never been demonstrated other than in association with HBV. The delta agent is most prevalent in intravenous drug abusers in Italy and the Mediterranean but has been detected worldwide. It appears to be a risk factor for acute hepatitis in drug abusers. About half of HBs positive hemophiliacs in the USA and Italy have anti-delta antibodies.

### HEPATITIS E (ENTERIC NON-A, NON-B HEPATITIS)

Hepatitis E is the enterically transmitted form of non-A, non-B hepatitis and is transmitted by the fecal-oral route. It is of major importance in resource limited countries as a cause of hepatitis due to waterborne epidemics, which mainly affect young adults, but rarely children. The mortality can be as high as 40% in pregnant women. The viral genome has been cloned and sequenced, and serological tests and PCR assays are available.

### HEPATITIS G

This single-stranded RNA virus of the flavivirus family usually results in an asymptomatic infection. It can cause chronic infection, but rarely hepatitis. It has been documented in adults and children, especially those whose mothers are co-infected with HCV or HIV.<sup>690</sup> It can be diagnosed by detection of viral RNA by PCR.

### HEPATITIS – THE ROLE OF OTHER VIRUSES

Other viral infections may involve the liver.

CMV is known to attack the liver in 85% of newborn infants suffering from cytomegalic inclusion disease; the same virus may also cause hepatitis when older children or adults contract the acquired form of the infection. *Infectious mononucleosis*, due to EBV, is frequently accompanied by some degree of liver involvement; most often this will reveal itself as a mild derangement of liver function tests though some cases will manifest obvious jaundice. Infection by *arboviruses* may cause a similar picture; yellow fever produces a more specific and severe form of hepatitis.

*HSV infection of the newborn* can manifest as severe and often fatal hepatitis.

Lastly, there are instances where transient liver involvement has been found in a variety of viral infections including ECHO viruses types 4 and 9, coxsackie viruses, adenoviruses and lymphocytic choriomeningitis virus. In most the involvement has been extremely mild with full recovery, although severe hepatitis may occur.

### MISCELLANEOUS VIRAL INFECTIONS

#### ORF (CONTAGIOUS PUSTULAR DERMATITIS OF SHEEP, CONTAGIOUS ECTHYMA OF SHEEP)

This is a common and widespread viral infection of sheep and to a lesser extent of goats. In general infection is from animal to animal but virus can persist in the soil of affected pastures for several months. Lambs are most commonly involved and they develop a papulovesicular eruption on the mouth, lips and non-hair-bearing areas of the skin. Transmission to man is relatively rare and the main incidence is in springtime. The infection is most commonly encountered in shepherds, farm and abattoir workers. However, children can be infected owing to their liking for handling young lambs.

Orf virus is included amongst the poxviruses and has certain similarities to the virus of molluscum contagiosum. It can be grown with difficulty on tissue culture but is usually identified by electron microscopy. Scrapings from the base of the bullae are preferred to vesicle fluid in these studies.

#### Clinical features

Lesions, which are usually but not exclusively single, most commonly appear on the hand or forearm. Initially there is an area of infiltration presenting as brawny edema but this soon develops into a flaccid bulla. However, on puncture a rather clear serosanguinous fluid is obtained. There is little or no constitutional upset but the progression of the lesion is slow and may take 6–8 weeks before it finally heals. No specific treatment is available or required in view of the benign nature of the condition but it is wise to protect the lesion with dressings to counteract the possibility of secondary infection.

#### MOLLUSCUM CONTAGIOSUM

This viral disease (see also Ch. 30) is seen in children more often than in adults. The responsible agent is a DNA virus belonging to the pox group but serologically unrelated to vaccinia or variola; it is readily identified by electron microscopy of the curettings from a lesion or on the histological appearances of a biopsy. Transmission is by close contact but infectivity is low.

## Clinical features

Molluscum contagiosum is unassociated with any constitutional upset and presents as a chronic viral infection of the epidermis. Lesions, which may be multiple, take the form of pinkish white or flesh-colored, dome-shaped nodules between 2 and 8 mm in diameter and most show a central depression or umbilication. They may appear on the face, arms, legs, buttocks, scalp or genitalia but sparing of the palms of the hands and the soles of the feet is a characteristic feature. Occasionally the margins of the eyelids are involved and chronic follicular conjunctivitis can supervene (Fig. 28.44). HIV infection may be associated with disseminated molluscum.

## Treatment

The disease is benign and self-limiting. Treatment is advised only to prevent spread by autoinoculation or to others. Treatment is simple and consists of the removal of the lesions with a sharp curette. Other methods include electro- or cryocautery. The lesions will usually heal without scarring and recurrence is rare.

## TRANSFUSION TRANSMITTED (TT) VIRUS

TT virus is a DNA virus that was first identified in 1997 in the serum of a patient with post-transfusion hepatitis of unknown etiology.<sup>691</sup> To date, there has been no disease association with this virus. It can be detected in the serum of 2% of healthy blood donors in the UK, and can be transmitted by transfusion, by fecal–oral spread and vertically.<sup>692</sup>

## ARENA VIRUSES CAUSING HEMORRHAGIC FEVER

### Lassa fever

Lassa fever was first reported from Lassa in Nigeria in 1969. The Lassa virus shows some morphological and antigenic similarities to lymphocytic choriomeningitis virus. It is one of the arenaviruses and it is widely distributed throughout West Africa. It is one of five African viruses (yellow fever, Lassa, Ebola, Marburg and Congo-Crimean) that cause hemorrhagic fever. The natural host is the rat *Mastomys natalensis*.

The virus is transmitted from person to person by close contact. It causes a diffuse serositis, hemorrhage and shock and is often fatal. Intravenous ribavirin reduces mortality from Lassa fever and is the treatment of choice. Additional treatment involves the use of plasma from a convalesced patient. For the adult 250–500 ml are used. Stocks of this are held in Nigeria, Sierra Leone, the London School of Hygiene and Tropical Medicine and the Communicable Disease Center, Atlanta, Georgia, USA. Strict isolation of patients is mandatory.

### Marburg virus disease (green monkey disease, vervet monkey disease, Jo'burg virus disease)

Marburg virus disease was first recognized in Germany in 1967 in personnel who had handled a consignment of African green monkeys

(*Cercopithecus aethiops*) from Uganda. Outbreaks have occurred in Sudan and Zaire. The Marburg virus is long, rod shaped (rhabdovirus-like) and does not appear to possess antigenic affinity with other known viruses. Although the Marburg outbreak appeared to follow contact with African green monkeys, no similar infections have been recognized as a result of other contacts with these monkeys and such monkeys suffer 100% mortality if experimentally infected. Thus the natural host and possible vectors are unknown.

The disease is highly infectious and carries a high mortality: 7 of the 31 Marburg cases died. Secondary cases appear to have a better prognosis than primary cases. There is as yet no protective vaccine. Strict isolation and barrier nursing of patients is necessary.

## Ebola virus disease

This disease is clinically indistinct from Marburg virus disease. The virus is morphologically identical to the Marburg virus, but antigenically distinct. The disease has been found in the Sudan and Zaire.

## INFECTIONS DUE TO ARBOVIRUSES (TOGAVIRUSES)

The principal feature linking the viruses of this group is the fact that all are arthropod borne (hence the name) and well over 200 such agents have been recognized. Most viruses in this group are natural parasites of animals or birds and multiply in arthropod vectors, which are unharmed by the process. Infection in the human may take several forms; most commonly encephalitis of varying severity results. Other diseases produced include yellow fever, dengue and sandfly fever. Arboviruses may also result in mild influenza-like illness. Children are particularly susceptible to this group of diseases. The arboviruses are subdivided into a number of families: Bunyaviridae (sandfly fever virus, Hantaviruses), Togaviridae (western equine encephalitis virus, eastern equine encephalitis virus), Flaviviridae (yellow fever virus, dengue viruses, West Nile virus), Reoviridae and Rhabdoviridae. They may also be classified according to the clinical syndromes they produce.

### Arboviruses group A

Some 20 arboviruses are included in this group, the best known being the viruses of eastern and western equine encephalitis, and more recently West Nile virus.<sup>693</sup> These present in humans as aseptic meningitis or meningoencephalitis of varying severity. Children tend to be more seriously affected and death may result. Those who survive the illness may have permanent mental retardation, deafness, epilepsy and paralysis. Mortality may vary with age and the responsible virus. On average, 5% of patients may die, but this figure is often considerably higher following infection by certain viruses, reaching 74% in eastern equine encephalitis.

Other viruses of this group produce a mild dengue-like illness and most have their animal reservoir in wild or domestic birds. Their arthropod vectors are culicine and anopheline mosquitoes.

### Arboviruses group B

This, a larger group, can be divided into (1) *mosquito-borne* and (2) *tick-borne* sections. The best-known disease associated with the former is yellow fever. The latter are mainly associated with a variety of encephalitic illnesses.

### Yellow fever (*yellow jack*)

Yellow fever has been a recognized clinical entity for over 300 years, and in 1881 Carlos Finlay suggested that *Aedes aegypti* spread the infection. This theory was substantiated by the classical studies of Walter Reed and his colleagues working on mosquitoes and yellow fever in Cuba.<sup>694</sup> Yellow fever occurs in parts of Africa, South America and central America, but not Asia. The last cases of infection acquired in the UK occurred in the latter part of the nineteenth century, when ships arrived carrying infected *A. aegypti*.

Disease may vary from a mild fever to a fulminant hepatitis with jaundice, hepatic necrosis, hemorrhage and shock. In the jungle it is

Fig. 28.44 Molluscum contagiosum.

predominantly an adult disease. Where infection occurs in an urban community, all ages and both sexes are equally affected.

There is no specific treatment.

Elimination of the responsible vector is of prime importance and infection has been eradicated from certain areas where this has been diligently performed. Vaccination with the 17 D attenuated strain of virus is compulsory for travel to endemic areas and immunity will usually last for up to 6 years. Complications of immunization are confined to an occasional case of benign encephalitis, usually encountered in young infants, and the vaccine is not recommended under 9 months of age if exposure to mosquitoes can be avoided.

### Dengue fever

Dengue fever is mosquito-borne like yellow fever, is also caused by a virus from group B, and the same vector, *A. aegypti*, is involved. The disease is widespread and is mainly found in warm areas, including Australia, Greece, Japan, India, Malaysia and Hawaii. So far, four antigenic varieties, known as types 1, 2, 3 and 4 have been described.

**Clinical features.** There is an incubation period of 5–9 days. The illness starts with high fever, malaise, headache, pain in the eyes, backache and excruciatingly painful limbs (it is sometimes called breakbone fever). Between the third and fifth days, a maculopapular, scarlatiniform or petechial rash appears and lasts up to 4 days. Following this there is usually a rapid recovery. Occasionally, however, particularly in children, the disease progresses to a severe hemorrhagic form, dengue hemorrhagic shock syndrome (DHSS), which may be fatal (see Hemorrhagic fevers below). It is thought that DHSS follows prior sensitization with a different strain of dengue virus, and is an example of antibody-mediated enhancement of disease.

**Control.** Eradication of the vector is desirable. Dengue viruses are poor antigens, which has frustrated efforts to produce effective vaccines.

### Hemorrhagic fevers

A number of virus infections may occur in a hemorrhagic form, e.g. Lassa fever, yellow fever and measles. The arboviruses, particularly the Chikungunya (group A) and dengue (group B) viruses, are also prone to cause hemorrhagic disease. Hemorrhagic fever due to the mosquito-borne Chikungunya virus has been reported in Africa, India and Thailand. In South East Asia, hemorrhagic fever due to dengue virus is transmitted by the bite of the *A. aegypti* mosquito which is common in urban areas.

The hemorrhagic fevers affect mainly children. Patients develop fever, erythematous or petechial rashes, hepatosplenomegaly and bleeding that may be mild or severe. The majority of patients recover, but some develop shock and die. Thrombocytopenia is common. In fatal cases there are gross effusions into the serous cavities, petechial hemorrhages on the surface of organs and bronchopneumonia. Treatment is symptomatic. In shocked cases, intravenous plasma should be administered, together with the usual measures for collapsed patients.

### Hemorrhagic fever with renal syndrome

This name is used for several similar conditions including Korean hemorrhagic fever and nephropathica epidemica occurring in Scandinavia, central Europe, Russia, China, Japan and Korea.<sup>695</sup> At least two viruses, Hantaan (Hantavirus) and Puumala, transmitted by arboviruses from rodents, are implicated. The clinical manifestations are fever, shock, massive proteinuria followed by acute renal failure, and thrombocytopenia and bleeding with bruising, hematuria, hematemesis and melena. With supportive treatment, the mortality is low.

### Tick-borne arbovirus infections

These including louping ill (a disease of sheep in Scotland and northern England; rarely aseptic meningitis can occur if man is infected by an infected tick), Russian spring–summer encephalitis (western and eastern forms), Omsk hemorrhagic fever and Kyasanur Forest fever. Illness associated with this group may range from aseptic meningitis to severe and even fatal encephalitis, although the prognosis is better than with

infection by group A strains. On occasion paralytic disease simulating poliomyelitis can occur and Omsk fever is usually characterized by bronchopneumonia and hemorrhage from various orifices.

### Arboviruses group C and unclassified arboviruses

Group C, comprising seven viruses, is responsible for influenza-like illness in parts of South America. Amongst the unclassified infections, sandfly fever is perhaps the best documented illness.

#### Sandfly fever (*phlebotomus fever, papataci fever*)

This illness results from infection by one of the unclassified arboviruses. It is relatively common in countries bordering the Mediterranean and occurs in parts of Africa, Russia, India and China. The responsible vector *Phlebotomus papatasi*, often called sandfly, is extremely small and may pass through mosquito nets. Infection in these sandflies may be permanent, due to trans-ovarian infection, and no definite animal reservoir is known. Several different strains of virus have been isolated with established immunological variation.

**Clinical features.** The incubation period is 3–7 days. Onset is sudden and rigors may occur. Headache, pain behind the eyes, muscular aching and fever are typical features. Occasionally photophobia, neck and back stiffness occur and mimic meningitis. After 3 or 4 days there is an abrupt termination by crisis. Severe apprehension often accompanies this illness and acute depression may follow an attack for a short time. Leukopenia is common. A clinical diagnosis is readily made in endemic areas or during an outbreak.

There is no specific treatment and the prognosis is good. Control is confined to attempts at eradication of the vector in its breeding grounds.

## RICKETTSIAL INFECTIONS

Rickettsial infection in man produces a number of different diseases, spread over a wide geographical area. The resultant illnesses have certain basic similarities and all but one are characterized by some form of skin eruption. Definitive clinical diagnosis can be difficult and confirmatory laboratory tests are desirable. A simple classification of rickettsial infection is shown in Table 28.36.

Rickettsiae have biophysical properties that place them in an intermediate position between viruses and bacteria and are small coccobacilli, usually less than half a micrometer in diameter, with rigid cell walls. They contain both RNA and DNA, but are obligate intracellular parasites and are sensitive to certain antibiotics.

### LABORATORY TESTS

Procedures to isolate the causative organisms exist, but should only be undertaken by a laboratory well equipped to deal with the risks involved. In view of the hazards involved in isolation, serological methods of diagnosis are usually employed.

The Weil–Felix agglutination reaction, used for several years, depends on the fact that patients with certain rickettsial infections develop agglutinins in their serum during the illness which agglutinate some strains of *Proteus* organisms, namely OX 19, OX 2 and OXK. There are now a number of other serological assays available in specialist reference laboratories. If possible, paired sera should be examined in the Weil–Felix test, but agglutinins may appear as early as the fifth or sixth day after the onset of the fever and usually reach a peak during the second or third week. Detection of rickettsial DNA in the blood or tissue by PCR may allow the diagnosis to be made earlier in the illness.

### TYPHUS FEVER (EPIDEMIC LOUSE-BORNE TYPHUS FEVER)

Historical writings suggest that typhus fever (classical or historic typhus) has been a scourge of humanity for many centuries. Typhus fever and war are inextricably linked. Although the responsible agent may be endemic in many parts of Europe, serious epidemics only arise

Table 28.36 Rickettsial diseases: causal agents, vectors, reservoirs and differential Weil–Felix reactions

	Disease	Causal rickettsiae	Principal vectors	Animal reservoir	Geographic occurrence
Typhus	Epidemic (louse-borne typhus)	<i>R. prowazekii</i>	Lice	Man	Worldwide
	Brill–Zinsser disease	<i>R. prowazekii</i>	–	Man	Worldwide
	Endemic murine (flea-borne) typhus	<i>R. mooseri</i>	Fleas	Rats	Worldwide
	Scrub typhus (mite-borne) (Tsutsugamushi fever)	<i>R. tsutsugamushi</i>	Mites	Small rodents	Japan, South East Asia, Pacific
Spotted fevers	Rocky Mountain spotted fever	<i>R. rickettsii</i>	Ticks	Small rodents	East and west USA
	Mediterranean fever (fièvre boutonneuse)	<i>R. conorii</i>	Ticks	Small rodents and dogs	Mediterranean, Caspian and Black Sea, Africa, South East Asia
Rickettsialpox		<i>R. akari</i>	Mites	House mice	USA, Russia, Korea
Q fever	Query fever	<i>R. burnetii</i>	Occasionally ticks	Cattle Sheep Goats Bandicoots	Worldwide

during times of war or in their aftermath, due entirely to the increased infestation by lice that occurs in these periods. Epidemics occur chiefly in winter when people are crowded together for warmth and shelter, enhancing chances of spread of the louse. Following the 1914–1918 war, it was estimated that 30 million cases of typhus occurred in Russia alone, and some 10% of these probably died. In the 1970s, large epidemics occurred in central Africa (Ruanda–Burundi).

The responsible organism is *Rickettsia prowazekii* and transmission is by the body louse *Pediculus corporis* or the head louse *Pediculus capitis*. The lice become infected by biting a human who is carrying the specific rickettsiae in the blood. Subsequent spread of the infection results from the infected feces of the lice rather than by an actual bite, and the irritation set up on the human body by the infestation results in the organisms being scratched into the skin. Infection may also result from the inhalation of louse feces in dust. At times fleas may act as a vector and also convey the infection through their feces.

### Clinical features

The incubation period is 6–15 days. There are three main clinical phases – prodromal, invasive and eruptive.

Prodromal symptoms, not always present, include mild headache, lassitude, weakness and pyrexia. The invasive stage is characterized by a sharp rise in temperature, severe headache and generalized aching. Rigors may occur and the fever may reach 40–41 °C. The pulse is rapid, the blood pressure reduced and a variable degree of prostration develops. A wide variety of additional symptoms and signs may be encountered including suffusion of the conjunctivae, facial flushing, photophobia, deafness, tinnitus, vertigo and cough.

The characteristic rash arises about the fifth day of illness and the initial lesions, comprising pinkish red macules, appear on the trunk and soon spread to the limbs. Most cases show sparing of the face, palms and soles. In mild cases the rash may develop no further, but in the more severely ill the eruption becomes hemorrhagic or even purpuric. During this eruptive phase the mental state becomes dulled. Stupor, delirium and coma may follow. Hypotension also becomes more intense and oliguria with azotemia is common. Severe cases will die between the 9th and 18th day of illness. Those who recover slowly improve after 2 weeks, the mental recovery being more rapid than the physical. Typhus is usually accompanied by leukopenia and normochromic anemia.

### Complications

Bronchopneumonia, otitis media, skin sepsis, arterial thrombosis and gangrene are all encountered. Less often there may be areas of skin necrosis and secondary infection of the salivary glands. Prolonged hypotension has a grave prognosis.

### Differential diagnosis

Typhus may be readily considered and diagnosed at epidemic times, but sporadic cases can cause considerable confusion. Amongst diseases that may require differentiation are other rickettsial infections, typhoid fever, measles, malaria and meningococcal septicemia.

### Treatment

In children, doxycycline 5 mg/kg/d 12 hourly (max 200 mg) or chloramphenicol 75–100 mg/kg/d (max 2 g) or tetracycline 50 mg/kg/d is used and should be continued until the temperature has settled for 48 h. Antibiotics should be re-instituted if there is clinical relapse.

Careful nursing and general supportive measures are required. A high protein diet is desirable and transfusion of blood or plasma may be needed. Electrolyte imbalance can readily occur and requires appropriate correction. Oxygen may be given for pulmonary complications and digoxin for cardiac failure.

### Prognosis

The disease is rarely fatal in children, but about 10% of young adults and 60–70% of people over 50 may die.

### Control

Killed vaccines prevent deaths, although not necessarily infection. Scrupulous hygiene is desirable and insecticides should be used to eliminate lice: DDT, lindane and malathion have proved effective.

### BRILL–ZINSSER DISEASE (RECRUDESCENT TYPHUS)

This condition represents a recrudescence of epidemic louse-borne typhus that occurs years after the primary attack. It is usually mild and the illness is drastically modified. Skin rashes are usually absent and the prognosis is good. In view of its atypical clinical nature and the fact that a case may arise when no other typhus infection is occurring, diagnosis is difficult. Less markedly abnormal laboratory tests can also be misleading. However, if a diagnosis is made, treatment is along the lines employed for epidemic typhus. The real danger of Brill–Zinsser disease is to the community. If epidemiological factors are favorable, especially if the environment is heavily louse infested, an epidemic could arise from such a case.

### MURINE TYPHUS (ENDEMIC FLEA-BORNE TYPHUS FEVER)

This disease is clinically similar to classical epidemic typhus but is milder and has a much lower fatality rate (2%); the management and treatment are also similar. The responsible agent is named *Rickettsia*

*mooseri* and it is usually spread to man from its animal host by the rat flea (*Xenopsylla cheopis*).

Widely distributed throughout the world, the disease appears to be on the decline, probably owing to stricter control of rats. It is more common in summer when rats are more numerous and has a higher infection rate amongst persons in the food trade where rats may abound. Unlike lice, which die from *R. prowazekii*, the rat flea is not killed by the multiplication of *Rickettsia mooseri* in its tissue. Control depends on flea eradication and extermination of rats.

### SCRUB TYPHUS (TSUTSUGAMUSHI FEVER)

This disease, known by many different names according to the locality where it occurs, is transmitted to man by the bite of the larvae of different species of chigger-like mites; best known of these are *Trombicula akamushi* and *Trombicula deliensiensis*. The responsible agent is known as *Rickettsia tsutsugamushi* and the cycle of infection involves chiggermite and various wild rodents. Clinical features are again like those of other rickettsial infections though fairly mild. A diagnostic finding in some is a small necrotic ulcer or eschar where the responsible mite has attached itself to the skin and introduced the infection. The disease occurs in the south west Pacific and South East Asia between Japan, the Solomon Islands and Pakistan.

Treatment is with doxycycline 5 mg/kg/d 12 hourly (max 200 mg) or chloramphenicol 75–100 mg/kg/d (max 2 g) and the mortality is under 5%. Elimination of the disease is difficult and mite-infested areas are best avoided. Alternatively protective clothing, treated with a mite repellent, should be used. Vaccines have not proved effective in this condition.

### ROCKY MOUNTAIN SPOTTED FEVER

This disease results from infection by *Rickettsia rickettsii* which is transmitted to man through a variety of ticks which are both the vector and the common reservoir for the responsible agent. Some rodents, dogs and sheep also act as additional but less prolific reservoirs. The clinical course has many similarities to classical typhus but the incubation period is often shorter (2–5 days in severe cases). Furthermore, the rash is usually more pronounced and frankly petechial. It can also be more widespread and may take some time to subside.

Complications, differential diagnosis, laboratory findings, treatment and management are all similar to epidemic typhus. Reported mortality rates have varied between 3 and 90% with an average, for all ages, of 20%. Despite its name, this disease is now much more common in the eastern than the western USA. In the western USA, adult males are most frequently attacked, whereas in the east children are most commonly affected.

Control is difficult owing to the disseminated nature of the vector in the wild, and where possible it is best to avoid tick-infested areas or to ensure that adequate protective clothing is worn.

### TICK TYPHUS FEVERS (FIÈVRE BOUTONNEUSE)

There are three tick-borne spotted fevers caused by rickettsiae which share the same group-specific antigen as *Rickettsia rickettsii*, the cause of Rocky Mountain spotted fever, but have distinct type-specific antigens.

*Rickettsia conorii* causes fièvre boutonneuse, which is also called Mediterranean fever along the Mediterranean, Black and Caspian sea littorals; called Kenyan tick typhus and South African tickbite fever; and called Indian tick typhus in South East Asia. *Rickettsia australis* causes Queensland tick typhus in eastern Australia. *Rickettsia sibirica* causes Siberian tick typhus which occurs throughout central Asia.

The main animal reservoir is dogs. These tick typhus fevers are clinically similar. A small, indurated lesion, the tache noire, develops at the site of the tick bite, and central necrosis gives way to eschar formation. There is regional lymphadenopathy. The tick typhus fevers are much milder than Rocky Mountain spotted fever, with a mortality under 1%. Antibiotic treatment is as for the latter disease.

### RICKETTSIALPOX

Due to *Rickettsia akari*, this disease is usually transmitted to man by a mite and the house mouse is the main animal reservoir. Epidemics tend to occur where mice and mites are found together, primarily in urban populations worldwide.

The illness is comparatively mild. The incubation period is 10–21 days. Fever is usual and a mild rash develops, most closely resembling adult chickenpox. Death is extremely rare. Doxycycline is the drug of choice.

### Q FEVER (QUERY FEVER)

This disease results from infection by *Coxiella burnetii* and usually presents as an influenza-like illness with fever and headache, often followed by an atypical pneumonic illness. Unlike other rickettsial infections, Q fever is unaccompanied by a rash.

*C. burnetii* is an obligate intracellular parasite which is highly pleomorphic and contains both RNA and DNA. It is more resistant to chemical and physical agents than other pathogenic rickettsiae and is relatively sensitive to certain antibiotics.

The natural reservoir of *C. burnetii* is animals such as cattle, sheep and goats, as well as certain ticks, and the latter are probably involved in animal-to-animal spread. Infection in humans may arise from the handling of infected meat and placentae, the inhalation of infected dust in farmyards and the consumption of infected raw milk. Cases are most likely to be found in farm workers, slaughtermen and shepherds. Where milk is the vehicle of transmission, the disease may occur without any apparent occupational link and involve children.

### Clinical features

Q fever is less commonly diagnosed in children than in adults because the illness produced in younger age groups is less severe and less intensively studied.

There is usually an incubation period of 2–3 weeks and the illness starts abruptly with fever, rigors, headache, malaise and weakness. In some instances the illness may terminate in approximately 1 week without any further progression, but in most diagnosed cases the patient goes on to develop a cough and chest pain. Physical signs may be absent or minimal, although the chest X-ray may show pneumonitis.

Severe cases may have symptoms for up to 3 weeks and radiological abnormalities can take a similar period to resolve. Inapparent infection can also occur. Occasionally Q fever presents with meningoencephalitis and diagnosis can be difficult.

### Complications

Q fever, or rickettsial, endocarditis has only been seen in people with pre-existing valvular disease of the heart and the clinical presentation is with culture negative subacute bacterial endocarditis. Granulomatous hepatitis and bone granulomas have been described.

### Laboratory diagnosis

*C. burnetii* can be isolated in laboratory animals or fertile hen's eggs. However, as it is a significant biohazard to laboratory workers, serological tests are preferred to confirm a clinical diagnosis, and a complement-fixation test or immunofluorescence is used on acute and convalescent sera. Detection of nucleic acid by PCR or hybridization techniques is also available.

### Treatment

Prodromal symptoms require symptomatic treatment. Once the diagnosis is made, doxycycline (5 mg/kg/d up to 200 mg) or tetracycline (25 mg/kg/d) or chloramphenicol should be given in standard dosage for 2 weeks. Therapy should not be withheld where the diagnosis is retrospective and the patient has recovered, because it is important to eradicate the infection and avoid the possibility of chronicity. Endocarditis has a grave prognosis.

## PROTOZOAL INFECTIONS

### AMEBIC INFECTIONS

Amebae are characterized by two forms – the motile, feeding trophozoite and the cyst. The cyst has a rigid wall, resistant to environmental conditions, which allows it to survive for variable periods without feeding. The major ameba of importance to man is *Entamoeba histolytica*, which is anaerobic and an obligate parasite of the gut. It has to be differentiated from other nonpathogenic gut amebae, e.g. *E. dispar*, *E. coli* and *E. hartmanni*. There are a number of free-living aerobic amebae which are found in the soil and feed on bacteria in muddy water. In dry conditions the cysts may be dispersed by wind. Species that are pathogenic to man and may cause meningoencephalitis are *Naegleria fowleri* and the opportunist *Acanthamoeba culbertsoni* and *Balamuthia mandrillaris*.

### AMEBIASIS

Amebiasis is caused by *E. histolytica* and is transmitted by the fecal–oral route. Sources of infection include sewage contamination of water supplies, infection by food handlers and direct fecal contact from person to person, as may occur in mental institutions. Transmission by sexual contact, including oral and anal sex, also occurs. Rarely, amebic colitis or liver abscess may present within the neonatal period.

Infection occurs worldwide, with a high prevalence in resource limited countries where hygiene is poor.

*E. histolytica* cannot be differentiated by microscopy from the morphologically identical but nonpathogenic *E. dispar*. Methods required include stool antigen tests, culture characteristics, zymodeme analysis and molecular techniques, such as PCR.<sup>696-698</sup> *E. histolytica* trophozoites characteristically demonstrate active erythrophagocytosis. *E. dispar* is 9 times more prevalent than *E. histolytica* and is the most likely species when ‘amebic cysts’ are detected in stools of asymptomatic subjects in any part of the world. Up to 10% of asymptomatic carriers of *E. histolytica* develop invasive disease; the remainder clear the infection within a year.<sup>696,698</sup>

Why *E. histolytica* is activated to invade is not known. Malnutrition, pregnancy, ulcerative colitis, immunosuppression, corticosteroids and intercurrent infection by bacteria or parasites may be precipitating factors. Inflammatory bowel disease should not be treated with corticosteroids until amebiasis has been excluded.

The incidence of disease does not necessarily correlate with prevalence of infection. Invasive disease is reported particularly from South East Asia, Natal (South Africa), the west coast of Africa, Mexico and parts of South America. In the USA, infection is associated especially with children of Hispanic origin.

### Pathogenesis and pathology

Infection occurs from ingestion of cysts, which, on digestion, release trophozoites in the intestine. The trophozoites feed on bacteria and fecal matter in the cecum and further down the colon. When they reach areas where the feces are more solid, they encyst and the cysts are passed in the stool. Trophozoites may be detected in the stool even if there is no intestinal hurry. The presence of either trophozoites or cysts in stool is not necessarily indicative of invasive disease. However, the presence of hematophagous trophozoites (containing ingested red blood cells) is usually suggestive of invasion. Invasion is accomplished by lytic enzymes secreted by the trophozoites which result in tissue necrosis and erosion of blood vessels, but with a surprising lack of inflammatory response. Initial lesions are small superficial erosions. With progression, they penetrate the muscularis mucosa and may expand to produce flask-shaped ulcers. Further extension may result in intestinal perforation, but more commonly the parasite is carried to the liver in the portal vein, and rarely to other organs such as the lung, heart or brain. The colonic lesions may vary from small pinhead erosions confined to the cecum and rectosigmoid to extensive, deep, confluent ulcers extending throughout the colon. It is probable that the majority of amebae

reaching the liver do not cause detectable disease. Possibly, an area of tissue necrosis is necessary for the disease to be established. As in the bowel, liver abscess is characterized by localized necrosis without much inflammatory response, unless there is secondary infection.

### Clinical features

The major organs affected in invasive amebic disease are the colon, the liver and adjacent organs, such as the right lung, pericardium and rarely the skin or eye.

### Intestinal amebiasis

Intestinal amebiasis has a wide spectrum of severity. It may occur within a few weeks of infection or be delayed several months. There may be mild, intermittent diarrhea with blood and mucus, usually with no systemic upset or fever. Severe, fulminating dysentery is associated with watery, blood-stained, mucoid stools resulting in dehydration, electrolyte disturbance and toxemia. Abdominal pain, tenesmus and tenderness may be present. Perforation, which is often multiple with slow leakage, and peritonitis may occur. Other complications include hemorrhage, ameboma, stricture, intussusception and rectal prolapse. Chronic or relapsing dysentery may occur unless the initial attack has been managed by adequate chemotherapy and nutritional support. Ameboma is a complication of previous amebic dysentery and presents as a tender mass in the cecum or colon.

Enlargement of the liver may occur without evidence of an abscess, presumably the result of toxic products transported in the portal vein from the diseased bowel.

### Amebic liver abscess and related disorders

Amebic liver abscesses may be single or multiple and more often involve the right lobe. Multiple abscesses are common in young children (Fig. 28.45). The liver is tender and, if the abscess is situated anteriorly, a mass is commonly visible (Fig. 28.46). There is nearly always fever and usually anemia, leukocytosis and raised erythrocyte sedimentation rate

Fig. 28.45 Typical multiple amebic abscesses in the liver of an infant aged 8 months.

Fig. 28.46 An African infant of 10 months with a large amebic liver abscess presenting as a fluctuant mass in the epigastrium.

(ESR) and often also alkaline phosphatase. Jaundice is infrequent and serum transaminases are usually not raised. There is dysentery or a history of previous dysentery in only half the cases. In over two thirds of cases, elevation and immobility of the right diaphragm produces corresponding signs in the right lung.

Complications of amebic liver abscess include secondary bacterial infection, extension, or rupture into the peritoneal cavity, the pleural cavity and/or the lung. Involvement of the left lobe of the liver may result in a pericardial effusion or rupture into the pericardium. Rarely, there may be extension to abdominal organs including the stomach, gut or kidneys. Blood-borne spread may result in a brain or lung abscess.

### Skin

Cutaneous amebiasis may be associated with rupture of a liver abscess, colostomy stoma or a laparotomy incision. In infants, amebic abscess of the perineum may result from direct contact with infected feces (Fig. 28.47).

### Diagnosis

The diagnosis of amebic dysentery is based on the finding of motile, hematophagous *E. histolytica* trophozoites in feces. Red cells and bacteria but few leukocytes are usually present. Examination of a freshly passed warm stool (within 30 min of being passed) is important because, when the stool cools, the amebae stop moving and release the contained red cells in their vacuoles. Three or more stool examinations may be necessary and both direct and concentrated methods should be used. *E. histolytica* stool antigen test is more sensitive than microscopy and can differentiate *E. histolytica* from *E. dispar*. Endoscopy may demonstrate amebic ulcers, which are usually shallow, covered with a yellowish-gray exudate and contain numerous hematophagous trophozoites. Biopsy should be taken from the edge of the ulcer. The intervening mucosa is often relatively normal in appearance. Serum antibody titers to *E. histolytica* may be raised in two thirds of cases early in disease and in over 90% during convalescence.<sup>697</sup> In endemic areas, positive serology in young children suggests infection, but in older children does not distinguish between past and current infection.

The definitive diagnosis of amebic liver abscess is made by aspiration of bacteriologically sterile pus. The pus is usually gray-yellow at the first aspiration and only at subsequent aspirations takes on the pink or red-brown 'anchovy-paste' color. Amebae are seldom detected in necrotic material from the center of the abscess, but are more common in the walls of the cavity and thus are more likely to be detected in the last portions of the aspirate.

In most cases an ultrasound scan can localize and delineate the size of the abscess cavity. Ultrasound, CT and MRI have equal sensitivity in detecting amebic abscesses. Differential diagnosis includes pyogenic liver abscess, subphrenic abscess and hydatid disease. X-ray and screening may demonstrate a raised diaphragm with reduced movement and there may be an effusion or other signs of inflammation at the lung

Fig. 28.47 Cutaneous amebiasis involving the vulva in an infant aged 5 months.

base. Usually there is a leukocytosis and a raised ESR. Antibody titers are usually high and may be detected in serum in over 95% of cases later on in disease.<sup>697</sup> ELISA has high sensitivity and specificity and usually becomes negative 6–12 months after response to treatment, whereas indirect hemagglutination titers may remain raised for many years. For unknown reasons, infection is only detected in the stool in about one third of cases, and usually only cysts are present.

### Management

Chemotherapy of invasive amebiasis must include drugs which can eliminate amebae both from the tissues and the lumen of the bowel. Metronidazole and tinidazole (longer half-life) achieve both but are less effective as luminal amebicides.

For asymptomatic patients, and following invasive disease, the luminal amebicide diloxanide furoate is given, using 20 mg/kg/d in three divided doses for 10 days. Paromomycin 25–35 mg/kg/d in three divided doses for 7 days is an alternative. In endemic areas, older asymptomatic children are usually not treated, as reinfection is so common.

In symptomatic intestinal disease, metronidazole or tinidazole is recommended. Metronidazole 35–50 mg/kg/d in three divided doses orally is given for 7–10 days depending on the severity of the infection. Side-effects such as nausea and a metallic taste in the mouth may make compliance difficult. Alternatively, oral tinidazole 60 mg/kg is given as a single daily dose for 5 days. Both drugs may also be given intravenously. In severe colitis, correction of fluid and electrolyte imbalance is important, and gastric suction is necessary when there is ileus. Blood transfusion may be required. Broad spectrum antibiotics may be necessary if septicemia or other infection is suspected. Perforation of the bowel with leakage into the peritoneum may require surgery.

For liver abscess, metronidazole or tinidazole is usually effective and is given in doses similar to intestinal disease. Diloxanide furoate or paromomycin should be given to eradicate the bowel infection.

Indications for aspiration of the abscess include: suspected pyogenic abscess (particularly when there are multiple lesions), a palpable mass, a markedly raised diaphragm, failure of symptoms to remit after 72 h of drug therapy, and abscess in the left lobe. Aspiration, by relieving the pressure within the liver tissues, allows better drug penetration of the abscess. Surgical evacuation may be necessary for multiple or inaccessible abscesses, or when secondary infection has occurred. For needle aspiration, a wide-bore needle with a three-way tap should be used and the abscess cavity evacuated fully. Aspiration is usually through the right chest wall at the point of maximum tenderness, or through the abdomen if the abscess is superficial. Aspiration should be guided by ultrasound scan. If repeat aspiration is required, or in the case of drug resistance, percutaneous catheter drainage for 24–48 h may be undertaken.<sup>699</sup>

Resolution of the abscess cavity may take many months. Follow-up should be arranged to ensure complete eradication of infection, otherwise relapse may occur.

Intrathoracic and intraperitoneal rupture of amebic liver abscesses usually responds to standard anti-amebic chemotherapy.

As humans and primates are the only reservoirs of *E. histolytica*, eradication of disease is possible and vaccines are being developed with this aim.

### NAEGLERIA AND ACANTHAMOEBA

Two distinct types of meningoencephalitis are caused by free-living amebae: primary amebic meningoencephalitis by *Naegleria fowleri*, and granulomatous amebic encephalitis usually by *Acanthamoeba culbertsoni* or *Balamuthia mandrillaris*.<sup>700</sup>

#### Primary amebic meningoencephalitis

This is an acute necrotizing meningoencephalitis caused by *N. fowleri* which gains access to the nasal cavities and results in direct invasion of the nervous system through the olfactory apparatus. There is usually a history of swimming under water or diving in warm fresh water or hot springs. Cysts transmitted in dust may colonize the nasal cavities

of children. The cerebrospinal fluid (CSF) has changes similar to bacterial meningitis, viz. a predominant neutrophil count, often accompanied by red cells, a raised protein (usually > 1 g/L) and low glucose concentration. Careful search for trophozoites should be undertaken on fresh CSF. Nasal secretions or washings should also be examined for amebae.

The course of the disease is usually rapidly fulminating within 3–6 days. Intravenous and, if necessary, intraventricular (through a reservoir) amphotericin is the main treatment. In addition, parenteral fluconazole is usually given by the intravenous (and intrathecal) route and rifampicin orally. Duration of therapy is 8–10 days.

### Granulomatous amebic encephalitis

This is a slowly progressive disease, occurring usually in immunocompromised individuals, although sometimes no immune defect can be demonstrated.<sup>701</sup> Infection by *acanthamoeba* may result from swallowing or inhaling cysts, or by direct skin or corneal contact. The CSF shows a lymphocytosis, a raised protein and low or normal glucose. *Acanthamoeba* may be detected in histological specimens. Sometimes the trophozoites may be detected by wet mount of CSF and subsequently cultured. Serology may also be of value.

Severe brain damage may have occurred by the time the diagnosis is made. Suggested drugs for treatment include polymyxin B, pentamidine isetionate, co-trimoxazole, ketoconazole and flucytosine.

Successful outcome is more likely in immunocompetent children.

### Acanthamoeba keratitis

Most cases of *acanthamoeba* keratitis are associated with use of contact lenses, owing to a combination of abrasions of the cornea and contamination of the lens from washing in homemade solutions, especially fresh or tap water.<sup>702</sup>

Treatment is difficult and often requires keratoplasty. Local application of a combination of biocides, e.g. 0.02% polyhexamethylene biguanide plus 0.1% propamide isetionate and neomycin, is used. Local chlorhexidine may also be of value.<sup>702</sup> Corticosteroids are required to control inflammation. Only fresh, sterile, commercial solutions should be used to clean contact lenses.

Research on vaccines to prevent *acanthamoeba* keratitis is in progress.

## BALANTIDIASIS

*Balantidium coli* is a parasite of pigs which may colonize the colon of man producing a disease similar to *E. histolytica*, but extracolonic disease does not occur. Treatment is with metronidazole or tetracycline for 8–10 days.

## CRYPTOSPORIDIOSIS

*Cryptosporidium* spp. are second only to the enteric viruses in importance as causes of diarrheal disease in children. There are a number of different species of *Cryptosporidium*, some of which infect humans (Table 28.37). *C. muris* was first described by Tyzzer in 1907 as an asymptomatic infection of the gastric glands of mice. *C. parvum* was first described also by Tyzzer in 1912 in the intestines of mice. *C. meleagridis* was described as a cause of diarrhea in turkeys by Slavin in 1955 and since then the number of different *Cryptosporidium* species has expanded, contracted and then expanded again. It was first described as a human pathogen in 1976<sup>703,704</sup> and thought to be zoonotic. Interest in cryptosporidiosis increased, first because it was possible to diagnose infection by microscopic examination of stained fecal smears and second because of its association with AIDS.<sup>705,706</sup> It was originally thought of as a zoonotic infection, but person-to-person transmission was described in 1983<sup>707</sup> and it is clear that both anthroponotic and zoonotic transmission occur.

Originally *Cryptosporidium* was classified as a member of the subclass *Coccidiosa* in the phylum *Apicomplexa*. However, recent molecular

Table 28.37 *Cryptosporidium* species

	Major hosts	Minor hosts
<i>C. hominis</i>	Humans	Cattle, dugong, sheep
<i>C. parvum</i>	Cattle, sheep, goats, humans	Deer, mice, pigs
<i>C. meleagridis</i>	Turkeys, humans	Parrots
<i>C. felis</i>	Cats	Humans, cattle
<i>C. canis</i>	Dogs	Humans
<i>C. wrairi</i>	Guinea pigs	Humans
<i>C. baileyi</i>	Chickens, turkeys	Other birds, humans
<i>C. muris</i>	Rodents, Bactrian camels	Humans, rock hyrax, chamoix
<i>C. andersoni</i>	Cattle, Bactrian camels	Sheep
<i>C. bovis</i>	Cattle

<i>C. serpentis</i>	Snakes, lizards	
<i>C. saurophilum</i>	Lizards	Snakes
<i>C. molnari</i>	Fish	

phylogenetic studies and the detection of extracellular stages have placed it closer to the Gregarines than Coccidia.<sup>708</sup>

*Cryptosporidium* spp. have a complex life cycle (Fig. 28.48) which can be simplified to (a) replication within the host and (b) the excreted infective form. The infective form is the oocyst, which is excreted in large numbers during acute infection (Fig. 28.49). It is highly resistant to disinfectants and is sufficiently small (c. 6 µm) to be able to pass through some water filtration units. The oocysts are infective as soon as they are excreted. Under the influence of gastric pH and duodenal enzymes, the oocyst excysts to release four sporozoites. These attach to and penetrate the enterocytes. Their location is just beneath the enterocyte membrane (Fig. 28.50) sometimes termed 'intracellular but extracytoplasmic'. It then undergoes cycles of asexual and sexual reproduction culminating in the production and excretion of the thick-walled oocysts. *C. hominis*

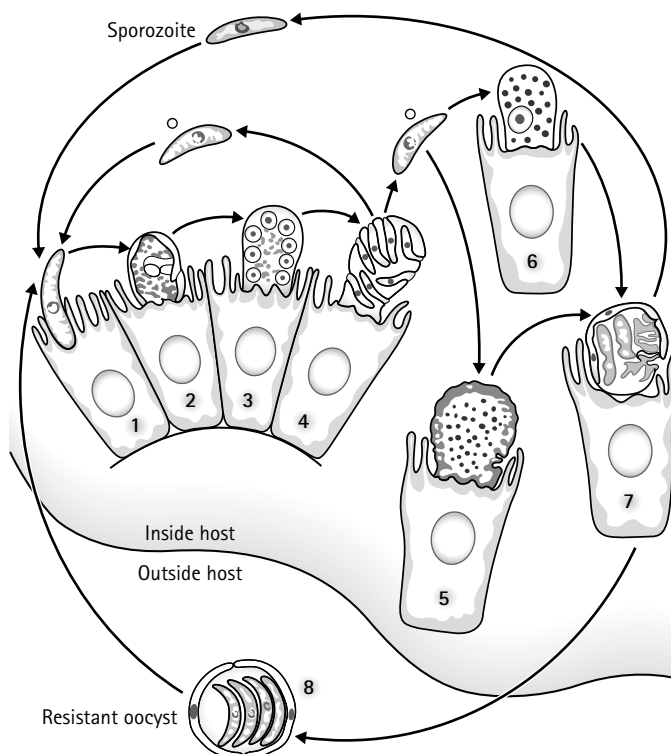

Fig. 28.48 The life cycle of *Cryptosporidium*.

Fig. 28.49 An oocyst of *Cryptosporidium hominis*.

has a 9.2 megabase genome encoded on 8 chromosomes, the full sequence of which has recently become available.<sup>709</sup>

## EPIDEMIOLOGY

Cryptosporidiosis has a worldwide distribution, being detected in every country where it has been sought. There are an estimated 250–500 million cases each year in Africa, Asia and Latin America.<sup>710</sup> It is an important cause of traveler's diarrhea and outbreaks can occur in crèches and day

Fig. 28.50 A trophozoite of *Cryptosporidium hominis* just beneath the enterocyte membrane.

care centers. School visits to farms where children handle farm animals and then eat without washing their hands are another risk activity. In addition, *Cryptosporidium* can be acquired by the waterborne route. The largest such outbreak occurred in Milwaukee, USA, and affected 403 000 people.<sup>711</sup> It was related to a water treatment failure, although the fecal coliform count (the standard measure of water quality) was within normal limits.

Large numbers of oocysts are excreted during acute infection and the infective dose is low (30–300 oocysts), varying by *Cryptosporidium* species.<sup>706</sup> In some volunteer experiments one oocyst was able to initiate infection. Transmission of *C. hominis* is usually considered to occur by person-to-person transmission, directly or indirectly, and the other species by zoonotic transmission. However, *C. hominis* has been detected in cattle and *C. parvum* can be transmitted person to person. Most of the cases of cryptosporidiosis are due to *C. hominis* and *C. parvum* followed by *C. meleagridis*, *C. canis* and *C. felis*.<sup>712–714</sup> *C. muris* is rarely a cause of human disease.<sup>712,715</sup> In the UK and other temperate countries there is a distinct seasonality with peaks in spring and to a lesser extent in autumn.<sup>705,710,716</sup>

The impact of cryptosporidiosis is greatest in children, and prevalence rates are much higher in children in resource limited countries (5–19%) compared to industrialized (<4%) countries.<sup>705</sup> The highest prevalence (19%) was recorded among children in Gaza.<sup>717</sup> Although children have the highest prevalence of infection, cryptosporidiosis can occur at any age. The youngest recorded case was 3 days and the oldest 95 years old.<sup>716</sup> Patients immunocompromised by AIDS, immunosuppression, congenital immune deficiency or cytotoxic therapy are at risk of severe and prolonged cryptosporidiosis (see ref. 705).

## PATHOLOGY AND PATHOGENESIS

Cryptosporidiosis is usually acquired by ingestion but there have been instances where it was acquired by the airborne route.<sup>718</sup> The shortest incubation period is presumed to be 3 days in a neonate who acquired infection intrapartum.<sup>719</sup> In a large study of Finnish travelers visiting Leningrad the mean incubation period was  $7.2 \pm 2.4$  days with a median of 8 days.<sup>720</sup> Infection affects the small and large intestine in immunocompetent hosts but can spread along mucosal planes to the biliary tree, pancreas, liver, sinuses and lung in immunocompromised patients.

The mechanisms by which *Cryptosporidium* causes diarrhea are not entirely clear. Possible mechanisms include malabsorption and a local intestinal inflammatory response with increased production of prostaglandins and several cytokines.<sup>721</sup> In addition, *Cryptosporidium* delays apoptosis in infected cells but promotes it in adjacent enterocytes.<sup>721</sup> The histopathologic appearance of the intestine in cryptosporidiosis shows minimal inflammatory infiltrates with blunting of villi (Fig. 28.51). Electron microscopic examination of infected mucosa shows minimal damage to the brush border (Fig. 28.49).

Fig. 28.51 Duodenal mucosal biopsy stained by hematoxylin and eosin showing villous blunting and cryptosporidia on the luminal surface.

## CLINICAL FEATURES

The clinical features vary according to whether the patient is immunocompromised or has an intact immune system.<sup>705,710,716</sup>

### Immunocompetent children

The severity of disease varies across a spectrum from a short mild illness to one of prolonged watery diarrhea lasting over 6 months which has been mistakenly diagnosed as celiac disease. Anorexia (60–70% of cases), vomiting (50–75%), fever > 38 °C (25–50%) and abdominal pain (50–90%) are commonly described. The stool is watery (60–100% of cases), green (60–70%) and has a particularly offensive odor (80–100%). The stool frequently varies from 3 to 20 per day with 60–70% of children producing > 5 stools per day. The average duration of diarrhea is 12–14 days but with a wide range (5–60 days).<sup>722,723</sup> On average, patients excrete oocysts for 10–14 days after cessation of diarrhea.<sup>724</sup> In approximately one third of children the diarrhea is intermittent with bouts lasting for 2–3 days with 1–2 days quiescence until the next bout. Up to a third of children have respiratory tract symptoms,<sup>723</sup> which might be related to the presence of *Cryptosporidium* in a case of laryngotracheitis in a child in Papua New Guinea.<sup>725</sup>

Cryptosporidiosis is not a major cause of severe dehydration in well-nourished children,<sup>705</sup> but is in children from resource limited countries.<sup>725</sup> A major feature is loss of weight and failure to thrive, which occurred in 25% of children admitted to a Liverpool children's hospital.<sup>723</sup>

### Immunocompromised patients

Although there is a spectrum of severity, cryptosporidiosis in immunocompromised patients is much more likely to be severe and also less likely to be self-limiting. The diarrhea is often described as profuse, voluminous and cholera-like. A stool frequency of up to 71 per day and a volume of 17 liters per day have been recorded in adults.<sup>716</sup> Another feature of cryptosporidiosis in immunocompromised patients is the occurrence of extraintestinal infection, which can involve the lung, sinuses, biliary tree or liver.

The immune deficits associated with severe cryptosporidiosis include B cell deficiency (hypo- or agammaglobulinemia, IgA deficiency), B and T cell deficiency (severe combined immunodeficiency, HIV/AIDS), immunosuppressive therapy (cytotoxic drugs, steroids, transplants), malnutrition, diabetes and measles.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The first human cases of cryptosporidiosis were diagnosed by examination of duodenal biopsies.<sup>703,704</sup> However, it was soon realized that patients with cryptosporidiosis excrete sufficiently large numbers of oocysts for them to be detected by microscopic examination of stained fecal smears. Stains now include modified Ziehl–Neelsen, Kinyoun and Safranin methylene blue.<sup>705</sup> An auramine phenol method has greater sensitivity as on UV illumination the oocysts fluoresce apple-green against a dark background. Such tests are labor intensive, and detection of copro-antigens by commercially available enzyme immunoassay kits allows large numbers of samples to be processed rapidly.<sup>726</sup> However, their efficiency depends upon the quality of the antibody used, they may not detect all species of *Cryptosporidium*, and recently one test was recalled because of problems with false positives.

Genome detection by PCR amplification of the 18S rRNA gene is a sensitive diagnostic tool and coupled with restriction fragment length polymorphism (RFLP) analysis will provide assignment to species. However, it is not commercially available.

Finally serological diagnosis by detection of antibody is possible, which although valuable for population-based surveys of exposure is not useful for acute diagnosis.

## TREATMENT

In most cases of infection in immunocompetent children only supportive therapy is needed. The infection is self-limiting. This is not the case in immunocompromised patients and a large number of drugs (> 150) have been tried in the treatment of cryptosporidiosis. Paromomycin and spiramycin produce symptomatic improvement but no alterations in oocyst excretion. A new agent, nitazoxanide, has been licensed for treatment of cryptosporidiosis and in double-blind placebo-controlled trials shows great promise.<sup>727</sup> The only other intervention possible is to decrease the immune suppression by giving antiretroviral drugs in AIDS or stopping chemotherapy for malignancies.

## CONTROL MEASURES

Great emphasis on personal hygiene is needed to limit person-to-person spread. In particular hand washing after toileting and nappy changing are very important. It is the mechanical effect of hand washing that is important as the thick-walled oocysts of *Cryptosporidium* are very resistant to most disinfectants and detergents. Prevention of waterborne disease is very difficult as evidenced by the Milwaukee experience.<sup>711</sup> The providers of potable water in the UK continuously screen the water to try to prevent infection. Boiling or freezing water should kill the oocysts. There is no vaccine to prevent cryptosporidiosis and as yet we still do not have a sound understanding of immunity to cryptosporidiosis.

## PROGNOSIS

Except in immunocompromised or malnourished children, the prognosis is very good providing there is adequate nutrition during the recovery phase. However, one study from Guinea-Bissau indicated that cryptosporidiosis in infancy was associated with a higher subsequent childhood mortality rate.<sup>728</sup>

## GIARDIASIS

The enteric protozoan *Giardia* is a major cause of diarrheal disease of humans and other animals including dogs and cats. Although frequently referred to as *Giardia lamblia* in the medical literature, this has no taxonomic validity. *Giardia duodenalis* is the species affecting most mammals including humans, companion animals and food animals.<sup>729</sup> Other recognized species are *G. agilis* in amphibians, *G. muris* in rodents, and *G. psittaci* and *G. ardae* in birds. The vegetative form of *G. duodenalis* or trophozoite is a pear-shaped flagellate protozoan 12–15 µm long and 5–9 µm wide (Fig. 28.52). It has two nuclei and four symmetrically arranged flagella originating from basal bodies at the anterior poles of the nuclei. The concave

Fig. 28.52 Thin section electron micrograph of *Giardia duodenalis* showing the ventral disc and flagella in cross-sections.

ventral surface has a ventral disc composed of microtubules, which are used by the protozoan for attachment to intestinal cells. The trophozoites are unusual among eukaryotes in having only a few rudimentary intracellular organelles.<sup>730</sup> The infective form is the cyst which is excreted in feces. It can survive water chlorination and for months in cold fresh water. The cysts are quadric-nucleate, ovoid and 7–10 µm in length. The genome is small and consists of approximately 12 million base pairs on five chromosomes encoding an estimated 5000 genes.

## EPIDEMIOLOGY

Giardiasis has a worldwide distribution and it is estimated that some 200 million people in Africa, Asia and Latin America have symptomatic infection and there are approximately 500 000 new cases each year.<sup>731</sup> It is an important cause of traveler's diarrhea and there is an increasing incidence of outbreaks in day care centers and crèches. Spread is fecal-oral, especially when hygiene is poor. Waterborne spread is increasingly important and, since a number of animal species can harbor *G. duodenalis*, a proportion of cases could be zoonotic.<sup>732</sup> Cyst concentrations excreted in feces are 150–20 000/g, but in contrast the infective dose is 10–100 cysts.

The impact of giardiasis is greatest in children. Prevalence rates are significantly higher in resource limited (20–30%) compared to resource rich (2–5%) countries. Recurrent and prolonged infections are not uncommon and some children may excrete cysts for long periods asymptotically. Patients with hypo- or agammaglobulinemia are at particular risk of chronic giardiasis, but HIV and AIDS do not apparently increase the risk greatly.

Recently it has been shown that strains infecting humans can be subdivided on the basis of 18S rRNA gene sequences into two major groups. These are called assemblages A and B and there are clusters of genotypes within the two assemblages.<sup>729</sup> Not only are these subdivisions useful for epidemiologic purposes, but it also appears that assemblage A isolates tend to be associated with intermittent diarrhea and assemblage B with more severe, persistent diarrhea.<sup>733</sup>

## PATHOLOGY AND PATHOGENESIS

Histologic changes in duodenal biopsies from cases of symptomatic giardiasis vary from entirely normal through partial, subtotal and total villous atrophy. Approximately 20–25% of patients will have normal villous architecture and <10% subtotal villous atrophy.<sup>734</sup> On electron microscopic examination there can be shortening and disruption of microvilli even in biopsies appearing normal on light microscopy.

Following ingestion, cysts are excysted by the sequential exposure to low pH in the stomach and higher pH in the duodenum, which activates giardial proteases.<sup>735</sup> Interestingly, the newly excysted protozoa express different surface antigens (variant surface proteins, VSP) to those expressed by the trophozoite before it was encysted. The trophozoites then can be found free in the small intestinal lumen (here motility by flagella is important to prevent flushing out) and closely apposed to the enterocyte surface, often embedded in mucin. Most often their ventral surface is towards the enterocyte surface and it is thought that attachment is by the ventral disc; however, they also have a mannose-binding lectin on their surface. The trophozoites reproduce by binary fission and it is thought that bile salts stimulate growth. Trophozoites encyst in the small intestine when they are at high cell densities and this is stimulated by high bile salt concentrations, lipid metabolites and neutral pH. How diarrhea is induced is not entirely clear. Suggestions include the trophozoites acting as a mechanical barrier to prevent nutrient absorption (which is unlikely), structural and ultrastructural damage to enterocytes, and malabsorption. Recently it has been demonstrated that giardiasis is accompanied by disruption of inter-enterocytic tight junctions perhaps mediated by anxin-like alpha giardins.<sup>736</sup>

## CLINICAL FEATURES

There are three clinical forms of giardiasis:

1. asymptomatic excretion of cysts;
2. acute diarrheal disease which is usually short and self-limited;
3. chronic diarrhea with malabsorption, weight loss and failure to thrive.

The asymptomatic carrier state can occur in children or adults but whether carriage follows symptomatic infection or carriage occurs with no prior disease is unclear. There is no information on whether the asymptomatic carrier has subclinical enteropathy. However, it is clear that carriers can act as a reservoir of infection for others.

Acute giardiasis follows an incubation period of 3–20 days (mean 7 days) and the illness usually lasts 2–4 weeks, but may last as long as 7 weeks. Diarrhea (in over 90%) is the major feature and weight loss occurs in 60–70%. Other features are abdominal discomfort, flatulence, nausea and vomiting (in 30%). Approximately half the patients will have signs of steatorrhea. In patients with cystic fibrosis, giardiasis may worsen the malabsorption of fat and fat soluble vitamins.

A proportion of those with acute giardiasis (estimated to be about 30%) go on to develop chronic diarrhea, most often with steatorrhea. Weight loss can be great, with fat malabsorption in about 50%. In infants and young children this can cause failure to thrive. In some cases malabsorption of vitamins such as B<sub>12</sub> or folate can lead to macrocytic anemia. Secondary lactase deficiency may occur and does not necessarily resolve with successful therapy.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Giardiasis should be considered in cases of acute or chronic diarrhea. Specific diagnosis is by detection of the protozoon, its antigens or genome either in stool or duodenal fluid obtained by endoscopy, a nasoduodenal tube or a weighted nylon thread ('string-test'). Stool is the most appropriate specimen, but more invasive specimen collection is indicated when there is a high index of clinical suspicion yet stool samples are repeatedly negative. Although trophozoites are shed in the initial phase of acute diarrhea, giardiasis is most often confirmed by detection of cysts on microscopy of wet-mount or formalin–ethyl acetate concentrated stool samples. A single stool sample will detect giardiasis in 70% of cases and examination of three samples on separate days will detect it in 85%. The sensitivity of microscopy can be increased by using anti-*Giardia* fluorescent labeled antibody (direct immunofluorescence). In general, antigen detection by ELISA is more efficient and cost effective.<sup>737</sup> A number of commercial kits are available, including one that can simultaneously detect *G. duodenalis*, *Entamoeba histolytica* and *Cryptosporidium parvum*.<sup>738</sup> Diagnosis by genome detection, for example by PCR, is at present experimental.

## TREATMENT

There is no evidence of benefit in treating asymptomatic infection. At least five classes of drugs – nitroimidazoles (metronidazole, tinidazole), benzimidazoles (albendazole), acridine dyes (mepacrine), nitrofurans (furazolidone) and nitazoxanide – are used for treating symptomatic giardiasis. A recent systematic review has concluded that drug treatment was associated with an improved cure rate (odds ratio 11.5; 98% confidence interval 2.3–58). Of the longer course regimens, metronidazole was the most effective (OR 2.4; 95% CI 1.2–4.4) with a smaller relapse rate. Tinidazole, which has a longer serum half-life than metronidazole, was best of the single dose regimens.<sup>739</sup> Unfortunately, there are few trials in children. The generally accepted regimen in children is metronidazole 15 mg/kg/d in three doses for 7–10 days. Mepacrine may be used as second line therapy (50 mg twice daily for children 1–5 years and 100 mg twice daily for children 5–10 years). Its use is limited by its bitter taste and induction of vomiting. In the USA, either metronidazole or furazolidone is preferred (tinidazole is not licensed for giardiasis). Furazolidone comes as a suspension, is given four times daily (6 mg/kg/d) for 7–10 days, and is less effective than metronidazole.

## CONTROL MEASURES

In nurseries, crèches and child care centers, personal hygiene should be emphasized. Hand washing by staff and children should be stressed, especially after toileting and nappy changing. In outbreaks, attempts should be made to identify and treat all of those with symptomatic giardiasis. Those with symptomatic giardiasis should be excluded from work or nurseries until the diarrhea ceases. Although such infection control measures will decrease transmission, it must be remembered that routes other than direct person to person (e.g. waterborne, zoonotic) are possible. Recently, a vaccine has been licensed for the prevention of giardiasis in dogs and cats.<sup>740</sup> The vaccine, which is made from killed whole trophozoite preparations, proved highly effective. This could be of benefit to humans, firstly in decreasing an animal reservoir for zoonotic transfer and secondly by paving the way for a human vaccine.

## PROGNOSIS

The prognosis is excellent, except in immunocompromised children, when relapse is common and treatment may need to be continued for prolonged periods. At the same time, attention must be paid to adequate nutrition and the treatment of concurrent infections.

## LEISHMANIASIS

Leishmaniasis is caused by infection with a number of species of protozoan parasites of the genus *Leishmania*. It occurs in many parts of the world, including southern Europe, and is particularly problematic in Central and South America, the Middle East, South Asia, China and East Africa. An estimated 1–2 million new cases occur annually. Most forms of leishmaniasis are zoonoses with rodent or canine reservoirs of infection; man and other vertebrate hosts become infected by the bite of sandflies (genera *Phlebotomus* and *Lutzomyia*). Clinical syndromes are determined by the infecting species and range from self-limiting cutaneous lesions to potentially fatal visceral leishmaniasis.

## LIFE CYCLE AND PARASITE BIOLOGY

Leishmania are transmitted by sandflies of the genus *Phlebotomus* in the Old World and *Lutzomyia* in the New World. Sandflies take in blood containing the aflagellate stage (amastigotes) from a hemorrhage made in the skin by their mouthparts. The amastigotes divide at least once before changing into the motile flagellate stage (promastigotes). These develop within the gut over 4–14 days and migrate forward to become inoculated when the sandfly attempts to take its next blood meal.<sup>741</sup> The intracellular stage in the vertebrate host (including man) is a small uninucleate ovoid body (2–5 µm long and 1–2 µm wide) containing a kinetoplast with a flagellar remnant and known as the amastigote (also referred to as the Leishman–Donovan body). The amastigote predominantly infects cells of the reticuloendothelial system and multiplies repeatedly by binary fission, eventually destroying the host cell.

### Parasite biology

Two major subgenera of importance in human leishmaniasis can be distinguished by the site of development within the sandfly vector: *Leishmania* subgenus *Leishmania* (*L. donovani*, *L. mexicana*, *L. tropica* and *L. major*) and *Leishmania* subgenus *Viannia* (*L. braziliensis* complex).<sup>742</sup> *Leishmania* that infect man are morphologically similar apart from minor variations in size of amastigotes. However, isoenzyme profiles, DNA characterization, PCR, monoclonal antibody techniques and serotyping can all be used to distinguish species.<sup>743</sup> Culture of leishmania can be performed using specialized media. Some *Leishmania* species grow poorly in culture, and culture characteristics have been used to differentiate *L. braziliensis* which is slow growing from *L. mexicana*.

The important leishmania affecting man and the clinical syndromes that they cause are summarized in Table 28.38.

### VISCERAL LEISHMANIASIS (KALA AZAR)

Visceral leishmaniasis (VL) is caused by leishmania of the *L. donovani* complex (*L. donovani*, *L. infantum* and *L. chagasi*).

Table 28.38 Summary of human leishmaniasis

Parasite	Geographical distribution	Animal reservoir	Disease
<b>Visceral leishmaniasis</b>			
<i>(Leishmania donovani complex)</i>

CL, cutaneous leishmaniasis; DCL, diffuse cutaneous leishmaniasis; LR, leishmania recidivans; MCL, mucocutaneous leishmaniasis; PKDL, post kala azar dermal leishmaniasis; VL, visceral leishmaniasis.

## Epidemiology

*L. donovani* is endemic and epidemic in north-eastern India and Bangladesh, predominantly affecting young adults and children. Infection is confined to man and no animal reservoirs have been identified. The vector, *P. argentipes*, is peridomestic and readily feeds on man. The parasite is similar in East Africa, where the disease is widespread with endemic foci and occasional epidemics, particularly in association with population movements and land development. Children are predominantly affected. Rodents are reservoirs of disease in Sudan, but no animal reservoir has been identified in Kenya. Transmission is often seasonal due to fluctuations in sandfly populations.

*L. infantum* is widely distributed through the Mediterranean littoral, southern Europe, the Middle East, southern regions of the former USSR and China. In endemic areas, children under 5 are predominantly affected although infection may occur at any age in visitors or the immunosuppressed. The domestic dog is an important reservoir host; wild canines and foxes also act as reservoirs.

*L. chagasi* in South and Central America resembles *L. infantum* clinically and epidemiologically. Infection occurs in Amazonian Brazil, Bolivia, Paraguay, Argentina, Colombia and Venezuela. Children are predominantly affected and both domestic and wild canines and foxes are reservoir hosts.

## Pathogenesis

After inoculation into the skin, the promastigotes convert to amastigotes in skin macrophages. These disseminate throughout the reticuloendothelial system and amastigote-laden macrophages are found in liver, spleen, bone marrow, lymphatic tissue and occasionally the skin. Progressive splenomegaly, hepatomegaly, anemia and thrombocytopenia result.

## Clinical features

Subclinical or asymptomatic infection is common and protects against subsequent infection; clinical disease only occurs in 10–20% of infections. The clinical features of visceral leishmaniasis are similar throughout the world. A small cutaneous lesion may occur at the site of inoculation, but is usually not observed. After a variable incubation period (usually 4–6 months), symptoms develop. Classical clinical features are a triad of fever, splenomegaly and anemia. However, the spectrum of VL ranges from an acute febrile infection with anemia, pancytopenia and splenomegaly to a protracted illness slowly progressing over 2 or more years with severe anemia and massive splenomegaly. *L. infantum* infections are usually more acute than infection with *L. donovani* but acute forms of *L. donovani* occur, especially in children. *L. infantum* may also cause simple cutaneous leishmaniasis in adults in Southern Europe.

Fever is frequent, commonly remittent or intermittent, and may have a characteristic double diurnal periodicity. In very acute forms, fever is high, with prostration, toxemia and minimal splenomegaly. However, many patients remain active despite high fever and some patients with chronic infection may be afebrile for prolonged periods. Most patients develop progressive splenomegaly and hepatomegaly; in chronic infections, the spleen may be grossly enlarged, smooth and hard. Generalized or localized (often cervical) lymphadenopathy occurs in some geographical areas and may be present in the absence of hepatosplenomegaly or other features of visceral leishmaniasis.

Patients with chronic disease are pale and, especially in India, develop an earthy grey color with areas of hyperpigmentation (kala azar). In Africa a diminution in skin pigmentation is more typical. Chronic VL leads to progressive wasting, nutritional skin changes and hair changes similar to those observed in kwashiorkor. Pancytopenia with associated immunosuppression leads to secondary infections such as pneumonia, bronchitis, meningitis and tuberculosis. Episodes of diarrhea are common and may be due either to secondary infection or submucosal infiltration with leishmania-laden macrophages. Patients are rarely jaundiced but dependent edema and ascites occurs. Hemorrhagic features, especially recurrent epistaxis, are common; major or fatal hemorrhagic episodes may occur.

## Visceral leishmaniasis and HIV

Visceral leishmaniasis is an important opportunistic infection in HIV, particularly in Southern Europe. Most cases occur in young adults but pediatric cases of co-infection have been reported. Both classical and atypical presentations with pulmonary, skin and gastrointestinal infection occur; fulminant infection without splenomegaly is also recognized. Leishmania serology is frequently negative, but parasites are usually easy to find in appropriate samples.

## Laboratory findings

The hematological features of visceral leishmaniasis are classically moderate to severe normocytic, normochromic anemia with hemoglobin levels of 6–8 g/dl, accompanied by neutropenia and thrombocytopenia, commonly  $80\text{--}100 \times 10^9/\text{L}$ . Lymphocytes are usually in the normal range and circulating eosinophils reduced or absent from the peripheral blood. The serum albumin is reduced and there is a substantial elevation of immunoglobulins, predominantly IgG.

## Diagnosis<sup>744,745</sup>

A parasitic diagnosis may be made by microscopy or culture of bone marrow or splenic aspirates. Splenic aspiration is more sensitive and reasonably safe in the absence of disturbed hemostasis or thrombocytopenia. Marrow aspiration is preferable in acute illness or in the presence of thrombocytopenia or disturbed hemostasis. Leishmania may also be identified by examination of the buffy coat and in lymph node and liver biopsy specimens. Smears are fixed in methanol and stained with Giemsa or Leishman that stain the cytoplasm of the amastigote blue, the nucleus pink or violet and the kinetoplast bright red. Culture is generally less sensitive than direct smear examination, but will detect some smear negative cases.

Anti-leishmania antibodies may be detected by a number of techniques, including IFAT, ELISA, and direct agglutination tests (DAT). ELISA and DAT techniques are highly sensitive and specific. High titers are associated with active disease and fall slowly after treatment. Rapid field diagnosis may be made by use of immuno-chromatographic strips which use recombinant antigens. PCR techniques can be used to detect leishmania DNA in peripheral blood and marrow with high sensitivity and specificity.

## Differential diagnosis

Visceral leishmaniasis should be considered in the differential diagnosis of acute or chronic fever accompanied by hepatosplenomegaly and anemia, especially when there is a history of residence in an endemic area. Many other infections including malaria, especially *P. malariae* infection, typhoid, brucellosis, relapsing fever and tuberculosis (which may coexist with visceral leishmaniasis) should be considered. Splenomegaly must be differentiated from schistosomiasis, tropical splenomegaly syndrome and lymphoma or leukemia.

## Treatment<sup>744,745</sup>

Pentavalent antimonial compounds remain the treatment of choice for most cases of visceral leishmaniasis. Two preparations are in common use: sodium stibogluconate containing 100 mg antimony (Sb) per ml (Pentostam) and methylglutamine antimonate containing 85 mg Sb per ml (Glucantime). Response rates are usually around 90%, but antimonial resistance, particularly in Bihar, India, is an increasing problem, and some regions report failure rates of up to 60%.

*Sodium stibogluconate* is administered by daily intravenous or intramuscular injection. The dose is 10–20 mg/kg Sb per day for 20–30 days. Children normally receive 20 mg/kg/d. Rapid extensive renal clearance occurs and dose adjustments should be made if renal function is poor. Common side-effects in adults include arthralgia, myalgia, biochemical and clinical pancreatitis, mild increase in liver enzymes and marrow suppression. The drug appears to be better tolerated by children.<sup>746,747</sup> Minor ECG changes are common; prolonged Q-T interval and dysrhythmias may occur in high dose regimens used for the treatment of antimony-resistant infections. Anaphylactic

shock is a rare complication following administration. Sodium stibogluconate has been used in pregnancy without untoward effects on the fetus.

**Amphotericin B.** Both conventional and lipid formulations have been proven to be effective in various regimens lasting for between 10 and 40 days depending upon geographical location and the immune status of the patient. Standard amphotericin B is now the first line of therapy in some areas of India. Lipid formulations are better tolerated, have the theoretical advantage of being preferentially being taken up by macrophages and can be used in shorter courses of 10 days. They are currently the treatment of choice if expense does not preclude their use. Reported efficacy in children in Mediterranean VL is over 95%.<sup>748</sup>

**Pentamidine.** This may be effective, but resistance appears to develop rapidly and relapse is not uncommon. The main concern is toxicity, particularly the development of diabetes mellitus. The drug is now rarely used, except in areas of high resistance to antimonials or in patients who relapse.

**Aminosidine (paromycin)** is an aminoglycoside that has high efficacy and is well tolerated. It is administered intravenously or by intramuscular injection at a dose of 12–20 mg/kg/d for 3–4 weeks. Phase three trials with new formulations are currently underway.

**Miltefosine** is a new oral drug that is emerging as a very effective treatment option. It is given in a 4-week regimen at 2.5 mg/kg daily and is effective against antimony resistant strains. Cure rates are over 90% in children.<sup>749,750</sup>

Supportive and symptomatic treatment is important in addition to chemotherapy. Intercurrent bacterial infections are common and should be appropriately treated and attention paid to correcting nutritional status and vitamin deficiencies. Patients with hemorrhage should receive vitamin K. Blood transfusions are often required for the treatment of anemia in children.

### Response to treatment

Fever normally subsides and patients start to feel better in the first week of treatment. Hemoglobin and white cell counts improve over 2–4 weeks while the splenomegaly reduces more gradually over subsequent weeks or months. Patients should be followed up for at least one year to detect relapse.

### Relapse and nonresponsiveness

Relapse normally occurs within 6 months and relapse rates vary considerably depending upon the geographical location and the initial treatment regimen. Treatment of relapse is usually with prolonged courses of sodium stibogluconate, but depends upon geographical patterns of resistance. Pentamidine, aminosidine, amphotericin B and liposomal amphotericin have all been used successfully to treat relapse. Systemic interferon-gamma may be useful as an adjunctive therapy in resistant infections. HIV infected individuals are more likely to relapse and may need maintenance therapy.

### Post kala azar dermal leishmaniasis

Post kala azar dermal leishmaniasis (PKDL) is most commonly seen in Indian visceral leishmaniasis (20%) and less often in African infections (1–5%). Following treatment of visceral disease, cutaneous lesions develop with symmetrical depigmented lesions especially on exposed surfaces. Lesions progress to become papular or nodular and mucosal surfaces may be involved with abundant leishmania (*L. donovani*) in lesions. Treatment with pentavalent antimonial compounds is effective although lesions also heal spontaneously.

## CUTANEOUS LEISHMANIASIS

### Epidemiology

*L. tropica* and *L. major* cause cutaneous leishmaniasis in the Middle East, Afghanistan, the southern Mediterranean, Sudan and sub-Saharan Africa. Clinical infection in endemic areas occurs mainly in children.

*L. tropica* has a human reservoir and transmission is mainly urban whereas *L. major* occurs in rural areas with rodent reservoirs.

*L. mexicana* and *L. braziliensis* cause cutaneous leishmaniasis in Central and South America. *L. mexicana* has a reservoir in forest rodents in Central and South America and particularly affects the pinna of the ear in forest workers, notably chicleros (chewing gum collectors). *L. braziliensis* has a reservoir in domestic animals and forest rodents. Cutaneous lesions may progress to mucocutaneous leishmaniasis (espundia).

### Clinical features

Clinical features of cutaneous leishmaniasis are similar throughout the world with some slight differences between species. Typically, after an incubation period of several weeks, a localized, small, raised cutaneous nodule occurs, surrounded by a zone of erythema. The lesion grows slowly and central shallow ulceration may occur. Lesions remain raised above the level of normal skin; ulcers are shallow and do not have undermined edges. Lesions continue to progress for 6–24 months followed by spontaneous healing eventually leaving a slightly depressed papy scar. Satellite lesions may develop and regional lymphadenopathy is found in some forms. Lesions may be single or multiple and are more common on the face, hands, feet or limbs. *L. tropica* tends to cause single lesions lasting for 1–2 years with little tissue reaction and sometimes non-ulcerating lesions, whereas lesions in *L. major* are often multiple with a greater degree of ulceration and tissue reaction. Spontaneous healing occurs in 50% of lesions by 3 months in *L. major* or *L. mexicana*, 10 months in *L. tropica* and much longer in *L. braziliensis*.

### Diffuse cutaneous leishmaniasis

In the Ethiopian highlands and western Kenya, *L. aethiops* causes initial skin lesions similar to *L. tropica*. In very rare cases, leishmania disseminate throughout the skin to cause widespread, often symmetrical, lesions that resemble lepromatous leprosy. Similar syndromes occur in Central and South America due to infections with *L. mexicana* and *L. amazonensis*. A cell-mediated immune response to leishmania antigens is absent.

### Leishmania recidivans

This is an unusual form of cutaneous leishmaniasis found in the Middle East and caused by *L. tropica*. The initial chronic skin lesion heals but then groups of lesions resembling lupus vulgaris occur around the healed scar. Leishmania amastigotes are difficult to find but the leishmanin skin test is strongly positive.

### Mucocutaneous leishmaniasis

*L. braziliensis* complex infections cause single, often self-healing, primary lesions of the skin. However, in less than 10% of cases, subsequent metastatic spread to the oro-nasopharynx may occur (espundia). The time interval between initial infection and mucosal infection varies from a month to many years. The nasal septum is often involved initially causing symptoms of nasal stuffiness and epistaxis. Granulomatous lesions cause necrosis and destruction of cartilage and soft tissue and extend to involve the nose, mouth, tongue and soft palate. Lesions may ultimately involve the pharynx and larynx. Secondary infection is common and contributes to tissue destruction. Aspiration pneumonia occurs in the late stages and may be fatal.

### Diagnosis of cutaneous leishmaniasis

The likelihood of finding parasites depends upon the infecting species and the stage of the lesion. Parasites are more numerous in early lesions and in *L. tropica* and diffuse cutaneous leishmaniasis. Aspirates and slit smear preparation from the raised margins of a lesion, dermal scrapings and biopsies are all useful. Care should be taken to reduce the chance of bacterial contamination of samples. Multiple sampling and a combination of techniques increase the chances of a successful diagnosis. Samples should be examined microscopically and cultured on appropriate media. Impression smears should be made from biopsy samples. Although histology is less sensitive in detecting parasites, it is useful in

excluding other causes of the lesion. Mucocutaneous disease is often difficult to diagnose due to the limited number of parasites. PCR may be helpful on lesion aspirates or biopsies and may distinguish between different species complexes. Species diagnosis may also be made on cultured parasites by isoenzyme analysis or other DNA diagnostic techniques.

The leishmanin skin test (a test of delayed hypersensitivity using leishmanial antigen) may become positive during the course of infection, but is now rarely used for diagnosis. Serodiagnostic tests are of limited value for the diagnosis of cutaneous disease but may be helpful for the diagnosis and follow-up of mucocutaneous disease.

Important differential diagnoses for cutaneous leishmaniasis include superficial mycoses such as sporotrichosis, cutaneous mycobacterial infections, yaws, syphilis, sarcoidosis and neoplasms. In mucosal disease, histoplasmosis, paracoccidioidomycosis and midline granuloma must also be considered.

### Treatment<sup>751</sup>

Many cutaneous leishmaniasis lesions heal spontaneously without specific treatment. Local treatment should include cleansing and antibiotics to control secondary infection and covering to prevent secondary contact lesions. Local infiltration with antimonials is used in some areas for treatment of early non-inflamed lesions to accelerate healing.<sup>752</sup> This can be painful. Topical paromomycin may be effective in *L. major* infection; success rates in other species are variable.<sup>744,745</sup>

Oral agents such as allopurinol and imidazoles (ketoconazole, itraconazole) have been used for cutaneous leishmaniasis with variable and generally disappointing results. Miltefosine may be effective orally for American cutaneous leishmaniasis.<sup>753</sup>

In *L. braziliensis* areas where mucocutaneous leishmaniasis occurs, all leishmanial lesions must be treated with prolonged systemic pentavalent antimonials (20 mg/kg stibogluconate for 20 days) to prevent metastatic spread. The clinical response may be poorer in children under 5.<sup>754</sup> Systemic therapy is also indicated for multiple or potentially disfiguring lesions of any species; shorter, lower dose courses may be adequate for *L. major* or *L. tropica*. Established mucocutaneous disease is difficult to treat and may require prolonged courses of systemic antimony or amphotericin. Diffuse cutaneous leishmaniasis is resistant to pentavalent antimonials but may respond either to combinations of aminosidine and antimonials or to prolonged courses of pentamidine.

### CONTROL OF LEISHMANIASIS

Control centers upon vector control and reduction in the reservoir host. In central Asia, the simultaneous use of rodenticide and insecticide in gerbil burrows has reduced markedly the incidence of *L. major* infection. Similarly, control of stray dog populations and residual insecticide spraying have reduced *L. infantum* infection in many areas. Effective control can be achieved by medical surveillance of the population at risk when man is the major host reservoir. Insecticide spraying of houses is useful for peridomestic vectors such as in Indian visceral leishmaniasis. Control remains problematic in the vast forested areas of the Americas; the use of insecticides in tropical rain forests is impractical and control of the extensive reservoir of infected wild animals equally impossible. A number of candidate vaccines have been developed but clinical trials have been disappointing in both cutaneous and visceral leishmaniasis. A number of studies suggest that treated or untreated bednets reduce the risk of visceral leishmaniasis.<sup>755</sup>

### MALARIA

Malaria is a disease of humans caused by infection with one or more of four species of protozoa of the genus *Plasmodium* (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae* and *Plasmodium ovale*). It is usually acquired through the bite of an infected female *Anopheles* mosquito, although it may also follow the transfer of infected blood as

in blood transfusion, or transplacentally or by the use of contaminated syringes. Worldwide some 45 *Anopheles* species effectively transmit malaria, although the identity, behavior and importance of local vectors vary widely with geographic location. The most effective vector is probably *Anopheles gambiae* – a mosquito that is widely distributed in tropical Africa. *P. falciparum* is the most pathogenic of the malaria parasites and infections with it must always be regarded as serious and potentially life threatening. The other three species tend to cause less serious illness, although on occasion a lethal nephrosis may complicate *P. malariae* infections.

### THE PARASITE LIFE CYCLE

Malaria parasites undergo a complex stage of asexual development in the human host and a stage of sexual development (sporogony) which occurs partly in man and partly in the mosquito vector.<sup>756</sup>

### Asexual development in man

This begins with the introduction of infective forms (sporozoites) in mosquito saliva during the biting act. Sporozoites circulate for less than 60 min, eventually gaining access to parenchymal liver cells either directly or after passage through Kupffer cells. The invasion process may entail specific ligand–receptor interaction. Once within the hepatocyte, the sporozoite initiates the exoerythrocytic (EE) phase of asexual development during which it grows and undergoes repeated nuclear fission (schizogony), eventually producing a cyst-like schizont filled with daughter parasites (merozoites). This phase usually proceeds without interruption and both the time taken to schizont maturity and the number of merozoites produced vary with the identity of the plasmodial species involved. *P. falciparum* completes its EE development fastest (about 5 days) and produces most merozoites per schizont (about 30 000). The other species are slower and less prolific, the respective values for *P. malariae*, for example, being about 15 days and about 15 000 merozoites. In two parasite species, *P. vivax* and *P. ovale*, some sporozoites initiate this uninterrupted EE stage of development but some do not. These latter, on entering hepatocytes produce small unicellular forms (hypnozoites) which persist without development for periods varying from several weeks to many months. Eventually the hypnozoites, activated by mechanisms as yet not known, resume growth and proceed to schizont maturation and merozoite liberation. Hypnozoites are currently widely believed to give rise to the relapsing parasitemias which characterize *P. ovale* and, particularly, *P. vivax* infections and which can occur even after drug treatment has effectively eliminated erythrocytic parasites. Hypnozoites do not develop in infections with *P. falciparum* and *P. malariae* and in these species recrudescence of parasitemia is generally considered to be due to persistent erythrocytic infection.

Merozoites liberated from EE schizonts are short lived and must find and enter a red blood cell within a few minutes. Within the erythrocyte each grows rapidly through ring form and uninucleate trophozoite stages eventually to form a schizont containing merozoites. On schizont rupture, the merozoites enter the bloodstream, attach to and penetrate fresh erythrocytes and again begin the cycle of erythrocytic asexual development. Attachment and penetration by merozoites are complex operations, which require specific ligand–receptor interactions. Erythrocyte invasion by *P. vivax* appears to require a ligand that is associated with Duffy blood group antigens, while attachment of *P. falciparum* merozoites to red cells requires one associated with sialic acid on the erythrocyte membrane. Age of the red cell also influences invasion by merozoites: *P. vivax* preferentially invades reticulocytes – a feature which tends to limit the density of parasitemia attained by this species – while *P. falciparum* can invade red cells of all ages.

The duration of the erythrocytic phase of asexual development and the merozoite yield per schizont vary with the plasmodial species. *P. malariae* has the longest cycle (72 h, i.e. quartan periodicity); the remaining species have cycles of about 48 h duration (i.e. tertian periodicity). *P. falciparum* has the greatest capacity to replicate and the

merozoite yield of its schizonts is in the range 8–32. For the others the yields are 8–24 for *P. vivax*, 4–16 for *P. ovale* and 8 for *P. malariae*. The ability of *P. falciparum* to replicate rapidly in both the hepatic and erythrocytic phases of development partly accounts for the severity of the illness this species causes.

The time taken for parasites to become detectable in the peripheral blood following sporozoite inoculation is termed the prepatent period, while the time from infection to the onset of symptoms is termed the incubation period. While the two periods may be of equal duration, more usually the incubation period is about 2 days longer.

Late in its asexual erythrocytic cycle *P. falciparum* withdraws from the peripheral circulation and sequesters in deep vasculature. The phenomenon, which probably contributes importantly to the serious pathological effects that this *Plasmodium* causes, is effected by the binding of receptors on the surface of red cells infected with nearly mature parasites to ligands exposed on the surface of the endothelial cells lining deep blood vessels. Sequestration does not occur in the course of infections with the other plasmodial species that infect man.

### Sexual development

In the course of blood stage schizogony in the human host some merozoites differentiate, by mechanisms which are not yet understood, to give rise to male and female sexual forms (gametocytes). In the case of *P. vivax*, gametocytes are formed early after the release of merozoites from the liver (before clinical symptoms), while *P. falciparum* gametocytes are generated after a number of erythrocytic cycles. Early treatment of fever with antimalarial drugs may therefore prevent gametocyte formation in *P. falciparum* but not in *P. vivax* infections. When mature, gametocytes circulate in the blood but do not undergo further development unless they are ingested by an anopheline mosquito during feeding. Once in the midgut of the mosquito, the female (macrogametocyte) escapes from the enclosing erythrocytic membrane and becomes a macrogamete. The male (microgametocyte) undergoes a process of exflagellation during which eight slender, uninucleate filaments (microgametes) are extruded and break free. Each microgamete seeks a macrogamete and, if successful, penetrates and fertilizes it. The two nuclei fuse and a zygote is formed. This is probably the only point in the life history of the parasite that genetic recombination occurs. The diploid zygote then undergoes meiosis and, as an ookinete, migrates to penetrate the epithelium of the mosquito midgut wall where it comes to rest on the external surface. There it rounds up, becomes an oocyst and begins a series of nuclear divisions. Oocyst maturity is reached after a period which is dependent on the identity of the plasmodial species and the ambient temperature to which the mosquito is exposed. It may be 1–4 weeks, or longer. At maturity the oocyst is filled with as many as 10 000 daughter parasites (sporozoites), each some 10–15 µm in length and feebly motile. The sporozoites escape at oocyst rupture and travel in the hemocelomic fluid to the salivary glands where they accumulate in the acinal cells to be discharged with saliva when the mosquito next feeds.

Infected humans constitute the only known source of mosquito infection for *P. falciparum*, *P. vivax* and *P. ovale*. For *P. malariae* some apes and monkeys may constitute reservoirs of infection in addition to humans.

### EPIDEMIOLOGY

Despite widespread operations promoted by the World Health Organization between 1955 and 1975 with the aim of achieving global eradication, malaria remains probably the most prevalent, important, communicable disease throughout much of the tropical and subtropical world, the greatest burden of disease being in sub-Saharan Africa. Estimates of the world annual incidence of malarial illness have ranged from 200–450 million episodes<sup>757</sup> to over half a billion.<sup>758</sup> The much-quoted estimate of around 1 million malaria deaths annually in Africa, >75% of them in children, is supported by available evidence.<sup>759</sup> Over the past 25 years *P. falciparum* parasites have become increasingly resistant to chloroquine and other currently available antimalarial drugs.

This development appears to have been accompanied by an increase in malaria-attributed mortality in some endemic areas<sup>760</sup> and has required the development of new drug policies for malaria control and new regimens for chemoprophylaxis for travelers and other at-risk groups.

Many factors influence the epidemiology of malaria. Atmospheric temperature is important. For successful development in the mosquito vector, *P. vivax* requires a sustained temperature of at least 16 °C, while *P. falciparum* requires one of 20 °C. The geographical limits of *P. vivax* transmission are thus more widely set than those of *P. falciparum*. Other factors relate to the identity and biology of the *Plasmodium*, the identity and behavior of the vector, the social and economic customs of human populations and the topography and climate of the region. It follows, therefore, that the epidemiological pattern of the infection is not uniform but varies considerably between and within countries.

Where transmission occurs the measurement of endemicity has, in the past, relied on establishment of spleen rates and parasite positivity rates in ambulant children aged 2–9 years. Thus categories classified as hypo-, meso-, hyper- and holoendemic were characterized by both spleen and parasite rates of <10%, 11–50%, constantly >50% and constantly >75% respectively. In hyperendemic areas spleens in adults were frequently enlarged; in holoendemic areas they were not (this observation was attributed to the greater acquisition of immunity in holoendemic areas).

However, the widespread use of antimalarial drugs in areas where malaria is endemic has adversely affected these classical indices of endemicity and they are less useful today than formerly. This change has prompted the use of seroepidemiological techniques in the identification of malaria transmission and the measurement of its intensity. These techniques detect and quantify specific malaria antibody in serum and establish age-specific profiles for prevalence and titer. Briefly, profiles which show little change with age denote low transmission while profiles showing values which rise rapidly with age denote high transmission.<sup>761</sup>

Epidemiologically malaria presents in two extremes, one of which is stable and shows little change from one year to another, and the other which is unstable and may fluctuate violently in intensity at regular or irregular intervals. Stable malaria is most in evidence in areas where transmission rates are high; it is characterized by rates of mortality and morbidity which are high in infants and young children and which fall to low, even negligible, levels as age advances and effective immunity is acquired. Unstable malaria occurs where transmission rates remain low for periods of several years then suddenly increase greatly for climatic or other reasons; it is characterized by the occurrence of epidemics in which morbidity and mortality are conspicuous at all ages. Acquired immunity is not a feature of unstable malaria, save possibly at the end of a protracted epidemic period. Between the extremes of stability and instability, a range of intermediate epidemiological presentation occurs.

### IMMUNITY

Malarial immunity may be innate, i.e. genetically determined, or acquired. Innate immunity may be due to a lack of ligands on the erythrocyte surface which bind to specific receptors on the merozoite surface at an essential stage in the invasion process, or to the presence of abnormal intramembranous erythrocytic components, which inhibit, but do not totally prevent, growth of the parasite within the red cell. An example of the former is the freedom from *P. vivax* infection that is apparent in people whose erythrocytes lack Duffy blood group antigens, while an example of the latter is the partial protection and survival advantage towards *P. falciparum* infections that heterozygosity for the sickle cell gene confers.<sup>762</sup>

Acquired immunity may be passive or active. Passive immunity due to the transplacental transfer of specific IgG malarial antibodies from mother to fetus probably accounts, at least in part, for the relative resistance to malaria that infants born in highly endemic areas show over the first few months of life. Acquired active immunity develops slowly

in response to infection with malaria.<sup>763</sup> The first evidence is an ability to restrict the clinical effects of infection despite the persistence of high density parasitemia. This 'clinical' immunity is usually discernible in young children in highly endemic areas around the third to fourth year of life. Later, an ability to restrict parasite density develops and slowly strengthens throughout later childhood and adolescence to reach maximum expression in adult life. When fully developed, malarial immunity is species, strain and stage specific.

Acquired active immunity entails the collaboration of different cell populations, notably T cells, B cells and macrophages, during which specific and nonspecific humoral factors are elaborated which restrict parasite growth and replication.<sup>764</sup> Knowledge of how this complex response is assembled and controlled remains incomplete. T cells play a central role and their recognition of, and response to, defined malarial antigens are probably controlled by immune response (Ir) genes. Sensitized T cells respond to antigen by replication and the secretion of lymphokines which promote further T cell replication and diversification, induce replication of B cells with antibody production and activate macrophages.

Specific malarial antibodies belong to the immunoglobulin classes G, M and A. They function by agglutinating parasites and parasitized cells, inhibiting interactions between host cell surface ligands and parasite receptors, mediating cellular cytotoxicity and phagocytosis and inhibiting sequestration of mature asexual erythrocytic forms of *P. falciparum* in deep vasculature. Antibodies do not kill parasites directly through the activation of complement. Natural malaria infection induces synthesis of a wide range of antibodies directed against specific parasite antigens. Thus antibodies with specificity for the antigens of sporozoites, EE forms, asexual blood stages and sexual stages can be detected and titrated in the sera of residents of endemic areas.

The killing of parasites, which is probably carried out mainly by activated macrophages and cytotoxic T cells, involves release from the host cells of toxic oxygen derivatives and occurs principally in spleen and liver. However, other killing mechanisms exist. Interferon-gamma released by sensitized T cells has been observed to kill EE stages in hepatic cells, while tumor necrosis factor (TNF) liberated from macrophages stimulated with endotoxin has been reported to inhibit replication of both EE and erythrocytic stages of the parasite.

## PATHOLOGY

The pathogenic sequences that develop in malaria are attributable to events that arise during the asexual erythrocytic stage of development of the parasite in man.

Anemia is common and is due partly to the rhythmic invasion and destruction of erythrocytes by parasites and partly to additional mechanisms, such as dyserythropoiesis and immune hemolysis following sensitization of nonparasitized red cells.<sup>765</sup> Bone marrow changes in dyserythropoiesis include erythroblast multinuclearity, karyorrhexis, incomplete and unequal nuclear division and cytoplasmic bridging. The marrow may contain large amounts of stainable iron and show evidence of phagocytosis of defective red cell precursors by macrophages. Whether these changes are initiated by toxic substances liberated by the parasite, or represent the nonspecific effects of macrophages rendered hyperactive by parasite antigens remains to be ascertained. The sensitization of uninfected red cells occurs commonly in malaria, often involves C3 and/or IgG and can be detected by the direct antiglobulin test (DAT) using specific antisera. DAT positivity of red cells, which is frequent in patients with falciparum malaria, has been found to be associated with enhanced blood destruction, but the association appears to be relatively uncommon.<sup>765</sup>

A characteristic feature of *P. falciparum* infections is the collection ('sequestration') of large numbers of late-stage parasites in the venules and capillaries of a variety of organs.<sup>766</sup> This results from the ability of this parasite, in the later stages of its development in the red cell, to display a number of proteins – known as *P. falciparum* erythrocyte membrane protein-1 (PEEMP-1) – on the red cell surface, by which the parasitized red cell attaches to host receptors on the microvascular endothelium.<sup>767</sup>

PEEMP-1 is a family of proteins encoded by recently identified highly variable var genes.<sup>768</sup> It is possible that sequestration is augmented by adhesion between parasitized erythrocytes, a phenomenon that can be demonstrated in vitro.<sup>769</sup> Sequestration is believed to be the mechanism underlying some of the clinical complications of *P. falciparum* infection, including the coma and convulsions of cerebral malaria. It is not known how sequestration may lead to tissue dysfunction: one possibility is that the huge number of actively metabolizing parasites consume oxygen and glucose at the expense of neighboring tissue, or produce toxic metabolites, including lactate, that may affect cellular function. Another possibility is that sequestration stimulates the release of host transmitters, such as nitric oxide, that may have a local effect on blood flow or on the conduction of nerve impulses. Host cytokines, too, are released and these may make endothelial cells more adhesive for the surface of parasitized red cells, thus augmenting sequestration.<sup>770</sup>

In some children with fatal cerebral malaria, histological changes include accumulations of platelets and microthrombi in cerebral and other microvessels.<sup>771</sup> CT scans of children surviving cerebral malaria with neurological sequelae show areas of brain infarction that may result from such vascular occlusions. Fortunately the majority of children and adults treated for cerebral malaria recover without neurological sequelae,<sup>772</sup> suggesting that microvascular occlusions from microthrombi are not a usual or major component of the pathology.

In children dying of encephalopathy with *P. falciparum* parasitemia, autopsies indicate that in a considerable proportion (about a quarter in one series<sup>773</sup>) the diagnosis may be a condition other than malaria, the parasitemia in these cases being incidental. This underlines the fact that, when a high proportion of a population is parasitemic, the diagnosis of severe malaria requires careful judgment and will sometimes be mistaken. This can result in failure to treat severe bacterial infection, often with fatal consequences.

Enlargement of the spleen and liver is common in acute and chronic infections and, on section, both organs are dark from the accumulation of malarial pigment (hemozoin). Evidence of phagocytosis of parasites, parasitized cells and hemozoin is usually present in the splenic pulp and in the sinusoidal macrophages and Kupffer cells of the liver.

In *P. falciparum* infections an acute diffuse glomerulonephritis may occur in which deposits of immunoglobulins, complement and malarial antigens are detectable in the mesangium and capillary loops. This is usually transient, but in non-immune adults with *P. falciparum* malaria it may lead to acute renal failure, usually characterized pathologically by acute tubular necrosis, from which recovery is usual if the patient can be sustained by supportive care and dialysis until renal function is restored. In *P. malariae* infections, however, a much more progressive and frequently lethal nephropathy may develop, again with evidence of antigen/antibody deposition. In children these lesions may progress despite antimalarial treatment to total glomerular sclerosis with secondary tubular atrophy. Clinically, the manifestations of a nephrotic syndrome develop with severe generalized edema and ascites accompanied by heavy proteinuria and hypoalbuminemia.

During pregnancy, *P. falciparum* may attain very high densities in the maternal placental blood and cause damage to the syncytiotrophoblast. Placental infection is associated with reduced infant birth weight and, in endemic areas, the association is most marked in first pregnancies. Occasionally, parasites cross the placenta, giving rise to congenital infection in the infant at or soon after birth. In endemic areas such infections seldom persist or cause disease in the neonate, but if the mother is a 'non-immune' individual, the baby may develop an illness with fever, anemia and jaundice.

Thrombocytopenia commonly occurs in *P. falciparum* infections for reasons that remain poorly understood. It usually occurs independently of changes in other measures of coagulation (prothrombin time, partial thromboplastin time) or to plasma fibrinogen concentrations and is usually unaccompanied by bleeding. Spontaneous bleeding may occur associated with disseminated intravascular coagulation (DIC), but this is an uncommon clinical feature of severe malaria in adults and is rare in children.

## CHEMOPROPHYLAXIS

Large scale continuous chemoprophylaxis for children is not recommended in endemic areas, the main reason being that it is economically and logistically almost impossible to achieve over the long term on a national scale. It may be a useful measure, however, in focal high risk communities, such as refugees who have moved from a nonmalarious to an endemic area. Theoretical but unproven disadvantages of community-wide chemoprophylaxis include interference with the development of acquired immunity, enhancement of the development and spread of drug resistance and risk of toxicity from long term drug usage.

For individuals traveling from nonmalarious to malarious areas, however, chemoprophylaxis remains an important means of protection.

Drug prophylaxis should be seen as only one component of prevention. At least as important is sleeping under a permethrin-impregnated net (malaria-transmitting mosquitoes bite mainly in the middle of the night). Other measures can help: application of insect repellents [dimethylphthalate (DMP) or dimethyl-m-toluamide (DEET)] to exposed skin areas over periods of mosquito activity, the screening of houses and the use of knock-down insecticides in bedrooms before retiring.

Most prophylactic drugs should be taken for at least a week before travel (mainly in order to ensure acceptability) and for a month after exposure ends (to eliminate parasites that have developed in the liver in the intervening time).

Expatriates from a non-endemic country who intend to reside with their children for many years in a country with *P. falciparum* transmission must decide whether to take drug prophylaxis over the long term. The decision must be based on the extent of local risk, its seasonality, the local pattern of parasite resistance to various antimalarial drugs, and the availability of prompt health care. With screening and indoor residual spraying of the home and consistent use of insecticide-impregnated bednets, the risk may be low enough to avoid prophylaxis, provided that any fever is promptly diagnosed and treated. Expatriates may consider using chemoprophylaxis only during seasons of increased transmission or when visiting parts of the country where transmission is known to be high.

No prophylactic regimen, even if adhered to fully, guarantees protection against malaria absolutely. If a febrile illness develops during or up to 6 months after the period of exposure, malaria remains a possibility and should be investigated accordingly. Parents should be advised to ensure that physicians attending illness in children after return from endemic areas are aware of the need to exclude a diagnosis of malaria. Similarly, parents who live in endemic areas and are visited from time to time by children being educated in non-endemic areas should ensure that guardians and school authorities are alerted to the need to exclude malaria as a diagnosis in any illness developing in the repatriated child.

When contemplating the need for chemoprophylaxis in particular instances, the physician should ascertain the risk to which the child is or will be exposed, the duration of exposure, the pattern of drug resistance of malaria in the area to be visited, and possible drug toxicity. Useful information on disease incidence and drug resistance in the malarious countries of the world is to be found in the periodic reviews published by the World Health Organization in its Weekly Epidemiological Record.

Suggested chemoprophylactic regimens<sup>774</sup> (see also [www.prodigy.nhs.uk/malaria\\_prophylaxis](http://www.prodigy.nhs.uk/malaria_prophylaxis)) are as follows:

1. Where only *P. vivax* malaria exists, prophylaxis should be by chloroquine proportional to an adult dose of 300 mg (two tablets) once weekly or by proguanil (Paludrine) proportional to an adult dose of 200 mg (two tablets) daily (see Table 28.39).
2. Where *P. falciparum* transmission occurs, options include:
  - Atovaquone–proguanil (Malarone), daily. This has the advantage of very little known toxicity and of attacking liver stage as well as blood stage parasites, so that it need be taken for only a week after exposure ends. Malarone is expensive.
  - Mefloquine (Lariam) once weekly. The weekly dosage is an advantage, but is easier to forget. Various side-effects are

Table 28.39 Age-related dosage of antimalarial drugs for chemoprophylaxis in children

Age	Fraction of adult dose
< 6 weeks	1/8
6 weeks–1 year	1/4
1–5 years	1/2
5–12 years	3/4
> 12 years	Adult dose

commonly reported, including insomnia and vivid dreams.

Mefloquine should not be given to children who have a history of epilepsy or psychiatric disease.

Various prophylactic regimens used in the past are no longer recommended as prophylactics, although some of the component drugs remain important for treatment. Amodiaquine as a weekly prophylactic has been associated with occasional hepatic necrosis or neutropenia; weekly pyrimethamine–dapsone (Maloprim) with occasional agranulocytosis; and weekly sulfadoxine–pyrimethamine (SP, Fansidar) with Stevens–Johnson syndrome. Doxycycline, a useful prophylactic in adults, is contraindicated in children.

Continuous chemoprophylaxis is indicated for indigenous children in malarious areas who are homozygous for the sickle cell gene, because malaria may precipitate a crisis. Malaria increases viral load in adults with HIV infection,<sup>775</sup> but it is not yet known whether chemoprophylaxis against malaria will improve life expectancy in children with HIV infection or AIDS. Co-trimoxazole prophylaxis is beneficial in HIV infected children<sup>776</sup> and co-trimoxazole is an efficacious antimalarial drug, but it is not known whether or to what extent the benefit of co-trimoxazole is dependent on its antimalarial activity.

## VACCINATION

A safe and effective vaccine for malaria is not yet available. Several candidate vaccines, making use of antigens from various combinations of sporozoite, erythrocytic and sexual stages of *P. falciparum*, are undergoing development or clinical trials. Promising results have been obtained among children in Mozambique in trials of the candidate vaccine RTS,S, a product consisting of sequences of the circumsporozoite protein of the *P. falciparum* merozoite linked to hepatitis B surface antigen and combined with the adjuvant ASO2.<sup>777</sup> In a double-blind randomized trial in children aged 1–5 years, the vaccine demonstrated 30% (95% CI 11%, 45%) protection against clinical malaria, 58% (16%, 81%) against severe malaria disease and 45% (31%, 56%) protection against *P. falciparum* infection, a benefit that was shown to persist over a subsequent year of observation.<sup>778</sup> Trials of this vaccine continue, with the aim of assessing its benefit when administered to young infants within existing standard EPI schedules.

## CLINICAL FEATURES

The manifestations of malaria in an individual are determined by the infecting species of *Plasmodium* and the resistance or immunity of the host.

Each of the four species of parasite causing human malaria may produce a febrile illness with nonspecific symptoms including anorexia, malaise, headache, chills, rigors, sweating, irritability and failure to eat and drink. Symptoms begin about 10 days after the infective mosquito bite, but longer incubation periods are common, especially with the nonfalciparum malarias, and sometimes the first symptoms are not experienced until months or years after exposure. Diarrhea, vomiting and cough are common, but not severe, early symptoms. Febrile convulsions commonly complicate sudden rises of temperature in young children. The pattern of fever is irregular at first; the classical periodicity appears only if the illness is protracted and untreated, when *P. malariae* may cause quartan fever (72 h between spikes), *P. vivax* and

*P. ovale* tertian fever (48 h intervals) and *P. falciparum* subtertian fever (less than 48 h intervals). The liver and spleen may become palpable during the first few days of fever; the spleen may become enlarged during the course of a single episode, and may become very large after repeated or untreated infections.

Anemia develops, its degree being greatest in those with the heaviest or most protracted infections. Minor abnormalities of hepatic enzymes may be found, but jaundice is unusual even in severe falciparum malaria.

The most important distinction between species in their clinical effects is in the capacity of *P. falciparum* to cause, in susceptible individuals, a rapidly progressive severe ('complicated') disease, which may be fatal. Most of the many deaths from malaria every year are due to *P. falciparum* infections in young children living in endemic areas, the majority in sub-Saharan Africa.

In endemic areas the patient's first encounter with *P. falciparum* may be in utero. Parasitemia is common in pregnant women, and both placenta and cord blood may contain parasites at the time of delivery. Babies born to infected primigravid mothers may have a low birth weight but are otherwise unaffected. Parasitemia usually clears rapidly in the newborn, who remains relatively resistant to falciparum malaria for the first few months of life, probably because of a combination of maternal anti-malarial antibodies and the fact that parasites grow less successfully in fetal than in adult hemoglobin. Occasionally (rarely in endemic areas) the newborn goes on to develop congenital malaria, features of which may include fever, failure to feed, anemia, jaundice and hepatosplenomegaly. Severe disease begins to affect children in endemic areas after the first few months of life, and for the next few years. During this time the majority of children are increasingly able to tolerate parasitemia with few or no symptoms, and malaria-related mortality decreases later in childhood.

In areas where there is little or no malaria transmission, children are susceptible to infection and severe disease at any age, and congenital malaria is sometimes seen.<sup>779</sup>

### Acute *P. falciparum* infections

*P. falciparum* malaria usually presents as a febrile illness similar to that caused by other species of malaria. In a proportion of patients, however, complications develop which may threaten life. The most important manifestations of severe malaria in children are altered consciousness, labored breathing (due to acidosis) and severe anemia. These features may occur singly or in any combination.<sup>780</sup> A variety of metabolic complications may develop, resembling those that may complicate any severe systemic infection (reviewed in ref 781). Hypoglycemia may accompany any of the above syndromes and is associated with increased mortality, especially when the hypoglycemia is profound.<sup>782</sup> Some of the organ complications of falciparum malaria which are common in non-immune adults are uncommon in children. Renal failure, pulmonary edema and disseminated intravascular coagulation are less likely to develop in children, and are not present in most of those who die of falciparum malaria.

### Cerebral malaria (CM)

When impaired consciousness in a child with falciparum malaria cannot be explained by the presence of hypoglycemia, seizures or a transient postictal state, and no other causative disease is present, the term 'cerebral malaria' is used.

Clinical measurements of the depth of coma are helpful in defining severity.<sup>772</sup>

CM develops rapidly. In the majority of children febrile symptoms precede coma by 2 days or less; in some the interval is only a few hours. Most patients have been feverish, irritable, listless and unable to eat or drink prior to losing consciousness. Convulsions are common and sometimes herald the onset of coma. In CM there is no postictal recovery of consciousness as occurs after a febrile convulsion. Other symptoms that may precede coma include vomiting and cough; minor looseness of stool may occur, but severe diarrhea is unusual.

The rectal temperature may exceed 40 °C, and is usually sustained during the first day or two of treatment. Occasionally a patient with CM may be afebrile when first examined, and rarely may remain so throughout the illness. Tachycardia is appropriate to the degree of fever, and the systolic blood pressure is normal in most patients. Dehydration is not clinically obvious, but vigorous fluid therapy in some patients leads to correction of acidosis and to improved tissue perfusion, suggesting that hypovolemia is commonly important. Respiration is rapid; in some patients breathing is stertorous, in others deep suggesting acidosis. About 5% of children with CM are jaundiced. The heart and lungs are normal on examination. The abdomen is soft; the liver may be moderately enlarged and the spleen may be palpable. In a minority of children with CM a shock-like state, with hypotension, cold peripheries and a wide core-to-skin temperature difference, may develop. Anemia is clinically apparent in some patients, and may develop during the course of illness in others.

The most striking clinical features are neurological. By definition the patient is unconscious and cannot be roused. Coma may be profound, the child being unable to withdraw from or localize a painful stimulus, and unable to moan or cry in response to pain. With less severe neurological impairment, motor and vocal responses to pain are retained but the patient is unable to watch or recognize familiar people. Corneal and pupillary reflexes are usually intact, but brainstem reflexes may be lost in the most severely ill. Retinal hemorrhages are common. Some of the most severely ill patients have papilloedema.<sup>783</sup> Recently two further features have been identified that constitute a characteristic 'malarial retinopathy' not seen in other infections: these are areas of discrete retinal whitening, and a silver, orange or white appearance of some of the smaller vessels, usually in a patchy distribution.<sup>784,785</sup>

In some patients the motor picture suggests decerebration or decortication, with symmetrical rigidity or posturing of limbs, which may be sustained or repetitive. These may represent underlying seizure activity. It is not uncommon for patients to be opisthotonic. Focal asymmetrical twitching movements of the face or of a limb may be witnessed, sometimes (not invariably) proceeding to a generalized convulsion. If available, electroencephalography may reveal cerebral seizure activity in some cases in whom there is minimal or absent convulsive movement. Both overt and subtle seizures may occur in the absence of extremes of fever, and they cannot be regarded as febrile convulsions. The plantar reflexes may be abnormal. Abdominal reflexes are almost invariably absent.

The peripheral blood film reveals ring stages of *P. falciparum*. Occasionally parasites may be scanty, and rarely absent, in the blood film of a child with CM, perhaps as a result of the synchronous sequestration of mature parasites, and especially in a non-immune child; parasitemia is usually revealed with repeated examination at intervals of a few hours. In an endemic area, in a child with suspected CM who has scanty or moderate peripheral parasitemia, alternative diagnoses must be considered with particular care, as peripheral parasitemia may be an incidental finding in a child whose encephalopathy is due to something else. The likelihood that *P. falciparum* is the cause of a cerebral disease increases with the density of the parasitemia; it is not uncommon for up to 20% of red cells to be parasitized, and in some patients the figure exceeds 50%.

The packed cell volume may be normal or may be reduced; it usually falls further as the illness progresses. Life-threatening anemia may develop rapidly in patients with hyperparasitemia. Commonly the fall in hematocrit exceeds what would be predicted from the level of parasitemia. The peripheral white cell count is normal in the majority of patients but may be elevated in the very ill. The most severely affected patients are acidotic. There are minor abnormalities of hepatic enzymes, and the plasma creatinine may be mildly elevated. Plasma sodium, potassium, chloride, phosphate and calcium concentrations may show mild abnormalities but are commonly normal. Plasma and cerebrospinal fluid (CSF) lactate levels are abnormally raised in some patients, commonly in association with hypoglycemia. CSF opening pressure is raised in most patients, and fluctuates over time.<sup>786</sup> The mean and distribution

of opening pressures were similar in a series of patients with fatal and nonfatal CM, and the pathogenetic importance of raised intracranial pressure remains uncertain.<sup>787</sup> The CSF is clear with normal cell counts and protein concentration.

A significant proportion of patients with CM are hypoglycemic when first admitted to hospital.<sup>782,788</sup> These patients do not differ from others in their duration of preceding illness, fasting or coma, or by any distinctive physical signs, but they tend to be younger and are more likely to be profoundly unconscious, to exhibit motor abnormalities and to have elevated levels of lactate and alanine in the plasma.

Even with optimal treatment, the mortality among children admitted to hospital with CM is 10–20%. The cause of death is not known, and in most cases cannot be attributed to renal, cardiac, pulmonary or hematological complications of malaria. Presenting features associated with an increased risk of death in children with CM include profound coma, age under 3 years, hypoglycemia, witnessed convulsions, motor abnormalities (hypertonicity, posturing), extreme hyperparasitemia (> 20% of red cells parasitized), acidosis, lactic acidemia and leukocytosis (>  $15 \times 10^9$  white blood cells/L).<sup>772</sup>

In patients who survive CM, the duration of coma after the start of treatment ranges from a few hours to several days, the average duration being about 30 h. The change from deep coma to full consciousness may be dramatically rapid, and usually occurs before the temperature has fallen to normal and before parasitemia has cleared. The great majority of children who survive CM make a full neurological recovery; 5–10% of patients, however, suffer neurological sequelae, including hemiparesis, spasticity and cerebellar defects, from which a gradual recovery is made in some patients over the subsequent months. Risk factors for the development of sequelae are the same as those associated with mortality. Areas of intracerebral infarction have been demonstrated by computerized tomography in some children with neurological sequelae after CM.<sup>789</sup> Long term follow-up studies suggest that children recovering from CM are at increased risk of epilepsy in subsequent years, and that some may have cognitive and learning defects.<sup>790</sup>

### Anemia

Anemia is a component of most episodes of malarial illness. In areas endemic for *P. falciparum* severe anemia (hemoglobin concentration < 5 g/dl) is an important clinical consequence of acute or recurrent malaria.<sup>791</sup>

The history of fever and associated symptoms may be similar to that of any malarial illness, but it is common for a child to present without such symptoms, or for anemia to be identified when a child is examined for an unrelated complaint. Some children with severe malarial anemia develop respiratory distress, which is usually due to acidosis resulting from impaired tissue perfusion and oxygenation.<sup>792</sup> Less commonly, breathlessness is due to cardiac failure, with enlarging liver, and a gallop rhythm on auscultation of the heart.

Peripheral blood films reveal parasitemia and a normochromic normocytic or, in chronic infections, hypochromic anemia. The reticulocyte count is inappropriately low. Unconjugated bilirubin may be increased in the plasma, free hemoglobin may be present in plasma and urine, and the plasma haptoglobin concentration is usually decreased or absent in the acute stage of the illness. The bone marrow shows normoblastic erythropoiesis with minimal dyserythropoiesis and increased myeloid precursors.<sup>765</sup> Unless other diseases are present, serum and red cell folate values are normal. Serum iron may be normal or moderately reduced, but there is usually normal or increased stainable iron in the bone marrow.

After the start of treatment for acute malaria, the hemoglobin level falls further in proportion to, or in excess of, the degree of parasitemia. In endemic areas, many children have a positive direct antiglobulin test. Reticulocytosis begins within a few days, and the hemoglobin level rises rapidly in convalescence.

Severe anemia recurs within a few weeks or months in an important proportion of children admitted to hospital for treatment of severe anemia. The role of malaria in this recurrence, and the potential for its prevention by antimalarial drugs, is under investigation.

### Hyper-reactive malarial splenomegaly

Some children with protracted or frequent *P. falciparum* infection develop hyper-reactive malarial splenomegaly, a condition in which massive enlargement of the spleen is accompanied by raised serum IgM, high titers of antimalarial antibody, and hepatic sinusoidal lymphocytosis.<sup>793</sup> Splenomegaly resolves slowly with prolonged antimalarial treatment.

### DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Delayed diagnosis of *P. falciparum* malaria can have tragic consequences. In endemic areas it is a justifiable policy for all fevers without another obvious cause to be regarded as malarial and treated accordingly. In non-endemic areas a history of travel should alert the physician to the possibility of malaria, even if travel was many months or years ago. Malaria should be considered in puzzling clinical situations, even in individuals who have not traveled to an endemic area, as mosquitoes may transmit plasmodia after 'commuting' on an aeroplane ('airport malaria'), and parasites may be transmitted transplacentally or by needle-stick injury. Malaria should be considered in the differential diagnosis of all fevers accompanied by cerebral complications, acidosis or anemia, and in patients with fever who develop hypoglycemia, acute renal failure, disseminated intravascular coagulation or pulmonary edema.

The diagnosis of malaria depends on finding the parasite in the peripheral blood. Thick smears stained with Field's or Giemsa stain, and thin films stained with Leishman's, Giemsa or a modified Field's stain, allow identification of the species and density of malaria parasitemia. There have been occasional well-authenticated reports of fatal falciparum malaria in which blood films were repeatedly negative during life. Treatment should therefore not be withheld from a patient with an illness suggestive of malaria even if films are negative. In such patients blood films should be repeated at intervals during treatment, when parasitemia may be revealed. Serological methods of identifying malarial infection are valueless for individuals in endemic areas, and of limited use to the clinician seeing patients elsewhere. Serology identifies past or current infection, and may help towards diagnosis in a patient with recurrent fever in a non-endemic area in whom parasitemia cannot be found on repeated testing. Antigen-detecting test strips and DNA probes can identify parasitemia; these methods are valuable in clinical and epidemiological research, but have not become standard methods for use in clinical practice.

In high transmission areas where more than half of the child population may be parasitemic but apparently well at any given time, diagnosis of malaria as the cause of an illness must be speculative and will sometimes be wrong. In the comatose child, finding the distinctive ophthalmoscopic changes of malarial retinopathy (Fig. 28.53) strengthens the confidence with which the illness can be attributed to malaria. Other possible causes of the patient's clinical disease must also be considered.

A proportion of children with malaria have bacteremia, which may be either the principal or an additional cause of the child's illness.<sup>794</sup> Nontyphi bacteremia is particularly associated with malaria and severe anemia in infants and young children.

### TREATMENT OF UNCOMPLICATED MALARIA

Most countries in endemic areas now have a national malaria control program with a stated policy of first line therapy for the treatment of presumed or proven malaria. In many areas it is a (necessary) part of national policy to base treatment on a presumptive diagnosis of malaria in the child with no obvious alternative explanation for fever. The correct drug, dosage and route are important. In general, antimalarial drugs should be given by mouth unless the patient is too ill to swallow. It is usual to prescribe additional symptomatic treatment, e.g. paracetamol, to reduce high fever, myalgia and headache.

In response to strong recommendations from WHO and funding bodies, countries are moving to adopt combination therapies as first line

Fig. 28.53 Ophthalmoscopy in a child with cerebral malaria, showing (a) patchy retinal macular whitening, close to the fovea, (b) whitening of vessels, and two white-centered hemorrhages.

antiparasitic treatment in areas with a predominance of *P. falciparum* (i.e. most of sub-Saharan Africa). Artemisinin-containing combination therapies (ACTs) are preferred because of the rapid antiparasitic action of artemisinin drugs, their lack of toxicity, and the expectation that combination with another drug will prevent or delay the evolution of drug resistance to each component drug.<sup>795</sup>

Combination therapies that are being increasingly introduced include: artemether–lumefantrine (Coartem) – the only combination yet available (2006) for which the different components are co-formulated in the same tablet; amodiaquine plus artesunate; and amodiaquine plus sulfadoxine–pyrimethamine. The first of these must be given twice daily for three days, the others once daily for three days. Chlorproguanil–dapson–artesunate (CDA) is a further option for which large scale field evaluations remain to be completed.

Policies usually include a second line therapy if the first line fails or is contraindicated in an individual. If a child vomits more than one attempted dosing by mouth, parenteral or rectal therapy with quinine or an artemisinin drug may be given.

### Treatment of nonfalciparum malaria

Chloroquine is the treatment of choice for acute nonfalciparum malaria. Some *P. vivax* infections are chloroquine resistant, but since *P. vivax* does not progress to life-threatening disease, a trial of chloroquine is justified.

*P. vivax* and *P. ovale* malaria (unless acquired congenitally or by blood transfusion) may relapse if treatment does not include a drug to eliminate hepatic hypnozoites. Primaquine (0.25 mg/kg daily for 2 weeks) will achieve this, but is not worth giving in areas where reinfection is inevitable, and it should not be given to children under the age of 5 years. Primaquine causes severe hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency; the red cell concentration of this enzyme should therefore be measured before the drug is given; if low, an alternative method of radical cure is weekly chloroquine for 6 months in prophylactic doses. Primaquine need not be given after malaria due to *P. falciparum* or *P. malariae*. Primaquine has the additional action of killing gametocytes of all species of malaria parasites; it therefore has the potential to reduce transmission and has occasionally been used for this purpose in areas of moderate endemicity, a function now more safely achieved using artemisinin drugs.

### MANAGEMENT OF SEVERE (COMPLICATED) FALCIPARUM MALARIA

Malaria due to *P. falciparum* differs from disease due to other plasmodial species in that *P. falciparum* infections may progress to severe and complicated disease. In the patient with falciparum malaria treatment must therefore be undertaken urgently; complications must be foreseen, recognized and treated; and the antimalarial drugs must be carefully chosen and correctly and promptly administered. Most of the deaths in children admitted to hospital with severe malaria occur before specific antiparasitic drugs can be expected to affect the disease: supportive care during the early phase of management is therefore critically important.

#### Supportive measures

##### Hypoglycemia

This complication should be suspected in any child with impaired consciousness, convulsions or acidosis, whether at the time of admission or during the course of treatment. Glucose should be administered as 10% or 20% solution by slow intravenous injection (0.5 g/kg). (If only 50% glucose is available, it should be diluted two- to three-fold with normal saline before being infused over a few minutes.) The blood glucose concentration must be measured again at hourly intervals until the patient's condition improves.

##### Convulsions

Hypoglycemia and hyperpyrexia should be corrected. Prolonged seizures should be treated with the optimal available drug regimen: drugs which may be used include lorazepam, diazepam, paraldehyde, phenytoin or phenobarbital, using drugs in sequence if convulsions prove refractory.

##### Acidosis

Deep or labored breathing due to acidosis is a common presentation of severe malaria in children. Possible contributory (and often additive) causes are dehydration, severe anemia, shock, repeated convulsions and hypoglycemia, all of which should be looked for and corrected in the acidotic child (see below under Severe anemia).

##### Hyperpyrexia

Hyperpyrexia (rectal temperature > 39 °C) should be corrected by administration of oral or rectal paracetamol (15 mg/kg 4–6-hourly). Although important to reduce the risk of seizures in infants and for

symptomatic relief in the conscious child, antipyretic measures have not been demonstrated to affect the prognosis in severe malaria.<sup>796</sup>

### Severe anemia

Because of the increasing risk of transmission of HIV by blood in parts of the world where malaria is endemic, blood transfusion should only be given if life-threatening anemia is present or can be predicted on the basis of the hematocrit and level of parasitemia on admission. Blood transfusion is particularly important for the child with severe anemia and respiratory distress.<sup>797</sup> Most children with severe malarial anemia who are breathless have acidosis rather than heart failure, and may be in urgent need of fluid volume replacement.<sup>792</sup>

Exchange transfusion has been advocated and successfully used for patients with hyperparasitemia, but no controlled trials have been done to prove the superiority of this measure. In countries with limited resources for blood transfusion and with high prevalence rates of HIV infection, exchange transfusion is not justifiable as a method for treating severe malaria.

### Fluid therapy

This must be sufficient to correct hypovolemia, acidosis and oliguria. When a child has both volume depletion and encephalopathy, there is a therapeutic dilemma: infusion of isotonic electrolyte solution may correct hypovolemia but increase the risk of cerebral edema.<sup>798</sup> In this situation an infusion of albumin, plasma or other plasma expander may be safer (in the anemic child, whole blood will serve all of the needed functions). Current studies are in progress to provide appropriate guidelines. The usual precautions are important to avoid overhydration and the risk of pulmonary edema. Acute tubular necrosis is uncommon as a complication of *P. falciparum* malaria in children, but if it occurs peritoneal or hemodialysis may be required.

### Antibiotics

Some children with severe malaria are bacteremic, the proportion differing between studies and sites. In a series in Kenya the overall rate of bacteremia among 421 children with malarial coma or severe anemia was 8.6% and mortality was three-fold higher in these patients than others, prompting the authors to recommend routine antibiotic treatment for patients with severe malaria.<sup>794</sup> Other studies have indicated a more specific association between severe malarial anemia (SMA) and nontyphoidal salmonella bacteremia, especially in infants and toddlers, suggesting that antibiotics should be considered in the management of SMA in very sick children and in those not responding to antimalarial and hematonic

therapy. Policies for antibiotic use in various severe malaria syndromes may best be decided on the basis of local experience.

In a child with malarial coma, it may be impossible on physical examination to exclude a diagnosis of bacterial meningitis. Since asymptomatic parasitemia is common in endemic areas, parasitemia in the febrile unconscious child cannot be assumed to be the cause of the disease. Some clinicians prefer to perform a lumbar puncture in these circumstances, to clarify the diagnosis. If lumbar puncture is deferred because of the child's clinical condition, antibiotics should be given to cover the possibility of bacterial meningitis.

There is no place for heparin, dexamethasone or dextran in the treatment of CM.<sup>799</sup>

### Antimalarial drugs for severe malaria

For severe or complicated *P. falciparum* malaria, the antiparasitic treatment of choice depends on the context. Recent multicenter studies in South East Asia<sup>800</sup> have shown that intravenous artesunate is superior to quinine in the treatment of adults with severe malaria, but there were insufficient children in these studies to detect a comparable difference among children. Africa differs from South East Asia in two important respects relating to the treatment of severe malaria: (1) in Africa most patients are children, while in South East Asia most patients are adults; and (2) in Africa quinine resistance is unknown among *P. falciparum* isolates, while partial quinine resistance is well described in South East Asia. Studies are therefore under way to compare parenteral quinine with intravenous artesunate in African children with severe malaria.

Meanwhile, for children in Africa, parenteral quinine remains the drug therapy of choice for severe malaria. If quinine is unavailable, quinidine is an equally effective alternative. Appropriate schedules for treatment are given in Table 28.40.

Quinine may cause severe hypotension if given by rapid intravenous injection, so a dilute solution (1–2 mg/ml) must therefore be infused slowly (over 3 or more hours). If the intravenous route is problematic or impossible, quinine may be given by intramuscular injection in the same doses, the solution (diluted to contain 60 mg/ml) being divided and administered in two sites simultaneously. Parenteral quinine is known to stimulate the secretion of insulin from the pancreatic beta cells, but hypoglycemia in children being treated for malaria is usually due to the disease rather than to drug therapy.<sup>782</sup> If intramuscular quinine is used in the treatment of a comatose child, supplementary glucose must be given or the blood glucose level checked frequently.

Oral drugs should replace parenteral as soon as a patient can take them. If given as the only drug treatment, quinine must be continued

**Table 28.40** Drug treatment of acute malaria. In this table the first regimen listed in each section is the treatment of choice

Diagnosis	If patient can take oral drugs	If patient unable to take oral drugs
Malaria due to <i>P. vivax</i> , <i>ovale</i> , <i>malariae</i> , and uncomplicated CQ-sensitive falciparum malaria	Oral CQ: 10 mg/kg first dose then 5 mg/kg after 6, 24 and 48 h  Or: AQ, same doses	CQ: 10 mg/kg over 8 h in saline or 5% dextrose; then 5 mg/kg by similar infusions × 3 (total 25 mg/kg in 32 h) Or: CQ i.m. or s.c. 2.5 mg/kg 4-hourly to 10 doses. Substitute oral CQ when possible
Uncomplicated falciparum malaria of doubtful CQ sensitivity	S/P single dose (S: 25 mg/kg, P: 1.25 mg/kg) Or: oral AQ as above Or: oral MQ 15 mg/kg first dose, then 10 mg/kg after 8 h	As for complicated falciparum malaria
Severe or complicated falciparum malaria	QN: i.v., first dose* 16.7 mg/kg over 4 h in 5% dextrose, then 8.3 mg/kg over 2–4 h each, 8-hourly, until oral drug can be taken (viz. quinine 8.3 mg/kg 8-hourly) to complete 7-day course Or: QN i.m. 8.3 mg/kg 8-hourly as solution containing 60 mg/ml. Give supplementary glucose. Substitute oral quinine as soon as possible, 8.3 mg/kg 8-hourly to complete 7-day course Or: quinidine i.v. 7.5 mg/kg 8-hourly, each dose over 4 h in 5% dextrose, until oral treatment can be taken; this may be QN 8.3 mg/kg 8-hourly or quinidine 7.5 mg/kg 8-hourly. Total course 7 days	

\*The first dose of i.v. quinine should be reduced to 8.3 mg/kg if the patient has received any quinine or mefloquine in the two preceding days.

CQ, chloroquine; AQ, amodiaquine; QN, quinine; MQ, mefloquine; S/P, sulfonamide-pyrimethamine combination, e.g. Fansidar. All doses of CQ, QN and quinidine refer to base, not salt (8.3 mg quinine base = 10 mg quinine dihydrochloride).

for at least 7 days. Alternatively, once oral treatment is resumed, quinine may be replaced by a locally efficacious oral combination therapy (as used for uncomplicated *P. falciparum* malaria).

## MALARIA CONTROL

Since the epidemiology of malaria varies greatly between and even within countries, control measures which are effective in one area may prove ineffective in another. It is important, therefore, that national control programs be designed having regard to local epidemiological, social and economic circumstances.

There are currently four principal methods of malaria control relevant to the well-being of children in areas of intense transmission:

1. *Prompt recognition and treatment of both mild and severe disease* at all levels of the health service, with referral to a larger health facility when necessary. This requires appropriate diagnostic policies (often including presumptive diagnosis of fever as malarial), effective, safe and affordable treatment schedules, competent health staff, and health facilities that are accessible to the majority of people. Because health services are inevitably distant from the homes of many rural people, complementary strategies are needed, and several are being assessed. These include administration of antimalarial drugs for treatment or prevention by village health workers,<sup>801</sup> the training of shopkeepers in appropriate prescribing and dosages (most first line treatment for malaria in village communities is obtained from local grocery stores),<sup>802</sup> schemes to involve traditional healers in treatment or referral of patients with malaria, and making rectal artesunate available at village level for the early treatment of the convulsing or unconscious child.<sup>803</sup>
2. *The use of insecticide-treated nets (ITNs) or curtains.* Several controlled trials and a meta-analysis have demonstrated that sleeping under ITNs can reduce all-cause child mortality in communities.<sup>804</sup> Inevitably there is concern that such results depend on the presence of a scientific team, providing materials and encouraging their use. A study in Tanzania showed a 27% increase in child survival among ITN users in the context of a bednet program promoted by social marketing, i.e. without the involvement of an investigative team.<sup>805</sup> Impregnated nets and curtains therefore have a potentially important place in malaria control, which may depend on local culture and malaria transmission patterns. The need for annual re-impregnation of nets poses a challenge to sustainability; new methods (the 'permanet') may make re-impregnation unnecessary.
3. *Intermittent presumptive treatment (IPT).* Pregnant women, especially primigravidae, are at increased risk of malaria, and placental malaria is associated with low birth weight and increased infant mortality. Provision of two, three or more therapeutic doses of an antimalarial drug such as pyrimethamine-sulfadoxine (Fansidar) between the fourth and eighth months of pregnancy, irrespective of symptoms or parasitemia – intermittent presumptive treatment in pregnancy, or IPTp – reduces placental malaria and improves birth weights.<sup>806</sup> IPTp is now an instrument for control of malaria-induced morbidity in many endemic countries. *Intermittent presumptive therapy for infants (IPTi)* proved promising in an East African study, in which infants given a therapeutic dose of sulfadoxine-pyrimethamine at 2, 3 and 9 months of age, irrespective of fever or parasitemia, had fewer episodes of malaria and of severe anemia during the first year of life than controls.<sup>807</sup> Some (not all) subsequent studies have shown similar benefits, and multicenter trials of IPTi are in progress. Similar studies in older age groups of children (IPTc) are being considered.
4. *Indoor residual spraying (IRS)* – the spraying of the inside walls of dwellings with residual insecticide – was a mainstay of the malaria eradication campaigns in 1950–70, parts of which were spectacularly successful. But IRS encountered both political

and vector resistance, was poorly sustained, and was never adequately achieved in Africa. IRS is now receiving renewed attention as novel methods and capacities are acquired, and it is being increasingly explored as a promising component of malaria control programs.

There is growing optimism that vaccination will, within the next few years, become a further weapon in the armamentarium available to fight malaria.

The success of any method or combination of methods of control is likely to be materially influenced by the degree to which the causes and consequences of malaria are appreciated by populations and by the willingness of communities to participate in, and even finance, specific operations.<sup>799</sup>

Meanwhile the international community is becoming more aware of the fact that tools for malaria control exist, and that their deployment needs expenditure on materials, infrastructure, health systems and staff development. Commitments of funding from major donors have increased in recent years and will need to be sustained if real progress is to be made.

## TOXOPLASMOSIS

Toxoplasmosis is mainly of importance to pediatrics as a congenital infection (see p. 1202). Infection acquired after birth can cause chorioretinitis or infectious mononucleosis and can cause significant disease in persons with underlying T cell immunodeficiencies. Occasionally, signs of congenital infection may not manifest until late in childhood or early adulthood.

The birth prevalence of congenital toxoplasmosis infection across Europe ranges from 1 to 10 per 10000 newborns.<sup>808</sup> In the UK, only 10% of women show evidence of past infection with toxoplasmosis, whereas in France up to 55% of pregnant women show antibodies to toxoplasmosis on antenatal screening.

## ETIOLOGY

The causative organism, *Toxoplasma gondii*, is, in its free active state, a small, crescentic protozoan, which is a strict intracellular parasite multiplying only within the cytoplasm of the nucleated host by binary fission or, probably more frequently, by internal budding (endodyogeny). The active form, responsible for acute infection, stimulates an immunological response by the host. At the same time, cyst forms of the parasite develop in any tissue, but chiefly in nervous tissue or striated muscle, and may persist for the life of the host.

## PATHOGENESIS

*T. gondii* infects virtually all species of mammals and several species of birds. The cat family is the definitive host. Cats usually acquire the infection after eating infected rodents, birds or uncooked meat. After primary infection, they shed millions of oocysts in their feces for up to 14 days. Oocysts may remain viable in soil for many months, and are not found on the cat fur, thus explaining the failure to link cat exposure with the risk of human toxoplasmosis infection.<sup>809</sup>

Humans are most commonly infected after ingestion of tissue cysts in raw or poorly cooked meat, or by ingestion of soil, food or water contaminated with oocysts. Infection from meat has been shown to be responsible for up to two thirds of all new infections in pregnant women.<sup>810</sup> Traditionally pork, lamb, goat or game meats hold the highest risk for human infection, although undercooked beef has been shown to be a risk factor for toxoplasmosis seroconversion,<sup>810</sup> possibly due to combination with cheaper meats.<sup>809</sup> Congenital toxoplasmosis infection usually occurs as a result of placental infection after a primary infection in a pregnant woman. The risk of transmission and the clinical outcome after maternal toxoplasmosis infection vary with the trimester of pregnancy, with the first trimester having the lowest risk of transmission to the fetus but the highest risk of damage.

Transmission has also been rarely documented in children after blood or blood product transfusion, heart or bone marrow transplantation<sup>811,812</sup> and through infected breast milk.<sup>813</sup>

## CLINICAL FEATURES

Acquired infection with *T. gondii* is uncommon in the UK in children under 5 years. Serological surveys suggest a peak acquisition of infection in early and mid teens. The disease is nearly always asymptomatic. The commonest manifestation, if clinical signs do occur, is lymphadenopathy, particularly of cervical nodes, which may be accompanied by no ill health, or may be accompanied by fever and prostration and resemble severe infectious mononucleosis. Muscle pain may also occur due, it is believed and occasionally confirmed, to infection of voluntary muscle. Acquired toxoplasmosis may also result in hepatosplenomegaly, lymphocytosis, and, rarely, pneumonitis, acute hepatitis, arthritis or cardiac arrhythmias (due to lesions in the region of the conducting system). The occurrence of cardiac failure due to toxoplasma infection of the myocardium is conjectural. Isolated visual disturbance due to toxoplasmosis retinitis in childhood used to be thought to be due to reactivation of an undiagnosed congenital infection, but is equally commonly due to acquired infection.<sup>814</sup>

Acquired toxoplasmosis infection has been documented in immunodeficient children with HIV infection, or post bone marrow or solid organ transplantation, but it occurs much less commonly than in adults. Toxoplasmosis in the immunocompromised child may manifest as encephalitis, pneumonitis or even a multiorgan systemic disease.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Acquired toxoplasmosis should be considered in any case of unexplained lymphadenopathy, particularly when maximal in, or confined to, the cervical region, whether or not it is accompanied by pyrexia. Lymph node enlargement in acquired toxoplasmosis may persist for several months, leading to the consideration of lymphoma and tuberculous lymphadenopathy in the differential diagnosis.

In the immunocompromised child, it enters the differential diagnosis for neurological disease (encephalitis, meningoencephalitis, brain abscess), for interstitial pneumonitis, and for myocarditis.

## Laboratory diagnosis

The most common laboratory aids to the diagnosis include serology, isolation of the organism, histology and the direct detection of *T. gondii* DNA in infected tissues or fluids by polymerase chain reaction (PCR). Other diagnostic methods used less commonly today include skin testing and the Sabin–Feldman dye test, which depends upon the inhibition by antibody-containing serum of methylene blue staining of laboratory cultures of *T. gondii*. The diagnosis of a congenital infection postnatally is discussed in Chapter 12.

Serological methods remain the most commonly used method for diagnosis. Acute infection in the older child or adult may be diagnosed by a four-fold rise in toxoplasma-specific IgG by indirect immunofluorescence, or enzyme immunoassay. Toxoplasma-specific IgM can be detected by 2 weeks post infection, and usually declines by 6 months, but at times may persist for months (and occasionally over a year) after the initial infection. Thus the detection of toxoplasma IgM may indicate either an acute or a recent past infection. Positive results should be confirmed by multiple tests in different laboratories, given a false positive rate of up to 2%. If timing of the infection is critical, as in the case of a pregnant woman, the presence of IgA and IgE antibodies to toxoplasmosis which decline more readily than IgM, and IgG avidity (high avidity suggests an infection > 12 months prior) may be helpful in differentiating an acute infection from a past infection. However, some suggest that even current serological assays cannot predict the time of infection within the first year after infection (reviewed in Petersen et al<sup>815</sup>).

The detection of *T. gondii* DNA by PCR in amniotic fluid is now commonly used for the prenatal diagnosis of congenital toxoplasmosis.

Sensitivity rates of up to 90% have been reported, but there is a wide range in the quality of assays available, with false positive rates ranging from 0 to 10% reported in some laboratories (reviewed in Petersen et al<sup>815</sup>). Other applications of the assay are on cerebrospinal fluid, or peripheral white blood cells in the immunocompromised or congenitally infected infant.

Culture of *T. gondii* from lymph node biopsy material, amniotic fluid, placenta or, less often, other tissue fluids is possible, although generally less widely used than serological methods. The organism can be cultured in suitable laboratory animals, particularly mice, embryonated eggs and tissue cultures. The most reliable of these procedures is that of intraperitoneal inoculation of mice. Histological examination of biopsy material is also of value, limited chiefly by the availability of suitable material. Cysts can be identified readily, but vegetative forms are recognized with difficulty.

In the immunocompromised child, such as those with HIV infection, the ability to document seroconversion to toxoplasmosis is impaired. A diagnosis must be made by demonstrating the organism by PCR, culture or histology in infected tissues, or presumptively by characteristic findings on imaging that respond to an empirical trial of antiparasitic therapy.

Dermal hypersensitivity to injection of a suspension of killed toxoplasma is indicated by a delayed tuberculin type response. There is good correlation between a positive skin test and a positive dye test titer of 1:8 or more. The test may be negative in very recent infections and is used chiefly in epidemiological surveys in man.

## TREATMENT AND PROGNOSIS

Treatment of acquired toxoplasmosis infection in childhood is usually only indicated for active ocular infection or severe disease in other organs.

Treatment of congenitally infected infants is discussed in Chapter 12. Antibiotics, other than spiramycin, have proved to be of little value in the treatment of acute toxoplasmosis. Sulfonamides have proved disappointing and sulfones too toxic in the doses required. The most effective form of chemotherapy is a combination of pyrimethamine and sulfadiazine for a total duration of 3–4 weeks. The hematological toxic effects of pyrimethamine, due to its antifolate acid action, can be prevented or reversed by folinic acid. Spiramycin, though less toxic than the pyrimethamine and sulfadiazine combination, is clearly less effective. An alternative is the use of a combination of trimethoprim and a sulfonamide, e.g. co-trimoxazole. Life-long suppressive therapy with these agents is indicated for HIV infected children after toxoplasmosis encephalitis.

In the pregnant woman, spiramycin may be given in early pregnancy for suspected primary toxoplasmosis to prevent transmission to the fetus, and after 17 weeks' gestation, pyrimethamine and sulfadiazine may be used for confirmed fetal infection to reduce the risk of transmission or complications in the child. However, a recent systematic review of randomized trials of antiparasitic treatment of toxoplasmosis in pregnancy concluded that there was still insufficient evidence available to determine whether such treatment has a positive effect on clinical outcomes or risk of transmission.<sup>816</sup>

Chemoprophylaxis to prevent reactivation of toxoplasmosis should be considered in the significantly immunosuppressed child with HIV infection or prior to heart transplantation.

## TRYPANOSOMIASIS

### AFRICAN TRYPANOSOMIASIS: SLEEPING SICKNESS

Human African trypanosomiasis (HAT) is caused by two 'subspecies' of *Trypanosoma brucei* which are transmitted by the bite of the tsetse fly. Sleeping sickness is widely distributed in 36 countries in sub-Saharan Africa. Approximately 18 000 cases are reported annually to the WHO, with an estimated total burden of 50–70 000.

*T. b. gambiense* occurs in west and central Africa and causes a disease which is slow in onset and progression (Gambian sleeping sickness). Infected humans provide long term sources of infection for the tsetse and the *T. b. gambiense* disease is largely an anthroponosis. Infection with *T. b. rhodesiense* occurs in east and south east Africa and causes an acute illness that is often lethal within a few months (Rhodesian sleeping sickness). It is a true zoonosis: infection is maintained within wild ungulate reservoirs. Both forms most commonly infect adults but any age may be affected; infection is 2–3 times more common in adults than children in *T. b. gambiense* endemic areas.<sup>817</sup>

## Life cycle

In the tsetse fly, stumpy trypomastigotes ingested with the blood meal transform into slender midgut forms. These eventually reach the salivary gland and transform via epimastigotes to the infective metacyclic trypomastigote. After inoculation, the metacyclic trypomastigotes are converted into long slender forms in the subcutaneous tissue of the host. Blood forms are polymorphic with both slender and stumpy forms. The continual movement of the trypomastigote is activated by a flagellum and a fold of membrane which is lifted up by the motion of the flagellum – the ‘undulating membrane’. Three ‘subspecies’ of *T. brucei* group exist; *T. b. brucei*, which is not infective to humans, cannot be distinguished morphologically from *T. b. rhodesiense* and *T. b. gambiense*. However, biochemical techniques, DNA analysis and isoenzyme characterization can distinguish different *T. brucei* populations. *T. b. rhodesiense* comprises two distinct zymodemes; the ‘Zambezi’ group in southern Africa and the ‘Busoga’ group in east Africa associated with more acute severe disease. *T. b. gambiense* is less variable.

## Epidemiology

The reported number of infections has declined considerably over the last 6–7 years, because of improved surveillance and control measures in some regions. However, recent epidemics have occurred in areas such as DRC, Angola and Sudan, partly because of breakdown of control measures and population movement due to civil unrest. *T. b. gambiense* accounts for the vast majority of cases of trypanosomiasis.

*T. b. gambiense* is restricted to west and central Africa and is transmitted by ‘palpalis group’ tsetse (*Glossina palpalis*, *G. tachinoides* and *G. fuscipes*), which inhabit dense vegetation along rivers and in forests. Vectors feed on man at water collecting points and river crossings. The man–fly–man cycle of transmission may maintain the disease in the absence of an animal reservoir; infected individuals may be asymptotically parasitic for years. Although human parasites infect both wild and domestic animals, their epidemiological significance remains uncertain.

*T. b. rhodesiense* is usually transmitted by ‘morsitans group’ tsetse (*G. morsitans*, *G. pallidipes* and *G. swynnertoni*) in East African woodland savannah and lake shores. Most infection is sporadic such as in Tanzania when game hunters or honey gatherers are bitten by *G. morsitans* which transmit disease from the bushbuck host, or in south east Uganda and western Kenya where fishermen are bitten by *G. pallidipes* on lake shores. However, epidemics have occurred in western Kenya and in south eastern Uganda with infections occurring in both sexes and all age groups. The vector is *G. f. fuscipes*, a ‘palpalis group’ tsetse which invades *Lantana camora* thickets close to human habitation; domestic cows may play an important part in maintaining infection in such situations. Imported trypanosomiasis is also relatively rare, but an increased number of cases have been reported over the last 5 years in Europe and the USA as a result of exposure in game parks. Congenital infection with *T. b. rhodesiense* and *T. b. gambiense* does occur, but appears to be very rare.

## Pathogenesis and pathology

Pathological processes are similar but vary in intensity between *T. b. gambiense* and *T. b. rhodesiense*. Parasites inoculated into the subcutaneous tissue multiply locally, forming a trypanosomal chancre, with edema and an infiltrate of polymorphonuclear leukocytes, lymphocytes and plasma cells. Parasites travel to regional lymph nodes where they

continue to multiply and cause parasitemia 5–12 days after infection. Waves of parasitemia occur, each differing in its surface antigens (particularly variant surface glycoprotein) as the parasite attempts to avoid the host immune response.

Hyperplasia of the reticuloendothelial system, with lymph node and spleen enlargement, occurs as a response to infection; lymph nodes may subsequently become atrophic and fibrotic. Morular cells (Mott cells) are found; these are plasmacytes that may have an important role in the production of IgM. Blood parasites invade the central nervous system via the choroid plexus leading to the second stage of infection, a meningoencephalitis. A lymphocytic meningoencephalitis and focal vasculitis with perivascular infiltrates occurs particularly in the frontal lobes, pons and medulla. Parasites in the CNS are accompanied by changes in the cerebrospinal fluid with a raised protein concentration and the presence of mononuclear cells, particularly lymphocytes. Parasites can also be identified in the CSF.

The succession of variable antigens induces a profuse production of IgM antibody in the serum and it is also locally produced in the central nervous system by plasma cells and the morular cells. Immune complex damage (type III hypersensitivity) may cause less common lesions of the kidney, lungs, liver and heart. Expression of cell-mediated immunity, induction of cell-mediated immunity and expression of humoral immunity have been shown to be impaired in *T. b. gambiense* infections in man.

## Clinical features

### The trypanosomal chancre

The primary lesion (trypanosomal chancre) is a painful, erythematous and edematous swelling at the site of the bite that appears within 2 or 3 days. Skin vesicles and ulceration may develop and the chancre heals with residual scarring over 2–3 weeks. Chancres commonly occur in *T. b. rhodesiense* infection but are less common in *T. b. gambiense*. As the chancre develops, the regional lymph glands become enlarged and tender.

### The hemolymphatic (first) stage

Waves of irregular remittent fever, in association with the waves of parasitemia, occur 5–12 days after the bite. This is most marked in *T. b. rhodesiense* infections; in *T. b. gambiense* the hemolymphatic stage may be mild, subclinical or asymptomatic. Febrile episodes, sometimes with rigors, are accompanied by malaise, headache, muscular tenderness, joint aches and weight loss. An annular erythematous rash (circinate erythema) may be visible, particularly on the trunk in the fair skinned. Generalized lymphadenopathy may develop, especially in *T. b. gambiense*. Winterbottom’s sign, posterior cervical triangle lymphadenopathy, occurs in *T. b. gambiense* due to the predilection for *G. palpalis* to bite on the head. Edema may affect the ankles or feet or face, producing a dull expressionless facies. Irritability, insomnia and confusion may occur even in the early stage. The spleen and liver may enlarge. In the acute stage of *T. b. rhodesiense* infection, tachycardia is common; pleural or pericardial effusions may occur and myocarditis with arrhythmias or cardiac failure may lead to death.

### Meningoencephalitic (second) stage

Meningoencephalitis is an inevitable consequence of untreated human African trypanosomiasis. In *T. b. gambiense*, it tends to occur after months or years while in *T. b. rhodesiense* it occurs early, often during the febrile illness, and progresses rapidly to a fatal outcome. Children develop meningoencephalitis more rapidly than adults. A wide variety of neurological signs occur. Behavioral changes and sleep disturbances are often the first signs; inappropriate diurnal somnolence with insomnia and agitation at night are common. Patients become apathetic, lacking in attention and may exhibit trance-like states. Behavior becomes inappropriate, aggressive or overtly paranoid. Nutritional deficiencies, intercurrent infections and progressive emaciation result. Generalized weakness, unsteadiness of gait, expressionless facies, slurred speech, tremors of the limbs, hyper-reflexia and delayed deep hyperalgesia all occur. In advanced disease, focal epileptic attacks, profound ataxia, choreoathetosis and psychotic changes may be followed by coma and death. There is little variation in symptoms or signs between adults and

children, apart from the incidence of malnutrition, which may be as high as 50–60% in children with second stage disease.<sup>818</sup>

### Diagnosis<sup>819</sup>

Clinical diagnosis of African trypanosomiasis may be difficult. Although the presence of a chancre is pathognomonic, the hemolymphatic stage must be differentiated from a wide range of febrile illnesses including malaria. Differential diagnosis of second stage disease includes other causes of meningoencephalitis, particularly cryptococcal and tuberculous meningitis in the HIV infected, and psychiatric illness. Routine laboratory tests show a normal total white cell count, raised ESR, anemia, thrombocytopenia, low serum albumin and elevated serum IgM. Bilirubin and transaminases may be raised. Hematological abnormalities, including coagulopathy, are particularly prominent in acute *T. b. rhodesiense*. A parasitic diagnosis must be attempted in all suspected cases.

### Parasitological diagnosis

In the early stages of *T. b. rhodesiense* infection, parasitological diagnosis is usually simple, as the concentration of trypanosomes in the blood or aspirates of trypanosomal chancres is high. Organisms can be seen by single or repeated microscopic examination of wet films or thick blood or aspirate fluid films stained with Field's stain or Giemsa. Blood film microscopy is less reliable in *T. b. gambiense*; repeated examination of blood films and concentration techniques are more often required. However, organisms are readily seen in fresh lymph node aspirates. Trypanosomes may also be identified in CSF, various effusions and marrow smears.

Concentration methods increase the sensitivity of microscopy; microhematocrit centrifugation and microscopic examination of the area above the buffy coat are commonly used. The quantitative buffy coat technique (QBC), where motile trypanosomes are stained with fluorescent acridine orange, tubes centrifuged and examined by fluorescent microscopy, is rapid and sensitive.<sup>820</sup> The miniature anion exchange centrifugation technique (MAEC<sup>821</sup>) involves passing a sample of blood through a DEAE-cellulose anion exchange column, which allows trypanosomes to pass into a collecting tube which is centrifuged and examined. This technique is sensitive but difficult in field conditions.

Once trypanosomiasis is diagnosed or suspected, the CSF must be examined, preferably within 15 min of lumbar puncture. Increase in cell count (more than 5 cells/mm<sup>3</sup>), protein elevation, CSF IgM or trypomastigotes in the centrifuged deposit indicate CNS involvement.

### Immunodiagnosis

Immunodiagnostic tests include IFAT, ELISA, CFT and IgM estimation. IFAT is valuable in epidemiological investigation and screening of populations and suspects but provides only presumptive evidence of infection. A card agglutination test for trypanosomiasis (CATT) has been developed for the diagnosis of *T. b. gambiense*. The test provides a rapid field test for preliminary screening of populations in endemic areas. Positive serological tests require confirmatory parasitic diagnosis prior to treatment.<sup>822</sup> Antigen detection techniques (CIATT) have also been developed and appear to be sensitive and specific; they have potential for following the response to therapy.<sup>823</sup>

### Treatment<sup>824</sup>

Treatment should be started as soon as possible after making a parasitological diagnosis although nutritional disturbances or intercurrent infection should first be treated in view of the toxicity of treatment. Routine use of antihelminth and antimalarial drugs is common. Examination of the CSF is mandatory to distinguish early stage from late stage disease as CNS involvement requires different, more toxic therapy. Lumbar puncture should not be performed until at least one dose of suramin (or pentamidine) has been given to clear parasites from the blood and prevent inoculation into the CSF at the time of LP.

### Treatment of hemolymphatic trypanosomiasis

Suramin is effective in treatment of the hemolymphatic stage of both *T. b. rhodesiense* and *T. b. gambiense* disease and will rapidly clear the

parasitemia in both early and late sleeping sickness. Pentamidine is the first line therapy for *T. b. gambiense* but is not effective in *T. b. rhodesiense*. Neither suramin nor pentamidine is effective in meningoencephalitis.

**Suramin.** Suramin is given intravenously with a test dose of 5 mg/kg on day 1 followed by 20 mg/kg on days 3, 7, 14 and 21. Fever, nausea, vomiting and urticaria are common side-effects; renal toxicity may occur.

**Pentamidine.** Pentamidine is usually given intramuscularly at doses of 4 mg/kg base daily or on alternate days for 7 days. Intravenous administration avoids local side-effects that include sterile abscesses, but requires close supervision. Side-effects include syncope and hypotension, vomiting and abdominal pain, especially in the first half hour after administration. Peripheral neuritis is a rare complication and severe hypoglycemic reactions may occur during the course of treatment. Adrenaline and glucose should be available when treatment with pentamidine is given.

### Meningoencephalitic (late stage) trypanosomiasis

**Melarsoprol.** Melarsoprol (Mel B) is an arsenical compound which enters the CNS. Use is limited to late stage trypanosomiasis because of its toxicity. A variety of different treatment schedules have been used. In *T. b. rhodesiense* infection, melarsoprol is usually given in three or four courses, each course lasting three days and separated by a week, giving a total dose of 35–37.5 ml melarsoprol. Regimens which use lower doses initially and increase through four courses of treatment may be less toxic.

Many regimens have been advocated for treatment of *T. b. gambiense*. Recently, shortened 10-day regimens (2.2 mg/kg daily) have been used for *T. b. gambiense* with no loss of efficacy, and no increased relapse.<sup>825,826</sup>

Thrombophlebitis is a frequent complication of melarsoprol treatment; extravasation causes severe local reactions. The major side-effect is a *reactive arsenical encephalopathy* (RAE), which occurs in up to 5% of patients, usually after the third or fourth dose. The onset is usually sudden with neurological deterioration, confusion, convulsions and coma. It occurs more commonly in severe meningoencephalitis and is fatal in 10–50% of cases. In *T. b. gambiense* (but not *T. b. rhodesiense*) prophylactic prednisolone significantly reduces the incidence of RAE.<sup>827</sup> Other toxicity common with melarsoprol includes agranulocytosis, aplastic anemia, thrombocytopenia and peripheral neuropathy. Melarsoprol should not be given as initial therapy to parasitemic patients; it may cause a Jarisch–Herxheimer-like febrile reaction after the first injection. Treatment normally leads to a striking improvement in the mental and physical condition of patients with sleeping sickness, but there is increasing concern about rising relapse rates.

**Eflornithine (difluoromethyl-ornithine, DFMO).** This drug has been used for the treatment of both early and late stage *T. b. gambiense* with good results but is poorly effective in *T. b. rhodesiense*. The drug is given intravenously in a dose of 100 mg/kg 6-hourly for 14 days (4 g/m<sup>2</sup> for young children); oral preparations are being evaluated. Major side-effects are diarrhea and reversible marrow depression. Response rates vary from 73 to 97% with some geographical variability; shorter courses are less effective. Recent studies suggest that eflornithine may be more effective and safer than melarsoprol in some settings,<sup>828,829</sup> although efficacy may be reduced in those who are HIV positive.

**Nifurtimox.** (an oral agent) has occasionally been used in the treatment of *T. b. gambiense*. As a single agent it has high relapse rates, but when used in combination with a low dose 10-day course of melarsoprol, the combination regimen was superior to a standard melarsoprol regimen.<sup>830</sup>

### Follow-up and relapse

Patients should be seen 3 months after treatment and followed up for 2 years to identify relapse which occurs in 5–20% of those treated, usually presenting as a chronic meningoencephalitis without a peripheral parasitemia. Follow-up should include routine lumbar puncture to identify a rising cell count or protein. Relapse in *T. b. gambiense* following treatment with suramin or pentamidine should be with melarsoprol; eflornithine can also be used in the treatment of relapse after melarsoprol therapy. Relapse in *T. b. rhodesiense* is usually treated with a second course of melarsoprol; nifurtimox may be effective, but more data are needed.

## Control of sleeping sickness

There are two major components of control activities: detecting and treating human cases and vector control. Sleeping sickness caused by *T. b. rhodesiense* is usually detected at fixed medical units in rural areas when patients present with the symptoms of early parasitemia (passive surveillance). In *T. b. gambiense*, limited clinical symptoms in the early stage mean that active surveillance for infected individuals is necessary. Active surveillance may also be useful in *T. b. rhodesiense* epidemics. Blood film examination is used to screen for *T. b. rhodesiense*, but in *T. b. gambiense* CATT tests or gland aspiration are frequently used for initial population screening. Diagnoses should be confirmed parasitologically; serologically positive but parasite negative individuals should be followed at regular intervals. Community education may play a large part in encouraging early diagnosis and reducing the number of parasitemic individuals. There is no role for mass community prophylaxis: it may mask second stage infections and lead to resistance.<sup>824</sup>

Vector control measures used include destruction of tsetse habitats and insecticide spraying. Insecticide-impregnated (and/or odor-baited) traps have been very effective in reducing fly populations without the environmental problems associated with widespread application of insecticides.

## AMERICAN TRYPANOSOMIASIS: CHAGAS' DISEASE

Chagas' disease is endemic throughout most countries of South and Central America. It is caused by *Trypanosoma cruzi*, which is transmitted to humans by triatomine bugs. Acute *T. cruzi* infection is usually benign; the major public health and socioeconomic significance of the disease arises from the chronic stages of the disease. Improved control has led to a reduction in disease: approximately 10 million are infected with an estimated 14 000 deaths annually.

### Life cycle of *Trypanosoma cruzi*

The organism occurs in three distinct forms: amastigotes found in tissues of mammalian hosts, epimastigotes found in the digestive tract of the triatomine bug, and trypomastigotes found in mammalian blood. After ingestion by the vector, trypomastigotes change and multiply as epimastigotes and in the succeeding 2–4 weeks develop into metacyclic trypomastigotes in the gut of the bug. Infective forms, excreted with the feces, enter through an abrasion in the skin or through intact mucous membranes such as the conjunctiva. Within 1–2 weeks trypomastigotes circulate in the bloodstream. After an undetermined period, the trypomastigote invades tissue cells and is transformed into the amastigote.

### Epidemiology

*T. cruzi* infect over 100 mammalian species; the commonest wild hosts are rodents and small marsupials. Many triatomine bugs are sylvatic and maintain infection among reservoir hosts. Three species have adapted to human dwellings: *Rhodnius prolixus*, *Triatoma infestans* and *Panstrongylus megistus*. Human infection usually occurs from transmission between man and domestic animals. There may be hundreds or thousands of bugs in a household due to factors such as poor housing, thatched roofs and lack of wall resurfacing. Up to 40–50% of bugs may be infected in some locations. Most transmission occurs rurally but peri-urban transmission is increasing as a result of the rapid urbanization occurring throughout much of South America.

Chagas' disease may also be acquired by blood transfusion, although widespread serological screening has decreased transmission considerably. Congenital disease is an important public health problem in rural areas of endemic transmission, occurring in up to 10% of seropositive women.

### Pathogenesis

Parasites multiply at the site of entry which may lead to a chagoma, consisting of interstitial edema and focal inflammation. Parasites reach the blood but soon disseminate to enter cells, particularly histiocytes, neuroglia,

smooth muscle, cardiac muscle and skeletal muscle cells. Amastigotes develop within cells to form pseudocysts. Pseudocyst rupture may lead to the development of acute inflammatory foci with tissue damage, such as the destruction of conducting tissue in the heart. A small proportion of individuals have acute complications, but in the vast majority the inflammatory reaction subsides and parasitemia and multiplication of parasites in the tissues is reduced by the immune response. Mechanisms of the chronic complications of Chagas' disease remain uncertain; tissue damage, neuronal loss and an autoimmune response are all likely to be important.<sup>831</sup>

## Clinical features

### Acute Chagas' disease

Acute Chagas' disease is usually an illness of children but can occur at any age. The acute phase of Chagas' disease is asymptomatic in over two thirds of affected infants and children. If symptomatic, the acute phase lasts for 1–3 months and resolves spontaneously. A chagoma may occur at the portal of entry. The skin over the chagoma becomes hard and may desquamate. Romaña's sign, unilateral eyelid edema and chemosis, is one of the classical syndromes associated with acute Chagas' disease, occurring when bug feces contaminate the conjunctiva.

One to two weeks later, a febrile reaction develops, often associated with headache and myalgia. Vomiting, diarrhea, lymphadenopathy, moderate hepatosplenomegaly and meningoencephalitis may all occur. Myocardial involvement, causing varying dysrhythmias to myocarditis and cardiac failure, may occur; these complications may occasionally be fatal. Meningoencephalitis in the very young has a bad prognosis. Leukocytosis and lymphocytosis accompany the parasitemia.

Following the acute phase, if untreated, low level infection may persist asymptotically for many years (sometimes termed indeterminate phase). Between 15 and 40% of these patients will develop chronic Chagas' disease.

### Chronic Chagas' disease

Chronic symptomatic disease is rarely a pediatric problem, usually occurring between the ages of 15 and 50 years. It is characterized by the reappearance of clinical disease 10–20 years after infection. In adults, classical manifestations are the development of a biventricular congestive cardiomyopathy or cardiac rhythm disturbances. Complete right bundle branch block with left bundle hemi-block is the most common abnormality; AV block, extrasystoles and Stokes–Adams attacks also frequently occur. Inflammatory changes and destruction of parasympathetic ganglion cells in muscle may also eventually lead to mega-esophagus and megacolon.

### Congenital Chagas' disease

Congenital infection with *T. cruzi* occurs in between 2 and 10% of maternal infections. Infection is associated with abortion, stillbirth and severe illness or death in early infancy in a high proportion. Clinical features include cardiac problems, mega-esophagus, pneumonitis and meningoencephalitis. Transmission is also thought to occur through breast milk.

### Chagas' disease in the immunocompromised

Chagas' disease in immunocompromised individuals is an increasing problem in South America due to HIV infection and the use of immunosuppressive drugs in transplant patients. Reactivation of latent *T. cruzi* infection or transplantation of an infected organ can cause the recurrence of parasitemia and the development of an intense myocarditis or severe neurological problems if careful monitoring and pre-emptive therapy is not used.<sup>832</sup>

## Diagnosis

### Parasitic diagnosis

A specific diagnosis, demonstrating *Trypanosoma cruzi* in the peripheral blood, is usually easy in the early acute illness. The parasite appears as a C- or S-shaped trypomastigote with a prominent kinetoplast in Romanowsky-stained thick or thin films. Centrifugation steps on separated red cells or lysed blood increase the sensitivity of microscopic examination. Culture requires specialized media and is difficult to perform outside a laboratory. Xenodiagnosis is a method for detecting

sub-patent parasitemia in chronic infections (and occasionally in acute infection) by allowing triatomine bugs to feed on the individual patient: it is preferable to animal inoculation which is unreliable. Bugs are then dissected to look for gut infection after 20–40 days. PCR methods have published sensitivities of 60–100% when compared with serology; the technique may be more sensitive in children than in adults. It may also be particularly useful in the early detection of congenital infection.<sup>833</sup>

### Serological diagnosis

An initial IgM response and life-long IgG response may be detected by a number of serological tests, including complement-fixation tests, indirect fluorescent antibody tests and enzyme-linked immunosorbent assays. Approximately 50% of individuals with positive serology will also be positive using xenodiagnosis, but there is a poor specificity with false positive tests from other parasitic infections, particularly leishmaniasis, and autoimmune disorders.

Following the response to therapy is difficult; xenodiagnosis may be negative in those with low parasite burdens and serological tests often remain positive after parasitological cure. PCR may be particularly useful in this situation.<sup>834</sup>

### Treatment

Chemotherapy in Chagas' disease is problematic. Two drugs have been widely used: nifurtimox (8 mg/kg body weight daily for 60–90 days) and benznidazole (6–10 mg/kg body weight daily for 30 or 60 days). The latter is now more commonly used as it is better tolerated. Benznidazole side-effects are more common in adults than in children and occur in 4–30% of cases; hypersensitivity reactions cause rashes and fever, vomiting and peripheral neuropathy. Treatment in acute disease suppresses parasitemia, shortens the course of the acute illness and helps to prevent complications and deaths from acute myocarditis or meningoencephalitis. However, elimination of parasites and prevention of chronic illness only occurs in 50–70% of patients.

The value of treatment in the indeterminate and chronic phase is less certain; results of clinical trials vary both geographically and according to the stage of the infection. Standard recommendations have been that chemotherapy is of no benefit. However, increasing evidence and a Cochrane review suggests that treatment of patients with benznidazole in the indeterminate phase (chronic asymptomatic) leads to parasite clearance in around 60% of patients (measured by negative serology or xenodiagnosis) and reduces the proportion developing ECG changes or progressing to heart disease.<sup>835,836</sup>

Both allopurinol and itraconazole have been used for treatment of chronic disease with parasitological cure in 40–50% and normalization of ECG abnormalities in 36–48% of individuals; itraconazole appears to be superior in preventing the development of new ECG changes.<sup>835,837,838</sup> Further work is needed to evaluate the true value of chemotherapy in chronic disease. Heart failure is usually treated with vasodilators such as ACE inhibitors; digitalis may aggravate arrhythmias. Pacemakers are commonly implanted for heart block. A number of surgical procedures are used for mega-esophagus and megacolon. Treatment of symptomatic congenital infection is often unsatisfactory. Recent evidence suggests that routine screening of babies of seropositive mothers with treatment of positive infants is a safe and effective approach.<sup>833,839</sup>

### Control

No vaccine exists for Chagas' disease. Major preventative efforts center upon control of transmission. Chagas' disease is predominantly a disease of poverty, which leads to poor quality housing and the inability to control domestic triatomine bugs. In recent years, control programs have been effective in countries in the southern cone of South America (Argentina, Brazil, Bolivia, Chile, Paraguay and Uruguay) with a reduction in incidence of between 60 and 99% from 1983–1997.<sup>840</sup>

Seroprevalence surveys are used to indicate areas and dwellings at risk, and pyrethroid insecticides are used for the spraying of housing and peri-domestic buildings; the use of fumigant canisters may also be useful. Community surveillance is then used to detect residual or new infections and further spraying performed. Housing improvements and

health education help to promote sustainability. Programs to control blood transfusion transmission are based on routine serological testing and usually combine serological tests for HIV and hepatitis B as well as *T. cruzi*. If seropositive blood has to be used, the addition of gentian violet 24 h before is effective and safe in preventing transmission.

## FUNGAL INFECTIONS

Fungi form a large and very diverse kingdom but only a small number are pathogenic for humans. Fungi are eukaryotes, that is, unlike bacteria, they have a nucleus and intracellular organelles. They also possess a cell wall composed of chitin. Infections are conveniently divided into superficial, subcutaneous and systemic or deep mycoses. In addition, an increasing number of opportunist fungi cause infection in immunocompromised children (Table 28.41).

Fungi can grow in a unicellular mode (yeasts) or a multicellular mode, when cells elongate and multiply to form long filaments called hyphae and collectively form a mycelium. Some fungi are dimorphic, existing as a yeast at one temperature but forming multicellular hyphae at another. Rather confusingly, some are given different names when in the different forms. Thus *Cryptococcus neoformans* is the name as a yeast and *Filobasidiella neoformans* is its hyphal form. *Actinomyces* and *Nocardia* spp. are not fungi but branching bacteria, but are more conveniently included in discussions of fungal disease (Table 28.42). Treatment of subcutaneous and systemic mycoses is most often by antifungals such as polyenes (e.g. amphotericin B) or imidazoles (e.g. ketoconazole) (Table 28.42). To prevent repetition, information on dosage, mode of administration and side-effects and toxicity is included at the end of the chapter.

## ACTINOMYCOSIS

### ETIOLOGY

Actinomycosis is an infection with a worldwide distribution that affects humans and other animals such as cattle and canines. *Actinomyces* spp. are Gram positive, non-spore-bearing, short or filamentous bacilli, which may exhibit true branching. Although *Actinomyces israelii* is the major pathogen, other species including *A. gerencserai*, *A. meyeri*, *A. naeslundii*, *A. odontolyticus*, *A. pyogenes*, *A. radidentis* and *A. viscosus* do cause human infection. *Actinomyces* spp. can be found as commensals in the oral cavity, gastrointestinal tract and female genital tract.

### PATHOGENESIS

*Actinomyces* spp. are incapable of invading normal tissues and thus require trauma to the mucous surface to initiate disease. This can result from mechanical (accidental or surgical) trauma, primary bacterial or viral infection or malignancy. In addition, this damage will produce injury that renders the tissue anaerobic which facilitates growth of the bacterium. Little is known of virulence determinants of *Actinomyces* spp. and, for example, toxins have not been detected. The commonest sites of actinomycosis are the cervicofacial region (60% of cases), abdomen (25%) and lungs (15%). In addition, *A. naeslundii* and *A. viscosus* are associated with periodontal disease and *A. radidentis* with dental radiculitis. In actinomycosis there is a dense cellular infiltrate with abscess and sinus formation. The small yellow particles (sulfur granules) characteristic of actinomycosis occur especially with infection due to *A. israelii*.

### CLINICAL FEATURES

Actinomycosis is uncommon in children but a case series has been reported.<sup>841</sup> Cervicofacial actinomycosis presents as an indurated swelling in the mandibular region. Subsequently one or more sinuses develop. Less commonly, the tongue, pharynx, lacrimal glands or bone can be affected. Regional lymph nodes tend not to be affected. Local spread to

Table 28.41 Medically important fungi

Superficial mycoses	Dermatophytes (tinea capitis, tinea cruris, tinea pedis, tinea unguium, endothrix, ringworm)	<i>Epidermophyton floccosum</i> <i>Microsporium audouinii</i> ( <i>M. gryseum</i> , <i>M. canis</i> )

Subcutaneous mycoses	Sporotrichosis Chromomycosis	<i>Sporothrix schenckii</i> <i>Phialophora verrucosa</i> , <i>Phialophora</i> ( <i>Fonsecaea</i> ) <i>pedrosoi</i> , <i>Cladosporium carrionii</i>
	Mycetoma	<i>Actinomyadura madurae</i> , <i>Nocardia</i> <i>asteroides</i> , <i>N. brasiliensis</i> , <i>Streptomyces somaliensis</i>
Systemic mycoses	Rhinosporeidiosis Zygomycosis	<i>Rhinosporeidium seeberi</i> <i>Basidiobolus haptosporus</i> <i>Conidiobolus coronatus</i>
	Histoplasmosis Cryptococcosis Blastomycosis Coccidioidomycosis Paracoccidioidomycosis Penicilliosis	<i>Histoplasma capsulatum</i> <i>Cryptococcus neoformans</i> <i>Blastomyces dermatitidis</i> <i>Coccidioides immitis</i> <i>Paracoccidioides brasiliensis</i> <i>Penicillium marneffeii</i>
Opportunist pathogens	Aspergillosis Candidiasis Mucormycosis Pneumocystosis	<i>Aspergillus fumigatus</i> <i>Candida albicans</i> and other species <i>Mucor</i> spp. <i>Pneumocystis carinii</i>

cause brain or spinal cord abscesses has been reported. In these cases there is usually a mixed bacterial population.

Thoracic actinomycosis can occur by aspiration of oral bacteria, hematogenous spread, or local spread from cervical or abdominal lesions. Thus the initial focus can be in the bronchial tree or lung parenchyma. Subsequently, multiple abscesses develop which form sinuses that traverse the chest wall. The main clinical features are chest pain, fever, productive cough and weight loss. Abdominal actinomycosis presents with fever, neutrophilia, chronic abdominal pain and an inflammatory mass. Sinus formation is uncommon. Most often abdominal actinomycosis follows a perforated appendix.<sup>842</sup> Pelvic actinomycosis occurs most often in association with intrauterine contraceptive devices (the coil) and is thus very uncommon in children. Disseminated actinomycosis is uncommon in pediatric practice but has been reported.<sup>843</sup>

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Cervicofacial actinomycosis is part of the differential diagnosis of an indurated swelling of the mandibular region, especially if there is sinus formation. Specific diagnosis is by bacteriological culture of aspirated pus, sinus discharge, biopsy tissue or fine needle aspirations, but care must be taken to avoid contamination by commensal bacteria. Cultures should be kept anaerobically at 35–37 °C for up to 14 days. More rapid diagnosis can be obtained by examination of crushed sulfur granules stained by Gram stain where filamentous, branching or beaded Gram positive bacteria will be seen. It must be distinguished from other chronic suppurative lesions of the cervical region including chronic pyogenic osteomyelitis and tuberculosis. Thoracic actinomycosis may be confused with other chronic lung infection, including bronchiectasis and pulmonary tuberculosis.<sup>844</sup> Culture of sputum, bronchial aspirates or biopsy material will confirm the diagnosis.

The mass of abdominal actinomycosis can mimic an appendix abscess, abdominal tuberculosis or intra-abdominal carcinoma.<sup>843</sup> Laparotomy with culture of pus or biopsy material is necessary to establish the diagnosis. Serologic diagnosis is unreliable.

## TREATMENT AND PROGNOSIS

Benzyl penicillin is the treatment of choice. It is given in high doses, intravenously for 2 weeks at least, then orally for 6–8 months. This may be accompanied wherever possible with surgical drainage. For penicillin-allergic patients, tetracycline and perhaps ciprofloxacin can be tried. The prognosis is generally good, although thoracic actinomycosis may require even more prolonged and energetic treatment.

## ASPERGILLOSIS

### ETIOLOGY

Aspergillosis is a fungal infection with a worldwide distribution. There are over 90 *Aspergillus* species described and 19 have been associated with human disease. However, most infections are due to *Aspergillus fumigatus*, *A. flavus* and to a lesser extent *A. niger*. *Aspergillus* spp. are widely distributed in the environment and some cause infection in other animals. *Aspergillus* is a member of the Eumycetes (true fungi) and produces a mycelium with a fruiting body, the conidium, from which spores are released into the atmosphere. The spores can be found in air sampled anywhere on earth.

### EPIDEMIOLOGY AND PATHOGENESIS

Most disease manifestations involve the lung. In general, community acquired disease tends to be non-invasive aspergillosis and hospital acquired disease either non-invasive or invasive aspergillosis. In addition,

Table 28.42 Subcutaneous and systemic mycoses

Disease	Causative organism	Geographical distribution	Predominant clinical features	Treatment
Actinomycosis	<i>Actinomyces israelii</i>	Worldwide	Abscesses and sinuses in face and neck, lungs, abdomen	Benzyl penicillin
Aspergillosis	<i>Aspergillus</i> spp.	Worldwide	Granulomata of lungs, skin or generalized, aspergilloma	Nystatin aerosol, i.v. amphotericin B or oral itraconazole or ketoconazole
North American blastomycosis	<i>Blastomyces dermatitidis</i>	North America	Granulomata of lungs or generalized	i.v. amphotericin B or oral itraconazole or ketoconazole
South American blastomycosis	<i>Paracoccidioides brasiliensis</i>	South America	Ulcerating granulomata of oropharynx, lungs or generalized	i.v. amphotericin B or oral itraconazole or ketoconazole
Candidiasis	<i>Candida</i> spp. usually <i>C. albicans</i>	Worldwide	Usually superficial infection. Systemic resembles septicemic illness	i.v. amphotericin B with or without 5-flucytosine or oral fluconazole i.v. caspofungin
Chromoblastomycosis	<i>Cladosporium werneckii</i> <i>Fonsecaea compacta</i> <i>F. pedrosoi</i> <i>Phialophora verrucosa</i> <i>Rhinochrysiella aquaspersa</i>	Tropics	Nodular, verrucose, tumors, plaque or cicatricial lesions of skin and deeper tissues	Surgery and i.v. amphotericin B, with 5-flucytosine, itraconazole or ketoconazole but mixed results
Coccidioidomycosis (San Joaquin Valley fever)	<i>Coccidioides immitis</i>	North and South America	Influenza-like illness. Progressive pulmonary or central nervous system infection in minority	i.v. amphotericin B or 5-flucytosine or i.v. miconazole or oral itraconazole
Cryptococcosis (torulosis)	<i>Cryptococcus neoformans</i>	Worldwide	Chiefly central nervous system infection, meningoencephalitis, or focal lesion but can cause pneumonia	i.v. amphotericin B or oral fluconazole
Histoplasmosis	<i>Histoplasma capsulatum</i>	Central USA	Granulomata in lungs, or in miliary distribution	i.v. amphotericin B or oral itraconazole or fluconazole
Mycetoma (Madura foot, maduromycosis)	Actinomycetoma <i>Actinomyces madurae</i> <i>A. pelletieri</i> <i>Nocardia brasiliensis</i> <i>N. madurae</i> <i>Streptomyces somaliensis</i> Eumycetoma <i>Madurella grisea</i> <i>M. mycetomatis</i> <i>Pseudallescheria boydii</i>	Tropics	Localized chronic infection involving skin, subcutaneous tissue and bone (nodule, sinuses and discharge)	Surgery (removal of lesions, amputation). Actinomycetoma: dapson plus streptomycin. Eumycetoma: griseofulvin or imidazoles plus penicillin (but poor results)
Mucormycosis	<i>Mucor</i> spp. <i>Absidia corymbifera</i> <i>Rhizopus</i> spp.	Worldwide	Rhinocerebral, rhino-orbital, cardiac involvement, pulmonary, gastrointestinal, skin and soft tissue, bone involvement	i.v. amphotericin
Nocardiosis	<i>Nocardia asteroides</i> or <i>N. brasiliensis</i>	Worldwide	Pulmonary suppuration, occasionally central nervous system infection	Sulfonamides
Penicilliosis	<i>Penicillium marneffei</i>	South East Asia	Generalized infection especially in immune compromised patients with skin, bone, liver, spleen and lung involvement	i.v. amphotericin and oral itraconazole
Pneumocystosis	<i>Pneumocystis carinii</i>	Worldwide	Acute or subacute pneumonia in children immunocompromised by HIV, malnutrition or cytotoxic drugs	Oral co-trimoxazole, nebulized pentamidine
Rhinopodriodiosis	<i>Rhinopodriodium seeberi</i>	India and Ceylon	Polypoid tumors of mucous membrane – nose, nasopharynx, conjunctival sac. Gelatinous lesions, bleeding easily. Diagnosis by microscopic examination of crushed fragments of polyp. Pulmonary and nasopalatal types with tissue destruction may occur in the patients subject to severe metabolic disturbance	Surgical removal
Sporotrichosis	<i>Sporothrix schenckii</i>	Worldwide	Subcutaneous nodule (usually on hands or feet) which enlarges and adheres to skin and breaks down to form chronic ulcer. Satellite nodules develop by lymphatic spread. Usually localized but may be widely disseminated. Diagnosis by culture of exudates or scrapings or antibody tests. Extracutaneous forms involving muscles, lungs eyes, CNS, urinary tract and wide dissemination may occur	For lymphangitic form, potassium iodide 30 mg/kg/d up to maximum tolerance. For disseminated form i.v. amphotericin B or oral itraconazole

mycotoxins such as aflatoxin may contaminate cereals, groundnuts and other foods. Aflatoxin is a potent carcinogen but its role in human disease remains to be clarified. The non-invasive manifestations of aspergillosis are extrinsic allergic alveolitis (EAA), allergic bronchopulmonary aspergillosis (ABPA) and aspergilloma. In the former two, disease results from an allergic response to *Aspergillus* spp., a type III hypersensitivity response in EAA and type I in ABPA. An aspergilloma is a fungal mycelial ball that develops in a pre-existing lung cavity. In each case, the fungus is acquired by inhalation. Invasive pulmonary aspergillosis occurs in those immunocompromised by radiation, steroids or chemotherapy, especially if there is neutropenia. An increase in numbers of cases is often preceded by building work in or near the hospital, which increases atmospheric contamination by aspergillus spores. Dissemination from invasive pulmonary aspergillosis can result in metastatic foci in most organs of the body.

## CLINICAL FEATURES AND DIAGNOSIS

ABPA in pediatric practice is particularly associated with cystic fibrosis, but may also occur in asthma. It presents insidiously with worsening bronchospasm and less commonly low grade fever. Up to two thirds of patients expectorate brownish sputum, which contains aspergilli. Eight diagnostic criteria (aspergillus precipitins, aspergillus specific IgE, chest radiographic infiltrates, blood eosinophilia  $> 500/\text{mm}^3$ , *A. fumigatus* skin test, total serum IgE  $> 1000 \text{ ng/ml}$ , bronchiectasis, cough and wheeze) are widely used,<sup>845</sup> but must be applied regularly to be of benefit.<sup>846</sup>

Invasive pulmonary aspergillosis occurs most often in the setting of relapse of the underlying condition or post bone marrow transplant<sup>847</sup> and presents with unremitting fever, new pulmonary infiltrates, dyspnea and unproductive cough. These, together with hemoptysis and tachycardia, can mimic pulmonary embolus. Massive hemoptysis is rare. Radiographic changes are variable, but most often, patchy bronchopneumonic infiltrates or nodular densities are seen. After 2–3 weeks, cavitation may occur. Dissemination is clinically indistinguishable from bacterial septicemia in immunocompromised patients. The presentation of metastatic disease, which can occur almost anywhere, will depend on the site of infection. Specific diagnosis depends upon culture of aspergilli from the infective site but blood cultures are very rarely, if ever, positive. Since aspergilli are so frequently present in the environment it is also necessary to demonstrate tissue invasion by histologic examination.

## TREATMENT, PROGNOSIS AND PREVENTION

Allergic bronchopulmonary aspergillosis requires early therapy with oral corticosteroids and addition of high dose inhaled steroids may be of benefit. Recurrence is common. The natural history of aspergillosis is variable but only a minority of children resolve spontaneously. If there is evidence of some pulmonary invasion from the aspergilloma, antifungal therapy with amphotericin B or oral itraconazole may be beneficial. Surgical removal is necessary, for example, if there is life-threatening hemoptysis; however, this does carry a risk of inoculating fungi into the field of surgery.

For invasive pulmonary or other aspergillosis, surgical drainage, debridement or resection is most important with antifungal therapy acting as an adjunct. Amphotericin B is the gold standard for therapy, and addition of 5-flucytosine might be of benefit. Itraconazole given orally is licensed for therapy but long term administration will be needed. The prognosis is generally poor but it is difficult to distinguish the relative contributions of the aspergillosis and the underlying condition.

## BLASTOMYCOSIS

### ETIOLOGY

*Blastomyces dermatitidis* is a dimorphic fungus. It exists as a yeast in human infection and when cultured at 37°C, but in a mycelial form at room temperature or in the environment. Two serotypes and several genotypes have been described. *Paracoccidioides brasiliensis* is

also dimorphic. In human lesions, it is found as a double-walled ovoid or round yeast 4–40 µm in diameter. In culture at 19–28°C or in the environment it has a mycelial form. Isolates of *P. brasiliensis* vary greatly in their ability to cause disease.

## EPIDEMIOLOGY AND PATHOGENESIS

Although sometimes referred to as North American blastomycosis, *B. dermatitidis* infection has been reported in North and South America, Europe, Africa and Asia. Within North America it has been reported from the mid-west and south east USA and parts of Canada. It appears that the environment along waterways is an important reservoir and infection is probably acquired by inhalation. Humans and other animals can be infected but person-to-person transmission does not occur and children are rarely infected. *P. brasiliensis* infection was originally called hyphoblastomycosis but is now known as South American blastomycosis, or, more correctly, paracoccidioidomycosis. It is limited to Central and South America from Mexico to Argentina but most cases (80%) are reported from Brazil. It is found in soil and is thought to be acquired by inhalation. It is rare in women, adolescents and children. Person-to-person transmission does not occur.

## CLINICAL FEATURES

It is likely that most infections with *B. dermatitidis* are asymptomatic, but when clinically apparent can range from acute self-limiting pneumonia to disseminated infection. Occasionally, the acute pneumonia does not resolve and chronic pulmonary blastomycosis occurs, which is clinically indistinguishable from pulmonary tuberculosis or histoplasmosis. Cutaneous lesions are the most frequent manifestations of disseminated infection. These begin as subcutaneous nodules or papules. They then become ulcerated with raised irregular borders and a crusted center. Histologically these are granulomas.

*P. brasiliensis* causes a spectrum of disease ranging from acute pulmonary infection with or without mucocutaneous involvement to a progressive disseminated form with involvement of the mucocutaneous tissue, reticuloendothelial system and adrenals. It may also give a miliary appearance in the lung.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Blastomycosis, although uncommon in children, should be suspected in patients from endemic areas with granulomatous and ulcerating lesions of the skin or mucous membranes, especially if it is of long duration or there is involvement of other organs. Acute pulmonary blastomycosis is difficult to diagnose clinically, as it presents as an influenza-like illness or with pleuritic pain. The chronic form is indistinguishable from tuberculosis, histoplasmosis or coccidioidomycosis. Specific diagnosis is by demonstrating the presence of *B. dermatitidis*, by culture of lesions or sputum, and for superficial lesions, biopsy stained by methenamine silver (the yeasts may not stain by hematoxylin and eosin).

Paracoccidioidomycosis has similar differential diagnoses to blastomycosis. Since children may present with an acute or subacute form with large numbers of yeast in the reticuloendothelial system and fungemia, specific diagnosis can also be aided by blood culture.

### Treatment and Prognosis

Without treatment the mortality rate of blastomycosis is over 60%. Amphotericin B is the mainstay of therapy but higher doses are needed. Treatment should continue until symptoms resolve and continue for 3–4 months thereafter. Even with this, relapses occur in 10–20% of patients (up to 5 years later). Oral ketoconazole or, better still, itraconazole appears as effective as amphotericin B but there are no trials directly comparing the regimens. Treatment should continue for at least 6 months. Ketoconazole is effective in 85% of cases of paracoccidioidomycosis and relapse rates are low (0–11%) if therapy is continued for at least 6 months. Itraconazole appears superior to ketoconazole.

## CANDIDIASIS

### ETIOLOGY AND EPIDEMIOLOGY

There are almost 200 *Candida* species and they have a worldwide distribution. They exist in budding yeast, hyphal or pseudohyphal forms (Fig. 28.54). *Candida albicans* is the commonest species found both as a commensal, particularly in the mouth, rectum, vagina or on skin, and as a pathogen. The others are found less commonly as commensals but *C. glabrata* can be found in the mouth, rectum or vagina and *C. parapsilosis* and *C. tropicalis* on skin. Infections occur particularly in neonates and immunocompromised children, especially those with T cell defects.

### PATHOGENESIS AND CLINICAL FEATURES

Different *Candida* spp. have differing virulence but *C. albicans* is the most competent pathogen. Virulence factors include adhesins, ability to switch from yeast to hyphal (invasive) forms, production of proteolytic enzymes, antigenic variability and host mimicry. In addition to these, however, there need to be breaches in the skin or mucosa, alterations in the normal flora (usually due to antibacterial therapy), or underlying conditions such as immune deficiency (congenital or acquired), diabetes mellitus or implanted devices.

#### Superficial candidiasis (thrush)

Oral thrush typically occurs in neonates. Adherent gray-white plaques on removal reveal a raw, red base. They are usually found on the tongue, gums or gingival mucosa but may extend into the esophagus or trachea, especially in HIV/AIDS. There may also be scaly, macular or vesicular, erythematous perianal lesions. In skin areas that are moist, occluded or irradiated, candidiasis can occur as intensely erythematous intertriginous lesions. These can be papular, plaque-like or confluent with surrounding satellite lesions. Commonly involved sites include the axillae, inguinal regions, perineum and digital web spaces. *Candida* spp. can also cause onychomycosis which, unlike that due to dermatophytes, is painful.

#### Chronic mucocutaneous candidiasis

This includes a heterogeneous group of patients with T cell deficits, some of which are highly specific to *Candida* spp. Most cases present in infancy or early childhood with oral thrush or perineal candidiasis which may become more widespread or just persist with localized lesions.

#### Deeper candidiasis

Candidal infection of deeper tissues and organs occurs rarely in otherwise healthy patients. Oral or esophageal candidiasis may be complicated by extension of infection to the intestine, typically with symptoms of diarrhea, abdominal pain and pruritus ani. The child may present with a celiac-like syndrome. In pulmonary candidiasis, the symptoms of fever and productive cough, sometimes with hemoptysis, are nonspecific. On radiological examination, patchy consolidation is seen, and cavitation may occur with infections of sufficient duration. Pulmonary candidiasis

Fig. 28.54 A thin section electron micrograph of *Candida albicans* showing a pseudohypha (bar = 1  $\mu$ m).

should be not diagnosed too readily on the evidence of culture of *Candida* from sputum, since the organism may be isolated in a proportion of healthy individuals, and particularly from hospital patients.

Disseminated *Candida* infection, although very uncommon in infancy and childhood, is thought to be increasing in frequency and has been reported in neonates, debilitated infants and children, particularly those treated with antibiotics or corticosteroids, or with diseases of the reticuloendothelial system, and in patients requiring prolonged intravenous therapy. Several *Candida* species have been isolated from such patients, whose clinical features are those of septicemia. Disseminated candidiasis, which may be confirmed by blood culture, should be suspected when a septicemic illness supervenes in premature neonates, debilitated infants, or children in the course of antibiotic therapy, especially in the presence of a portal of entry for the organism such as an indwelling intravenous cannula.

The isolation of *Candida* from a specimen of urine obtained by suprapubic aspiration is highly suggestive of disseminated infection but must be interpreted in the light of other clinical data. Urinary tract infections with *C. albicans* do occur, especially in neonates or in association with indwelling urinary catheters. In neonates infection can ascend to produce fungal balls in the renal pelvis. The appearance of papular lesions on the skin containing *Candida* has been noted in preterm infants under such circumstances.

*Candida* endocarditis, though rare, has been reported in childhood. Previously damaged heart valves are the site of localization of infection in a patient with disseminated *Candida* infection.

### DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Oral thrush can usually be diagnosed on observation of the typical lesion, which may be confused with deposits of milk. The latter can be scraped off without effort, revealing a normal mucosal surface. Candidal napkin rash may be confused with ammoniacal dermatitis, and, although it is common for the two lesions to coexist, the sharply demarcated edges of the former and its association with oral thrush should suggest the diagnosis. Confirmation of superficial candidiasis is readily made by the finding of typical pseudohyphae on microscopic examination and by culture of the organism from swabs from superficial lesions. Yeast cells are not significant in feces as they occur in 15% of normal children but hyphal forms occur only with invasion of mucous membranes and their presence can therefore be taken as an indication of enteric candidiasis.

The clinical and radiological features of pulmonary candidiasis can be confused with a number of subacute and chronic bacterial infections of the lungs. The presence of characteristic predisposing circumstances should suggest the diagnosis, especially if pulmonary cavitation is present. Laboratory confirmation is best made by repeated sputum culture, or preferably, by culture of tracheal or bronchial aspirates.

In disseminated candidiasis the organism can be isolated by blood or urine culture.

### TREATMENT AND PROGNOSIS

Oral candidiasis is best treated by local application of antifungal agents. Preparations in common use are suspensions of nystatin (100 000 units/ml) and miconazole (2% in a gel). Gentian violet (1% aqueous solution) is by far the cheapest but it is messy, may produce excoriation of buccal mucosa, and generally fails to eradicate the fungus from the lower alimentary tract; it is now little used in Western countries. Nystatin and miconazole are probably equally effective. Nystatin is given in a dose of 1.0–2.0 ml dropped in the oral cavity 4 to 6 hourly for 7–10 days while miconazole gel is applied as 5.0 ml, two to four times each day. Apparent failure of such treatments is seldom, if ever, due to the presence of antibiotic-resistant species of *C. albicans*. While resistance to nystatin and amphotericin B by *Candida* species other than *C. albicans* can readily be induced in vitro, only a minor degree of diminished antibiotic sensitivity can be induced in *C. albicans*. A dose of 1 ml of nystatin by oral instillation 6 hourly may be inadequate; higher and more frequent

doses should be employed if the infection appears to be unresponsive. In perianal forms or candidiasis of skin or nails, topical nystatin (100 000 units/g of ointment) or miconazole is effective. Oral therapy with either antibiotic is effective in candidal enteritis.

In the treatment of candidiasis of deeper structures and organs, oral nystatin therapy is not recommended, since absorption from the gastrointestinal tract is poor. Oral ketoconazole may be effective. In pulmonary candidiasis, nystatin may be administered by aerosol, e.g. 500 000 units in 15 ml distilled water. In systemic candidiasis and candidal endocarditis and probably in pulmonary candidiasis, the most effective treatment is the intravenous administration of amphotericin B. Recent reports have indicated that the liposomal amphotericin B (AmBisome) treatment is less toxic and at least equally effective.<sup>848</sup> Flucytosine has the advantages over amphotericin B of oral administration and lower toxicity. Many strains of *C. albicans* are resistant, however, and the drug cannot be administered parenterally to those patients too ill to take it by mouth. It should be reserved for those patients in whom amphotericin B has proved to be too toxic. Echinocandins such as caspofungin are also useful in treating such infections.

The prognosis of superficial candidiasis is excellent; that of candidal enteritis has to be guarded. Disseminated candidiasis carries a poor prognosis, largely related to the nature of the predisposing conditions. Meningeal candidiasis, however, may run a surprisingly mild course.

## CHROMOBLASTOMYCOSIS

### ETIOLOGY, EPIDEMIOLOGY AND PATHOGENESIS

This is the commonest infection by the dematiaceous or black pigmented fungi. A number of fungi including *Fonsecaea pedrosoi*, *E. compacta*, *Phialophora verrucosa*, *Cladosporium carrionii*, *Rhinochrysiella aquaspersa* and, less commonly, *Exophiala jeanselmei* cause chromoblastomycosis. Although most common in the tropics, cases have been reported from more temperate regions such as Europe and the USA. The habitat of each of the fungi is soil, decomposing vegetation and woodland. Humans most often become infected by traumatic implantation of such material for example when walking barefoot. Person-to-person transmission has not been described.

### CLINICAL FEATURES, DIAGNOSIS AND TREATMENT

Chromoblastomycosis usually begins as a small pink papule which enlarges to a nodule. Over time it evolves to a scaly, fissured pink brownish plaque which eventually becomes verrucose. Eventually thick, crusted, hyperkeratotic masses occur which are prone to secondary infection, leading eventually, after many years, to lymphatic blockage and elephantiasis. The differential diagnosis includes blastomycosis, lupus vulgaris, leishmaniasis and tertiary syphilis. Specific diagnosis is by histologic examination and isolation of the fungi, which requires up to 6 weeks incubation at both 25 and 37 °C. Treatment is difficult. For small lesions, wide surgical excision is possible. Itraconazole for 6–24 months is effective in above 60% of cases. Amputation may be required.

## COCCIDIOIDOMYCOSIS

### ETIOLOGY AND EPIDEMIOLOGY

*Coccidioides immitis* is a dimorphic fungus which exists as a mycelial saprophyte in soil but as an endospore-forming spherule in the human lung. Infection is acquired by inhalation of arthroconidia from soil and is particularly prevalent in the San Joaquin Valley in California. Although most cases occur in and around this area, cases have been described in Central (Guatemala, Honduras) and South America (Venezuela, Colombia, Paraguay, Bolivia, Argentina). It may also occur when dust storms blow the arthroconidia into other areas.

## PATHOGENESIS

Inhalation of arthroconidia results in a disease attack rate of about 40%. Once in the lungs the arthroconidia convert to the spherule-endospore phase within 3 days. This causes an initial influx of neutrophils and an inflammatory response which changes to a mononuclear cell infiltrate with granulomata once the spherule-endospore phase is well established. The spherules are too large (20–150 µm) to be ingested by neutrophils or even macrophages but they are important in defense presumably because they can engulf the released endospores (c. 2–5 µm). A brisk T<sub>H</sub>1 (T helper type 1) response is needed for recovery from infection.

## CLINICAL FEATURES

Most often coccidioidomycosis is a somewhat prolonged influenza-like illness, often with pneumonia, which follows an incubation period of 1–3 weeks. In 90%, recovery is complete; the remainder are left with pulmonary cavities and nodules.<sup>849</sup> Nonpulmonary features include fever, malaise, headache, arthralgia, myalgia and skin rashes. Approximately 25% of patients develop erythema nodosum 6–16 days after onset of symptoms. In about 1% of patients, there is dissemination with skin (subcutaneous abscesses), bone, meningeal and even miliary manifestations. Dissemination is particularly found in immune compromised patients including cardiac allograft recipients (5% of those in Arizona) and those with HIV/AIDS.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Coccidioidomycosis should be suspected in children in or from endemic areas, especially if non-white, who develop an acute febrile illness. Primary pulmonary coccidioidomycosis especially with erythema nodosum can be confused with primary tuberculosis, and the postprimary nodular or cavitating disease with secondary tuberculosis. Diagnosis can be confirmed by culture of sputum, pus or blood (if disseminated), but the laboratory should be warned since this is a significant pathogen that will need special containment. The coccidioidin skin test (similar to tuberculosis) will become positive within 21 days of infection. Serologic tests such as complement-fixing titers are available and useful for confirmation of diagnosis.

## TREATMENT AND PROGNOSIS

Primary coccidioidomycosis seldom requires more than symptomatic treatment. Amphotericin B, the most effective drug, should, in view of its toxicity, be reserved for severe primary or postprimary pulmonary disease. Intravenous amphotericin B therapy is, however, essential in disseminated coccidioidomycosis and, where there is infection of the central nervous system, may be given by intrathecal infection. Until recently, the only alternative form of therapy was intravenous miconazole but oral itraconazole has been shown to be of value and of relatively low toxicity.

The prognosis of primary coccidioidomycosis is excellent, while that of postprimary pulmonary disease is good. Disseminated coccidioidomycosis carries a poor prognosis, especially with meningeal infection, unless treated vigorously and at an early stage.

## CRYPTOCOCCOSIS

### ETIOLOGY AND EPIDEMIOLOGY

*Cryptococcus neoformans* exists as a yeast in mammalian infections and on artificial culture but in a mycelial form in the environment. *C. neoformans* has a worldwide distribution and there are two variants: *C. neoformans* var. *neoformans* and *C. neoformans* var. *gattii*. *C. neoformans* is subdivided into four serotypes (A–D). *C. neoformans* var. *neoformans* falls into serotypes A and D, and var. *gattii*, serotypes B and C. The former is associated with soil, especially that contaminated by pigeon droppings

and causes infection in patients immunocompromised by HIV/AIDS, chemotherapy or steroid administration. The latter is associated with the tropics and has been isolated from debris around *Eucalyptus camaldulensis*, the Australian red river gum tree. It causes infection in immunocompetent individuals. Although infection occurs in all age groups, children are less often infected.

### PATHOGENESIS AND CLINICAL FEATURES

Infection is acquired, it is thought, by inhalation of the fungus. Person-to-person transmission does not occur. Virulent strains of *C. neoformans* have a thick polysaccharide capsule (Fig. 28.55) that protects them from phagocytic killing by macrophages and neutrophils. In the lungs, they can cause pneumonia but this occurs in less than 15% of patients with cryptococcosis. Most often the organism passes through the lungs silently to infect at secondary sites. The major manifestation is chronic meningitis with headache, personality changes, dementia and focal neurologic signs. It can be entirely asymptomatic early in the infection and, especially in HIV/AIDS patients, neck stiffness and fever are not major presenting features (<50% of cases). In approximately 15% of cases of cryptococcosis there is skin or bone involvement. The cutaneous manifestations can be acneiform, abscesses, ulcers, granulomas or plaques.

### DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Specific diagnosis depends on demonstrating the fungus or its capsular antigen in CSF, blood or other infective sites. However, it must be remembered that *C. neoformans* can be present in sputum in the absence of disease. In CSF the cellular response varies. In AIDS patients, the cell count is low (<5/mm<sup>3</sup>) whereas in non-AIDS patients it ranges from 10 to 300/mm<sup>3</sup>, but in each case there is a prevalence of lymphocytes (>80%). *C. neoformans* will stain violet on Gram stain (Gram positive), but the India ink stain is best for demonstration of the yeasts. This is a negative stain because the stain does not penetrate the yeast but shows it with its thick polysaccharide capsule against a black background. There are commercially available latex agglutination kits for detection of capsular antigen in CSF or serum. These can also be used to measure response to therapy. Finally *C. neoformans* can be cultured on suitable fungal culture medium. The differential diagnoses include other bacterial and viral causes of acute or chronic meningitis or meningoencephalitis, in particular tuberculous meningitis, and for the skin lesions molluscum contagiosum, penicilliosis and histoplasmosis, especially in AIDS patients.

Fig. 28.55 A thin section electron micrograph of *Cryptococcus neoformans* showing its thick polysaccharide capsule (bar = 1  $\mu$ m).

### TREATMENT AND PROGNOSIS

For non-AIDS patients a combination of amphotericin B and 5-flucytosine for 6 weeks is curative in 75% of patients. In AIDS patients a number of regimens have been tried, principally because relapse is common after stopping therapy. Amphotericin B with or without 5-flucytosine for 2 weeks followed by 8 weeks of therapy with either fluconazole or itraconazole appears optimal in these cases. This is then followed by long term oral suppressive therapy with fluconazole. However, with the advent of combination antiretroviral therapy for HIV/AIDS the outlook is much better.<sup>850</sup> In addition to frequent relapse, obstructive hydrocephalus is a major complication of cryptococcal meningitis.

### HISTOPLASMOSIS

#### ETIOLOGY AND EPIDEMIOLOGY

*Histoplasma capsulatum* is another dimorphic fungus which undergoes reversible morphologic variation according to the environment in which it is placed. Its normal habitat is soil, especially below where birds and bats have roosted. Here it exists in a mycelial form with hyphae bearing macroconidia (8–14  $\mu$ m diameter) and microconidia (2–5  $\mu$ m), which are the infective forms. At temperatures above 35 °C *H. capsulatum* grows as a yeast (2–3  $\times$  3–4  $\mu$ m) and this is the form found in human infections. Histoplasmosis is endemic in North America (especially the Ohio and Mississippi valleys) and Latin America, but cases have been reported from Europe and Asia. The taxonomy of *H. capsulatum* is currently under discussion. Three varieties are recognized: *H. capsulatum* var. *capsulatum*, *H. capsulatum* var. *duboisii* (which causes African histoplasmosis) and *H. capsulatum* var. *farciminosum* (which causes skin ulcers in horses and mules) but genetic analysis suggests *H. capsulatum* might harbor six species.<sup>851</sup> It is estimated that there are 200 000–500 000 cases each year worldwide. In endemic areas of the USA, it is estimated that 90% of the population have been exposed with frequent re-exposure.<sup>852</sup>

#### PATHOGENESIS AND CLINICAL FEATURES

Infection occurs when microconidia are inhaled. Most often this occurs when individuals disturb soil or dust containing microconidia, but they can travel for miles in the wind. In the lungs, the spores germinate to the yeast form, which elicits an influx of neutrophils, macrophages and lymphocytes and formation of granulomas. The yeasts are able to survive within macrophages,<sup>853</sup> and may persist for years within the reticuloendothelial system. Infection is more likely to progress, persist or disseminate if there is abnormal T cell function. Infection is also likely to disseminate in infants under 2 years,<sup>854</sup> but there is often an associated T cell defect. With exposure to a low infective dose, only 1% of patients develop clinical disease, but the rest have serologic evidence of infection. With a higher inoculum only 10–50% are asymptomatic. Most clinically expressed infections are self-limited and include acute pulmonary histoplasmosis, mediastinal lymph node enlargement, pericarditis and rheumatologic manifestations.

Approximately 80% of the symptomatic cases are of acute pulmonary histoplasmosis, which presents as a 'flu-like' illness with fever, chills, headache, myalgia and a nonproductive cough. This usually resolves within a few weeks. More diffuse pulmonary disease leading to respiratory insufficiency can occur with a higher infecting dose. The rheumatologic manifestations include erythema nodosum with arthralgia or frank arthritis, which can persist for months. Pericarditis occurs as an inflammatory complication of pulmonary disease. Chronic pulmonary histoplasmosis is very rare in children. It occurs mostly in middle-aged men with chronic obstructive airways disease. Disseminated histoplasmosis is a progressive illness with extrapulmonary spread of the fungus. It can occur following acute infection or years later. In infants it presents as fever, splenomegaly and/or hepatomegaly.<sup>854</sup> Subsequently, shock, liver or renal failure and central nervous system involvement can

occur. Cutaneous or mucosal granulomas in children in endemic areas should also be considered as possible histoplasmosis.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnosis requires a high index of clinical suspicion in a child living in, or coming from, an endemic region. Specific diagnosis requires a battery of tests including histology, antigen and antibody detection and fungal culture of bone marrow, spleen, lymph node, liver or bronchoalveolar lavage samples.<sup>854</sup> The histoplasmin skin test is not useful, especially in those with T cell impairment and disseminated disease. The differential diagnosis includes pulmonary or miliary tuberculosis.

## MYCETOMA<sup>855</sup>

Mycetoma is a chronic, subcutaneous granulomatous disease caused by either fungi (eumycetoma) or branching bacteria (actinomycetoma). It has a worldwide distribution and is endemic in a belt between latitudes 15°S and 30°N, which encompasses Senegal, Sudan, Somalia, Mexico, India and parts of Central and South America. In Sudan it is estimated that there are 300–400 new cases each year, mostly in males aged 20–40 years, but children may rarely be affected. The clinical triad of subcutaneous nodules, sinuses and discharge is suggestive. The differential diagnosis includes Kaposi's sarcoma, neurofibroma, malignant melanoma, syphilitic osteitis and bone tuberculosis, but specific diagnosis can be made by histologic examination. Culture is difficult and takes a long time. Surgical treatment is to remove all affected tissue, which can involve amputation of affected feet or hands. Actinomycetoma can be treated with dapsone and streptomycin for 1 month. Medical treatment of eumycetoma is much more difficult. Griseofulvin, ketoconazole or itraconazole have had mixed success but treatment must be continued for 1–10 years.

## NOCARDIOSIS

### ETIOLOGY AND EPIDEMIOLOGY

*Nocardia* spp. are Gram positive, acid alcohol fast, nonmotile, branching bacteria in the suborder *Corynebacterineae* that are closely related to the actinomycetes. There are 20 *Nocardia* spp. but most human infections are by *Nocardia asteroides* and less commonly by *N. farcinica* and *N. nova*. In tropical countries infection can also be by *N. brasiliensis* and *N. africana*.<sup>856</sup> *Nocardia* are environmental organisms living in soil and decaying vegetation. Person-to-person spread does not occur, and although *Nocardia* spp. can cause infections in animals they are not zoonotic. Primary infections do occur but most infections occur in immunocompromised individuals.

### PATHOGENESIS AND CLINICAL FEATURES

Infection is acquired either by inhalation or direct inoculation into the skin. Characteristically *Nocardia* spp. produce abscesses and granulomas. Virulent strains of *N. asteroides* can evade phagocytic killing by inhibiting phagolysosome fusion or acidification of phagosomes.<sup>857,858</sup> Dissemination is much more likely to occur if there is some form of immune compromise and has been reported in HIV/AIDS when it may involve the skin, kidneys and adrenals. In 5% of patients it involves the central nervous system either as diffuse meningitis or abscesses.

Pulmonary infection is found in 75% of patients with nocardiosis, alone or in association with disseminated infection, and may produce no symptoms. In other patients malaise, cough, fever and dyspnea may develop. Hemoptysis is an uncommon symptom. Involvement of the central nervous system may result in the clinical features of meningoencephalitis, or, if the lesion is a single abscess, of a localized intracranial or intraspinal tumor. Primary cutaneous nocardiosis can present as cellulitis or as an abscess with or without lymphadenitis and can be

mistaken for *Streptococcus pyogenes* or *Staphylococcus aureus* infections.<sup>859</sup> *Nocardia* spp. are also pathogens in mycetoma.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

There are no typical symptoms and signs, and the pulmonary form may readily be confused with other suppurative lung conditions. Radiological examination of the chest similarly provides no characteristic features, the most common being patchy infiltration perhaps with cavitation. Specific diagnosis depends upon laboratory help but unfortunately *Nocardia* spp. are difficult to recognize and identify in the routine diagnostic laboratory, compounded by the fact that they are slow growing.

## TREATMENT AND PROGNOSIS

Prior to the advent of the sulfonamides, nocardial infection was usually fatal, and at present the outlook is poor, partly because of the nature of the predisposing conditions and partly because of delay in diagnosis.

The treatment of choice is prolonged administration of sulfonamides or co-trimoxazole. Treatment may be necessary for several months, and may be combined with surgery. It is recommended that sulfonamides be given in a dose adequate to maintain a blood level of not less than 10 mg/100 ml.

Treatment with antibiotics, including benzyl penicillin and chloramphenicol, has been reported to be successful on occasions and, as indicated by sensitivity of the organism in vitro, may be given in addition to sulfonamides.

## PENICILLIOSIS

This is an emerging infection which is the third commonest opportunist infection in HIV infected patients in South East Asia.<sup>860</sup> Most cases are due to *Penicillium marneffei* but occasional cases of *P. chrysogenum* occur.<sup>861</sup>

Approximately 80% of patients with penicilliosis are immunocompromised. Penicilliosis can present as cutaneous or disseminated infection or both. The skin lesions are usually umbilicated papules resembling molluscum contagiosum. Disseminated disease usually presents as fever, weight loss and anemia. Specific diagnosis is by isolation of the fungus from skin, bone marrow or blood. Mild to moderate disease can be treated with itraconazole or ketoconazole but severe disease will require amphotericin B. There are no controlled trials of therapy.

## SPOROTRICHOSIS<sup>862</sup>

Sporotrichosis is caused by the dimorphic fungus *Sporothrix schenckii*. It grows as a saprophyte in decaying vegetation and infection occurs following traumatic inoculation into the skin. Some cases have been transmitted by domestic cat scratch.<sup>863</sup> It has a worldwide distribution but, for example, is the commonest subcutaneous mycosis in Latin America. Infection is often related to occupation (e.g. farmers, florists, gardeners) and occurs most often in adults, although infections do occur in children.<sup>864</sup> The initial nodule at the inoculation site enlarges becoming red, pustular and ulcerating in turn. Extension occurs up the lymphatics to draining lymph nodes which themselves enlarge and drain to the skin. Spontaneous healing can occur but most often the lesions persist with gradual extension and scarring. Diagnosis depends upon demonstrating *S. schenckii* in lesions by immunohistochemistry or immunofluorescence. Fungal culture, however, provides the definitive diagnosis. There are no controlled trials of therapy, but oral itraconazole for 3–12 months has cure rates of 89–100%. Saturated potassium iodide (10 drops diluted in fruit juice three times daily) can be used in a resource poor setting but it is poorly tolerated. If disease is unresponsive to itraconazole, it might be necessary to use amphotericin B.

## ANTIFUNGAL CHEMOTHERAPY<sup>865</sup>

Only a small number of antifungal drugs are available for treatment of systemic mycoses and there are very few controlled trials to demonstrate efficacy, none in children. Most of the antifungals act on the fungal cell membrane by either chelating ergosterol (polyenes) or inhibiting its synthesis (imidazoles, triazoles). 5-Flucytosine is a nucleoside analog that inhibits fungal transcription.

### POLYENES

Nystatin is a microcrystalline suspension so should not be given parenterally. It is very effective in treating superficial infections due to sensitive fungi and resistance has developed very slowly if at all. Amphotericin B is active against a wide range of fungi in vitro including *Candida* spp., *C. neoformans*, *H. capsulatum* and *Aspergillus* spp. However, up to 40% of *P. marneffei* are resistant and the agents of chromoblastomycoses are usually resistant as are those causing eumycetoma.

For systemic mycoses, amphotericin B must be given intravenously by slow infusion but can also be given intrathecally, intraventricularly or intraperitoneally. The lyophilized powder must be reconstituted in 5% dextrose solution (not saline, which may cause it to precipitate) and is given as a slow infusion over 4–6 h at a concentration of 100 µg/ml. Usually treatment begins with a dose of 0.25 mg/kg/d with a gradual increase up to about 1 mg/kg/d as can be tolerated. A daily dose of 1.5 mg/kg/d should not be exceeded. For intrathecal use, doses of 0.1–0.5 mg or even 1 mg have been given to children according to weight and tolerance of the drug. Only 2–5% of the daily dose of amphotericin B is excreted in urine in the active form, and in experimental animals 20% is excreted in bile. The fate of the major part of the administered dose is unknown, but there are reports of detection of the drug in liver, spleen and kidney one year after cessation of therapy. There are no trials delineating duration of therapy, but treatment is usually given for 1–3 months depending upon the rate of clinical and laboratory improvement. Amphotericin B has a high toxicity profile. During a 4–6 h infusion, 50–90% of patients experience fever, chills, malaise, muscle and joint pains, nausea and vomiting. The major side-effect is nephrotoxicity: glomerular filtration rates fall by 40% in most patients and stabilize to 20–60% after multiple doses. Toxicity is manifest by increased blood urea and creatinine levels and the appearance of red cells, white cells and casts in the urine. If blood urea rises above 16.7 mmol/L or creatinine above 170 µmol/L treatment should be stopped until levels return to normal. Hematological side-effects occur in 75% of patients, most frequently a normochromic, normocytic anemia, and cardiac arrest, hepatotoxicity, neurotoxicity and allergic reactions do occur but are rare.

Encapsulating amphotericin B in liposomes (AmBisome, Abelcet) or in a colloidal dispersion (Amphocil) gives better tolerance and fewer side-effects in doses up to 3–5 mg/kg/d.

### FLUCYTOSINE

5-Flucytosine is a fluorinated pyrimidine that was originally developed as an antineoplastic drug. Its mechanisms of action are, on conversion to 5-fluorouracil in the fungus, to act as an analog of uracil, inhibiting protein synthesis and to inhibit thymidylate synthetase and thus DNA synthesis. It has a narrow spectrum of activity but is usually active against *C. albicans* and *C. neoformans*. However, resistance even in these fungi can develop, so it is most often used in combination with amphotericin B. It is well absorbed orally and is usually given at 50–100 mg/kg/d in four divided doses in neonates and children. Although less toxic than amphotericin B, it can cause bone marrow suppression, cutaneous reactions (particularly in AIDS patients) and diarrhea. The risk of bone marrow suppression is greater with concomitant amphotericin B therapy and appears more likely in children. For these reasons, it is advisable to measure peak (2 h post oral or 30 min post intravenously) and trough (just prior to dose) serum levels twice weekly during therapy. Peak levels should not exceed 100 mg/L and the trough is around 25 mg/L.

## IMIDAZOLES

Of the licensed imidazoles, clotrimazole is solely a topical agent, while ketoconazole can be given topically or orally and miconazole topically or intravenously. Miconazole has a broad range of antifungal activity in vitro but is less active against *Aspergillus* spp., *Hansenula* (now *Pichia*) *anomala* and *Mucor* spp. It is particularly useful for topical application in dermatophyte infections and in oral and cutaneous candidiasis. Intravenous miconazole should be considered in patients unable to tolerate amphotericin B and as an alternative to the latter drug in systemic infections with *Candida* resistant to flucytosine.

Recommended dosage for oral candidiasis is 5 ml of miconazole gel (20%) two to four times per day. For systemic infections, an ampoule containing 200 mg of miconazole should be diluted with 5% dextrose or physiological saline solution and administered by slow intravenous infusion three times daily. In children, the total daily dose is of the order of 40 mg/kg body weight.

Toxic effects are in general less frequent and less severe than those encountered with amphotericin B therapy. They include gastrointestinal, mental and liver enzyme disturbances. The poor water solubility of miconazole necessitates the use of a lipophilic solvent causing major problems with venous irritation and occlusion.

Ketoconazole has an even better antifungal spectrum of activity. It is a less toxic alternative to amphotericin B but does cause gastrointestinal problems (in 3–40%) and hepatocellular damage (most often in females over 40 years). Its use has been reported in systemic candidiasis, coccidioidomycosis and histoplasmosis. An appropriate dose is 3 mg/kg daily orally for a child and 200–400 mg once daily for an adult. Treatment should be maintained for 10 days, in the case of oral thrush, and for at least 1 month in the case of systemic infections. Less than 10% of either drug is excreted in urine, so they are of little use in urinary tract infections.

## TRIAZOLES

The two major antifungals in this recently introduced class of drugs are fluconazole and itraconazole. Fluconazole has high bioavailability, and peak serum concentrations are similar by either the oral or intravenous routes. It is active against most *C. albicans* and *C. neoformans* but some other *Candida* spp. (e.g. *C. krusei*) are resistant. Its main clinical use is in treating cryptococcosis and candidiasis. In children over 4 weeks, recommended doses are 3 mg/kg/d for mucosal candidiasis, 6–12 mg/kg/d for systemic candidiasis or cryptococcosis and 3–12 mg/kg/d for prophylaxis in neutropenic children. Neonates aged 2–4 weeks should be given similar doses but every 2 days, and those aged 2 weeks and under every 3 days. Fluconazole is generally well tolerated with nausea, vomiting, abdominal pain and diarrhea in less than 5%. Asymptomatic elevation of hepatic aminotransferase enzymes occurred in 12% of children after 4 days of intravenous therapy.<sup>866</sup> About 80% of the drug is excreted by the renal route. Itraconazole has an even broader spectrum of activity being active against most *Candida* spp., *H. capsulatum*, *B. dermatitidis*, *C. immitis*, *P. braziliensis*, *P. marneffei*, *A. flavus* and *A. fumigatus*. It has an equally broad clinical use for infections by the above and in sporotrichosis, chromoblastomycosis and phaeochromomycosis. For the latter two, response depends on the infecting fungus. The dose is 2.5–5 mg/kg daily by the oral route. The duration of therapy depends upon the infection being treated. Itraconazole has a good safety profile but very little of the drug is excreted in urine.

## ECHINOCANDINS

This novel class of antifungals includes caspofungin, micafungin and anidulafungin. They inhibit β(1,3)-D-glucan synthesis in the fungal cell wall. They are clinically effective in invasive candidiasis and candidemia but less effective in aspergillosis.<sup>867</sup> They have little or no activity against the rest of the fungi described here.

## HELMINTH INFECTION

Helminth or worm infections occur worldwide, although in warmer, moister areas, especially where standards of hygiene are low, the range of species and prevalence tends to be greater and multiple infections are common. Because children tend to live more closely with nature and with their pets, many helminth infections are more common in children than in adults. Reviews listing the estimated prevalence of the variety of worm infections in humans worldwide indicate that a vast health problem exists. New and emerging helminth zoonoses continue to be identified.<sup>868</sup>

Many tentative prevalence figures are undoubtedly underestimated. One review<sup>869</sup> concluded that there are more trematodes infecting humans than any other group of animal parasites, over 75 species, mostly acquired from poorly prepared or cooked food.<sup>870</sup>

Helminth infections are by no means confined to tropical or resource limited countries and the increase in travel and of refugee movements in recent years has led to an increasing awareness in resource rich countries of the dangers of imported diseases.<sup>871</sup>

Helminth infections differ in most cases from those caused by viruses, bacteria or protozoa, in that the clinical effects exhibited by the host are mostly related to the worm load carried, and the latter in turn is usually related to the infective dose. The controversy regarding the possible adverse effects of helminth infections and the value of anthelmintic treatment on cognitive function and learning or educational ability remains unresolved, but the concept may well be valid.<sup>872,873</sup>

The common parasitic helminths infecting humans include the Nematoda (roundworms) and Platyhelminthes (flatworms) which comprises the Trematoda (flukes) and Cestoda (tapeworms). Less commonly humans may be infected with such worms as the Acanthocephala (thorny headed worms).<sup>874</sup>

The control of human helminth infections usually depends on a detailed knowledge of the epidemiology and life cycles of the species concerned – the aim being to break the cycle. The following principles are utilized, either alone or in combination, depending upon the species:

1. treatment of infected individuals, including mass treatment;
2. control of animal reservoirs where such exist;
3. hygiene, which includes education and provision of adequate and acceptable toilet facilities;
4. vector control where applicable;
5. the wearing of shoes where infection occurs from the soil through the skin;
6. instruction in food preparation and cooking;
7. immunization – a field which continues to be of great interest.

Of all the above, the most important method for the control of human helminthiasis remains education combined with improved sanitation and personal hygiene. However, mass de-worming may play an important role in the control of some helminthiasis and, in relation to immunization, Maizels et al<sup>875</sup> expressed the view that ‘vaccines are the one major goal of the helminthological community’.

## NEMATODES (ROUNDWORMS)

Nematodes are nonsegmented worms, round in transverse section with separate sexes. They possess both gut and body cavity (pseudocoel). Species particularly important to humans include amongst others: *Ascaris lumbricoides*, *Toxocara canis*, *Enterobius vermicularis*, *Ancylostoma duodenale*, *Necator americanus*, *Trichuris trichiura*, *Strongyloides stercoralis*, *Trichinella spiralis*, *Onchocerca volvulus*, *Loa loa*, *Wuchereria bancrofti*, *Mansonella perstans*, *Mansonella ozzardi* and *Brugia malayi*.

## ASCARIASIS

The intestinal roundworm *Ascaris lumbricoides* is cosmopolitan but variable in distribution, thriving in a moist climate, temperate or tropical, and especially under conditions of overcrowding. Ascariasis (like trichuriasis) tends to have a lower prevalence and worm load at higher

altitudes.<sup>876</sup> The adult ascarids, male and female, live in the lumen of the small intestine, maintaining only an intermittent attachment to the mucosa. The gravid female lays an average of 200 000 eggs each day. Newly excreted eggs may remain dormant for a long period. If conditions are suitable they develop into an infective egg in about 2 weeks, in which condition they can remain viable for months or years until ingested.<sup>877</sup> The only hosts of these worms are humans, although cases of human infection with *A. suum*, the pig ascarid, have also been recorded. The life cycle of *A. lumbricoides* is depicted in Figure 28.56.

## Clinical features

In 80% of cases the only manifestation of ascariasis is the asymptomatic passage of eggs and adult worms in the stool. Symptoms are related to three phases of the ascarid's life cycle:

1. invasion and migration of larvae;
2. presence of a large adult worm load;
3. migration of adult worms from their normal habitat.

To this one may add symptoms associated with the development of true allergy to the ascarid.<sup>878</sup>

Ascariasis is potentially serious and can contribute to a significant proportion of abdominal emergencies in children.<sup>879</sup>

## Larval pneumonitis

The initial migration of larvae through the intestinal wall and via the portal circulation to the lungs may, in the case of heavy infection, or with repeated reinfections, cause a characteristic and often seasonal clinical picture.<sup>880</sup> The patient develops a dry spasmodic cough with intermittent wheezing and breathlessness, transient rhonchi and crackles in the lung fields; rarely, hemoptysis occurs. There may be malaise, with fever as high as 40 °C, discomfort over the liver, and urticarial rashes. Radiological examination of the chest reveals diffuse, mottled opacities, peribronchial infiltration or areas of pneumonitis. Marked eosinophilia is present. Symptoms and signs subside after 2 or 3 weeks and the eosinophilia generally diminishes to 3–5% of the total white cell count. Chronic lung disease occasionally results from repeated larval onslaughts. Severe pulmonary infiltration with asthma, eosinophilia and raised IgE levels can occur in children infected with *A. suum*.

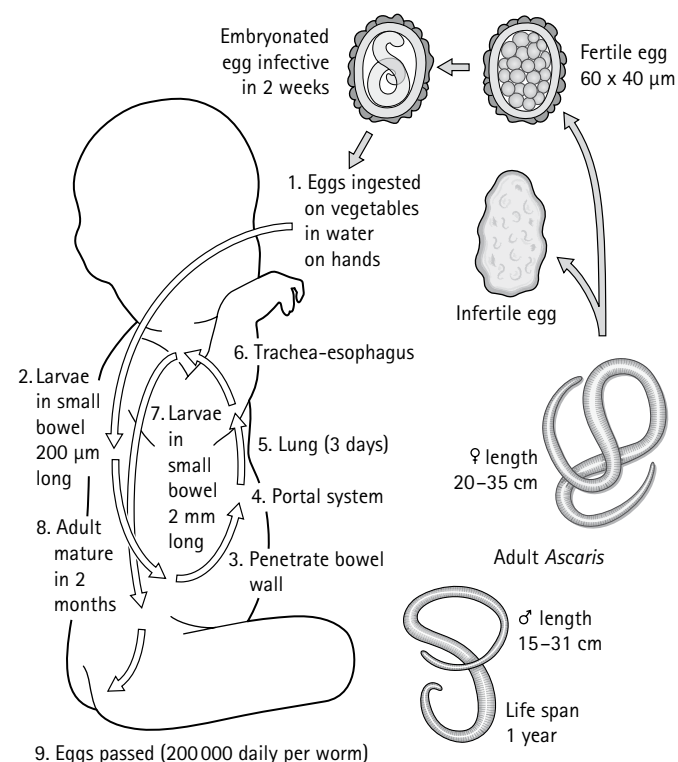

Fig. 28.56 Character and life cycle of *Ascaris lumbricoides*.

### Worm load

Although some features of intestinal ascariasis are of an allergic nature, in the healthy child on a normal diet it is unlikely that the presence of a few ascarids will cause any significant disturbance.<sup>880</sup> A large worm load will, however, drain off a considerable proportion of a child's nutritional intake and in children can be associated with impaired lactose digestion and absorption.<sup>879</sup> Heavy infections are usually seen in underprivileged communities where nutrition is already inadequate. The combination of malnutrition, vitamin and iron deficiency, and the almost invariable presence of intestinal parasites of other types, makes the part played by ascarids difficult to assess. However, studies in Colombia have shown that steatorrhea and D-xylose malabsorption associated with heavy loads of *Ascaris* improved after de-worming. These children are ill, stunted and marasmic, with abdominal distention. Colicky abdominal pain is frequent. There may be low grade fever and a mass of worms can often be palpated abdominally. Toxins from ascarids may play a part in producing the chronic illness.

Intestinal complications associated with a heavy worm burden are frequently seen in hyperendemic areas.<sup>881</sup> A bolus of worms (usually both dead and living) may impact, particularly near the ileo-cecal junction (Fig. 28.57). A mass of ascarids may also precipitate temporary obstruction from spasm, cause inflammatory reactions and adhesions, or lead to volvulus or intussusception.

### Migration of adult worms

Under certain circumstances, particularly with high fever, gastrointestinal upset or ineffectual anthelmintic therapy (e.g. the use of tetrachlorethylene for a concomitant hookworm infection), an ascarid may migrate from its normal habitat in the bowel and be vomited, or wriggle up the esophagus and emerge through the nose. Lodgment in the appendix or Meckel's diverticulum can result in obstruction and perforation. The common bile duct may be blocked by a roundworm, leading to severe upper abdominal pain, vomiting, tenderness and enlargement of the liver, a palpable gallbladder, and jaundice. Pancreatitis is a further complication. Other manifestations of the migrating ascarid include intestinal perforation with peritonitis, chronic peritonitis due to the presence of eggs, soft tissue or liver abscess, laryngeal impaction and

Fig. 28.57 Intestinal obstruction by *Ascaris lumbricoides* in a 14-year-old boy.

even the passage of a worm per urethram. Ascarids can also penetrate perforations, suture lines and into drainage or suction tubes.

Roundworm sensitivity can produce a variety of allergic manifestations: nasal, pulmonary, dermal, or gastrointestinal.<sup>880</sup>

### Diagnosis

Larval pneumonitis (Löfller syndrome) is generally suggested by the presence of eosinophilia, but other parasites can produce this syndrome (Table 28.43), and proof of diagnosis can only be obtained if a larva is identified in the sputum. Adult worms may later be passed in the stool or seen on radiological examination (Fig. 28.58) of the abdomen using barium. Diagnosis, however, rests almost wholly on finding eggs in the stools (Fig. 28.59), except in the event of early infection or a population of purely male worms. Serological and intracutaneous tests are available but as yet are of little practical value although they have been used in epidemiological surveys.<sup>882</sup>

### Treatment

No treatment is known to remove migrating larvae, although some have claimed success using piperazine or pyrantel. The pneumonitis responds dramatically to prednisone.<sup>880</sup> Albendazole is a very valuable, broad spectrum anthelmintic with a wide activity against intestinal nematode species. It is generally well tolerated at doses recommended for these helminths and has, in fact, been designated as a 'WHO essential agent'. It is given at a dose of 400 mg as a single dose (200 mg for children < 10 kg).<sup>877,880,883,884</sup>

Two anthelmintics highly effective in ascariasis and with minimal side-effects are pyrantel embonate/pamoate (10–20 mg/kg, max. 750 mg) and mebendazole (100 mg 12-hourly for 3 days; children < 10 kg 50 mg 12-hourly for 3 days). Levamisole is also effective and

piperazine has been used with success in the past. Tiabendazole, although effective, is best avoided owing to its side-effects.<sup>885,886</sup>

Overall, albendazole seems to be the drug of choice for ascariasis but, while results can be achieved quickly with chemotherapy, they are

Fig. 28.59 (a) Pair of *Ascaris* in appendix (approx.  $\times 10$ ). (b) Fertilized egg of *Ascaris lumbricoides* (approx.  $\times 600$ ). (c) Decorticated fertilized egg of *A. lumbricoides* (approx.  $\times 600$ ). (d) Unfertilized egg of *A. lumbricoides* (approx.  $\times 600$ ).

only temporary in the absence of other control measures. Prevention of ascariasis depends on improving living conditions and the sanitary disposal of feces, on preventing contamination of drinking water and raw vegetables, and on education in hygiene. There is evidence too, to indicate that the mass delivery of anthelmintic treatment to children may be an important option in the control of geohelminth infections, including ascariasis. The 1993 World Development Report of the World Bank<sup>887</sup> includes mass de-worming in its 'essential package of health interventions' and school-based mass delivery is singled out as one of the most cost-effective measures – a concept supported by studies such as that of Guyatt.<sup>888</sup>

### TOXOCARA CANIS AND VISCERAL LARVA MIGRANS

*Toxocara canis* is a close relative of *Ascaris*. Its natural hosts are the young dog and the fox, in which it undergoes a cycle essentially similar to *Ascaris* in humans (Fig. 28.60). The cycle in dogs is complicated by the development of immunity with expulsion of adult worms by the animals at about 6 months of age. In pregnant bitches, however, this immunity is lost and dormant larvae in the tissues are reactivated or reinfection occurs, resulting in the puppies being infected in utero and being born with worms. Children ingest infective eggs from dirt contaminated with dog feces or directly from the animals themselves, especially young puppies or lactating bitches.<sup>889</sup> The larvae, after penetrating the intestinal wall, are incapable of completing their pulmonary migration in an unnatural host and wander aimlessly, never to find their intestinal habitat. They pass through, or become encysted in liver, lungs, kidneys, heart, muscle, brain or eye, causing an intense local response from the tissue.

### Clinical features

The child (most commonly 1–5 years of age) with visceral larva migrans (VLM) shows failure to thrive associated with pica (90% of cases), anaemia (Hb  $< 9$  g/dl in 45%), fever (80%) and enlargement of liver (65%) and spleen (45%). There is cough (80%), bronchospasm and wheezing (63%).<sup>889</sup> A single organ may bear the brunt of the infection so that pulmonary symptoms or neurological abnormalities due to brain involvement (convulsions, disturbances of consciousness, hemiparesis) may predominate. Intense and persistent eosinophilia lasting months or years and reaching levels as high as  $80 \times 10^9/L$  is characteristic and may be the only abnormality found. Serum globulin levels are raised, particularly IgM, IgG and IgE, and elevated titers of anti-A and anti-B isoagglutinins have been described in 39% of cases. Transient chest shadows are recorded in about 50% of cases and the CSF may show an eosinophilia where the CNS is involved. The infection usually runs a chronic, benign course of 18 months or so and generally the prognosis is good, although deaths have been reported.

Ocular manifestations of toxocariasis (ocular larva migrans, OLM) may be the only evidence of the disease. The age of maximal ocular involvement is higher than that of systemic involvement, the average age being about 7–8 years. Loss of sight in the affected eye generally results, and usually only one eye is involved. A diagnosis of ocular toxocariasis should be considered when there is inflammatory detachment of the retina or retinitis of the posterior pole in a child, especially in one with geophagic habits, who has contact with young dogs. The diagnosis can be confused with retinoblastoma, which may lead to the unnecessary surgical removal of an eye in a child with ocular toxocariasis.

It appears, therefore, that there are two toxocaral syndromes in humans:

1. larvae in the eye, presenting as granulomatous pseudotumors of the retina (OLM);
2. generalized toxocariasis with numerous larvae in the liver and other organs and associated with fever and eosinophilia (VLM).

Because ocular lesions are seldom found in the generalized forms, and because ocular disease is almost entirely confined to children, it has been postulated that ocular toxocariasis could be the manifestation of congenital infection of the child from an infected mother, in a similar fashion to the transplacental infection of puppies. This

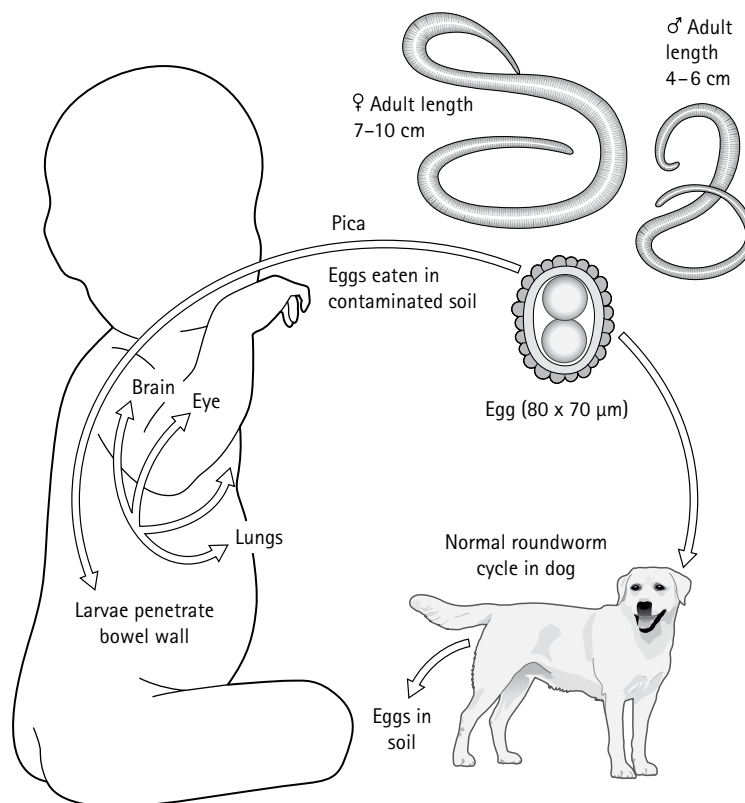

Fig. 28.60 Character and life cycle of *Toxocara canis*.

hypothesis, if true, would have important implications for expectant mothers. Similarly, contact with cats or cat litter might entail risk of fetus-damaging infection due to toxocariasis from *Toxocara cati* as well as toxoplasmosis.

It has been suggested that the eosinophilia so often seen in children suffering from lead poisoning resulting from pica may well be due to concurrent *Toxocara* infection. Physicians managing children with lead intoxication should be aware of this possibility and treat the toxocariasis concurrently.

A similar clinical syndrome can be caused in children by filarial parasites of animal origin and by larvae of other types<sup>889</sup> (Table 28.43). It still remains unclear whether *T. cati* (the cat roundworm) can be responsible for systemic larva migrans, and another dog ascarid, *Toxascaris leonina*, previously thought to be non-infective to humans, should be considered as a potential cause of visceral larva migrans.

## Diagnosis

Acquisition of a puppy in the preceding year has proved to be a good suggestive indicator of *Toxocara* infection in symptomatic patients.<sup>889</sup> The diagnosis can only be established with certainty, however, by a biopsy (generally of the liver) or, undesirably and rather drastically, after enucleation of the eye. Skin tests and serological tests such as the indirect fluorescent antibody test and the *Toxocara* enzyme immunoassay (EIA) are available with the latter having a reported sensitivity of 78% and a specificity of 92%.<sup>889,890</sup> It is worth noting that 2–7% or more of symptomless adults and up to 23% of children with no symptoms may have detectable *Toxocara* antibodies.<sup>889,891</sup>

Fluorescein angiography, ultrasound and CT scans are also described as useful adjuncts to diagnosis.<sup>890</sup>

## Treatment

Diethylcarbamazine (DEC) (2 mg/kg 8-hourly for 7–10 days) is reportedly effective.<sup>883,890</sup> An alternative regimen is up to 6 mg/kg in divided doses for 3 weeks.<sup>889</sup> Repeated courses may be necessary and if

respiratory distress or myocardial involvement develops, corticosteroids may be life-saving.

Tiabendazole at a dose of 50 mg/kg per day for 3–5 days or 25 mg/kg for 1–4 weeks has also been recommended in the past and has been considered especially useful for early ocular cases where diethylcarbamazine should not be used, as the cellular response it elicits could aggravate visual problems. Corticosteroids are also important in controlling ocular lesions and should be given before the DEC is started.<sup>890</sup> Albendazole (400 mg 12-hourly for 3–5 days) has shown promise and flubendazole has also proved encouraging.<sup>890,892</sup>

Overall, however, the chemotherapy for toxocariasis remains unsatisfactory.

## Prevention

While the dangers of infection from pets cannot be overstressed, this is a very emotive issue. Hungerford<sup>893</sup> stated: 'In our stress distorted society, pets...may be the critical factor in maintaining or restoring mental health or happiness to an only child, or to a psychotic, mentally distraught or lonely child or adult.'

The answer, therefore, is not destruction of pets, but regular and routine de-worming of dogs, especially puppies and pregnant bitches, with mebendazole, fenbendazole, piperazine or pyrantel pamoate. Also important is education to impress upon children and expectant mothers the need to wash their hands after handling pets and not to allow dogs to lick them on the face. Dogs and cats should also be prevented from defecating where children play (sandpits, etc.).

## ENTEROBIUS VERMICULARIS (OXYURIASIS)

*Enterobius vermicularis* (threadworm, pinworm, seatworm) is common worldwide, but unlike most nematodes it is more prolific in temperate and cold climates. The incidence is highest in schoolchildren from 5 to 9 years with another peak at 30–49 years.<sup>894</sup> Boys and girls are equally affected. Enterobiasis is particularly common in highly populated

districts, institutional groups, and among members of the same family. Incidences as high as 40–50% have been reported and in institutions such as mental hospitals, prevalence may reach 90–100%. The absence of a prolonged developmental stage outside humans (Fig. 28.61) favors reinfection and transmission from child to child. Hands are contaminated by scratching the perianal area where eggs are deposited, and by contact with soiled underclothing, nightclothing or bedding. Infection is also acquired by inhalation of egg-containing dust, which may be disseminated from bedclothing by shaking, or movements of the sleeper. At room temperature eggs survive for 2–3 weeks. Furthermore, retroinfection may occur when the eggs hatch on the perianal area and larvae find their way back through the anus into the intestinal tract.

The usual habitat of the threadworm of both sexes is the caecum and adjacent appendix, lower ileum, and colon. The worms are free in the intestinal lumen or lie with their heads attached to the mucosa. Gravid females migrate to the lower colon and rectum and crawl through the anus to deposit thousands of sticky eggs on the anal verge and perineum at night, usually dying thereafter. It is worth emphasizing that dogs and cats play no part in the transmission of enterobiasis to humans.

### Clinical features

Threadworm infection is generally asymptomatic. The most common manifestation is anal pruritus due to migration of the worms and the presence of eggs. Restless sleep, nightmares, teeth grinding, and perhaps bed-wetting may result. In up to 20% of girls, vulval irritation and vaginal discharge are caused by threadworms and can persist for years<sup>877</sup> and night crying may be due to a threadworm in the vaginal introitus. Excoriation and pyogenic infection can follow from constant scratching.

It is most unlikely that threadworms play any significant part in causing the variety of symptoms commonly attributed to them. For example, threadworms are no more common in children with recurrent abdominal pain than in those without pain. Similarly, threadworms are found as often in normal appendices as in appendices showing acute or chronic inflammation, so that they are not considered to play any material role in the production of appendicitis, although appendiceal blockage resulting in a simulated chronic appendicitis may occur at times.<sup>894</sup>

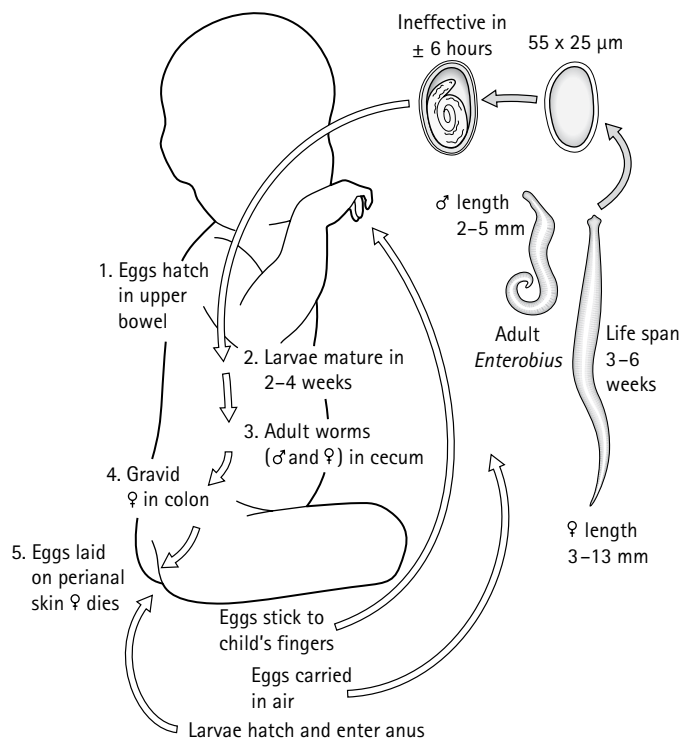

Fig. 28.61 Character and life cycle of *Enterobius vermicularis*.

Nail biting, nose picking, masturbation, convulsions, hyperkinesia and other behavior disturbances are also often erroneously ascribed to these parasites.

Very heavy infections can, however, result in catarrhal inflammation of the bowel from the attachment and irritation of worms, resulting in gastrointestinal disturbance. Intestinal obstruction has even been reported. Rarely, heavy infections have led to invasion of the bowel and appendiceal walls, peritoneum or viscera by larvae and immature worms. In their external migration gravid threadworms may occasionally crawl up the vagina into the uterus and Fallopian tubes or into the urethra and bladder depositing eggs in these sites with resulting low grade salpingitis, cystitis or urethritis, and cases are on record of worms penetrating the intestinal wall, probably through a pre-existing mucosal breach, to reach the peritoneal cavity.

Enterobiasis may be associated with infection by the protozoan flagellate, *Dientamoeba fragilis*, which is believed to be transmitted within the egg of the threadworm and may be a cause of diarrhea.<sup>895</sup>

Eosinophilia is usually absent in enterobiasis but may occur in up to 12% of cases.

### Diagnosis

Often the first evidence of infection is the discovery of the adult worms in the feces, particularly after enemas, or on the perineum. Worms may be clearly visible on proctoscopy. The most widely used and effective method of obtaining eggs from the perianal region is the adhesive cellulose tape method. The adhesive side of a piece of transparent tape is applied to the anus and surrounding skin – either directly or wrapped round a test tube – and the tape then transferred adhesive side down to a glass slide. The adhering eggs are clearly visible under a microscope (Fig. 28.62a). The test is best performed in the morning before bathing or defecation, and in view of the irregular migrations of gravid worms at least three examinations should be made on consecutive days. Eggs are found in the stools in only 5–10% of cases, but five perianal swabs reveal eggs in 97% of infections.

### Treatment

Drugs of choice for enterobiasis include mebendazole, albendazole and pyrantel embonate/pamoate. Mebendazole given in a single dose of 100 mg (one tablet) stat. is recorded as giving a cure rate of about 95% with no or very few side-effects.<sup>877</sup> Although some authorities advise that mebendazole should not be used in children < 2 years of age, others accept that a dose of 50 mg can be used for a child < 10 kg.<sup>884</sup> Albendazole is also reported as effective, at a dose of 400 mg orally (200 mg in children 10 kg or less).<sup>896</sup> Neither mebendazole nor albendazole should be used during pregnancy.<sup>884</sup>

Fig. 28.62 (a) Fully developed egg of *Enterobius vermicularis* (approx. × 600). (b) Hookworm egg (approx. × 600).

Pyrantel 11 mg/kg is also very effective as a single dose treatment, giving cure rates greater than 90%. Side-effects are usually mild (e.g. nausea and vomiting), occurring in about 3% of cases.<sup>877,886</sup>

Piperazine citrate and pyrvinium pamoate are no longer in general use for enterobiasis, and tiabendazole, while efficacious, has unpleasant side-effects.

When a child is treated for enterobiasis, the whole family should be treated, and a second course should be given after 3 weeks. Unfortunately, reinfection is the rule rather than the exception. Intractable family infections can be controlled by the treatment of all family members with 100 mg (50 mg for children <10 kg) mebendazole a week for 12 weeks.

Prevention of recurrence is extremely difficult, particularly in crowded communities and in humid temperate climates, which facilitate prolonged survival of eggs. Personal cleanliness is essential and this includes cutting fingernails, regular hand washing before meals and after using the toilet, washing the anal area on rising, and regular changing of underclothing and bed linen.

## HOOKWORM (ANCYLOSTOMIASIS)

*Ancylostoma duodenale* (Old World hookworm) and *Necator americanus* (tropical hookworm) are morphological variants, tropical hookworm being rather smaller with differences of fine morphology.

Hookworm occurs in most tropical and subtropical areas of the world, with *A. duodenale* distributed mainly around the Mediterranean littoral and *N. americanus* in south and central Africa and southern America. Both species are, however, widely distributed today in Asia as well as in most other tropical countries. In South East Asia and Brazil, *A. ceylanicum* infections of humans occur as well and *A. malayanum* is yet another species from humans.<sup>877</sup> Hookworm is one of the world's chief causes of anemia.

*A. braziliense*, one cause of cutaneous larva migrans (Table 28.43) and a natural parasite of dogs and cats, is widely distributed throughout tropical and subtropical areas, while the common dog hookworm *A. caninum* is also widely distributed, and *Uncinaria stenocephala* infects dogs in temperate regions. These latter two species can also cause cutaneous larva migrans in humans and it is claimed that in northern Queensland in Australia, *A. caninum* may be a cause of eosinophilic enteritis in humans as discussed by Smyth.<sup>897</sup>

The excreted egg, in favorable damp, shady conditions, hatches on the soil in about 2 days, releasing a rhabditiform larva which develops 8–10 days after hatching into the infective (filariform) larva. This larva penetrates the skin of the host, although *A. duodenale* is believed also to enter via the oral route with fecally contaminated food and water and may infect by the transmammmary and transplacental routes from infected mother to child.<sup>898</sup> The life cycle in humans from larval penetration to oviposition lasts about 5 weeks (Fig. 28.63). The adult worm may survive within its host for 7 years or longer.

Adult worms are attached to the wall of the jejunum, or, less commonly, the duodenum, by their buccal capsules, sucking blood from their hosts. Each worm may suck up to 0.5 ml of blood per day; thus heavy worm loads may result in a loss of 100–150 ml/day. Significant damage is therefore produced by hookworms, but clinical manifestations depend on the host's general resistance, on the worm load, and on the child's dietary intake and iron reserves.

### Clinical features

#### Larval invasion

Penetration of the skin, usually of the feet or buttocks, by the filariform larvae may produce, within minutes, a series of wheals, which soon develop into an itchy, papular and vesicular eruption ('ground/dew itch'). The rash may become ulcerative or pustular, but generally

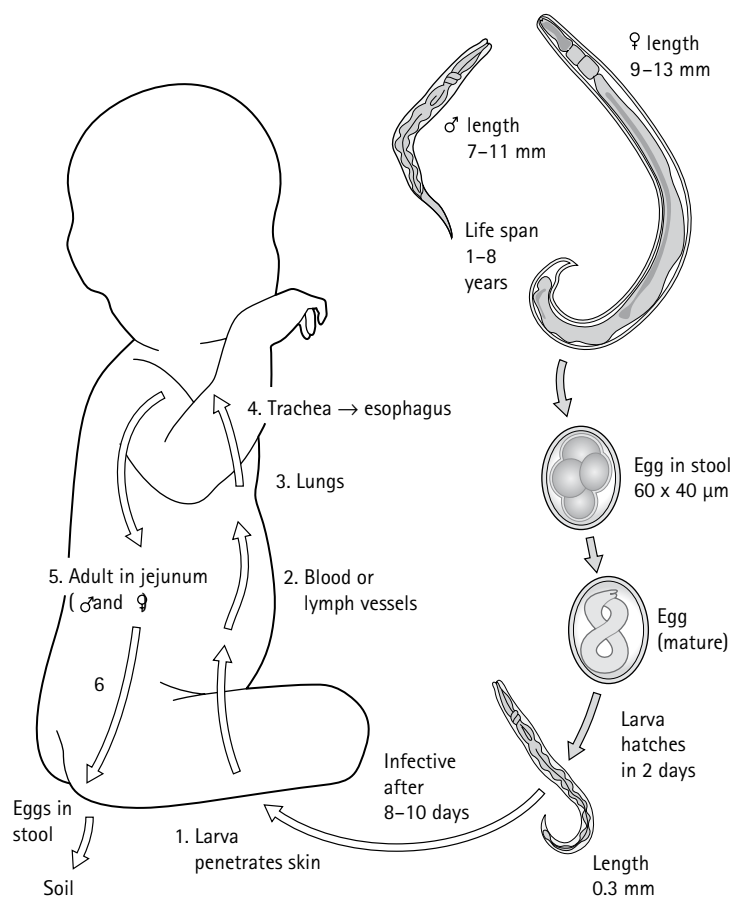

Fig. 28.63 Character and life cycle of hookworm.

subsides within 10 days and the larvae do not wander within the skin as in the case of cutaneous larva migrans (see below).

### Migration through the lungs

After penetration of the skin, larvae reach the small intestine via the heart and lungs as in ascariasis.

Respiratory symptoms are unusual in children except in the case of heavy or repeated infections, particularly of *N. americanus*, when there may be cough, sore throat, bloody sputum and pulmonary changes on X-ray (Table 28.43).

### Adult worms in the intestine

A distinction should be made between hookworm infection (where patients carry a subclinical worm load) and hookworm disease, which results from heavy worm loads and inadequate diet. Where heavy infections occur, symptoms develop 2–7 weeks after initial infection and consist of abdominal discomfort especially after meals, anorexia and sometimes nausea and vomiting. There may be intermittent diarrhea, general debility and undue tiredness. Once the adult worms are well established, there is little disturbance to the child, provided that the intake of iron, vitamins and protein keeps pace with the chronic blood loss produced by the parasites. When diet is inadequate and worm load heavy, severe hookworm disease results, characterized by profound iron deficiency anemia, hypoalbuminemic edema, cardiac failure and even death. It has been estimated that 100 worms will cause a daily loss of 4 mg of iron. A balanced diet easily compensates for this loss, but iron deficiency soon develops on a marginal dietary intake. Children with heavy hookworm infections are stunted, marasmic and anemic; their skin is dry and their face puffy. All aspects of development are retarded. An important concomitant which makes hookworm infection much more serious is sickle cell anemia.

A marked eosinophilia (40%) is characteristic of early hookworm infection. It reaches maximum intensity at about 3 months after initial infection and then diminishes gradually to levels of 5–20%. A partially effective protective immunity seems to develop in hookworm infection.<sup>899,900</sup>

### Diagnosis

This depends on finding the eggs (Fig. 28.62b) in the feces, and an egg count should be performed if a causal relationship with a concomitant iron deficiency anemia is to be established. An egg count > 2000 eggs/g of feces is generally considered to be of clinical significance.

In old stool specimens rhabditiform larvae are occasionally found and can be distinguished from those of *Strongyloides* by the short buccal chamber and larger genital primordium of the latter.

Eggs similar to those of hookworms can be recovered from humans infected with *Trichostrongylus* spp., *Oesophagostomum* spp. and *Ternidens deminutus*. The eggs of the former species are more pointed than those of hookworm and the eggs of *T. deminutus* are significantly larger than those of the hookworm species. These infections can be treated as for hookworm.<sup>901</sup>

### Treatment

Albendazole is reported to be effective against the migrating larval stages of the human hookworms, *A. duodenale* and *N. americanus*.<sup>902</sup> The avermectins (ivermectin) have shown promise against all stages of hookworm development, including migrating larvae.<sup>877</sup> Children with severe anemia, malnutrition or a heavy worm load should receive preliminary supportive treatment in the form of blood transfusion, high calorie and protein diet, vitamins and iron therapy before definitive treatment of the worms. A highly effective anthelmintic for hookworm infection is albendazole and at a single dose of 400 mg (200 mg for children 10 kg or less) it has also proved highly effective against a wide range of other intestinal helminths.<sup>877,884</sup> Albendazole is additionally reported to have ovicidal activity against hookworm, ascariasis and trichuriasis, making it especially valuable in integrated control programs for these infections.<sup>902</sup> Mebendazole also gives excellent cure rates for both species

of hookworm at a dose of 100 mg twice a day for 3 days or 50 mg for children 10 kg or less – and with few or no side-effects.

Pyrantel embonate/pamoate (11 mg/kg, max. 750 mg) is effective for *A. duodenale* given in a single dose regimen,<sup>903</sup> but for *N. americanus* needs to be given as a multiple dose treatment.

Other treatments for hookworm include phenylene diisothiocyanate and bephenium hydroxynaphthoate.

The preventive aspects of hookworm are complex and include education of the public into the mode of spread of the disease, provision and proper usage of latrines, improvement of diet, and, where the incidence is high, mass population treatment. The wearing of shoes will also help to prevent infection. Studies from Papua New Guinea by Quinell et al<sup>903</sup> suggest that host susceptibility differences may explain why different individuals are predisposed to heavy or light burdens. Interest continues regarding the possibility of vaccination against hookworm infection.<sup>898,900,904</sup>

## CUTANEOUS LARVA MIGRANS (CREEPING ERUPTION, SAND WORM)

### Clinical features

The larvae of the dog hookworms, *A. braziliense*, *A. caninum* and *U. stenocephala*, together with certain other parasites (Table 28.43), can produce in humans a long-lasting skin eruption which differs from that caused by 'human' hookworms. The larva, after penetrating the epidermis, is unable to enter the bloodstream or lymphatics and instead burrows just below the corium, traveling up to an inch a day. Papules mark the site of entry and advancing end of the larva and the tunneling causes slightly elevated, erythematous and serpiginous lines which itch intensely (Fig. 28.64). Vesicles may form along the course of the tunnels and scaling develops as the lesions age. The most common sites in children are the buttocks and the dorsum of the feet, but any area can be affected. The eruption generally disappears after 1–2 months, but may persist for 6 months or longer. The diagnosis is clinical.

### Treatment

Topical tiabendazole 15% cream is the treatment of choice and can easily be made from the oral preparation by dissolving 500 mg tablets in a water base, if not commercially available. Ivermectin (children > 5 years) 200 µg/kg orally as a single dose, or albendazole 400 mg (200 mg for a child < 10 kg) orally, once daily for 3 days, is also effective.<sup>884</sup> Cryotherapy is unpleasant, ineffective and no longer used.

## TRICHURIS TRICHIURA (TRICHOCEPHALIASIS, WHIPWORM)

The whipworm, so called for its thin anterior lash-like end (Fig. 28.65), is widely distributed, being most common in hot, damp environs. The adult nematode frequents the cecum but can occur in the appendix, colon or

Fig. 28.64 Cutaneous larva migrans.

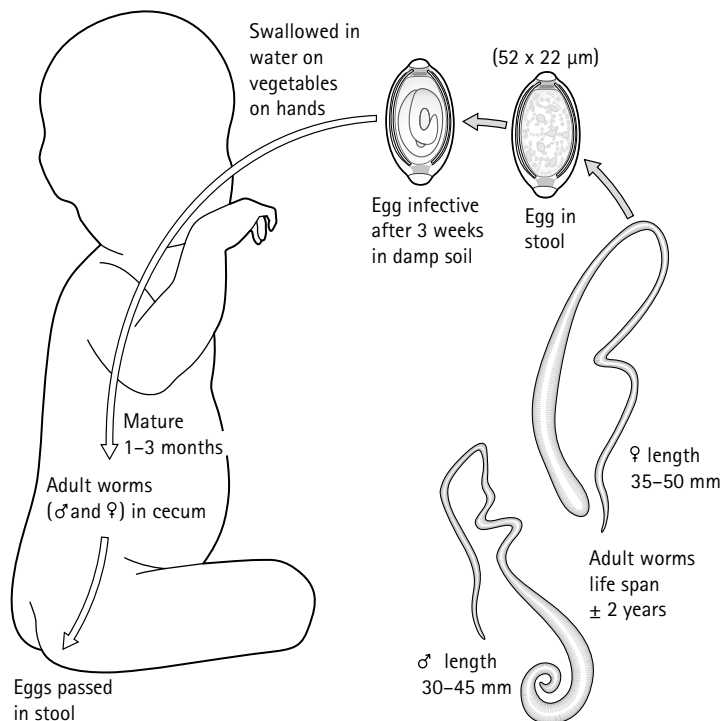

Fig. 28.65 Character and life cycle of *Trichuris trichiura*.

terminal ileum, its thin anterior extremity threaded or embedded in the mucosa. Eggs pass out with the feces and mature on the soil in about 2-3 weeks. Children usually acquire whipworm by sucking fingers or objects contaminated with fecal-polluted soil containing infective eggs, but contaminated vegetables and fly-borne contamination of food are also important means of spread. Trichuriasis is by no means confined to the tropics<sup>905</sup> and may prove troublesome in mental institutions.

*Trichuris vulpis*, the dog whipworm, may occasionally infect humans.<sup>891</sup>

### Clinical features

Whipworm infection is often asymptomatic but should not be underrated as a pathogen in humans.<sup>905</sup> Heavy worm loads may be responsible for intestinal symptoms including abdominal pain, which is most marked in the right iliac fossa simulating appendicitis, bloody diarrhea, tenesmus, and sometimes mild pyrexia. Heavy loads can lead to marked anemia, weight loss, and a picture closely resembling hookworm disease or amebic colitis. Clubbing of the fingers and toes is seen and is reversed with eradication of the infection. Rectal prolapse is a well-recognized complication. Trichuriasis often causes insidious disease and is frequently associated with growth retardation.<sup>906</sup>

### Diagnosis

This is readily accomplished by finding the characteristic eggs (Fig. 28.66) in the stools. A barium enema may assist in diagnosis (Fig. 28.67).

Fig. 28.66 Egg of *Trichuris trichiura* (approx.  $\times$  600).

Fig. 28.67 *Trichuris trichiura*. Double contrast barium enema examination showing infestation and numerous small circular or sigmoid defects in barium coating of colon.

### Treatment

Albendazole at a dose of 400 mg, or 200 mg for children 10 kg or less, given once, is the drug of choice,<sup>884</sup> but mebendazole can also be used at a dose of 100 mg (50 mg for a child 10 kg or less) 12-hourly for 3 days.<sup>877</sup> Difetarsone has been reported to be most useful in the treatment of whipworm, and oxantel pamoate is also reported to be effective.<sup>877</sup>

### *STRONGYLOIDES STERCORALIS* (STRONGYLOIDIASIS)

*Strongyloides stercoralis* (sometimes termed 'threadworm' in the American literature) has a human cycle closely resembling hookworm, except that autoinfection is common and a free-living cycle can occur if external conditions are favorable (Fig. 28.68). Strongyloidiasis is most common in tropical or semitropical climates but may occur sporadically in temperate regions. The minute adult worms are to be found in the crypts of Lieberkuhn glands in the upper part of the small intestine, where they burrow into the mucosa.

In central Africa, *Strongyloides fülleborni* is often found in humans and a similar species is reported to cause 'swollen belly syndrome' in infants about 6 weeks of age in Papua New Guinea (PNG).<sup>907</sup> The species in PNG has been designated as *S. fülleborni Kellyi*, and infants as young as 18 days of age can become infected, possibly by transmammary infection, as may also occur with *S. fülleborni* in Africa.<sup>908</sup>

### Clinical features

Skin penetration by filariform larvae may cause a transient prickling sensation, but following heavy infection there is a pruritic petechial rash with local edema. Internal and external autoinfection frequently occurs, especially in immunodeficient patients or patients on immunosuppressant drugs or corticosteroids, larvae in the feces entering through the rectal mucosa, anus or skin in the perianal region. This gives rise to an often recurring eruption resembling cutaneous larva migrans (termed larva currens) but of shorter duration. Generalized urticaria is sometimes seen as a result of hypersensitivity. Eosinophilia is common. Clinical manifestations of pulmonary migration of larvae are infrequent, but respiratory symptoms can occur and, rarely, chronic lung disease develops due to larvae maturing within the lung.

In chronic strongyloidiasis the presence of the adult worms in the intestine is often asymptomatic.<sup>909</sup> A heavy worm load causes epigastric pain, episodes of acute appendicitis,<sup>896</sup> bowel upset often with bloody diarrhea, iron deficiency anemia and debility. Infection can last 20 years or more, owing to constant internal and external autoinfection.<sup>910</sup>

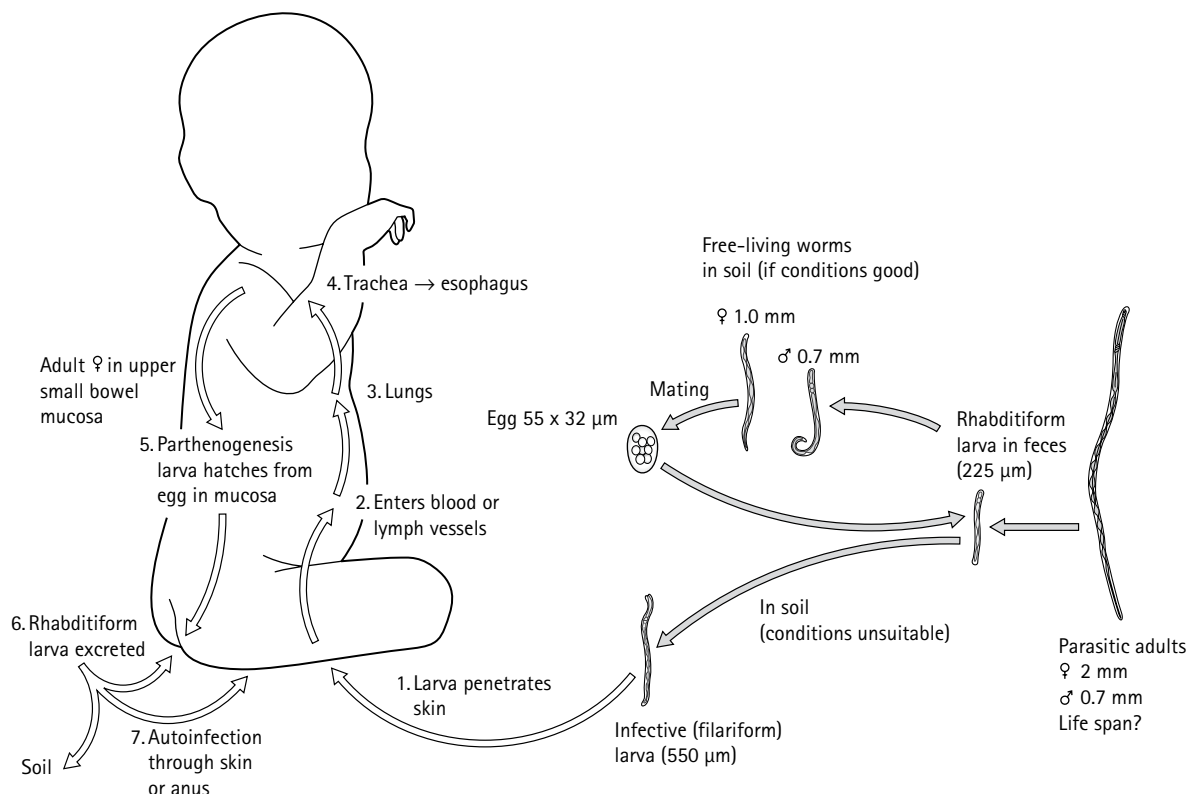

Fig. 28.68 Character and life cycle of *Strongyloides stercoralis*.

In immunocompromised patients, fatal infection can occur, but it is noteworthy that despite the HIV/AIDS pandemic in sub-Saharan Africa and elsewhere, *S. stercoralis* has not proved an important opportunistic pathogen, although an epidemiological association between strongyloidiasis and HTLV-1 has been reported.<sup>901,909</sup> *Strongyloides* hyperinfection syndrome may be complicated by Gram negative bacteremia in both immunocompromised and non-immunocompromised individuals and has a high mortality.<sup>911,912</sup>

### Diagnosis

Considerable eosinophilia is usual and can be an important diagnostic indicator in some circumstances.<sup>910</sup> Diagnosis of *S. stercoralis* is established by demonstrating rhabditiform larvae (Fig. 28.69a) in fresh stools (repeat examinations may be necessary) or duodenal fluid. A useful method for diagnosing *S. stercoralis*, giardiasis, and other upper intestinal parasites is duodenal drainage or the use of the duodenal capsule (Enterotest), or 'string test'; a special pediatric size is available. The capsule, containing a length of thread and 3-ply nylon yarn, is swallowed while the protruding free end of thread is held at the mouth. The yarn within the capsule plays out, and within 3–4 h the line has almost invariably extended to the duodenum or jejunum. The gelatin capsule dissolves. The nylon yarn is then pulled back through the mouth and the adhering mucus examined for parasites.

Serological tests such as EIA are available in some countries, with sensitivities in the order of 80–90% and specificities of about 90%. These tests do not usually differentiate present from past infection and may cross-react with other nematode infections.<sup>890</sup>

In *S. fillicornis* infections, fully embryonated eggs (Fig. 28.69b) are passed in the feces. They are similar in appearance to hookworm eggs but much smaller, about 50 × 36 µm in size, are fully developed at time of passage<sup>901</sup> and hatch after about 2–3 h.

### Treatment

Because of the dangers of autoinfection, especially in the immunocompromised, strongyloidiasis must always be treated when diagnosed.<sup>913</sup>

The treatment of choice for strongyloidiasis is now albendazole 400 mg 12-hourly, orally for 3 days (children 10 kg or less 200 mg), repeated after 7 days if the infection is disseminated.<sup>884,902</sup> Ivermectin 200 µg/kg orally each day as a single dose for 1–2 days can also be used

Fig. 28.69 (a) Rhabditiform larva of *Strongyloides stercoralis*. Note short buccal cavity and large genital primordium. Also in the field, an *Entamoeba* cyst and a hookworm egg (approx. × 600). (b) Egg of *Strongyloides fillicornis*. Note its small size. It contains a fully developed, motile larva when passed (approx. × 600).

for children > 5 years of age.<sup>884,913,914</sup> Tiabendazole, which is effective (25 mg/kg 12-hourly, orally, given morning and evening for 3 days up to a maximum total of 3 g daily), is an alternative, but can have unpleasant side-effects.<sup>884,913</sup>

## ANGIOSTRONGYLIASIS

*Angiostrongylus cantonensis* is a natural parasite in the lungs of rats over much of the world, human infection being recorded from Indonesia, Papua New Guinea, Northern Australia, Africa, the Pacific, South East Asia, Cuba and Puerto Rico. The intermediate hosts are snails (such as the giant African land snail *Achatina fulica*) and slugs, which are eaten by the rodents. Humans become infected by eating certain edible snails or by accidental ingestion of small infected slugs on food plants or ingestion of paratenic (or 'carrier') hosts such as edible crustacea.<sup>915</sup>

In humans, larvae migrate to the brain causing eosinophilic meningitis, with neck stiffness, photophobia, pyrexia, decreased consciousness and vomiting.

The diagnosis can be suspected when large numbers of eosinophils are found in the CSF in patients with a history of eating snails or perhaps crustacea. Blood eosinophilia may also be present. Occasionally adults or larvae of *A. cantonensis* can also be detected. Surgical intervention may be necessary.<sup>916</sup> No effective specific treatment is presently available and may in any case be inadvisable as dead worms cause more clinical problems than live ones. However, mebendazole (100 mg 12-hourly for 5 days) together with corticosteroids (30–60 mg/day) is recommended for *A. cantonensis*.<sup>890,913</sup>

Other forms of angiostrongyliasis include an abdominal form caused by *A. costaricensis* in several Latin American countries. This species causes intestinal and liver lesions similar to those caused by *Toxocara*. It is usually diagnosed at surgery and has an epidemiology similar to *A. cantonensis*.<sup>917</sup> This species may require a higher dose of mebendazole than that recommended for *A. cantonensis*.<sup>913</sup>

## HELMINTHOMA

Nodules in the bowel wall which contain the adult worms (helminthomas) can be caused by the nodular worms which belong to the genera *Oesophagostomum*, occurring naturally in simian and ruminant hosts, and the false hookworm, *Ternidens deminutus*, a natural parasite of non-human primates. These are known in Central Africa to cause human disease characterized, particularly in *Oesophagostomum*, by tumor-like granulomatous reactions in the wall of the colon.<sup>918</sup> *Ternidens* infections in humans have also been reported from Surinam and Thailand.<sup>919,920</sup> Eggs of these species are hookworm-like but those of *Ternidens* are larger in size.<sup>901</sup>

The drug treatment of choice for the expulsion of the adult worms is mebendazole (100 mg 12-hourly for 3 days). Albendazole is promising.<sup>901,918</sup>

## ANISAKIASIS (ANISAKIDOSIS)

Anisakiasis in humans is caused by the larval stages of some 30 genera of anisakid nematodes, of which the most common are *Anisakis*, *Contracaecum*, *Terranova* and *Pseudoterranova*.<sup>896,921</sup> These helminths are intestinal parasites of a range of fish-eating vertebrates, including dolphins, and the larval stages of the worm are found in intermediate hosts such as small fish (e.g. mackerel, herring, salmon), squid or octopus.<sup>922,923</sup> Humans become infected when they eat raw or undercooked fish.

The ingested worms live in the human gastrointestinal tract or penetrate the tissues, giving rise to abscesses or eosinophilic granulomata.

Clinically the infection may be asymptomatic or mild with nausea, vomiting, epigastric pain and often an eosinophilia, which may exceed 40%. Rarely, death may result from peritonitis following perforation of the gut.<sup>922</sup>

While the infection has for many years been recognized in Japan, an increase has been noted in the USA owing to better diagnostic techniques.<sup>923</sup> Diagnosis is established at laparotomy, by X-ray or, most reliably, by endoscopy. Serological tests for diagnosis include the radioallergosorbent test (RAST) and counterimmunoelectrophoresis.

The most effective treatment, where possible, is removal of worms from the stomach by endoscopy. Prevention is best achieved by removing worms from fish prior to eating and by thorough cooking of fish. No effective anthelmintic treatment is presently available,<sup>922</sup> but Shorey et al<sup>890</sup> express the view that mebendazole might have some value, and albendazole at a dose of 400 mg 12-hourly for 21 days proved promising in one case.<sup>921</sup>

## TRICHINOSIS

The genus *Trichinella* contains at least four species, the best known being *Trichinella spiralis*. This species has a cosmopolitan distribution, usually being transmitted to humans by eating inadequately cooked, infected pig meat, although outbreaks from other meat sources (e.g. horse meat) are recognized.<sup>924,925</sup> The disease may occur in outbreaks (Fig. 28.70). Trichinosis due to *T. spiralis* is rare in communities which shun pork and in those with vigilant agricultural control, but human disease, especially with other species (e.g. *T. pseudospiralis*, *T. nelsoni*, *T. britovi* or *T. nativa*), may follow eating the meat of other species of animal. Adult *T. spiralis* infect humans, pigs and rats, as well as other animals. Porcine infection usually results from the ingestion of either infected rats or garbage containing uncooked pork meat.

## Clinical features

Human trichinosis is frequently mild or symptomless. Although symptoms may occur as early as 24 h following a pork meal, it is usually during the incubation period of 5–7 days or longer,<sup>926</sup> in which the ingested larvae mature into adults, that a clinical picture resembling food poisoning develops – nausea, vomiting, diarrhea and abdominal pain. This phase lasts about 5 days and is followed by signs and symptoms as the larvae enter the bloodstream and encyst in the muscle, a phase lasting a further 2–3 weeks. There is pyrexia, edema of the face and eyelids, splinter hemorrhages under the fingernails, tender lymphadenopathy and myalgia, often extreme. Cough may occur and in severe cases the illness may suggest encephalitis or myocarditis. Marked eosinophilia is usual. Final encystment of the larvae occurs only in voluntary muscles, particularly those of the diaphragm, throat, chest wall, extrinsic ocular apparatus and tongue, and patients may die of toxemia or myocarditis. The encysted larvae may live for many years.

## Diagnosis

Diagnosis in the early stages can be made by finding worms in the feces, but in the later stages of the disease, diagnosis is established by muscle biopsy. Intracutaneous and fluorescent antibody tests, together with other serological procedures, are useful adjuncts.<sup>890,926</sup>

## Treatment

Albendazole (400 mg for 3 days; 200 mg for children 10 kg or less) is the drug of choice. Mebendazole (200–400 mg daily for 3 days and then 400–500 mg for 10 days) is also recommended.<sup>890,913</sup>

There is evidence that tiabendazole (25 mg/kg per day 12-hourly for 5 days; max. 3 g daily) rapidly kills off migrating larvae and relieves the symptoms.<sup>883</sup> If taken early, the drug also kills larvae in the bowel but is not lethal to the adult worms. Corticosteroids, previously recommended for the treatment of trichinosis, should be restricted to critically ill cases,<sup>916</sup> and then only used in conjunction with anthelmintics.

## PARACAPILLARIA PHILIPPINENSIS (CAPILLARIASIS)

It has long been known that the nematode *Capillaria hepatica* can cause a visceral larva migrans-like syndrome in people who have eaten meat (e.g. infected liver) or sand containing the eggs of the worm. Infected

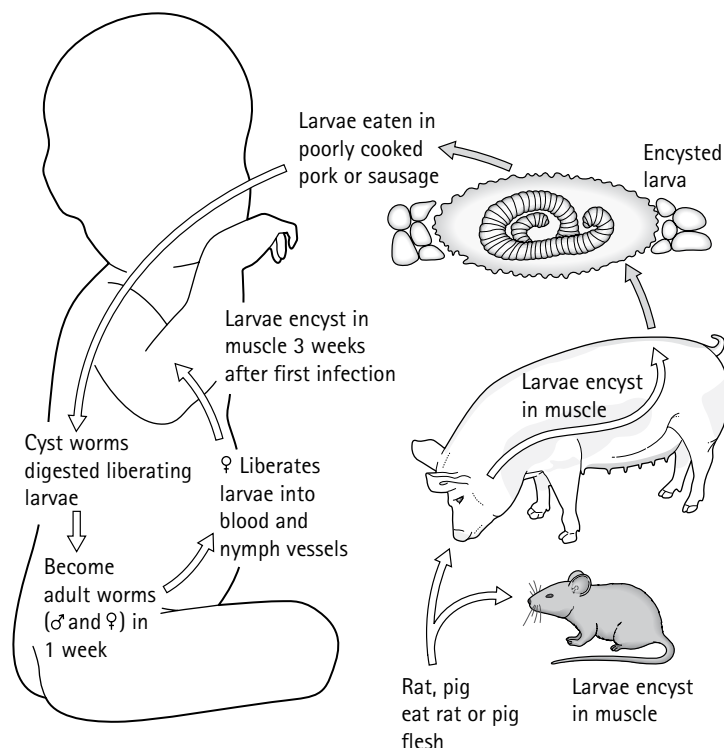

Fig. 28.70 Character and life cycle of *Trichinella spiralis*.

children exhibit such symptoms as fever, eosinophilia, abdominal pain and hepatomegaly, with large numbers of typical eggs being found in the liver on histological examination.

Another species of the genus, *Paracapillaria philippinensis*, has also been shown to be an important cause of epidemic diarrhea in humans in South East Asia and the Middle East. Clinical features in these cases include abdominal pain, malabsorption and diarrhea, which is often severe and not uncommonly fatal (35%) without medical care.<sup>927</sup>

*P. philippinensis* is a parasite of the small intestine, and is believed to be a zoonotic infection from birds and freshwater fish. Humans become infected by ingestion of eggs or infected raw fish, the usual intermediate host, and the host parasite load may increase as a result of autoinfection.<sup>896</sup>

*Capillaria aerophila* is found in the lungs of cats, and occasional human infections have been recorded.<sup>890,896</sup>

Diagnosis of capillariasis is based upon histology or finding eggs and larvae in feces. The eggs are like those of *Trichuris*, but the polar plugs are inset and the shells are striated or pitted. *C. hepatica* eggs can be found as spurious 'transit eggs' in feces of patients who have recently eaten infected liver.<sup>928</sup>

Tiabendazole has been used for treatment, but side-effects and relapses are common.<sup>927</sup> Mebendazole (200 mg 12-hourly for 20 days) and albendazole (400 mg daily for 10 days) are reported to be effective for the treatment of capillariasis.<sup>896,913</sup>

## DRACUNCULOSIS (DRACONTIASIS)

Despite its bizarre mode of propagation, the guinea worm (*Dracunculus medinensis*) is widely distributed in equatorial Africa, the Middle East and India. However, with new international efforts to improve drinking water supplies, dracontiasis eradication may well be achievable.<sup>929</sup>

### Clinical features

Children from the age of 2 years may be infected by drinking water containing *Cyclops*, a tiny crustacean which is infected with the larvae of *Dracunculus*. During the asymptomatic incubation period, lasting approximately 1 year, the guinea worm matures in retroperitoneal tissues. The male, having fertilized the female, apparently dies. The gravid female, often over 100 cm in length by 1.5 mm in width, then migrates

through the subcutaneous tissues to distal parts of the extremities, usually the lower limb, to form a large pruritic papule. This vesiculates, then bursts leaving a shallow ulcer. On immersion in water the worm's uterus prolapses through the ulcer releasing myriads of larvae. Occasionally adult worms may develop in ectopic sites.

Papule formation may be associated with a marked allergic reaction (vomiting, diarrhea, urticaria and bronchospasm).

Secondary infection of sinuses, subcutaneous cysts, sterile abscesses and periarticular fibrosis with joint deformity are recognized complications. Calcified worms may be discovered on radiological examination.

### Treatment

The ancient technique of repeatedly stimulating the parturient worm with cold water, grasping the uterus which then protrudes, and then cautiously winding the worm round a stick an inch or two per day is still used. However, drug treatments recommended for dracontiasis include the use of niridazole (12.5 mg/kg 12-hourly for 7–10 days) and tiabendazole which has also been reported to be effective at a total dose of 25 mg/kg orally daily for 3 days.<sup>883</sup> Metronidazole is also claimed to be highly effective at an oral dose for children of 7.5 mg/kg (max. 250 mg) 8-hourly for 5–10 days.<sup>883,885,913</sup>

## FILARIASIS

Filariasis is included among the diseases given priority by the United Nations Development Program/World Bank/WHO Special Program for Research and Training due to the huge number of people infected and the enormous burden of morbidity affecting whole communities in endemic regions.<sup>930</sup>

Humans are the primary hosts to several species of filariae, the adult worms living in the tissues. The adult female worms produce eggs which hatch to release pre-larval microfilariae. These are ingested by an appropriate blood-sucking arthropod vector, in which they undergo metamorphosis to form infective larvae. Important characteristics of the principal human filariae are shown in Table 28.44).

During the early stages of all filarial infections moderate to high eosinophilia is usual, but this gradually diminishes in those who have

Table 28.44 Types of filaria worms responsible for human disease

Type and distribution	Insect vector	Important features of microfilaria	Human adult worm location
<i>Onchocerca volvulus</i> , west, central and east Africa, Guatemala, Mexico, and Surinam	<i>Simulium</i> black flies	Do not occur in blood, but in skin as unsheathed intradermal microfilariae (microfilariae may penetrate eye)	Subcutaneous tissue
<i>Mansonella perstans</i> , tropical and subtropical areas mainly of Africa and South America	<i>Culicoides</i> midges	Occur in blood. Nonperiodic. Unsheathed. Nuclear column extends into tip of thick blunt tail	Mesenteric, perirenal and retroperitoneal tissues
<i>Mansonella ozzardi</i> , South America	<i>Culicoides</i> midges	Occur in blood. Nonperiodic. Nuclear column does NOT extend into tip of thin, pointed tail	Mesentery and serous body cavities
<i>Wuchereria bancrofti</i> , tropical and subtropical areas throughout the world	Many mosquitoes belonging to the genera <i>Culex</i> , <i>Aedes</i> , <i>Anopheles</i> , and <i>Mansonia</i>	Occur in blood. Nocturnal periodic. Sheathed. Nuclear column does NOT extend into tip of thin pointed tail	Lymphatic tissue
<i>Brugia malayi</i> , <i>B. timori</i> , East Indies and Southern Asia	Many mosquitoes belonging to the genera <i>Mansonia</i> , <i>Culex</i> , and <i>Anopheles</i>	Occur in blood. Nocturnal periodic. Sheathed. Nuclear column extends into tip of tail with single spaced nuclei in terminal bulb and subterminal swelling	Lymphatic tissue
<i>Loa loa</i> , west and central Africa	<i>Chrysops</i> flies	Occur in blood. Diurnal periodic. Sheathed. Nuclear column extends into tip of thick blunt tail	Subcutaneous tissue

been infected for long periods. Apart from *Onchocerca volvulus*, where microfilariae are found in skin snips, parasitological diagnosis is best achieved by using stained blood films or concentration techniques applied to peripheral blood. However, very promising and effective serological tests for the detection of circulating filarial antigen have been developed.

### *Onchocerca volvulus*

Onchocerciasis is a filarial disease transmitted to humans by bites from black flies of the genus *Simulium*. It is characterized by subcutaneous nodules, containing adult worms of *O. volvulus*, by skin eruptions due to microfilariae, and by serious eye disease. The condition is only seen in Central Africa and in parts of South America (Table 28.44), especially along the banks of fast flowing rivers, in which the flies breed.

### Clinical features

Adolescents are most commonly affected, but children down to 1 year of age may be afflicted. Signs of disease begin to appear after 4–18 months, and the commonest manifestation is the *Onchocerca* nodule. These subcutaneous fibrous nodules (onchocercomata), each containing one or more adult worms, vary from a few millimeters to about 3 cm in diameter and become fully developed within a year of exposure. In Africa, they tend to occur most commonly in the pelvic region, especially over the hips and on the buttocks, while in Latin America the head is more usually involved. Nodules do not generally give rise to much discomfort, but at times they may be painful, and secondary infection with abscess formation can occur. The number and size of nodules increases with intensity of infection.

Typical skin lesions (onchodermatitis) consist of an intensely itchy, papular dermatitis, with edema in the early stages, progressing to lichenification and atrophy ('lizard skin'). Large numbers of microfilariae are present in the skin, and involvement may be generalized or limited to one area of the body. Transient urticaria is often the only skin manifestation, and indeed the condition may be entirely asymptomatic despite the presence of microfilariae in the skin. General well-being is seldom disturbed.

Ocular lesions (river blindness), due to microfilariae penetrating the eyes, represent the most serious feature of onchocerciasis and are a frequent cause of blindness in endemic areas. They occur especially when the disease is present in the upper half of the body and are more common in South America. Children rarely show advanced ocular lesions,

but hyperemia of the conjunctiva and nummular keratitis may be seen in older children. Any part of the eye can be involved.

### Diagnosis

Diagnosis is best established by demonstrating microfilariae in skin snips and the adult worms on nodule biopsy. Serological tests, including tests for antigen, are also available in onchocerciasis but there may be some cross-reaction with other filarial species (e.g. *Mansonella ozzardi*) in areas where they coexist.<sup>931</sup> Microfilariae are not uncommonly found in urine.

### Treatment

Microfilariae are killed by diethylcarbamazine, but the drug is no longer considered justified for the treatment of onchocerciasis due to the common and often severe adverse reactions that it causes. Ivermectin is now accepted as the treatment of choice for onchocerciasis at a single dose of 150–200 µg/kg for both adults and children.<sup>913,932–934</sup> As it kills only the microfilariae but not the adult worms, treatment is long term and may need to be repeated every 3–6 months for 2–3 years.<sup>890,935,936</sup> It has been found, however, that adding doxycycline (100 mg daily for 6 weeks) to the ivermectin regimen significantly enhances microfilarial suppression by sterilizing female worms through depletion of the symbiotic *Wolbachia* bacteria.<sup>937,938</sup> The use of ivermectin for mass treatment has given hope for the effective control of this disease. Suramin is lethal to the adult worms but it may cause severe adverse reactions. Excision of nodules, especially those near the eyes, is sometimes recommended prior to chemotherapy, because of the danger of ocular involvement. Regular urine tests should be made as the drug is nephrotoxic. Amocazine and albendazole are also being evaluated for efficacy in the treatment of onchocerciasis.<sup>896</sup>

Vector control requires the simultaneous application of control measures (spraying with appropriate insecticides) over whole river systems.

### Loa loa

*Loa loa* is transmitted by flies of the genus *Chrysops*, which are infected by sucking human blood containing microfilariae. These are present in blood during the daytime, thus corresponding with the diurnal biting habits of most *Chrysops*. The disease is endemic in western and central Africa. Adult worms are found migrating through subcutaneous tissues, the male being some 3 cm and the female 6 cm in length. They may remain viable for as long as 30 years.

### Clinical features

Symptoms of loiasis are usually trivial. The most characteristic manifestation is a recurrent, painless, puffy, pink swelling, often referred to as a calabar, or fugitive, swelling. This lesion marks the journey of the adult worm in the subcutis. It develops over a period of 3–4 h and may acquire a diameter of 10 cm or more, before subsiding in a few days. The upper extremities and eyelids are most often involved and on occasions the thin worm may be seen rapidly traversing the bulbar conjunctiva and sometimes accompanied by periorbital edema. The appearance of the calabar swelling is frequently associated with fever and malaise. Eosinophilia is present.

Some patients remain afebrile, no microfilariae being found in the peripheral blood despite intensive investigation.<sup>939</sup>

### Treatment

Diethylcarbamazine is used in the treatment of loiasis but can cause severe adverse reactions in people with microfilarial counts > 2000 mf/ml blood.<sup>940</sup> It is usually recommended that the drug be given in slowly increasing doses.<sup>913</sup>

Day 1: 50 mg (child 1 mg/kg) after food;

Day 2: 50 mg (child 1 mg/kg) 8-hourly;

Day 3: 100 mg (child 1–2 mg/kg) 8-hourly;

Days 4–21: 3 mg/kg 8-hourly.

In afebrile patients, side-effects can be controlled by steroids and/or antihistamines. In patients with large numbers of microfilariae in their blood, meningoencephalitis may result from lysis of dead microfilariae and thus in these patients benefits of treatment must be weighed against the danger of the side-effects. In these people, steroids and antihistamines may not be effective in preventing side-effects.

Ivermectin (200 µg/kg stat repeated every 6–12 months) has been recommended<sup>890</sup> while mebendazole and albendazole have also been tried.<sup>939</sup>

### *Wuchereria bancrofti* and *Brugia malayi*

Infections by *Wuchereria bancrofti*, *Brugia malayi* and *B. timori* (termed 'lymphatic filariasis') occur in the tropics and in some semitropical areas, being transmitted by various species of mosquito. The adult female and male worms (some 85 mm and 40 mm in length respectively) attain maturity in the lymphatic system about 1 year following entry to the body, after which time the nocturnal periodic sheathed microfilariae are demonstrable in peripheral blood between 10 pm and 2 am. Some Pacific strains of *W. bancrofti* are nonperiodic.

### Clinical features

First infection may occur in children but the full clinical picture may take many years to develop. As with other filarial diseases, the early phases may be entirely asymptomatic or associated with florid allergic manifestations. The commonest manifestations of the mature filariae are acute and recurring lymphangitis. The affected lymph node, together with its afferent vessel, usually in the groin, is painful and tender. The lymphatic vessel becomes palpable and cord-like and is associated with a linear red streak in the overlying skin. This stage is often accompanied by pyrexia, malaise, nausea and headache. Dreyer et al<sup>941</sup> believe that acute attacks of lymphatic filariasis can be divided into a number of clearly defined clinical syndromes. The acute attacks, which subside after several days, have a variable periodicity of weeks or months, gradually becoming less severe, often with persistence of residual subcutaneous swelling. Recurrent funiculitis may occur and involvement of intra-abdominal lymph nodes may give rise to the clinical picture of peritonitis. Chylous ascites, chyluria, varicose groin nodes, hydrocele and elephantiasis are classical end results but as they arise from chronicity over many years, emphasis on this aspect is out of place in a pediatric context. Nevertheless, early manifestations of chronic disease may sometimes appear in the late years of childhood.

Work by Hightower et al<sup>942</sup> has suggested that children born to mothers infected with *W. bancrofti* are more susceptible to this infection than those born to uninfected mothers.

**Tropical eosinophilia syndrome.** In some patients, an abnormal response to *W. bancrofti* infection results in a clinical picture which reflects a specific allergic sensitization to filarial antigens, a condition known as tropical pulmonary eosinophilia or tropical eosinophilia syndrome. These patients present with cough, asthma-like symptoms, respiratory distress and eosinophil counts of 3000/mm<sup>3</sup> or greater. X-ray of the lungs usually shows extensive changes. These patients often do not develop filaremia, hence the term 'occult filariasis'.

A similar condition can be caused by infection with *Brugia malayi* and perhaps by infection with nonhuman filariae.

### Diagnosis

The clinical diagnosis of lymphatic filariasis based on symptoms can now be greatly aided by ultrasonography and lymphoscintigraphy.

The recovery of typical sheathed microfilariae in midnight blood slides and occasionally in urine will establish the diagnosis. Concentration techniques may need to be used to recover microfilariae from the blood.

In the case of tropical pulmonary eosinophilia, diagnosis is made clinically and confirmed by serology or rapid response to diethylcarbamazine.<sup>943</sup>

It is worth noting that visitors to endemic areas who contract lymphatic filariasis often do not develop a microfilaremia, which can make parasitological confirmation of the infection impossible. Thus the development of an EIA test (TropBio, Australia) to detect circulating filarial antigen has provided a major breakthrough in the diagnosis of lymphatic filariasis, the test for *W. bancrofti* being highly specific and very sensitive. Antigen-detecting tests, including DNA detection from blood spots, have also been developed for *B. malayi*, show great promise and are very cost-effective.<sup>944–946</sup>

### Treatment

Diethylcarbamazine rapidly removes circulating microfilariae but large doses are required to kill adult worms. The dosage regimen for children utilizes increasing doses as for loiasis.<sup>883,885,913</sup> There is often an acute exacerbation during therapy, for which antihistamines should be given. Ivermectin, which has significantly fewer side-effects than diethylcarbamazine, is also very effective in the treatment of lymphatic filariasis. It kills microfilariae but not adult worms and the single oral dose of 150–200 µg/kg should be repeated at yearly intervals. Albendazole and doxycycline are also mentioned as showing promise.<sup>938</sup>

A single oral dose of ivermectin has been recommended for controlling lymphatic filariasis<sup>934,947</sup> and the use of yearly or 6-monthly doses of ivermectin or the regular use of salt fortified with diethylcarbamazine has proved invaluable in the control of this condition in endemic regions. The control of lymphatic filariasis is a public health problem which is neither easy nor straightforward.<sup>948</sup> Even small areas omitted from a general filariasis vector control program due to, for example, difficult terrain, have the potential to disperse the infection.<sup>949</sup> As Molyneux<sup>950</sup> says: 'environment remains a key determinant in changing patterns of vector-borne infections. Changes are rapid and vectors have the capacity to change equally rapidly, a capacity not matched by health systems'. He believes less time will be spent in future on developing new pesticides for insect vector control, and that the emphasis will be on genetic approaches to make insects less effective vectors.

### *Mansonella perstans* and *Mansonella ozzardi*

*Mansonella perstans* has had many recent changes in its name<sup>951</sup> and is widely distributed in those tropical and subtropical areas which favor the habitat of the vector. The unshathed microfilariae are transmitted by *Culicoides* midges from person to person, and the adult worms develop in the mesentery, perinephric and retroperitoneal tissues where they may survive for many years (Table 28.44).

### Clinical features

This form of filariasis is often held to be harmless, but symptoms can be associated with infection, particularly in people visiting from non-endemic regions. Infection with these helminths may result in lethargy, arthralgia, urticaria and headache. Less frequently calabar-like swellings around the

eye ('bung eye'), and pericardial or pleural effusions occur. Among indigenous inhabitants of endemic areas *M. perstans* is often asymptomatic.

The period from exposure to the appearance of nonperiodic microfilariae in the blood is unknown.

Diethylcarbamazine is ineffective in treatment of mansonellosis,<sup>890,940</sup> but trichlorophone has been used with success. Albendazole (400 mg bd for 30 days), mebendazole (100 mg 12-hourly for 30 days)<sup>913</sup> or a combination of mebendazole and levamisole have all been reported as effective.<sup>940</sup> The judicious use of corticosteroids is valuable in severe cases. Ivermectin (150 µg/kg stat p.o.) is reported to be effective in the treatment of *M. ozzardi* but not *M. perstans*.<sup>890,940</sup>

In rain forest areas of Central Africa, a related species, *M. streptocerca*, infects humans. Microfilariae of this species are unsheathed and have a curled tail with nuclei extending to the tip. The adult and microfilariae of this species are found in skin, and diagnosis is by skin snips as for *Onchocerca*. Symptoms include dermatitis, with macules and papules. Infection is more common in older people than in children.

*M. ozzardi* in South America is a species with many clinical similarities to *M. perstans*. In the past it has been considered a commensal, but studies have suggested that this parasite may also not be as harmless as is often believed (Table 28.44).

### *Dirofilaria immitis*

The dog heartworm is a common filarial nematode infecting dogs in most tropical regions of the world including parts of the USA and northern Australia. It is transmitted by mosquitoes.

Occasional human cases are diagnosed during serological surveys or on biopsy for investigations of pulmonary 'coin' lesions found on X-ray.<sup>897</sup> Cases of pleural effusion, intraocular infection and eosinophilic meningitis are also caused by *D. immitis* in humans. Most cases of dirofilariasis are recorded in adults, but clinical infections are seen at times in children and Hungerford<sup>893</sup> believes that dirofilariasis is much more common in Australia than is believed at present.

As *D. immitis* infection in humans does not usually exhibit a filariemia, diagnosis is usually made on biopsy of a lung lesion or on removal of a worm from the eye. Skin tests or serological tests are unhelpful.

Other species of *Dirofilaria* are also recorded from humans, usually from subcutaneous tissue or from the conjunctival sac.

## CESTODES (TAPEWORMS)

The cestodes are platyhelminths, which are dorso-ventrally flattened, have no gut or body cavity and are hermaphroditic. Adult tapeworms have a characteristic morphology with a scolex armed with suckers and sometimes hooks, an unsegmented neck region and a long segmented strobila.

Life cycles are complex, with the adult tapeworms living in the gastrointestinal tract of the vertebrate definitive hosts and larval stages occurring in a range of vertebrate or invertebrate intermediate host species. Larval forms vary from the free-living, ciliated coracidium larva and worm-like proceroid and plerocercoid (sparganum) larvae of the pseudophyllidean tapeworms (e.g. *Diphyllobothrium latum*) to the cysticercoid, cysticercus (bladderworm) or hydatid larvae of the cyclophyllidean tapeworms.

Humans can become infected with a range of cestode species and mostly harbor the adult tapeworm although human infection with larval cestodes includes sparganosis (*Spirometra* sp.), cysticercosis (*Taenia solium*) and hydatidosis (*Echinococcus granulosus*).

The main cestodes relevant to humans are *Taenia saginata*, *Taenia solium*, *Hymenolepis nana*, *H. diminuta*, *Dipylidium caninum*, *Diphyllobothrium latum*, *Echinococcus granulosus*, *E. multilocularis* and *Inermicapsifer madagascariensis*.

### TAENIASIS

Taeniasis is caused by infection with adult *T. saginata* or *T. solium* (Table 28.45). In both these infections, the adult tapeworm is found in the

Table 28.45 Characteristics of *Taenia saginata* and *Taenia solium*

	<i>Taenia saginata</i>	<i>Taenia solium</i>
Parasite		
Scolex	4 suckers only	Crown of hooklets and 4 suckers
Length	5–20 m	3–15 m
Lateral branches of uterus	15 or more	8–13
Intermediate host	Cattle	Pig, but occasionally man
Final host	Man	Man

intestinal tract of humans – the only definitive host. The intermediate hosts harboring the larval stage (cysticercus) of the tapeworm are cattle in *T. saginata* (the beef tapeworm) and usually pigs in *T. solium* (the pork tapeworm). However, in the case of *T. solium*, in addition to pigs, a wide range of mammals, including humans, can harbor the cysticerci.

It has been suggested that in the Asia-Pacific region, other, but as yet incompletely defined, species of *Taenia* may infect humans.<sup>952,953</sup> One such species found in Indonesia, Taiwan and Korea morphologically resembles *T. saginata* but is acquired from pork and has been named *T. asiatica*.<sup>870,896</sup>

Infection with adult *Taenia* results from ingestion of infected meat and, as such, is not common in very young children.

### *Taenia saginata* (the beef tapeworm)

The beef tapeworm is cosmopolitan, occurring in almost all countries where beef is eaten. It is especially common where local eating habits favor the consumption of raw or undercooked beef. The cysticerci in the beef can even survive salting and a moderate degree of drying.

The adult worm is harbored in the human intestine, attached by its scolex to the mucosa of the small intestine. It may reach 20–25 m in length and gravid proglottids (or segments), their uteri packed with eggs, break from the strobila singly or in chains of 2–5 segments, and either migrate actively out of the anus or pass out passively with the feces.

These proglottids crawl about on the ground releasing eggs, which are also liberated when the proglottid dies and disintegrates on pasture land. Eggs lying on the grass are ingested by grazing cattle (Fig. 28.71). The oncosphere (hexacanth) larva is released in the intestine, penetrates the intestinal wall using its six hooklets and is carried via the bloodstream to the heart and voluntary muscles, especially the tongue, shoulder

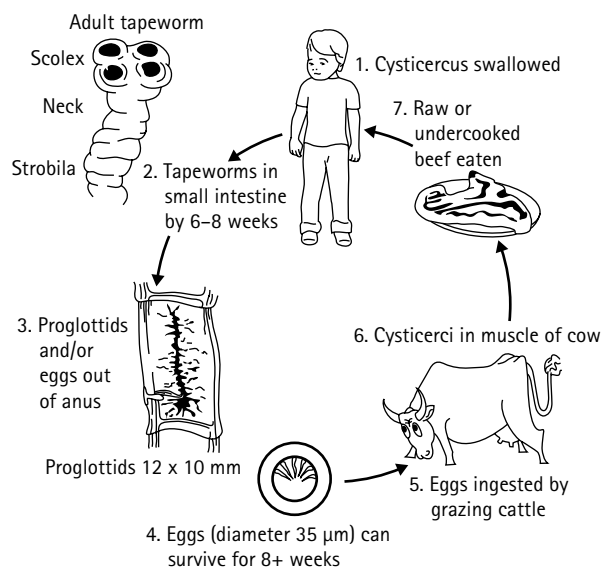

Fig. 28.71 Life cycle of *Taenia saginata*.

and masseter muscles. Here it loses its hooklets, develops an inverted scolex with suckers but no hooks and changes into a bladderworm (or cysticercus) larva, termed *Cysticercus bovis*, over about 3 months. These cysticerci are about 8 × 5 mm in size and meat infected with them is commonly termed 'measly' owing to its spotted appearance.

When ingested, the cysticercus evaginates the scolex and elongates into the adult stage. Humans eating such 'measly' beef raw or undercooked thus become infected with adult tapeworm. Gravid segments are shed about 3 months after infection.

Epidemics of 'measles' in cattle have not uncommonly resulted from cattle grazed on pastures fertilized with untreated effluent from sewage outlets. Such cattle become infectious about 3 months after ingestion of eggs.

### Clinical features

In most cases infection with *T. saginata* is quite symptomless, the only feature being the intermittent passing of segments. In 5–50% of cases, eosinophilia may occur while abdominal pain, weight loss, malaise, an increase or decrease in appetite and such allergic features as urticaria and pruritus ani may be seen.

Adult tapeworms absorb digested food through their cuticles and thus they compete for food with the host and in this process food deprivation and digestive upset may occur.

Rarely, intestinal obstruction results and at times proglottids wander into the appendix and, impacting there, may cause obstructive appendicitis.

### Diagnosis

Diagnosis is generally made when proglottids are seen in the stool. These can readily be identified by pressing them between two glass microslides and counting the number of uterine branches on each side of the central stem. In *T. saginata*, there are usually 15 or more primary uterine branches on each side.

In the cases where proglottids cannot be found, eggs (Fig. 28.72) may be detected in the feces or on anal tapes as used for *Enterobius*, a process which is more effective for recovery of *T. saginata* eggs than stool examination. Eggs of *T. saginata* and *T. solium* are identical.

### Treatment

The treatment of choice for *T. saginata* infection is praziquantel as a single oral dose of 10–20 mg/kg.<sup>883,884</sup> Niclosamide is also effective, being usually given without purgation at a dose of 1 g (11–34 kg) or 1.5 g (34 kg and over), which should be chewed before swallowing.<sup>883</sup> The worm is passed in a partially digested state. Treatment can be followed, if desired, by a saline purge after 2 h.

Treated patients should be re-checked 3 months after treatment to assess cure. With modern anthelmintics it is not feasible to examine post-treatment stools for the scolex.

Prevention of *T. saginata* infection depends upon avoidance of consumption of raw or undercooked beef and hygienic disposal of human feces to prevent infection of cattle.<sup>870</sup> Freezing of meat (–10°C for 10 days) is also reported to be effective in killing cysticerci.

Fig. 28.72 Complete egg of *Taenia* sp., the embryophore being surrounded by the remains of the vitelline cell. (b) Other egg has lost all traces of the vitelline cell and consists only of the oncosphere larva surrounded by its thick, striated embryophore (approx. × 600).

### *Taenia solium* (the pork tapeworm)

*T. solium* is widely distributed, but less so than the beef tapeworm. It is common, however, in Africa, Asia, Latin America and parts of eastern Europe.

The life cycle of *T. solium* (Fig. 28.73) is similar to that of *T. saginata* but with some very important differences. In both species humans comprise the only definitive host and may harbor one or more tapeworms. In *T. solium* infections humans become infected with the adult tapeworm after eating raw or undercooked 'measly' pork containing cysticerci. The range of intermediate hosts of *T. solium* is wider than that of *T. saginata* and, besides pigs, can include the domestic dog. In fact, in areas where dogs form a significant part of human diet, they may serve as an important source of human *T. solium* infection. Humans too can become infected with cysticerci of *T. solium* (known as *Cysticercus cellulosae*) after ingestion of eggs, a condition termed cysticercosis.

The adult *T. solium* is, on average, a little shorter than *T. saginata*, reaching about 1.5 m in length. The scolex has both suckers and a double row of hooks. The cysticerci of both species are essentially similar, but again the invaginated scolex of *C. cellulosae* has hooks which are absent in *C. bovis*.

### Clinical features

**Taeniasis solium.** Infection with the adult *T. solium* is much the same as with the adult *T. saginata* except that proglottids of the pork tapeworm are less mobile than those of the beef tapeworm and so such features as appendiceal blockage are more rare. Most cases are asymptomatic, but diarrhea and constipation have been recorded and a moderate eosinophilia may develop.

**Cysticercosis.** The greatest danger in infection with *T. solium* is the danger to others of infection with eggs via food or water (heteroinfection) and the danger to the patients themselves of autoinfection by external means (hand-to-mouth transfer of eggs) or internal means (vomiting up and re-swallowing of proglottids).

The clinical effects of cysticercosis are essentially dependent upon the number and sites of the cysticerci. Cysticerci can develop almost anywhere in the body: beneath the skin (subcutaneous cysticercosis); in the myocardium; in the muscles; within the eye or in the brain (cerebral cysticercosis or neurocysticercosis). If within the ventricles of the brain the cysticerci can become greatly enlarged resulting in a racemose cyst.

Usually cysticerci do not cause clinical symptoms until they die, swell and calcify – a process which occurs about 3 years or longer after infection. Whether or not they cause symptoms is also dependent upon their site. In the muscles, heart or beneath the skin they are relatively benign but within the eye they can cause retinal detachment, loss of vision and even blindness. If sited in the brain they may result

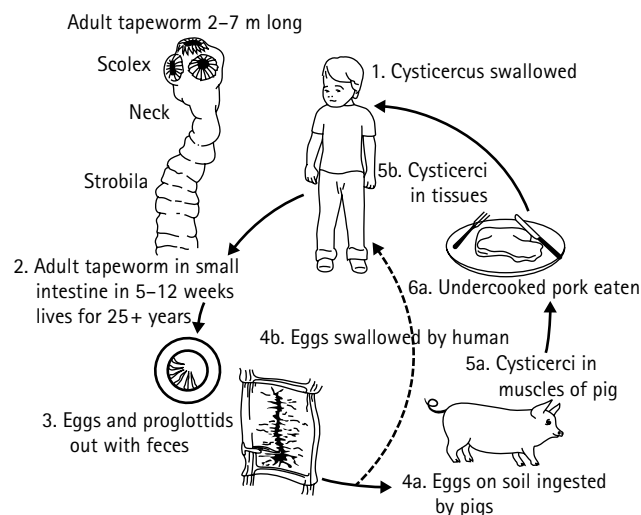

Fig. 28.73 Life cycle of *Taenia solium*.

in neurological disorders, personality changes or epileptic convulsions. Neurocysticercosis is a common cause of epilepsy among Africans in southern Africa and, although more common in adults, it has even been recorded in children as young as 3 years of age.<sup>954</sup> Death can follow hydrocephalus resulting from blockage of the ventricular spaces.

### Diagnosis

**Taeniasis solium.** Diagnosis of infection with adult *T. solium* is established by the finding of eggs (indistinguishable from those of *T. saginata*) in feces (Fig. 28.72) or by the passing of typical gravid proglottids. The proglottids of *T. solium* have fewer than 13 lateral uterine branches on each side and so can be differentiated from those of *T. saginata* although some degree of overlap may occur. (Note: gloves must be worn when examining proglottids for counting of the uterine branches, as eggs of *T. solium* are infective to humans.)

**Cysticercosis.** Cysticercosis can be diagnosed by palpation and biopsy of cysticerci if accessible and their microscopic examination after squashing between two glass microslides or after histological sectioning.

In patients in whom cysticercosis is clinically suspected confirmation can sometimes be obtained by radiology, where calcified cysticerci are visible as millet seed-shaped shadows in the muscles or small spotted areas on skull X-ray (Fig. 28.74a,b). X-rays are also useful in differentiating cerebral cysticercosis from CNS infection due to *Angiostrongylus*, *Gnathostoma* and *Paragonimus*.<sup>955</sup>

Eosinophils can at times be found in the CSF of patients with cerebral cysticercosis. About 25% of patients with cerebral cysticercosis will be found to harbor adult *T. solium* in their intestines or have a history of such infection.

Fig. 28.74 (a) Cerebral cysticercosis. (b) Calcified cysticerci visible in the muscles in X-ray of pelvis.

Serological tests for blood or CSF are available for the diagnosis of cysticercosis.<sup>955-957</sup> In addition, tests have been developed to detect cysticercal antigen in CSE.

CT scans are of great value, not only for the diagnosis of cerebral cysticercosis, but also for an assessment of the length of infection and for post-treatment progress evaluation.<sup>955,957,958</sup>

### Treatment

Treatment for *T. solium* is similar to that for *T. saginata*, with praziquantel or niclosamide being the drugs of choice.<sup>913,959</sup> Mepacrine, while effective, tends to cause nausea and vomiting and should thus be avoided because of the danger of regurgitation of proglottids into the stomach and re-swallowing them.

**Cysticercosis.** Albendazole (5 mg/kg 8-hourly for 8–15 days) is probably the treatment of choice for cysticercosis.<sup>890</sup> Although clinical studies have shown that praziquantel at a dose of 25–50 mg/kg/d in three divided doses for 14 days may be effective for the treatment of cysticercosis,<sup>883,885,886,913,960</sup> it is frequently associated with side-effects in neurocysticercosis and its use is not universally accepted in this situation.<sup>883,961</sup>

A number of authors have argued that the risks of cysticidal therapy in neurocysticercosis sometimes outweigh the benefits, and should be considered for each individual patient.<sup>890,913,962</sup> The simultaneous administration of steroids may help reduce inflammatory complications which can follow the death of the cysticerci after anthelmintic treatment.<sup>896</sup>

Surgical removal of cysticerci is seldom feasible, especially if the cysticerci are numerous and deep seated.

Anticonvulsants to control fits, steroids to control raised intracranial pressure and occasionally surgery to control hydrocephalus may be required for controlling the fits in neurocysticercosis.

Prevention of *T. solium* infection and cysticercosis is essentially the same as for *T. saginata*. Cysticerci can be destroyed during cooking by heating the meat to 50 °C.

### Hymenolepis spp.

Two species of this genus of tapeworm infect humans, *Hymenolepis nana* (the dwarf tapeworm) and *H. diminuta* (the rat tapeworm). These are small tapeworms, reaching only 40 mm in length for *H. nana* and 40 cm in length for *H. diminuta*.

#### Hymenolepis nana

*H. nana* is harbored in the small intestine of the human (or sometimes rodent) host and the gravid proglottids disintegrate in the gut so that eggs pass out in the feces. When an egg is ingested by another person, it releases an oncosphere into the small intestine, and this burrows into a villus, forming a cysticercoid. It develops here before leaving the villus after about 14 days to grow into an adult tapeworm in the intestinal lumen (Fig. 28.75).

Because of its direct person-to-person mode of transmission, *H. nana* is a common tapeworm in resource limited countries and tends to be more common in children than in adults. In a survey in Zimbabwe, 18.7% of children were infected with *H. nana*, but only 3.8% of adults.<sup>963</sup>

Diagnosis is based on detecting characteristic *H. nana* eggs (Fig. 28.75). The treatment of choice is praziquantel or niclosamide as for taeniasis.<sup>886,913</sup> Praziquantel at a dose of 25 mg/kg has a cure rate of 98.5% and minimal side-effects.<sup>964</sup>

#### Hymenolepis diminuta

The rat tapeworm, *H. diminuta*, is common in many parts of the world in rats and mice. Its intermediate hosts are fleas and flour beetles. Children may become infected when they accidentally swallow the intermediate host – often with insect-infested meal or flour.

Diagnosis of *H. diminuta* infection is based on finding the eggs in feces. These eggs differ from those of *H. nana* in being larger, rounder, lemon yellow in color, and having a striated shell and no polar filaments.

Treatment is as for *H. nana*.

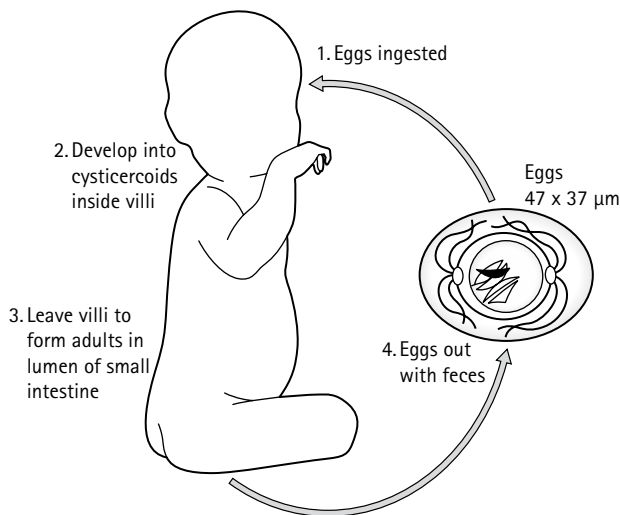

Fig. 28.75 Life cycle of *Hymenolepis nana*. Egg inset (approx.  $\times 600$ ).

Neither *H. nana* nor *H. diminuta* causes serious clinical effects, but abdominal pain, diarrhea, loss of appetite and eosinophilia may occur when loads are heavy. One problem with *H. nana* is a build-up of worm load as a result of external autoinfection by ingestion of eggs.

***Dipylidium caninum***

This tapeworm is worldwide, commonly infecting both dogs and cats. The intermediate hosts are fleas, such as the common dog and cat fleas (Fig. 28.76a), which contain the cysticercoids, and infection of the final host occurs when the flea is swallowed. Children can become infected when they accidentally swallow a flea or when they are licked on the mouth by a dog which has been ‘fleaing’ itself and has cysticercoids on the tongue.

Fig. 28.76 (a) *Ctenocephalides* sp. – dog flea intermediate host of *Dipylidium caninum* (approx.  $\times 50$ ). (b) Egg capsule of *Dipylidium caninum* (approx.  $\times 600$ ). (c) Stained gravid proglottid of *Dipylidium caninum*. Note characteristic double set of reproductive organs and twin genital pores (approx.  $\times 20$ ).

*Dipylidium caninum* is a relatively small tapeworm (20 cm long) and usually causes little discomfort, although at times diarrhea, fever, restlessness and even convulsions have been recorded.

Diagnosis is made when actively motile proglottids with two genital pores (Fig. 28.76c) are found by the mother on nappies or when typical egg capsules (Fig. 28.76b) are found in the feces on microscopic examination.

Niclosamide is reported to be effective in treatment although in some cases repeated treatments with this drug have failed.<sup>965</sup> The recommended drug of choice is praziquantel at a single dose of 5–10 mg/kg.<sup>965</sup>

***Diphyllobothrium latum***

The adult fish tapeworm can reach 20 m or more in length. It is a common tapeworm of a variety of fish-eating mammals, including dogs and cats, in Scandinavia, the Baltic, South America, the Great Lakes of North America, parts of the Middle and Far East and Indonesia, while occasional cases are encountered in other parts such as Labrador and Australia.<sup>896,959</sup>

The scolex of this species has sucking grooves, and eggs are shed from the gravid proglottids to pass out with the feces.

When the eggs fall into water, a ciliated coracidium larva develops and is released through the operculum into the water. This is ingested by the microscopic crustacean, *Cyclops*, in which a proceroid larva is formed. When the *Cyclops* is eaten by a fish, the proceroid changes into a plerocercoid (sparganum) larva in the muscles of the fish. Finally the life cycle is completed when the fish is eaten by the mammalian definitive host (Fig. 28.77), which may include humans.

Clinical effects of heavy worm loads include diarrhea, abdominal pain, generalized weakness<sup>959</sup> and occasionally intestinal obstruction. *D. latum* is also recorded as causing a megaloblastic (macrocytic) anemia in susceptible patients who have a genetic predisposition and who are on a diet deficient in vitamin B<sub>12</sub>, by competition with the host for this vitamin – especially when the worm is attached high up in the small intestine. Eosinophilia is not usually a feature of infection.

Diagnosis is based on finding typical operculate eggs in the feces (Fig. 28.78). Proglottids in the feces can be recognized by their centrally situated uterus and genital pore.

The recommended treatment is praziquantel 2.5–10 mg/kg orally as a single dose for people > 4 years old. Niclosamide 1 g orally as a single dose for children 11–3 kg is an alternative.<sup>890,913</sup> Whichever anthelmintic is used, concurrent vitamin B<sub>12</sub> should also be given if the patient is anemic.

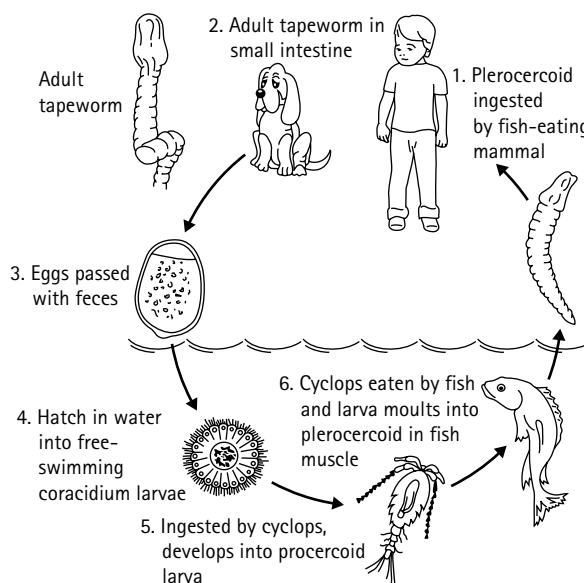

Fig. 28.77 Life cycle of *Diphyllobothrium latum*.

Fig. 28.78 Operculate egg of *Diphyllobothrium latum* (approx.  $\times 600$ ).

A common source of human infection is eating raw or smoked fish, so cooking fish is an important preventive measure.<sup>870</sup> Freezing fish ( $-10^{\circ}\text{C}$  for 15 min) is also effective in killing plerocercoids.

The plerocercoids of certain species belonging to the related genus, *Spirometra*, the adults of which inhabit the intestines of dogs, can infect humans and cause a condition called sparganosis. These elongated plerocercoid (sparganum) larvae can infect humans after ingestion of infected frogs or *Cyclops* with water (East Africa, North America) or by application of infected frog flesh to skin ulcers or eye wounds as poultices. Plerocercoids in the frog muscle migrate into the human flesh where they settle – a condition occurring in South East Asia.

These spargana can encyst in any tissues. Perhaps the commonest manifestations are nodules about 2 cm in size under the skin with painful surrounding edema. They can be detected radiologically as elongated shadows and can usually be removed surgically if accessible. One species of sparganum can bud and proliferate so spreading through the tissues.

### ECHINOCOCCOSIS (HYDATID DISEASE)

Echinococcosis (hydatid disease) in humans is caused by the larval stage of *Echinococcus granulosus* and to a much lesser extent by *E. multilocularis*, *E. oligarthrus* or *E. vogeli*.

The life cycle of *E. granulosus* is shown in Figure 28.79. The small adult tapeworms (Fig. 28.80a) live in the intestine of the dog and related canids such as dingoes in Australia. After ingestion of the eggs by the intermediate hosts, which are usually sheep or sometimes cattle and in

(a)

(b)

(c)

Fig. 28.80 (a) Adult *E. granulosus*. Note scolex and proglottids (approx.  $\times 12$ ). (b) Hydatid cyst in human liver. (c) Histological appearance of the wall of a pulmonary hydatid cyst.

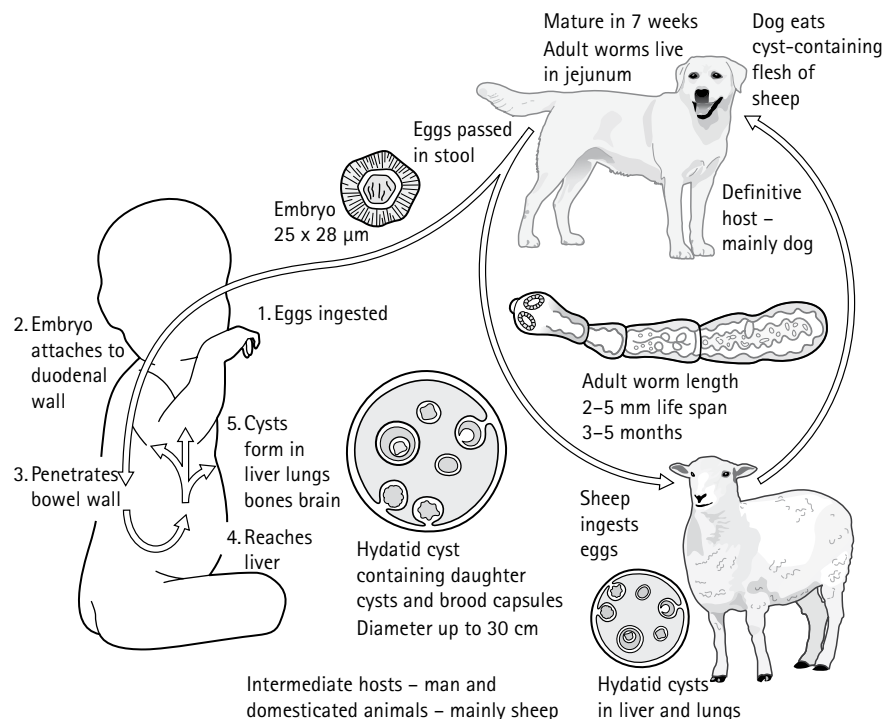

Fig. 28.79 Character and life cycle of *Echinococcus granulosus*.

Australia wallabies or other marsupials, the larval tapeworms develop into hydatid cysts in the viscera. Humans can also become infected when they ingest the tapeworm eggs, and children are particularly at risk because of their often intimate contact with dogs. They may pick up eggs contaminating the animal's coat or from the dog's tongue after being licked.

The infection is particularly common in rural sheep and cattle farming areas, especially where dogs are used for herding. It is widespread throughout Africa, Australasia, Asia, the Near East and South America and is also found in the Mediterranean, the USA and the UK.<sup>871,966</sup> *E. multilocularis* is widespread in the northern hemisphere, with human cases being common in parts of the former USSR, China, northern Japan, Alaska and central Europe, including possible spread into eastern Germany.<sup>966-968</sup> Cycles involving wild animals are also found in certain parts of the world.

In hydatidosis due to *E. multilocularis*, wolves, coyotes and foxes are the definitive hosts, and small field rodents serve as the natural intermediate hosts. Urban cycles involving the domestic cat and house mouse have been demonstrated.

The incidence of echinococcosis is decreasing in some areas owing to regular anthelmintic treatment of dogs and strict controls prohibiting the feeding of offal to dogs,<sup>969</sup> and global control has been mooted.<sup>970</sup>

### Clinical features

Because development of cysts is slow, an infection acquired in childhood may only become clinically evident in adulthood, but manifestations of the disease in children are by no means uncommon.

The most frequent sites for cysts are the liver (Fig. 28.80b) and lungs (Fig. 28.80c). Spleen, peritoneum, kidneys, bone, orbital fossae, brain, heart and reproductive organs may also be invaded. In children, lung disease is reported to be the commonest form. Cysts sited in parenchymatous organs are large unilocular, well-circumscribed, fluid-filled structures in *E. granulosus* infections.

In bone, the parasite ramifies along bony canals, eroding bone and later involving the medullary cavity to form a large osseous cyst, which often results in spontaneous fracture. The much rarer *E. multilocularis* infection may produce complex, multilocular alveolar cysts with a gelatinous matrix and this alveolar hydatid disease has a 93% mortality within 10 years of diagnosis.<sup>970</sup>

Many cases of hydatid disease are silent. When symptoms occur they are usually those of a slow-growing tumor, with pressure on, or blockage to, the affected organ. Thus, recurrent pyrexia, paroxysmal cough, chest pain, hemoptysis and even expectoration of cyst fluid and membrane (should rupture occur into a bronchus) may occur as manifestations of pulmonary hydatidosis. Abdominal pain, vomiting, hepatomegaly and obstructive jaundice may indicate liver involvement. Intracranial localization can produce symptoms and signs indistinguishable from those of a tumor. Orbital cysts produce proptosis.

Sensitivity to cyst contents, resulting from slow leak of fluid, may develop with resulting allergic symptoms, notably urticaria. Severe anaphylaxis and even death can follow rupture of a cyst, while secondary metastatic cysts may develop in other parts of the body following such rupture.

### Diagnosis

Diagnosis depends initially upon clinical awareness. A moderate eosinophilia is almost invariably present in childhood cases, except during febrile illnesses.

Often an X-ray provides the first indication of hydatid disease, especially in thoracic cases (Fig. 28.81). Ultrasound or CT scanning may be required to demonstrate the cystic nature of the lesion.<sup>957</sup> Serological tests may be helpful in confirming diagnosis. The historic Casoni skin test is no longer used because better serological tests are available, including the indirect hemagglutination test, a hydatid ELISA test and the improved immunoelectrophoresis, Arc 5 test and the double diffusion Arc 5 test.

Fig. 28.81 Hydatid cysts in lung. Noncalcified cyst in right lung. Cyst in left lung has ruptured into a bronchus and contains fluid and air.

Pulmonary hydatids appear less serologically active than cysts in other parts of the body. After surgical removal of hydatid cysts, antibodies may be detectable in low titers for a while, but sooner or later disappear completely.

At times a cyst in the lung may rupture and diagnosis can then be made by finding hydatid sand or hooklets in the sputum. The latter are easily detected by using a standard Ziehl-Neelsen or auramine stain with UV microscopy, as they are intensely acid fast.

If hydatid cysts are suspected, diagnostic aspiration must *not* be attempted because of the danger of anaphylaxis and metastatic spread.

If children vomit what appear to be hydatid cysts, care should be taken to confirm their nature microscopically by the presence or absence of a germinal membrane (Fig. 28.80c), as gel cysts, closely resembling small hydatids, can easily mislead the unwary. These gel cysts may be vomited, by children up to 2 years, after ingestion of commercial fruit gels containing carrageenan.

### Treatment

Treatment is surgical, if cysts are accessible, but due precautions must be observed to prevent release of hydatid fluid and to sterilize cysts prior to removal, using a scolical agent. Shorey et al<sup>890</sup> have summarized an approach to the treatment of uncomplicated hepatic hydatids using puncture; aspiration of cyst contents; introduction of a scolical agent such as alcohol or hypertonic saline; re-aspiration of the solution – termed PAIR therapy.

Results of chemotherapy for hydatid cysts using mebendazole have been disappointing, but albendazole can be used as an adjunct to surgery or for the treatment of inoperable hydatids at a dose of 400 mg bd for 28 days, repeated as necessary or as 15 mg/kg/d in 2 doses (max 800 mg) for 28 days and repeated as necessary.<sup>913,965</sup> Albendazole can also be used in the treatment of infection with *E. multilocularis*, but treatment of multilocular hydatidosis remains largely surgical drainage.<sup>958</sup>

### Prevention

While highly successful control programs have resulted in decreases in the prevalence of hydatid disease in Tasmania and New Zealand, elsewhere the disease remains common and may even be spreading.<sup>871,966,970</sup>

Dogs should not be allowed access to offal, to limit canine infection, and their regular treatment with an effective teniafuge such as praziquantel is indicated. In endemic areas this de-worming should be carried out every 2 months.

### ANOPELOCEPHALID TAPEWORMS

This group of cestodes includes *I. madagascariensis*, *Raillietina* spp. (tapeworms of rodents with various arthropod intermediate hosts probably

involved) and *Bertiella studeri* (a monkey cestode). Human infection with *I. madagascariensis* is particularly common in southern Africa but it has been sporadically reported also from a number of other tropical and subtropical areas. Outside Africa, the parasite seems to have dispensed with a need for a rodent reservoir.

These cestodes may reach 42 cm in length and their small, actively motile proglottids are shed in the stool and have the appearance of rice grains; they contain characteristic parenchymatous egg capsules.

*I. madagascariensis* most frequently involves children between the ages of 1 and 5 years, and while the infection is usually asymptomatic, anorexia, asthenia, anemia and abdominal pain have occasionally been attributed to it. It has been found to be the most common tapeworm affecting white children in Zimbabwe and more cases in African children are coming to light as awareness increases.<sup>971,972</sup>

Niclosamide is the treatment of choice for *I. madagascariensis*, one tablet (0.5 g) repeated in 1 h, while niclosamide or praziquantel is recommended for *Bertiella studeri*.<sup>972</sup>

## TREMATODES (FLUKES)

Trematodes are parasitic helminths belonging to the class Platyhelminthes (flat worms). Trematodes are dorsoventrally flattened worms which have a gut, no body cavity and possess an oral and a ventral sucker. Most are hermaphrodite, except the schistosomes. The flukes have a complex life cycle involving various species of aquatic snail as intermediate hosts. Trematodes infecting humans include blood flukes (*Schistosoma*), liver flukes (*Fasciola*, *Clonorchis*, *Opisthorchis*), intestinal flukes (*Fasciolopsis*, *Heterophyes*, *Metagonimus*) and lung flukes (*Paragonimus*).

## BLOOD FLUKE INFECTION (SCHISTOSOMIASIS OR BILHARZIASIS)

Schistosomiasis has been increasing as a hazard to humans through the construction of dams and the movement of human populations.

Adult blood flukes live in the veins of the final host. There are three main species which infect humans: *Schistosoma japonicum*, *S. mansoni* and *S. haematobium*<sup>973</sup> (Table 28.46). *S. japonicum* is a zoonotic species which frequents the superior mesenteric veins of humans and causes a more virulent and rapidly progressive illness than the other species, involving mainly the small and large intestine and liver. Adult *S. mansoni* worms live in the inferior mesenteric veins with resultant damage to the colon and liver while *S. haematobium* is found in the veins of the vesical plexus of humans, the disease thus predominantly affecting the urinary tract.

Other blood flukes less commonly recorded in humans include *S. intercalatum* (Central and West Africa), *S. mekongi* (Viet Nam), *S. malayensis* (Malaysia), *S. bovis* (in North Africa and Iraq) and *S. matthei* (in southern Africa). The latter two are zoonotic species of cattle and sheep.

The life cycle of the human blood flukes is shown in Figure 28.82.

## Pathogenesis and clinical features

Humans are usually infected by direct penetration of the cercariae through intact skin. The pathological changes in schistosomiasis are produced by cercariae, schistosomulae, adult worms and eggs – by their physical presence, by virtue of metabolic products or from the body's immune response to the infection. The severity of the disease depends primarily upon the number of parasites that can gain entry to the body and mature.

Despite the wealth of knowledge that has accumulated regarding the pathophysiology of schistosomiasis, the extent of ill health and mortality caused by this disease is still debatable.<sup>974</sup>

While large sections of a population may harbor the parasites, many individuals come to terms with the disease and suffer virtually no morbidity, owing to an interplay of factors such as immunological tolerance, worm load and rate of reinfection. The role of protective immunity in schistosomiasis continues to be a subject of debate.<sup>975</sup> Increased prevalence and intensity of infection in childhood lend credence at least to

Table 28.46 Geographical distribution of schistosomiasis (After Warren Et Mahmoud 1975<sup>973</sup>)

Species	Distribution

<sup>2</sup>Species known as *S. mekongi*.

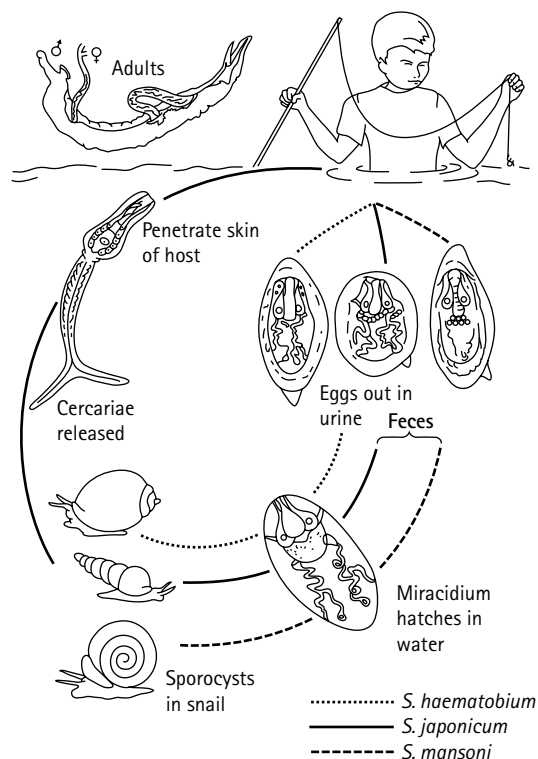

Fig. 28.82 Life cycle of schistosomes.

some protective immunity playing a part.<sup>976</sup> The immunity involved in schistosomiasis is complex,<sup>975</sup> being described as concomitant immunity, whereby the adult worms are not affected by the host's immune response to the infection, but newly invading cercariae are destroyed.<sup>977-980</sup>

The later stages of schistosomiasis generally take many years to develop so that the spectrum of clinical disease in children is narrowed. Nevertheless, such late manifestations as portal hypertension, calcification of the bladder and even vesical carcinoma are by no means rare in adolescents living in hyperendemic areas. A further difference in the disease as it affects children compared with adults is related to the caliber of blood vessels. Because of the smaller and more tenuous venous plexuses and collaterals, schistosomes are less able to migrate to sites far removed from their normal habitat in children than in older persons. The relative lack of immunity in young patients renders them more liable to severe systemic disturbance during the early stages of the disease. Determinants of infection in human communities are varied and involved.<sup>981</sup>

Clinical features can be related to the phase of parasitic invasion, and symptomatology is generally, but not always, proportionate to worm load. The pathogenesis of schistosomiasis is complex but it is essentially an immunological disease.<sup>982-985</sup>

### Penetration of cercariae

At the time of penetration, within a few hours to a few days of exposure, a dermatitis termed swimmer's, or Kabure, itch may develop and last for 2-3 days. The condition is more common in non-indigenous inhabitants. It can also be caused by avian or mammalian schistosomes in countries where human schistosomiasis is unknown. For example it is quite common in Australia where it is sometimes termed 'pelican itch' and in the USA where it is known as 'seabather's eruption'. These latter cercariae, however, die while attempting to penetrate the skin. A prickly sensation is followed by intense itching and an urticarial, papular or occasionally vesicular rash appears, lasting from a few hours to several days.

### Migratory/toxic stage: the Katayama syndrome

Having passed through the skin, the cercariae lose their tails and the resulting schistosomulae enter the lymphatics, pass to the veins and

travel to the heart and hence to the lungs to circulate freely in the systemic circulation. Many die, but those that gain access to the portal system reach the liver where they mature into adult male and female worms. Rarely, worms mature in other ectopic sites such as veins of the brain and spinal cord. Coupling takes place in the liver and the male transports the female against the flow of blood to their sites of predilection where egg laying begins. The prepatent period in schistosomiasis (i.e. from infection to egg laying) is normally about 5-9 weeks.

During the migratory stage of the life cycle with a crescendo just prior to egg laying, the patient may develop an illness known as the Katayama syndrome due to antigenic challenge by the parasitic metabolites in the non-immune host. Malaise, pyrexia, liver tenderness and splenomegaly occur. Eosinophilia is constant. Urticaria, joint and muscle pains, cough, abdominal discomfort and diarrhea may also occur. Encephalopathy, myocarditis and anaphylactoid purpura are reported complications.<sup>896</sup>

Katayama syndrome is most common in *S. japonicum* infections, but can also occur when a previously uninfected individual is exposed to a heavy invasion by *S. mansoni* cercariae.

### Early egg laying stage

Many eggs laid by female worms in the submucosal venules of the intestine or bladder pass through the tissues and are discharged in the feces (*S. japonicum* and *S. mansoni*) or urine (*S. haematobium*). This early egg laying stage may be associated with dysenteric symptoms or with dysuria, frequency and terminal hematuria.

### Late egg laying stage – pathology of chronic schistosomiasis

Initially eggs pass through the tissues relatively easily but as infection progresses, marked tissue reaction occurs, eggs can no longer pass through the tissues so readily, and many are swept back by the flow of blood to be deposited elsewhere.

The morbidity of chronic schistosomiasis is mainly related to the presence of eggs,<sup>985</sup> which initially stimulate a granulomatous reaction characterized by a pseudotubercle, rich in eosinophils. This is followed by degeneration and calcification of the eggs with much reactive fibrosis. The principal pathological effects are as follows.

**Genitourinary system.** *S. haematobium* is the principal cause. The early bladder lesions usually occur on the trigone where deposition of phosphates round the egg deposits imparts a velvety appearance termed 'sandy patches'. Subsequent mucosal proliferation may produce multiple papillomata before ulceration, calcification (Fig. 28.83) and fibrosis lead to diminished bladder capacity. A similar process may involve the ureters, especially at their lower ends, leading to ureteric stricture and consequent hydronephrosis. This complication can also occur from vesical reflux

Fig. 28.83 X-ray showing bladder calcification due to schistosomiasis in a 10-year-old girl.

in the absence of overt ureteric involvement. Vesical or ureteric calculi may occur. An important long term complication is the predisposition of the bladder affected by schistosomiasis to develop carcinoma, usually of squamous cell type. The pathogenesis of bladder carcinoma in *S. haematobium* infection is complex and has still not been fully elucidated. While most common in adults, it is recognized to occur in adolescents. Genital lesions are usually diagnosed after puberty. These include epididymo-orchitis (often with associated secondary hydrocele), salpingo-oophoritis and chronic cervicitis. Large schistosomal granulomata (bilharziomas) consisting of masses of eggs enveloped in granulation tissue may involve the skin of the perineum and vulva. The lesions have a warty papillomatous appearance and when situated at the urethral meatus such a lesion is indistinguishable from a caruncle. Cutaneous schistosomiasis may rarely involve other parts of the body, and bilharzial granuloma of the conjunctiva has even been described in children.

An extended bacteremia with *Salmonella typhi* or *S. paratyphi* can occur, including a prolonged urinary carrier state, in concurrent *S. haematobium* infections.

Bacteriuria is generally considered to be more common in patients with *S. haematobium* than in uninfected controls.

**Intestinal tract.** Involvement of small bowel is usually only seen in *S. japonicum* infection but schistosomiasis of the colon may be due to both *S. japonicum* and *S. mansoni*. Eggs of *S. haematobium* may also be encountered in rectal snips taken from the lower part of the rectum. Mucosal involvement of the bowel gives rise to a similar appearance to that seen in the bladder with a velvety roughening of the mucosa. This may be associated with dysentery in the early egg laying phase of the disease, especially with *S. japonicum* infection. Gross lesions of the bowel are rare, but on occasions papillomata, granulomata, ulcers, stricture and fistulae occur. The appendix is frequently involved and signs of chronic appendicitis are common, although acute obstructive appendicitis consequent upon fibrosis is a rare complication.

**Liver.** Hepatic fibrosis may result from the presence of eggs of *S. mansoni* or *S. japonicum* with formation of granulomata and healing by fibrosis leading to thick tracts of periportal fibrous tissue traversing the liver in different directions. This 'pipe stem' fibrosis (Symmers' liver) gives the surface of the liver an irregular bosselated contour due to tethering of the capsule. In the later stage, eggs are scanty and may even be absent from biopsy material, in which the essential features are of preserved liver architecture associated with gross thickening of the portal tracts by collagenized bands of fibrous tissue. Kupffer cells usually contain schistosomal pigment. Liver involvement can lead to portal hypertension with ascites and splenomegaly, which is occasionally massive ('Egyptian splenomegaly'). Anemia is frequent and may be due to chronic hemorrhage from varices or to associated 'hypersplenism'. There is usually only mild impairment of liver function and thus the results of portal systemic shunting procedures usually give good results in selected cases. Splenectomy combined with lienorenal anastomosis is a helpful procedure if there is associated hypersplenism.

A relationship has been postulated between schistosome infection and carcinoma of the liver.

**Cardiopulmonary systems.** Lung involvement is usually the result of pulmonary embolization by eggs of *S. haematobium*. Though generally rare, it is reported with some frequency from Egypt. Two forms of lung disease occur:

1. a bronchopulmonary form, characterized by parenchymal egg granulomata: chronic bronchitis and bronchiectasis may result;
2. a cardiovascular form, due to occlusion of pulmonary arterioles by obliterative endarteritis, resulting in Ayerza's syndrome with cor pulmonale.

**Nervous system.** Eggs may lodge in any part of the CNS, generally seeded there by gravid females ectopically situated in nearby veins. Migrating schistosomes may also be arrested in the nervous system if treatment is administered during the early migratory phase of the disease. However, neurological complications are unusual in schistosomiasis, cerebral involvement being best known with *S. japonicum* and spinal cord lesions with *S. mansoni* and *S. haematobium*.

Neuroschistosomiasis may well be more common than is currently recognized and is probably underdiagnosed according to Hughes and Biggs.<sup>957</sup>

It has been claimed that school performance can be adversely affected by chronic schistosomiasis.

In patients infected with *S. mansoni*, glomerulonephritis has been reported due to the deposition of immune complexes (IgM and IgG) in the kidney.

### Laboratory diagnosis

Confirmation of the diagnosis of active schistosomiasis can only be obtained by finding typical viable eggs (Fig. 28.84a,b,c). Eggs can be recovered by examination of urinary deposit (*S. haematobium*) or from stool (all other species) by direct smear (including a Kato smear), sedimentation or water centrifugation.<sup>986</sup> Flotation techniques are not satisfactory and formol ether concentration kills the eggs with the result that no report can be made on egg viability as judged by miracidial activity or flame cell activity. Confirmation of viability of the egg is important to differentiate active disease from past infection.

Egg recovery is not easy and as many as 20% of infected persons may not pass eggs. Repeated examination of stool and urine specimens, the latter collected at midday, is essential. If urine or stools fail to reveal

Fig. 28.84 (a) Egg of *Schistosoma japonicum* (approx.  $\times 600$ ). (b) Egg of *Schistosoma mansoni* (approx.  $\times 600$ ). (c) Egg of *Schistosoma haematobium* (approx.  $\times 1000$ ).

eggs, a rectal snip may prove rewarding in *S. japonicum*, *S. mansoni* and *S. haematobium* infections. In fact a single rectal snip gives more positives than three urines and stools. Cystoscopy may be indicated where urinary symptoms are present, the cystoscopic picture depending on the worm load.

A type I response skin test and various serological tests are available. These may be negative in early disease and positive results may indicate present or past infection, so a positive result is not, in itself, an indication for treatment. However, these tests often provide good negative screens to exclude a diagnosis of schistosomiasis and are particularly useful in screening returned travelers from endemic regions.

**Treatment**

The treatment of choice for all forms of schistosomiasis, and the only effective and safe treatment for *S. japonicum* infections, is praziquantel.<sup>886,987-989</sup> This drug is designated as a 'WHO essential agent', being extremely safe and highly effective when given as a single dose of 40 mg/kg (can be divided into two doses) for *S. haematobium* and *S. mansoni*<sup>913,965,988,989</sup> and at a dose of 60 mg/kg divided into three doses and given in a single day for *S. japonicum*.<sup>884,885,965,990</sup>

Of the other treatments available for schistosomiasis, metrifonate, an organophosphorus compound, appears to be less effective for treatment in cases of infection with *S. haematobium* than praziquantel.<sup>989</sup> It is not used for other species of schistosome. The dose used for children is 7.5 mg/kg per fortnight for a total of three doses.<sup>885</sup> Although side-effects are minimal, some have been recorded. The drug does depress cholinesterase levels and caution is needed in cases where patients may require some form of surgery necessitating the use of the muscle relaxant, suxamethonium. Oxamniquine is only effective against *S. mansoni* infections. The dose regimen is 10-20 mg/kg given as a single or divided doses over 1-2 days after food.<sup>883,885,913,965,988,990</sup> High cure rates and few side-effects are recorded.<sup>886</sup> This drug is useful for treating children orally at a rate of 20 mg/kg/d in 2 doses for 1 day.<sup>913</sup> Antischistosomal drugs such as the antimonials, niridazole and hycanthone have been superseded by the newer, more effective and safer compounds.

**Prevention**

As reinfection often follows successful treatment,<sup>989</sup> the control of schistosomiasis remains a priority. However, control is complex and generally employs a two-pronged attack on the life cycle of the fluke. The first is aimed at eliminating the snail population. Planned water systems for irrigation, which give a flow rate too high for survival of snails, are an ideal, but not always feasible method. Nontoxic molluscicides such as Frescon or Bayluscide have been found effective.

The experimental introduction of snail-eating predators and parasites has not had any lasting effect.

The second approach to control is aimed at preventing pollution of waterways by human excreta and involves public health education combined with provision of adequate and effective toilet facilities. In some control projects, mass treatment of infected humans has been used in conjunction with snail control. However, these aspects of prevention are ineffective in the case of *S. japonicum* which is extensively propagated by rodents. In *S. japonicum*, cercariae can be prevented from penetrating the skin by using topical applications of niclosamide or niclosamide-impregnated leggings.

Mass de-worming, repeated chemotherapy and the provision of safe water supplies through pump systems have all been proposed for the control of schistosomiasis.<sup>991</sup>

By 1988, schistosome vaccines were entering phase 1 trials<sup>992</sup> and research continues into the development of vaccines and chemoprophylaxis. The results to date appear to be encouraging, but there are concerns about the application of vaccine programs.<sup>993-996</sup>

**OTHER TREMATODES**

The life cycles of these flukes involve a variety of snail hosts with infective metacercariae settling on plants or aquatic invertebrates or vertebrates<sup>870</sup> (Table 28.47).

**Liver fluke infection**

The main trematode infections of the liver are fascioliasis, caused by the cattle and sheep liver flukes *Fasciola hepatica* (temperate regions) and *F. gigantica* (tropical Africa, Asia and Hawaii); clonorchiasis caused by *Clonorchis* (*Opisthorchis*) *sinensis* in the Far East; and opisthorchiasis, caused by *Opisthorchis felineus* in parts of Europe and Asia or *O. viverrini* in Thailand.

**Clinical features**

Infection with these flukes results when the metacercariae are ingested with aquatic plants (*Fasciola*) such as watercress to which the encysted metacercariae are attached, or in undercooked fish (*Clonorchis*, *Opisthorchis*).<sup>870</sup>

Symptoms of liver fluke infection depend largely upon the worm load and mild infections are often asymptomatic. Heavier infections tend to produce a triphasic response with an initial phase of invasion being accompanied by irregular fever and eosinophilia. Diarrhea and urticaria are common and there may be tender hepatomegaly. This phase lasts for about 4 weeks and is followed by an asymptomatic latent period

Table 28.47 Life cycles of intestinal and lung flukes

usually lasting several months before the stage of obstructive jaundice occurs. Rarely the parasites of *F. hepatica* may settle in ectopic sites such as the pharynx after eating raw liver and mature there with resulting local reaction. Pharyngeal fascioliasis is known in the Middle East as *halzoun*. Individual worms may migrate into the liver parenchyma resulting in liver abscess formation. Eosinophilia is often present and the ESR is usually raised.

In Thailand, cholangiocarcinoma has been found to be associated with infection by *O. viverrini*.<sup>997</sup>

Local prevalences are often dependent upon social customs and dietary habits, and epidemic outbreaks of fascioliasis have been recorded.<sup>997,998</sup>

### Diagnosis

The diagnosis is usually based upon the finding of typical operculate eggs in the feces (Fig. 28.85) although in some infected patients stools are consistently negative for eggs. The finding of eggs of *Fasciola* in the feces must be regarded with caution, as persons eating infected cattle or sheep liver can pass 'transit eggs' and this condition of spurious infection or false fascioliasis must be distinguished from true fascioliasis by the examination of repeat stool specimens.<sup>928</sup>

### Treatment

On the whole, treatment of liver fluke infection remains unsatisfactory. For fascioliasis, treatment now consists of triclabendazole 12 mg/kg orally once daily for 1–2 days.<sup>890,913,916</sup> Bithionol 50 mg/kg orally in divided doses on alternate days for 2–3 weeks has been used,<sup>965</sup> and chloroquine, dehydroemetine and praziquantel have also been tried. Drug treatment of choice for clonorchiasis and opisthorchiasis is praziquantel 25–75 mg/kg/d in 3 doses for 1–2 days with albendazole (10 mg/kg for 7 d) as an alternative.<sup>890,913,965</sup>

### Intestinal fluke infections

Many species of fluke infect the human intestinal tract<sup>870,999</sup> including the large intestinal fluke *Fasciolopsis buski* in parts of South East Asia, the small intestinal fluke *Heterophyes heterophyes*, in the Nile Delta and Far East, *Metagonimus yokogawai* in the Far East and eastern Europe and *Brachylaima* sp. in Australia.<sup>1000</sup>

Infection with these flukes results from ingesting metacercariae with aquatic vegetation (*F. buski*), with raw or undercooked fish (*H. heterophyes* and *M. yokogawai*) or by snail ingestion (*Brachylaima*). As in the case of liver fluke infection, a local high prevalence may be caused by local eating habits.<sup>870,998</sup>

Fig. 28.85 Eggs of (a) *Fasciola hepatica* – ruptured to demonstrate operculum (approx.  $\times 600$ ); (b) *Opisthorchis sinensis* (approx.  $\times 600$ ); (c) *Fasciolopsis buski* – ruptured to demonstrate operculum (approx.  $\times 600$ ); (d) *Paragonimus westermani* (approx.  $\times 600$ ).

Symptoms of intestinal fluke infection may vary from a mild inflammatory reaction at the site of worm attachment in the small intestine to ulceration or abscess formation in the bowel wall, associated with severe bloody diarrhea.

Infections due to *F. buski* may result in vague abdominal symptoms, ascites and edema, probably as a result of protein-losing enteropathy and toxemia.<sup>999</sup> An eosinophilia may be present, and iron deficiency anemia is common in fasciolopsiasis.

### Diagnosis

As with liver fluke infection, diagnosis is made by finding typical operculate eggs in the feces of infected patients (Fig. 28.85).

### Treatment

Intestinal fluke infections due to *F. buski*, *Heterophyes heterophyes* and *Metagonimus yokogawai* in children can be treated with praziquantel in a dose of 75 mg/kg in three doses for 1 day.<sup>883,885,913,965</sup> Niclosamide has also been used to treat intestinal fluke infections, while tetrachlorethylene has been described as an effective and cheap anthelmintic.<sup>886,896</sup>

### Lung fluke infection

Human lung fluke infection is caused by 11 species of the genus *Paragonimus*. In the Far East, South East Asia and the Philippines, the species involved is *P. westermani* while in central and west Africa (and probably South Africa) the species is *P. africanus* or *P. uterobilateralis*. In the western hemisphere, *P. mexicanus* and *P. kellicotti* are the more common species.<sup>896</sup>

Infection occurs with the ingestion of the metacercariae in crabs and crayfish. Again local high prevalences are largely dependent upon dietary habits and culinary practices of preparing and cooking the crustacean intermediate hosts.<sup>870,998</sup> However, an interesting epidemic is on record which resulted from the use of crab juice as an antipyretic for children suffering from measles.

Symptoms of lung fluke infection are often suggestive of pulmonary tuberculosis, which may also often be present concurrently. The onset is insidious with cough and chest pain. Hemoptysis is usual, with copious blood-tinged sputum containing many eggs. Bronchiectasis and pulmonary fibrosis are late results, and finger clubbing is often present. An eosinophilia may occur and variable symptoms may result from flukes developing in ectopic sites, e.g. transverse myelitis and skin ulceration. In a small percentage of patients with paragonimiasis, the adult worms may settle in the CNS resulting in epilepsy, hemiplegia, visual impairment or an eosinophilic meningitis.<sup>957</sup>

### Diagnosis

The diagnosis of paragonimiasis is established by finding the characteristic asymmetrical operculate eggs in sputum or feces (Fig. 28.85). X-rays, CT scans and serology may all prove useful.

### Treatment

The drugs of choice are bithionol (or Bitin) at a dose of 30–40 mg/kg in divided doses given orally every other day for 10–15 days, or the newer derivative of bithionol, Bitin-S, given at a dosage regimen of 10–20 mg/kg every other day for 10–15 days. Praziquantel is very effective at a dose of 75 mg/kg/d in three doses for 2 days<sup>883,885,886,913,965</sup> and may be used in conjunction with corticosteroids if there is CNS involvement.<sup>890</sup>

Side-effects include diarrhea, nausea, vomiting and abdominal pain, but these are mild and soon subside.

## ACANTHOCEPHALA

This group of helminths, the thorny-headed worms, are intestinal parasites of rats throughout the world. They are characterized by a proboscis covered with rows of recurved hooklets and have as their intermediate hosts insects such as cockroaches. The only species recorded from humans are *Moniliformis moniliformis* and *Macracanthorhynchus hirudinaceus*.

Humans, especially children, are occasionally infected after accidental ingestion of the intermediate host.<sup>874</sup> The worms live in the small intestine and diagnosis is made by passing adult worms or finding eggs in the feces. Spurious transit eggs can be passed by humans after eating of rodents as food.

Pyrantel pamoate and tiabendazole appear to be ineffectual, and mebendazole (Vermox) is the drug of choice, at a dose of 100 mg (one tablet) twice a day for 3 days.

## FLIES, FLEAS, MITES AND LICE

### MYIASIS

Myiasis is the infection by fly maggots of tissues of living animals, including humans. The larvae of a number of fly species may penetrate the skin of children or enter wound tissue.<sup>1001</sup> While the maggots of some myiasis-causing fly species only feed on dead and necrotic tissue (and even today are sometimes used in the medical treatment of wounds), the maggots of species such as the screw worm flies (*Callitroga americana* in the New World and *Chrysomya bezziana* in the Old World) can be dangerous, as they extend their activities from necrotic to healthy tissue around the wounds.

Various clinical forms of myiasis are recognized: cutaneous (including wound infection), gastrointestinal, ocular, aural and urogenital. The clinical relevance varies according to the site and the species of fly involved, but infection of the sinuses and nasal cavities may be the most dangerous.<sup>1002</sup>

The tumbu, or putsi fly, *Cordylobia anthropophaga*, is found in tropical and subtropical Africa, and recently in Northern Europe.<sup>1003</sup> The large pale brown tumbu deposits her eggs on shady soil contaminated with urine, or damp clothing, where they hatch to release larvae in about 3 days. Laundry placed out to dry is an ideal site for oviposition, especially if laid out on grass or on the ground, so thorough ironing of clothes is desirable in endemic areas. The larvae penetrate intact skin where they grow rapidly, and unless removed, abandon the host and drop onto the ground in about 8 days to pupate.

Cutaneous lesions, which may be single or multiple, can occur on any part of the skin, particularly the waist, back (Fig. 28.86a) and feet. The characteristic lesion is a tender, large, furuncular swelling with a dark, central pore (Fig. 28.86b). Following application of petroleum jelly, the pore widens revealing movement of the posterior spiracles. The larva, about 0.5–1.0 cm in length, may then be squeezed out or grasped with forceps and extracted. Secondary infection of these lesions is rare.

In South America, the eggs and larvae of the tropical warble fly *Dermatobia hominis* may be transferred to the human skin by flies, mosquitoes or ticks and produce similar papular lesions.

Cutaneous myiasis is being increasingly recognized as an imported infection in many nontropical areas.<sup>1003</sup>

In areas of the world where sheep are farmed, the sheep nasal bot fly, *Oestrus ovis*, has been at times recorded as causing ophthalmomyiasis, a self-limiting but extremely painful condition.

Other larvae (e.g. those of *Gasterophilus*) may produce itching skin lesions related to the wanderings of the larvae, or tender short-lived subcutaneous cystic swellings. *G. intestinalis* can cause intestinal myiasis.

Maggots of some fly species tend to infest neglected wounds with excess necrotic tissue, even in hospital situations, and can be controlled by adequate wound toilet.

Myiasis may occur rarely in mucous membrane-lined orifices such as the mouth, anus and vagina, and in the eye. One species, *Auchmeromyia luteola*, lives in cracks and crevices of floors in Africa, coming out at night to suck blood from the sleeping human host.

### TUNGIASIS

Tungiasis is infection with the jigger (or chigoe) flea, *Tunga penetrans*, originally endemic to South America, but now also endemic in central Africa and parts of India.

Fig. 28.86 (a) Child with multiple putsi lesions on back. (b) Lesion due to *Cordylobia anthropophaga* on leg to show characteristic appearance.

Fig. 28.87 Lesion due to jigger flea (*Tunga penetrans*). (Courtesy of Dr K. Ott)

The adult fleas live in soil or in the dust and cracks of earth floors of houses. After mating, the female flea penetrates the skin of the host (rodents, dogs, cats or humans) and develops in the epidermis under the stratum corneum, her abdomen swelling tremendously with developing eggs. The initial small lesion becomes inflamed and erythematous, developing into a pustule which may crust over or even form a suppurating ulcer if secondarily infected by bacteria. Lesions mostly occur on the feet, especially under the toenails or between the toes (Fig. 28.87). Itching, pain and even regional lymphadenopathy are common.

Eggs are expelled by the female flea, fall to the ground and form free-living larvae and pupae in the soil.

Diagnosis is made by finding the flea in the lesion and carefully removing it. In unsuspected cases, diagnosis may be made after biopsy of the lesion and finding the fragmented flea in the lesion.

Treatment consists of a careful removal of the flea, without rupturing it, using a sterile needle, followed by a cleaning of the wound with chloroform and a careful curetting of the affected area.

Jiggers are a potential source of tetanus in unimmunized children.

## DEMODICIDOSIS

The hair follicle mite, *Demodex folliculorum* (Fig. 28.88), is one of the commonest parasites of the human skin, with infection rates of 25% or higher.

Human infection is probably acquired by direct person-to-person contact, often at a very young age (e.g. suckling babies infected from their mother). Human infection with other species of *Demodex* from animals has not been ruled out.

The mites live in the pilosebaceous glands and hair follicles especially of the face, scalp, external ear and breast. They are common in the eyelids and mites can often be found clinging to removed eyelashes.

Clinically the condition may be asymptomatic or infected hair follicles may result in the formation of 'blackheads' with crops of red papules appearing on the forehead. In heavy infestations, or in sensitized patients, dermatitis may follow, with scaling of the skin. Demodicidosis may be associated with HIV infection, causing an acute papulo-nodular rash, usually localized to the head and neck.<sup>1004</sup>

Diagnosis is established by finding the mites, often in sero-purulent fluid expressed from the lesions, or in biopsied specimens of skin in which mites can be found.

Treatment consists of good hygiene, soap and water together with sulfur ointment or gamma-benzene hexachloride if necessary.

Fig. 28.88 *Demodex folliculorum* (approx.  $\times 300$ ).

## SCABIES (see Ch. 30)

Scabies is a disease caused by the mite *Sarcoptes scabiei* (Fig. 28.89b). It occurs worldwide, especially in areas of crowding and in countries with a low standard of living. Scabies appears to sweep the world in cyclical pandemics.<sup>1003,1005</sup> It can afflict both rich and poor alike, and is more common in women and children.<sup>1006</sup> Most cases of human scabies are contracted from other infected humans, but occasionally animal strains of the scabies mite can infect humans.<sup>1002</sup>

The gravid female mites burrow into the horny layers of the skin, forming tunnels (Fig. 28.89c) in which the eggs are laid. The female mite lives for about one month, laying 2–3 eggs daily, which hatch in 3–4 days into six-legged larvae. These migrate to the surface and then burrow into the skin again and moult into eight-legged nymphs before becoming adults about 10 days after hatching. On average, each patient is infested with only 10–12 mites at any one time and much of the observed symptomatology is due to sensitization of the host to the mite and its products.<sup>1007,1008</sup>

### CLINICAL FEATURES

Although the main sites infested can vary with the age of the patient, the commonest sites found to harbor mites include the hands (especially the sides of the fingers and the interdigital spaces), the finger webs, the wrists, the elbows, the feet, the penis and the scrotum, the buttocks and the axillae, with a lesser involvement of the body. The head and face is spared in most cases, except in infants.<sup>1006,1009</sup>

The feeding activities of the mites and host sensitization result in itching and the development of an extensive rash, which does not correlate with the predilection sites of the mites (Fig. 28.89a).

The characteristic lesions of scabies are the burrows in the skin, but there may also be pruritic papules, vesicles and pustules. Often there is eczematization and crusting of the lesions, especially when they are secondarily infected by bacteria. Scabies lesions can provide an entry site for infection with Group A beta hemolytic streptococci and thus glomerulonephritis may follow scabies.<sup>1009</sup>

Scabies may present in variable forms.<sup>1006</sup> In some healthy persons and in patients on corticosteroids, scabies may present with minimal signs and symptoms. In young children, vesicles rather than tunnels are often the rule, while in some patients the disease occurs in the nodular form. In mentally handicapped patients, debilitated patients and the immunosuppressed, extensive crusted or 'Norwegian scabies' is sometimes seen and in HIV infected individuals scabies can be particularly severe and persistent. In such cases the infestation is highly contagious and large numbers of mites can be found.

A common feature of scabies is the characteristic nocturnal itching, especially when the patient is warm in bed.

The infestation is transmitted by direct contact, including sexual contact. Fomites such as clothing and blankets generally play no part in the transmission of scabies.

### DIAGNOSIS

Scabies is usually diagnosed clinically and should be considered in any patient presenting with an itchy rash covering the whole body but sparing the head and face.<sup>1008,1010</sup> In infants, scabies may present in an atypical form which can involve the face.<sup>1006</sup> Confirmation by the finding of mites is often difficult, even extensive lesions being associated with very few mites. Mites or their fecal pellets can sometimes be found in the tunnels after careful removal of the horny layers of skin. An improved method of obtaining mites is to scrape a suspect lesion and then float the mite out using mineral oil.

### TREATMENT

The treatment of scabies involves the widespread application of topical preparations. Permethrin 5% cream or benzyl benzoate 25% emulsion are the treatments of choice.<sup>1006,1008–1010</sup> Full strength benzyl benzoate can cause an unpleasant stinging, so for children and sensitive adults it should be used diluted to half strength and in children under 2 years should be diluted with 3 parts water. Monosulfiram and crotamiton are possibly less effective, but the latter is said to have some antipruritic activity. Gamma-benzene hexachloride 1% has in the past proved to be cheap and effective,<sup>1009</sup> but is toxic if ingested. It should not be used in premature babies and should be used with care in pregnancy and in infants under 1 year of age.<sup>1011</sup> Children younger than 2 months can be treated with 5% sulfur cream daily for 2–3 days.<sup>884,1006</sup>

Resistance to both lindane and the pyrethroids (including permethrin) has been recorded and it may be difficult to distinguish resistance from incomplete treatment.<sup>1009</sup>

For adequate treatment and control, *all members of the family must be treated whether or not they exhibit symptoms*, or relapses and treatment failure will result.<sup>1006</sup> In conditions of overcrowding and poor hygiene, the regular use of monosulfiram soap prevents reinfection.

For mild scabies a single treatment should suffice but moderate or severe scabies might require re-treatment after 14 days. Symptoms may persist due to sensitization to treatment, and some patients have a 'parasitophobia' and see imaginary parasites; in these cases over-treatment must be avoided.

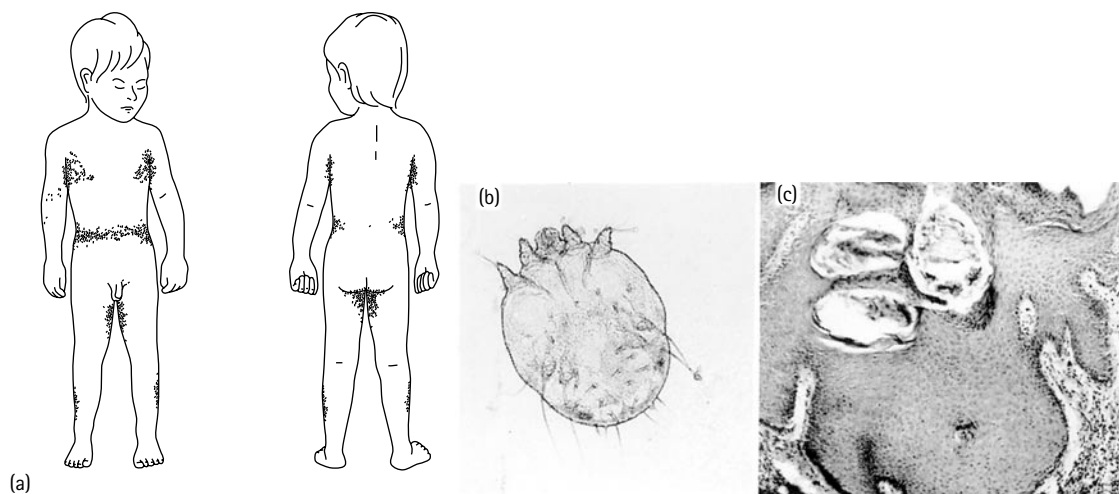

Fig. 28.89 (a) The distribution of the rash in scabies. (b) Adult *Sarcoptes scabiei* (approx.  $\times 100$ ). (c) Histological section of skin in scabies showing tunnels (approx.  $\times 300$ ).

Giving a child a hot bath before treatment for scabies commences is unnecessary.

Many animal parasitic mites (e.g. *Dermanyssus* and *Ornithonyssus* from rodents or birds and mange and cheyletid mites from dogs and cats) as well as many free-living and nonparasitic mites can attack humans and cause an extensive rash with a severe dermatitis and an itchy allergic reaction resulting in the formation of papules, vesicles and skin blotches. This condition can be very distressing and infestation usually derives from pets, animals nesting in roofs, straw and other packing materials.<sup>1012</sup>

The use of oral ivermectin (200 µg/kg orally as one dose for children > 5 years together with scabicides)<sup>884,1006</sup> may be required for the treatment of crusted scabies; toxicity can be a problem.<sup>1008,1009</sup> One review<sup>1013</sup> found no difference in clinical cure rates between crotamiton and lindane or benzyl benzoate and sulfur and concluded 'the evidence that permethrin is more effective than lindane is inconsistent. Lindane, permethrin and ivermectin appear to be associated with rare but serious drug reactions'. More research is needed on the safety and effectiveness of ivermectin and malathion compared to permethrin, on community management, and on different regimens and vehicles for topical treatment.

## LOUSE INFESTATION

Humans can become infested with three types of lice: the head louse (*Pediculus humanus capitis*; Fig. 28.90); its morphologically identical, but behaviorally different variant, the body louse (*P. h. corporis*); and the crab or pubic louse, which forms a distinct species, *Pthirus pubis*. All three types are confined to humans worldwide and tend to be more prevalent in areas with poor living standards.<sup>1014</sup>

### PEDICULUS HUMANUS CAPITIS (THE HEAD LOUSE)

*P. h. capitis* is worldwide in distribution. Its incidence is subject to unpredictable increases and decreases, with sporadic extensive pandemics. The prevalence varies from country to country and from year to year but may reach 60% or more of schoolchildren.<sup>1007,1014</sup>

Head lice tend to be confined to the scalp but are occasionally found on other hairy parts of the body. The insects live close to the scalp and feed on blood which they obtain with their sucking mouthparts. After mating, the female louse lays 6–8 eggs every 24 h. These eggs or 'nits' (Fig. 28.91) are glued tightly to the hairs close to the scalp and hatch in about 7 days into nymphs, which feed and pass through three instars before becoming adult in 10–11 days.<sup>1014</sup>

Head louse infestation is usually asymptomatic but heavy infestations may be manifested by scalp pruritus and, with secondary bacterial infection, by cervical gland enlargement.

*Pediculosis capitis* is found in people of all ages but is most common in children aged 3–13 years, and maximal at 6–9 years. Although not

Fig. 28.90 Photomicrograph of adult *Pediculus humanus capitis* – the head louse (approx. × 50).

Fig. 28.91 Egg of crab louse (*Pthirus pubis*) attached to hair (approx. × 60).

directly correlated to hair length, head lice are more common in girls than in boys. Both rich and poor alike are afflicted, but infestation is more frequent in low socioeconomic areas.

Diagnosis of pediculosis capitis is based on careful examination of the scalp for lice or their eggs. This is greatly facilitated using a hand lens. A more effective method for diagnosis involves treating dry hair with white conditioner, combing it with a fine tooth 'nit' comb, and examining the comb or, better still, the combings spread on a sheet of paper for nits.<sup>1015,1016</sup>

Head lice can only be controlled by regular inspection and treatment of infected cases and all their family members, whether or not lice or nits can be found in the latter. Dead nits remain tightly attached to the hairs and may have to be combed out with special fine toothed 'nit combs'.

In the past, DDT has been used for treatment, but its toxicity and resistance in the lice led to its replacement by gamma-benzene hexachloride (gamma BHC, gamma HCH; lindane). However, resistance is being recorded to HCH and this, plus its toxicity, has resulted in its being considered obsolete in many parts of the world.<sup>1007,1017,1018</sup> It is being replaced by safer preparations such as carbaryl, malathion and the synthetic pyrethroids such as permethrin. Of these, malathion (a 0.5% preparation in a spirit base) is the most widely used. It is twice as safe as HCH and has the added but variable advantage of possibly being residual for at least a month, through bonding to the hair. Additionally, malathion and carbaryl are reported to be ovicidal, killing both lice and nits, a feature absent in HCH which is not ovicidal. However, the concept of an inherent ovicidal efficacy for malathion and carbaryl has been challenged.<sup>1019</sup> Repeat treatments after a week or so might be advisable, irrespective of the insecticide used. Pyrethrins, especially those in a mousse formulation, may also be effectively used to treat head lice,<sup>1014</sup> with the third generation synthetic pyrethroids such as permethrin proving the most promising.<sup>1017,1018</sup> Permethrin, synergized pyrethrum and malathion are all effective in head louse treatment and the choice between them really depends on local resistance patterns.<sup>1020</sup> All these preparations are toxic to some extent and care should thus be exercised in their use, with particular care being taken to avoid accidental ingestion or contact with eyes. Shampoos and lotions are both available, but lotions are far superior.<sup>1014,1021,1022</sup> Developing resistance to head louse preparations may prove a problem, albeit a sometimes controversial one.<sup>1014,1020,1023</sup> Ivermectin may be considered for the treatment of more difficult cases.<sup>1024</sup>

The use of levamisole for pediculosis, although considered to be safe and economical by some,<sup>1025</sup> does not really seem a practical alternative to the more conventional methods of head louse control.

An alternative, non-insecticidal approach to the treatment of head lice involves applying hair conditioner to wet hair, then combing the hair thoroughly using a fine toothed comb to remove the lice and their eggs, a technique known as 'bug-busting' in the UK.

This does need dedication to ensure that the process is effectively carried out and results of its efficacy compared to insecticidal treatment vary.<sup>1026–1028</sup>

In the control of head lice, sterilization of clothing, bedding, combs, etc., is unnecessary, as insecticide treatment of the hair will provide sufficient protection from re-invasion by the short-lived lice that have strayed from the head.

In community control programs, education and involvement of all participants, parents, education and health professionals, as well as hair-dressers, is necessary, and anti-lice preparations should be changed on a regular basis to prevent the emergence of resistance.

### PEDICULUS HUMANUS CORPORIS (THE BODY LOUSE)

*P. h. corporis* is identical to the head louse in appearance, but differs in that it lives on the clothing and only visits the skin to suck blood. The eggs are glued to the clothing, especially the seams, and hatch in about one week to nymphs, which like those of the head louse, develop into adults in 7–10 days.

Pediculosis corporis may be characterized by the presence of feeding punctures appearing as small papules which, in sensitized patients, may become swollen, pigmented and hardened, a condition formerly known as vagabond's disease or *morbus errorum*.

Body lice are more limited to areas of overcrowding and poorer standards of living but may reach epidemic proportions during periods of social upheaval and unrest such as war, earthquakes and floods. They are the vectors of epidemic typhus (*Rickettsia prowazekii*) and epidemic relapsing fever (*Borrelia recurrentis*).

Transmission of body lice is directly from person to person and from shared clothing and blankets. Control is with 0.5% malathion lotion or 5% carbaryl dust and treatment of clothing, blankets, etc., with methyl bromide fumigation, washing in hot water at 60 °C or higher by heating in a domestic tumble drier for at least 5 min.

### PTHIRUS PUBIS (THE CRAB OR PUBIC LOUSE)

*Pth. pubis* has a distinctive appearance and is usually found in the pubic region of humans only. It may also be found tightly attached to the hairs of the leg, the axilla or the beard (Fig. 28.92). Eggs are laid attached to hairs or even eyelashes (Fig. 28.93). It is usually transmitted during sexual intercourse and because of this, it is mostly found infesting

Fig. 28.92 Photomicrograph of nymph of *Pthirus pubis* tightly attached to hair (approx.  $\times 100$ ).

Fig. 28.93 Eggs of pubic louse on eyelashes.

adults. However, children can harbor the lice and even young children may become infected from heavily infested parents through close non-sexual contact. Thus, toddlers are at times found to have phthiriasis, the lice being found attached to the eyelashes and even the hair of the forehead. The lice can survive for 9–44 h off the host, and infestation from clothing and toilet seats is thus feasible, although unlikely.

Heavy infestations may result in itching and, rarely, *maculae cerulae* or bluish spots due to repeated biting may be found.

Treatment is similar to that for head lice, using insecticides such as gamma-benzene hexachloride (lindane) as a lotion, shampoo or powder. This insecticide is toxic and treatment needs to be repeated, as it is not ovicidal. 0.5% malathion or carbaryl are safer and, being ovicidal, are more effective, but spirit base preparations should not be used. Pyrethroids are also effective and are widely used.

When on the eyelashes (Fig. 28.93), *Pth. pubis* should be dealt with by removal of individual lice or by treating each egg individually with a paint brush dipped in an ovicidal insecticide. Alternatively, the thick application of Vaseline twice daily for 8 days may be effective.<sup>1014</sup> Laundering of clothing, sheets, etc., in hot water is advisable to prevent spread.

## DISEASES TRANSMITTED BY ANIMALS

These are summarized in Table 28.48.<sup>1029</sup>

### CAT-SCRATCH DISEASE (CSD)

Cat-scratch disease is a relatively benign, widely encountered infection characterized by malaise, low grade fever and lymphadenopathy. About half of the patients with CSD develop a nonpruritic, erythematous primary lesion 3–30 days after getting a scratch. This lesion may form a small pustule but overall the infection usually resolves spontaneously in a few weeks. Rarely, complications can occur such as encephalitis, conjunctivitis (Parinaud's oculoglandular syndrome), neuroretinitis and thrombocytopenic purpura.<sup>1029–1031</sup> Contact with cats followed by skin lesions associated with a scratch or bite are found in the majority of cases. There may be a maculopapular rash. Chronic lymphadenitis may occur with the cervical lymph nodes frequently involved. Murano et al<sup>1032</sup> reported a giant hepatic granuloma as associated with *Bartonella henselae* infection and suggested that this infection should be considered in the differential diagnosis of a large hepatic mass. Overall, systemic symptoms are unusual in CSD, but severe disease may occur in HIV positive patients. Isada et al<sup>1033</sup> reported that in the USA, 22 000 cases of CSD occur annually with 10% requiring hospitalization.

Table 28.48 Diseases transmitted/harbored by dogs, cats and rodents\*

Dogs	Cats	Rodents
Rabies	Rabies	Lassa fever
Ringworm	Cat-scratch fever ( <i>Bartonella henselae</i> )	Hantavirus disease
Scabies	Ringworm	S. American arenavirus hemorrhagic fevers
<i>Echinococcus granulosus</i> infection	Scabies	Omsk hemorrhagic fever
<i>Toxocara canis</i> infection (larva migrans)	<i>Toxocara cati</i> (larva migrans)	Kyasanur forest disease
Leptospirosis	Pasteurellosis ( <i>Pasteurella multocida</i> )	Group C virus disease
Canicola fever ( <i>Leptospira canicola</i> )	Cutaneous larva migrans	E. Hemisphere sandfly fever
Leishmaniasis	Toxoplasmosis	Vesicular stomatitis fever
<i>Dipylidium caninum</i>	<i>Bartonella clarridgeiae</i>	Venezuelan equine encephalitis
Cutaneous larva migrans	<i>Capillaria aerophila</i>	Lymphocytic choriomeningitis
<i>Dirofilaria immitis</i>	Cutaneous dirofilariasis	Rat bite fever ( <i>Spirillum minor</i> )
<i>Capnocytophaga canimorsus</i> (DF-2)	Paragonimiasis	Haverhill fever ( <i>Streptobacillus moniliformis</i> )
<i>Bartonella clarridgeiae</i>	Q fever	Bubonic plague ( <i>Yersinia pestis</i> )
<i>Bartonella vinsonii</i>	Ctenocephalides felis	Campylobacteriosis
Spotted fever (some forms)	Salmonellosis (gastroenteritis)	Salmonellosis (gastroenteritis)
Ehrlichiosis	Giardiasis	Leptospirosis (e.g. Weil disease)
Cutaneous dirofilariasis	<i>Strongyloides</i> sp.	Endemic relapsing fever
Paragonimiasis	<i>Tunga penetrans</i>	Scrub typhus
Q fever		Murine typhus
Salmonellosis (gastroenteritis)		Rickettsialpox
<i>Ctenocephalides canis</i>		Spotted fever (some forms)
Giardiasis		Q fever
<i>Diphyllobothrium latum</i>		<i>Bartonella</i> spp.
<i>Fasciola hepatica</i>		<i>Babesia microti</i>
Lyme disease		Toxoplasmosis (where rodents are eaten)
<i>Trichuris vulpis</i>		Cutaneous leishmaniasis (some forms)
<i>Strongyloides</i> sp.		Clonorchis sinensis
<i>Tunga penetrans</i>		<i>Schistosoma japonicum</i>
Eosinophilic enteritis		Multilocular hydatid
		<i>Hymenolepis nana</i>
		<i>Hymenolepis diminuta</i>
		<i>Inermicapsifer madagascariensis</i>
		Angiostrongyliasis
		<i>Capillaria hepatica</i>
		<i>Moniliformis moniliformis</i>
		<i>Cordylobia anthropophaga</i>
		<i>Xenopsylla cheopis</i>
		<i>Tunga penetrans</i>
		Dermanyssid mites
		Trombiculid mites

\*Not all of these infections are directly transmissible to humans from the animal reservoir and in some cases the animal may only be an occasional reservoir for the infection. For details of these and other infectious diseases relating especially to control, the reference edited by Chin<sup>1029</sup> is strongly recommended.

## ETIOLOGY

The bacterium *Bartonella* (formerly *Rochalimaea*) *henselae* is considered the cause of CSD and the role of *Afipia felis* in the causation of CSD (if it has one) is small.<sup>1029,1034,1035</sup> Kordick et al.,<sup>1036</sup> however, have described *B. clarridgeiae* as causing a cat-scratch disease-like syndrome.

Other species of the genus *Bartonella* can infect humans but are not involved in causing CSD. The species of *Bartonella* and their disease associations are summarized in Table 28.49.

## DIAGNOSIS

The diagnosis of CSD is confirmed if the history of cat contact and a primary skin lesion is associated with typical silver-staining bacteria identified on histopathological sections of lymph nodes, skin or eye lesions. A skin test for cat-scratch disease is available, but this is being superseded by serology using an indirect fluorescent antibody test for *B. henselae* which is said to be more sensitive.

## TREATMENT

As most patients with this disease are not ill and spontaneous recovery is common, treatment is usually symptomatic. Antibiotics should be reserved for patients with severe disease. The most commonly used antibiotics are not effective and a recent review indicated that only four antimicrobial drugs are useful, with the oral drugs in decreasing order of efficacy being rifampicin (87%), ciprofloxacin (84%) and trimethoprim-sulfamethoxazole (58%). Intramuscular gentamicin was 73% effective.<sup>1037</sup> Isada et al.,<sup>1033</sup> while admitting that no controlled trials have been carried out in the treatment of CSD, report that erythromycin, doxycycline or co-trimoxazole, in that order, might be effective.

## CAT-SCRATCH ENCEPHALOPATHY

CNS complications may develop from a few days to some weeks after the first evidence of illness, usually a mildly tender lymphadenopathy. Fever is not characteristic and may occur in only 50% of cases. Convulsions

Table 28.49 Disease associations in the genus *Bartonella* in humans

Species	Disease association	Comments
<i>B. henselae</i>	Cat-scratch disease (CSD)	From cat bite/lick
<i>B. quintana</i>	Bacillary angiomatosis	From body lice
	Trench fever	
<i>B. bacilliformis</i>	Oroya fever, verruga peruana	<i>Lutzomyia</i> flies
<i>B. elizabethae</i>	Subacute endocarditis	From cats/dogs
	Neuroretinitis	
<i>B. clarridgeiae</i>	Subacute endocarditis	From cats/dogs
	CSD-like syndrome	
<i>B. vinsonii</i>	Subacute endocarditis	Various subspecies

of varying severity will also affect about 50% of the children with encephalopathy, and they may remain lethargic or even comatose for several weeks. In the recovery phase, 'transient combative behavior' seems to be a characteristic feature of this particular type of encephalopathy. Changes in the CSF are neither consistent nor characteristic and peripheral blood counts are not helpful. In addition to the control of convulsions and supportive measures, the most important aspect is to establish the diagnosis and differentiate it from other causes of encephalopathy as quickly as possible to avoid extensive and invasive investigations. The prognosis is excellent with no evidence of lasting neurological impairment.<sup>1038</sup>

## RAT-BITE FEVERS

Rat-bite fevers comprise two separate and distinct infections, both of which are characterized by a relapsing fever usually following a rat bite. They are particularly prevalent in rat-infested communities of low socioeconomic status. Children living in such areas are at especial risk and may even be bitten by rats while asleep. Children may also become infected following a bite from a pet mouse or rat. *Streptobacillus moniliformis* (streptobacillary rat-bite fever; Haverhill fever; erythema arthriticum epidemicum) has been recorded worldwide, including from Europe and the USA; *Spirillum minus* (spirillary rat-bite fever; sodoku or sokosha) has also been reported worldwide, but mostly from Japan.<sup>1029</sup> Streptobacillary rat-bite fever is a more common cause of fever following a rat bite than is the spirillary form.

### STREPTOBACILLUS MONILIFORMIS (STREPTOBACILLOSIS)

*Streptobacillus moniliformis* is a commensal in the rat nasopharynx and has also occasionally been recorded from other small mammal species such as squirrels, weasels and gerbils.<sup>1029,1031,1039</sup> While transmission is usually through a rat bite, epidemic outbreaks in humans are believed to have resulted from ingestion of raw milk or water contaminated with rat urine or saliva.<sup>1029,1031</sup> The incubation period is usually 3–10 days,

occasionally longer, during which a gastroenteritis may be present. The infected bite usually heals rapidly but a fever develops which is often relapsing and, although usually subsiding within 10 days or so, may continue for months if untreated. A generalized erythematous, morbiliform or even purpuric rash, particularly on the hands and feet, may develop and arthralgia (especially of the large joints) and sore throat, extreme prostration and headache may occur. Complications may include infective endocarditis, pericarditis and abscesses of soft tissue or brain.<sup>1029,1040,1041</sup> The fatality rate may reach 10% if untreated.

Streptobacillary rat-bite fever needs to be differentiated from coxsackie infections, meningococcal septicemia and erythema multiforme but infection can be confirmed by isolation of *S. moniliformis* from blood, infected joint fluid, abscesses or pustules. Serological diagnosis using an agglutination test is available and becomes positive in the second to third week of the infection. Penicillin, given as soon as possible after the bite, is effective,<sup>1031</sup> as are cephalosporins, but strains resistant to penicillin, streptomycin and erythromycin have been recorded.

### SPIRILLUM MINUS (SPIRILLOSIS)

Transmission of *Spirillum minus* is most commonly via the bite of an infected rat but can occur following the bite from other mammals including cats, which can serve as healthy reservoirs. Food contaminated by infected rat urine may also presumably cause infection.

The incubation period varies from 7 to 28 (mean 8) days after the bite, which may heal or become necrotic and chancre-like. Recurrent fevers occur at 5–10 day intervals, sometimes continuing for weeks in untreated patients, and may be accompanied by profuse sweating, often with a marked flare up of inflammation at the site of the bite. Regional lymphadenopathy usually develops and a characteristic purplish, papular (or sometimes nodular) rash or urticaria may be present, especially on the chest and arms. Muscle pains, but rarely joint pains and arthritis, hyperesthesia and localized edema are additional signs. In severe cases, a meningoencephalitis with delirium may develop, as may endocarditis and involvement of other organs. In untreated cases, the mortality may reach 10%, being associated with neuronal degeneration of the brain and degenerative changes in the liver and kidneys.

The differential diagnosis should consider other febrile infections, including those caused by spirochetes (such as relapsing fever), viruses, rickettsiae (such as the spotted fevers), bacterial infections (such as plague), tularemia and also malaria, in endemic regions. A puffiness of the face may suggest nephritis and children may present with persistent diarrhea and weight loss, which may further confuse the correct diagnosis. During febrile paroxysms there may be a leukocytosis and occasionally eosinophilia and anemia may be present. CSF pressure may be raised.

Diagnosis of spirillosis can be confirmed by detecting *S. minus* in lesion/tissue exudates, in an enlarged lymph node or, during a febrile episode, in peripheral blood by dark ground microscopy or by inoculation of guinea pigs, mice or laboratory rats. No specific serological tests are available.

Penicillin is the treatment of choice for spirillosis<sup>965,1031</sup> but streptomycin, erythromycin, chloramphenicol and tetracyclines (not during pregnancy or for children under 7–8 years of age) are also effective.

Musculoskeletal symptoms are common in children and frequently present to pediatricians. A comprehensive review of all conditions affecting the musculoskeletal system in childhood would not be possible within the scope of a single chapter. We have tried to cover in some detail those condi-

tions most commonly seen in pediatrics while also giving sufficient information to enable consideration of many of the more unusual conditions that may be encountered. We have also endeavoured to highlight areas of recent progress.

## ASSESSMENT OF THE MUSCULOSKELETAL SYSTEM

Clinical assessment of the musculoskeletal system should be part of the routine pediatric examination. A few simple screening questions and assessments can be used to determine whether or not an abnormality is likely. If a child has no pain, swelling or stiffness of the joints, walks with a normal gait, and is able to keep up with his or her peers in normal activities then it is unlikely that a significant problem exists. Any suggestion of a musculoskeletal problem merits detailed assessment. It must be remembered that some rheumatic conditions may present with constitutional symptoms such as a rash, fever or fatigue before the development of any musculoskeletal problems. This section describes a general approach to the examination of the musculoskeletal system. The more detailed assessment of individual problems is described in the relevant sections of the chapter.

A meticulous history and clinical examination will lead to the correct diagnosis in the majority of cases. Investigations may be diagnostically helpful but are more usually used to confirm the clinically suspected diagnosis.

When assessing the musculoskeletal system in a child, knowledge of normal development is clearly important as normal findings vary considerably at different ages. For example a significant degree of joint laxity is normal in the young child and should not be confused with abnormal hypermobility.

### HISTORY

As with many areas of pediatric practice the clinical history is often the most informative part of the assessment. Information must be gleaned from both the parents/carers and the child, even the very young child contributing to the history when age-appropriate questions are used. Questions must be asked about musculoskeletal symptoms such as joint pain or swelling, muscle pain; functional difficulties and about relevant non-articular symptoms.

### Non-articular symptoms

Children with musculoskeletal or rheumatic conditions frequently have prominent constitutional symptoms. Fever, fatigue, anorexia and weight loss are common to many inflammatory conditions but may also occur in infection and malignancy. Rashes may be characteristic of individual conditions and may be helpful diagnostically.

### Pain

Pain is the most frequently reported musculoskeletal symptom, and musculoskeletal pain is a frequent cause of presentation in both primary care and pediatric practice.<sup>1</sup> Detailed enquiry should be made into its location and characteristics including severity, precipitating and relieving factors, radiation and diurnal variation. It must be remembered that joint pain (arthralgia) is common in children and that most do not have serious pathology (Table 29.1). It should also be noted that not all children with a significant musculoskeletal problem will complain of pain.

Based on the history of the pain, its characteristics and associated features, musculoskeletal problems can be usefully divided into three broad categories: inflammatory, mechanical and idiopathic.

### Inflammatory

Inflammatory pain is characteristic of arthritis but also occurs in other conditions such as myositis, the hallmark being a relationship to immobility. The affected child is frequently worst first thing in the morning (morning stiffness) or after periods of inactivity ('gelling'). A young child with arthritis may be unable to walk first thing in the morning but be running around later in the day. Exercise will generally relieve the pain which is usually described as aching or uncomfortable rather than severe. Occasionally children with acute exacerbations of arthritis experience severe pain, sufficient to disturb sleep.

Table 29.1 The differential diagnosis of joint pain in children

1. <b>Arthritis</b>
Infective and reactive
Juvenile idiopathic arthritis
Other: autoimmune rheumatic disorders (e.g. systemic lupus erythematosus, dermatomyositis); vasculitis; miscellaneous
2. <b>Mechanical/degenerative</b>
Trauma: accidental and non-accidental
Hypermobility
Avascular necrosis, osteochondritis and apophysitis, including Perthes, Osgood-Schlatter and Scheurmann
Slipped capital femoral epiphysis
Anterior knee pain
3. <b>Non-organic/idiopathic</b>
Idiopathic pain syndromes – localized and diffuse
Benign idiopathic limb pains (growing pains)
Psychogenic
4. <b>Other</b>
Osteomyelitis
Tumors:
Malignant: leukemia, neuroblastoma
Benign: osteoid osteoma, pigmented villonodular synovitis
Metabolic abnormalities: rickets, diabetes, hypophosphatemic rickets, hypo/hyperthyroidism
Genetic disorders: skeletal dysplasias, mucopolysaccharidoses, collagen disorders

Inflammatory pain in arthritis is almost universally accompanied by objective evidence of persistent joint swelling without which the diagnosis of arthritis should not be made.

### Mechanical

By contrast, mechanical pain is generally exacerbated by exercise and relieved by rest. It is frequently intermittent rather than persistent and tends to be described as more severe than that associated with arthritis. Mechanical problems are more common in older children and adolescents and frequently affect the joints of the lower limb and the back.

Associated symptoms are common. Joint 'locking' is frequently described. True joint locking, where there is a block to extension, is uncommon and may indicate a meniscal problem or patellar dislocation. Joint instability may occur with ligamentous laxity and a complaint of the knee 'giving way' is common with anterior knee pain. Joint swelling may occur with mechanical problems but is usually intermittent rather than persistent.

### Idiopathic

Children and adolescents with the most severe pain frequently fall into this category where there is no identifiable organic pathology. Their pain is severe, unremitting and frequently associated with fatigue, poor sleep and significant functional impairment.<sup>2</sup> Complaints of intermittent joint swelling are common but seldom corroborated on clinical examination, which is usually normal.

### Functional difficulties

It is important to enquire about the ability of the child to function normally both in activities of day-to-day living such as dressing and toileting and in more physically demanding activities such as sports. Such questions are informative in determining both the type of problem and its severity. It must be remembered that young children are particularly good at compensating for loss of function in one area by using another and absence of functional impairment does not imply absence of pathology. Conversely, the most functionally disabled children may be those with idiopathic or non-organic problems.

Discriminating questions of function are useful in determining progress of disease and are important in assessing response to treatment in conditions such as juvenile idiopathic arthritis. There are a variety of validated quantitative functional assessment tools available for use in children with rheumatic disorders.<sup>3</sup> The Childhood Health Assessment Questionnaire (CHAQ) is the most widely used and has been validated for use in both juvenile arthritis and dermatomyositis<sup>4</sup> in a number of different countries and languages.

## EXAMINATION

As with any system, examination of the musculoskeletal system of a child must be age appropriate.<sup>5</sup> Much information can be gained particularly in the younger child by observing the child at play before attempting any more formal examination. Observing the child's general demeanour, gait and ability to get up and down off the floor is informative. Ideally the musculoskeletal system should be examined in detail, with assessment of all joints and muscle groups. This is frequently impractical in the very young or the child who is in a lot of pain. The examination may need to be opportunistic, focusing initially on problem areas which will have been identified by initial observation of the child.

A simple screening examination (Table 29.2) may be appropriately used to identify children who merit more detailed assessment and can be incorporated into the routine physical examination of any child.

### General systemic examination

The child should be examined for evidence of any systemic features that may be relevant to musculoskeletal disorders. Rashes may be useful diagnostically. Growth impairment is common in many chronic disorders and documentation of height and weight is mandatory. Temperature, blood pressure and urinalysis should be measured where systemic involvement may occur.

### Gait

Observation of the gait may help identify the nature and site of the problem, particularly in the younger child who may find it difficult to localize pain.

A child who is unable to weight bear may have a serious disorder such as septic arthritis or a malignancy. A child with fixed flexion deformities at the hips will adopt an exaggerated lordosis to compensate. Weak hip and pelvic muscles will result in a waddling gait, while a painful hip or knee will result in an antalgic gait, where the child walks in such a way as to spend as little time as possible on the affected leg.

### Examination of joints

Joints should be inspected, palpated and their range of movement determined. Preprinted tables or cartoon figures are available to aid systematic documentation of the results.

Inspection of joints yields useful information. The position of the joint and any limb deformity should be documented. The limb should be inspected for evidence of wasting of surrounding muscles or limb length discrepancy, resulting from overgrowth at an inflamed joint. Erythema or unusual laxity of the skin overlying the joint should be noted. Joint swelling is frequently obvious on inspection.

**Table 29.2** The screening musculoskeletal examination in a child

1. Extend the arms straight out in front then make a fist
2. Place palms and fingers together with wrists extended to 90°: 'prayer position'
3. Raise arms straight above the head
4. Turn neck to look over each shoulder
5. Walk normally, on tip-toe and on the heels
6. Sit cross-legged on the floor then jump up

A child who can perform all these actions without difficulty is unlikely to have a significant musculoskeletal problem

Following inspection the joint should be palpated for warmth, swelling or tenderness. Documenting the presence of joint effusions is important in assessing and diagnosing arthritis. It must be remembered that in some joints, e.g. the hips, effusions can not be detected clinically and must be sought in other ways, e.g. using ultrasound (Fig. 29.1).

In many musculoskeletal conditions loss of joint range is one of the earliest objective signs of a problem. Examining for this requires experience, patience and a knowledge of the normal range of movement of the joints. Where the problem is clearly localized to a particular joint, the examination may focus on this area. If the child has evidence of a condition that may affect more than one area, e.g. a polyarthritis, a meticulous assessment of all joints should be made. Arthritis in children is usually asymmetrical enabling the contralateral joint to be used for comparison.

Range of movement should be assessed both actively and passively. Assessment of active joint range involves observing the child moving the joints. Passive range is assessed by the examiner moving the joints through their full range. A useful sign of early arthritis in a joint is pain at the end of the range of passive movement. The child may deny pain but withdraw the limb consistently when pushed to the end of its range.

Joints frequently forgotten, but important in the overall assessment of the child, are the sacroiliac joints, the temporomandibular joint and the cervical spine.

### Examination of muscles

Assessment of muscles is also an essential part of the musculoskeletal examination. Muscle tenderness may indicate an underlying inflammatory process, while wasting and weakness may indicate a disorder of the muscle itself, of the surrounding joints or of the nervous system. Gait abnormalities, or an inability to get up off the floor easily, may be indicative of muscle weakness. The well-known Gower sign, where the child uses his/her hands to push off the body when attempting to stand is an indicator of proximal muscle weakness and not specific to any one group of disorders.

Muscle strength should be formally assessed using a standard scale for grading muscle strength. This requires experience in young children ensuring that clear, understandable instructions are given and taking care not to underestimate the strength of the younger child. A five-point scale for grading muscle strength is familiar to most clinicians. A ten-point scale may be more precise and is equally simple to use (Table 29.3).<sup>6</sup>

In children with inflammatory myositis the childhood myositis assessment scale (CMAS)<sup>7</sup> is a validated method of quantitating muscle strength by scoring the child's ability to perform a variety of maneuvers. Its use in conjunction with manual testing of muscle strength gives reproducible scores which can be used to assess a child's response to treatment.

## CONGENITAL AND DEVELOPMENTAL PROBLEMS

In broad terms congenital abnormalities can be classified into:

1. failure of formation (transverse or longitudinal);
2. failure of differentiation;
3. duplication;
4. overgrowth (or gigantism);
5. undergrowth (or hypoplasia);
6. congenital constriction band syndrome;
7. generalized skeletal abnormalities.

It is important to bear in mind that, although congenital abnormalities may be isolated, they may also occur in association with other abnormalities, sometimes as part of a recognized syndrome.

### SPINAL PROBLEMS

#### Congenital spinal problems

The child with a vertebral anomaly must be fully assessed for associated abnormalities as in the VATER (Vertebral, Anorectal, Tracheo-Esophageal, Renal, Radial) and VACTERL (Vertebral, Anorectal, Cardiac,

Fig. 29.1 (a) Hip ultrasound showing effusion; (b) normal hip for comparison.

Tracheo-Esophageal, Renal, Limb) syndromes. Deformities occurring as result of vertebral anomalies include scoliosis, kyphosis and lordosis.

Congenital spinal anomalies are classified into failure of formation or failure of separation of individual vertebrae or parts of vertebrae. Failure of separation is termed an unsegmented bar, the position of such a bar determining the deformity. With a lateral unsegmented bar the growth of the spinal column is tethered on that side, continued growth on the opposite side leading to a progressive scoliosis. Failure of formation may involve the anterior, posterior or lateral side of a vertebra and once again the site will dictate the deformity. A hemivertebra on one side

of the spinal column leads to extra growth on that side versus the side with the absent segment and a scoliosis may result (Fig. 29.2).

Treatment of the vertebral anomaly depends on its potential to lead to progressive deformity. Some abnormalities have only modest potential and two separate abnormalities may cancel each other out. Other anomalies or combinations have significant potential to progress and will need careful management to prevent progressive deformity.

### Idiopathic infantile scoliosis

This usually presents during the first 3 years of life and is distinguished from congenital scoliosis by the absence of a spinal malformation. In contradistinction to adolescent idiopathic scoliosis the condition is more common in boys and the convexity of the thoracic scoliosis is to the left in 90%. The condition is often self-limiting but some cases do progress leading to poor cardiopulmonary development. Prolonged molded plaster jacket treatment is often successful although some may require surgery.

### Congenital muscular torticollis

Congenital muscular torticollis, resulting from a contracture of the sternocleidomastoid muscle, is the most common cause of torticollis in the infant. The etiology is unknown. Theories include in-utero crowding and muscle fibrosis following a compartment syndrome within the muscle as a result of compression of the neck during a difficult delivery. Clinically a nontender 'tumor' or swelling can be palpated in the sternocleidomastoid muscle in the first 4–6 weeks, but subsequently regresses. Radiographs of the cervical region should be obtained if there is any suspicion of an underlying cervical abnormality.

Left untreated, plagiocephaly and facial asymmetry may develop. Treatment initially consists of passive stretching exercises together with encouragement of head rotation in the restricted direction

Table 29.3 Manual muscle testing: 5- and 10-point scales for grading of muscle strength

5-point scale	10-point scale	
0	0	No evidence of muscle function
1	1	Slight flicker of contractility; no effective function
2	2	Movement with gravity eliminated
3	3	Movement against gravity
	4	Movement against gravity: unable to hold position
	5	Movement against gravity: able to hold position
4	6	Resists slight pressure
	7	Resists slight/moderate pressure
	8	Resists moderate pressure
	9	Resists moderate/strong pressure
5	10	Full power

Fig. 29.2 Congenital hemivertebra resulting in scoliosis.

by placing objects of interest toward that side. Passive stretching begun early is successful in 90%.<sup>8</sup> After the age of 1 year surgical treatment may be necessary. This involves division of the tight tendon and is best done before 4 years of age. Established facial deformity or a limitation of more than 30° of rotation usually precludes good results.

### Klippel–Feil syndrome

Klippel–Feil syndrome results from failure of the normal segmentation of the cervical vertebrae so that two or more are joined forming block vertebrae. The etiology is unknown. The most consistent clinical finding is limitation of neck motion. Shortening of the neck is subtle.

Associated anomalies include facial asymmetry, torticollis or webbing of the neck in 20%. Sprengel shoulder (a high riding scapula) occurs in up to one third and other associated abnormalities occasionally include ptosis of the eyelid, lateral rectus muscle palsy of the eye, facial nerve palsy, a cleft or high arched palate and abnormalities of the upper limbs including supernumerary digits, hypoplasia of the thumb or even the entire upper limb. Abnormalities of the lower limbs are infrequent.<sup>9</sup> Affected patients should be screened for other abnormalities which include scoliosis or kyphosis in up to 60%, renal abnormalities in 30%, cardiovascular abnormalities in 14%, deafness or hearing impairment in 30%. Twenty percent of patients demonstrate mirror motions (synkinesia) or involuntary paired movement of the hands.

## UPPER LIMB PROBLEMS

### Sprengel shoulder

The scapula develops within the upper limb bud and descends to overlie the second to seventh thoracic vertebrae and ribs. Failure to descend fully gives rise to congenital elevation of the scapula – Sprengel deformity. The condition is usually sporadic but occasionally inherited in an autosomal dominant fashion. It is commoner on the left but can be bilateral. Radiographs of the chest and the cervical spine should be taken to rule out associated rib abnormalities and anomalies of the cervical vertebrae such as Klippel–Feil syndrome.

Shoulder elevation is usually only modestly limited and significant functional problems are rare. Treatment is directed toward maintaining the existing range of movement. Surgical procedures to remove the prominent superomedial tip of the scapula are cosmetic and do not improve shoulder function. Procedures to bring about descent of the whole scapula are associated with significant potential complications and long, sometimes ugly scarring.

### Pseudoarthrosis of the clavicle

This rare condition presents as a nontender lump at about the midpoint of clavicle. When identified soon after birth it may be mistaken for a fracture, but should be distinguished by the absence of rapid callus formation and persistence of the pseudoarthrosis (Fig. 29.3). It should also be differentiated from cleidocranio-dysostosis where parts of both clavicles are deficient and associated anomalies are found in the skull, facial bones and pelvis. The clavicle develops from medial and lateral ossification centers and the condition may represent a failure of these centers to fuse. Pseudoarthrosis of the clavicle is almost always seen on the right, thought to be a consequence of pressure attrition from the somewhat higher right-sided subclavian vessels.

Shoulder and upper limb function is normally good but the prominent lump is unsightly, and overhead activity may become uncomfortable in maturity. Unlike congenital pseudoarthrosis of the tibia and radius, the condition is not associated with neurofibromatosis and readily unites after excision and bone grafting. Surgery is best performed around the age of 4 years.

### Radial club hand (preaxial absence)

Radial dysplasia is the commonest of the major longitudinal failures of formation (Fig. 29.4). It may present as partial or complete absence, bilateral or unilateral. When sporadic the etiology is unknown. The abnormality was seen previously in association with thalidomide when two thirds of cases were bilateral.

Radial dysplasia is always associated with thumb hypoplasia. The spectrum of clinical abnormality can range from mild radial deviation of the wrist and minimal thumb hypoplasia, to complete absence of the preaxial structures including the thumb, the carpal and metacarpal bones and the radius with associated shortening of the ulna and a stiff elbow joint. The deformity is characterized by a weak, radially deviated wrist and a short forearm which grows to only one half to two thirds of normal length. The hand is usually correctable upon the wrist after birth and the elbow lies extended with reduced active and passive flexion.

Early passive stretching and splinting is indicated and should continue until a decision is made regarding surgical treatment. The standard surgical management is centralization of the carpus over the third metacarpal with subsequent pollicization of the index finger.

Fig. 29.3 Pseudoarthrosis of the clavicle.

Fig. 29.4 Radial club hand.

Pollicization is the surgical shortening and rotation of an index finger to allow opposition with the other digits, so compensating for the absent thumb. Elbow mobility is a prerequisite for centralization procedures to ensure that hand to mouth movement is possible.

Radial deficiency may occur in isolation. Forty percent of patients with unilateral and 27% with bilateral radial club hand have associated malformations including those of the cardiac, genitourinary, respiratory, skeletal and neurological systems.<sup>10</sup> Syndromes associated with longitudinal radial deficiency include the VATER syndrome; the Holt–Oram syndrome (an autosomal dominantly inherited condition characterized by upper limb and cardiac malformations); thrombocytopenia absent radius (TAR) syndrome (a recessively inherited disorder where thrombocytopenia is present at birth and usually improves with growth); and Fanconi anemia.

### Ulna club hand (postaxial absence)

This condition is about ten times less common than absence of the radius. It is usually a partial absence of the lower two thirds of the ulna and sometimes the postaxial rays. The absent bone may be represented by a fibrous remnant which becomes a deforming force during growth, leading to progressive ulnar deviation of the wrist and secondary curvature of the radius. As the forearm grows, the radial bowing increases and the radial head may subluxate or dislocate proximally at the elbow joint.

Complete absence of the ulna is usually associated with a severe flexion contraction of the elbow and surgery has little to offer. In partial absence the deforming fibrous band can be excised to prevent progressive deformity. Other treatment strategies include ulna lengthening procedures as well as procedures to construct a so-called ‘one bone forearm’ where the proximal ulna is fused to the distal radius.

### Congenital dislocation of the radial head

Congenital dislocation of the radial head is rare and usually occurs in isolation (Fig. 29.5). It frequently presents late, often not until school age,

Fig. 29.5 Congenital dislocation of the radial head.

and may be difficult to distinguish from an overlooked post-traumatic dislocation. Radial head dislocation may also be acquired as a result of differential growth disturbance between the radius and ulna or secondary to conditions such as Madelung deformity or familial osteochondromatosis. Features that suggest congenital dislocation include a positive family history, bilateral involvement and the absence of a history of trauma. Radiographic features more typical of congenital dislocation include a small dome-shaped radial head, a hypoplastic capitellum and ulnar bowing.

Children present during school years with limited elbow extension, a palpable mass (the radial head) or pain with athletic activities. The radial head is most commonly dislocated posterolaterally and can be palpated at the lateral side of the elbow joint.

If identified under 2 years, consideration may be given to open surgical reduction of the radial head and anular ligament reconstruction. Though some promise is reported following this procedure the indications are yet to be properly defined, particularly the upper age limit at which surgery might be helpful.<sup>11</sup> Most children present beyond infancy and are best managed conservatively. If significant discomfort occurs, management may include the removal of degenerate fragments of bone or excision of the entire radial head, a procedure to be approached with caution in the immature skeleton because of its association with progressive valgus deformity at the elbow and subsequent elbow, wrist and ulnar nerve problems.

### Congenital radioulnar synostosis

Congenital synostosis of the proximal radius and ulna is a rare congenital abnormality caused by a failure of separation (Fig. 29.6). Forearm rotation is therefore prevented and the hand fixed in a degree of pronation. Many children present late because of their ability to compensate for the absent rotation of the affected forearm with rotational hypermobility of the wrist and compensating shoulder movement. If the fixed pronation is more than 60°, or if the condition is bilateral, children may present earlier with functional problems related to manual dexterity.

In the absence of functional limitation no treatment is required. Functional difficulties may lead to consideration of surgery to remove the abnormal fusion between radius and ulna, but this has generally proved disappointing.

### Congenital pseudoarthrosis of the forearm

Congenital pseudoarthrosis of the forearm is very rare but affects the ulna more commonly than the radius. Like its more common counterpart in the tibia it is associated with neurofibromatosis and nonunion after attempted reconstruction precludes successful treatment.

### Madelung deformity

This wrist deformity results from an unexplained premature growth arrest of the ulnar aspect of the distal radial physis (or growth plate). Continued normal growth of the ulnar physis and the radial and dorsal aspects of the distal radial physis leads to progressive deformity. The distal ulna becomes more prominent and the distal radial articular surface becomes angulated toward the ulna. The carpus sinks into the developing gap between the radial and ulnar styloids.

Madelung deformity usually occurs in girls and is most often bilateral. It is usually sporadic but may be inherited as part of dyschondrosteosis (Leri–Weill disease), and has been associated with a variety of conditions including Hurler syndrome, Turner syndrome, multiple hereditary exostoses and Olliers disease. Damage to the growth plate from trauma or infection can also give rise to Madelung-like deformities.

Most patients do not present until adolescence when deformity and discomfort with activity are often marked. Treatment strategies include corrective radial osteotomy and ulnar shortening or other procedures to remove or stabilize the distal ulna, which is frequently the site of pain and wrist degeneration.

### Syndactyly

Syndactyly is classified as simple, if the failure of separation involves only skin, and complex, if other structures such as nail, bone, tendon, nerve or blood vessels are involved. It is complete if the skin bridge is present to the distal tip of the finger. The interspace between the third and fourth fingers is most commonly affected, with that between the first and second less frequently involved. Treatment depends upon the site and complexity, border digits being separated early to prevent progressive angulation. The separation of simple syndactyly gives excellent results.

### Polydactyly

Polydactyly is classified as preaxial (thumb), central (index, middle) or postaxial (ring, little). Genetic transmission of polydactyly is

Fig. 29.6 Congenital radioulnar synostosis.

common especially in native Africans, where postaxial duplication is predominant. The extra digit may be fully formed or vestigial. Before embarking on surgical correction it is important to determine which digit has the majority of intact parts and is therefore most suitable for reconstruction.

### Camptodactyly

This is a flexion deformity affecting the proximal interphalangeal joint of the fingers and often inherited as an autosomal dominant trait. The precise etiology is unknown but it usually presents during periods of rapid growth, i.e. infancy and adolescence. In infants there is an equal sex distribution and any finger can be affected. Adolescent cases are more common and invariably affect the little finger, usually in girls. Treatment in infancy involves passive stretching and splintage and occasionally surgical release of soft tissues. In adolescence dynamic splintage may lead to modest improvement.

### Clinodactyly

This is angulation of a digit in the radial or ulnar direction. Radial angulation of the tip of the little finger is the most common and often inherited as an autosomal dominant trait. Treatment is seldom necessary.

### Trigger thumb

This is the commonest hand anomaly in infants and small children. It is something of a misnomer because the thumb does not really 'trigger' with sudden extension, as does the adult trigger finger, but is usually stuck in a flexed position. Clinically there is a palpable swelling in the thumb flexor tendon and flexor sheath on the volar aspect of the base of the thumb. About one third of cases resolve spontaneously in the first year but later persistence makes spontaneous resolution unlikely. Surgical treatment to divide the entrance to the flexor sheath is simple and gives excellent results. It should be done before 4 years of age.

### Hypoplastic thumb

Thumb hypoplasia is a form of preaxial longitudinal failure of formation and like radial club hand is associated with congenital anomalies in other systems (e.g. VATER, VACTERL syndromes). It ranges from a mild anomaly where the thumb is fully formed but small, to complete absence of the thumb. In mild hypoplasia no treatment is necessary but if function is impaired by a tight thumb–index finger web space or thenar muscle hypoplasia, reconstructive surgery can be helpful. If the thumb is absent or unreconstructable pollicization of the index finger can be considered.

### Constriction band syndrome

This condition occurs sporadically and is alternatively known as Streeter dysplasia or amniotic band syndrome (Fig. 29.7). The etiology remains uncertain; hypotheses include constriction by intrauterine amniotic bands and localized failures of formation. Bands can be multiple and are asymmetric. Structures proximal to the band are normal but distally may be deformed or even amputated. Tight bands can cause severe distal edema and vascular compromise with urgent 'Z'-plasty release required in the neonatal period.

## LOWER LIMB PROBLEMS

### Congenital abnormalities of the femur

Congenital abnormalities of the femur fall into two main groups: proportional hypoplasia of the whole femur and a deficiency of part or all of the bone. Both can be associated with more distal abnormalities, including absence of the anterior cruciate ligament at the knee and congenital abnormalities of the lower leg and foot.

Children present with a limb length discrepancy either at birth or during early development. The femoral head and neck are radiolucent for the first 6 months of life even when no abnormality is present and ultrasonography provides a more reliable assessment.

Fig. 29.7 Constriction band syndrome.

### Proximal femoral focal deficiency (PFFD)

PFFD or deficiency of the proximal part of the femur varies in severity (Fig. 29.8). Clinical examination typically reveals a position of flexion at the hip and the knee. Management of these children is complex and depends not only upon the potential limb length discrepancy, but also upon the stability of the hip joint and the presence of associated limb problems.

### Developmental coxa vara

The neck-shaft angle of the proximal femur measures a mean  $144^\circ$  in the first years of life, gradually falling to a mean  $125^\circ$  at maturity. Coxa vara is present when the neck-shaft angle falls below these parameters.

Coxa vara can be congenital, developmental or acquired as a consequence of a variety of conditions including developmental dislocation of the hip, slipped upper femoral epiphysis, Perthes disease, infection, trauma, tumors and metabolic disorders.

Congenital coxa vara is present at birth and commonly associated with other congenital musculoskeletal abnormalities.

Fig. 29.8 Proximal femoral focal deficiency.

Developmental coxa vara is a specific entity of unknown etiology and an incidence of 1 in 25 000 births. There is an equal sex ratio and 30–50% of patients have bilateral disease. Most patients present between 1 and 6 years of age with a progressively deteriorating, but painless, Trendelenburg gait. Radiographs classically reveal coxa vara often with a neck-shaft angle of  $90^\circ$  or less and a vertically orientated physis (growth plate). A triangular piece of metaphysis outlined by an inverted 'Y' formed by the physis on one side and radiolucent dystrophic bone on the other, is pathognomonic of the condition (Fig. 29.9). If left untreated the condition will lead to progressive degeneration, disability and pain. Valgus osteotomy to correct the deformity has been shown to be effective.<sup>12</sup>

### Developmental dysplasia of the hip (DDH) and congenital dislocation of the hip (CDH)

The term developmental dysplasia of the hip (DDH) encompasses the located hip with a shallow acetabulum (dysplasia), through subluxation to frank dislocation. DDH is a more accurate term than congenital dislocation of the hip (CDH) and was introduced in recognition of the concept that a hip, located at birth, can become dislocated postnatally. When dislocation of the hip presents at birth or in the neonatal period it is termed an early presentation. Dislocation presenting beyond this period, commonly after 6 months, is termed a late presentation. The term 'missed dislocation' should be avoided because it can be inaccurate. The term teratological dislocation is used to describe a dislocated hip in association with underlying problems such as arthrogryposis multiplex congenita or neuromuscular conditions.

One in 60 neonates have hip instability demonstrable at birth, although most of these hips stabilize spontaneously within the first weeks of life. Before the introduction of routine clinical screening in the UK the incidence of late dislocation was about 1–2/1000 live births. Screening has reduced but not eradicated late presentation in the UK, a recent MRC trial showing the incidence to be at least 0.78/1000 live births.<sup>13</sup> There is considerable racial variation in the incidence of DDH. The incidence is very high in Navajo Native Americans, in the order of 50/1000 live births, but very low in peoples of Chinese and African descent. DDH is six times more common in females than males, and more common in first-born infants. It can present bilaterally but is usually unilateral and twice as common on the left.

Environmental factors both in utero and after delivery can influence hip development. The most common fetal lie places the infant's left hip adducted against the maternal sacrum and it is thought that this might be the explanation for the predilection for the left side. Breech position in utero is a significant risk factor, as is oligohydramnios which limits fetal movement. Other conditions considered to be a result of intrauterine molding, including metatarsus adductus and torticollis, are associated with DDH. Postnatal influences include nursing habits such as swaddling. The infant hip and knee joints in utero are in a flexed position and normally have modest flexion contractures at birth. An attempt

Fig. 29.9 Developmental coxa vara.

to straighten and adduct the limbs prematurely results in compression forces along the shaft of the femur, pushing the femoral head postero-superiorly, where it is unstable. Cultural swaddling may in part explain the differing incidence of DDH between races. The hips are best allowed to rest in flexion and abduction, the position most infants naturally adopt. Early diagnosis gives the best chance of a satisfactory outcome.

Clinical examination to identify DDH is based on the observations of Ortolani and Barlow. The first part of clinical examination is to determine whether the hip is in or out of joint. Clinical signs suggestive of dislocation include limited abduction, limb length asymmetry and asymmetrical skin creases (Fig. 29.10). If the hip is considered to be in joint, its stability is evaluated with a Barlow maneuver. The hip is first placed in a vulnerable position of slight extension and adduction before longitudinal compression is applied along the shaft of the femur (Fig. 29.11a) (the positioning is important because the hip is more stable and resists subluxation or dislocation if held incorrectly in a position of flexion and abduction). If the hip is unstable there is a palpable sensation of the femoral head riding posteriorly over the posterior rim of the acetabulum, the so-called 'clunk'. There is a similar sensation when compression is released and the femoral head returns to the acetabulum or if an Ortolani maneuver is used to reduce the joint. If the hip is considered to be dislocated, a gentle attempt can be made to return it to the acetabulum using an Ortolani maneuver. Once again positioning is important. The hip is held in 90 degrees of flexion so that the femoral head is directly posterior to the acetabulum. Gentle traction is applied to the leg and the long fingers of the examiner's hand are placed on the greater trochanter where they gently lift the femoral head (Fig. 29.11b). If the dislocation is reducible, the femoral head can be felt passing across the posterior lip of the acetabulum and into the joint. Once in joint, the hip can be gently abducted and flexed to a more stable position so that the reduction can be maintained.

These examinations are difficult and the introduction of clinical screening has not eradicated late presenting dislocations. The sensation of dislocation or reduction is difficult to elicit in the conscious child over about 3–4 months of age and thereafter limited abduction, or limb asymmetry are more reliable. After walking age the child with a unilateral dislocated hip stands either with the 'long' leg flexed at the knee or with the 'short' leg standing tiptoe to compensate for the length discrepancy. The child will walk with a limp, which can be a simple short leg gait, sometimes with a classic waddle or Trendelenburg gait pattern. Symmetry in bilateral dislocation can make these signs less easily identifiable. Radiographs reveal a subluxed or dislocated femoral head with a small ossific nucleus and a dysplastic acetabulum (Fig. 29.12).

The limitations of clinical examination and the inability of radiographs to image the cartilaginous infant hip has led to the development of ultrasound screening. Population ultrasound screening has been introduced in Germany and parts of Europe but remains sporadic in the UK.

Fig. 29.10 Dislocated right hip showing limited abduction, asymmetrical skin creases and short limb.

(a)

(b)

Fig. 29.11 (a) Barlow and (b) Ortolani maneuvers.

Many units practice selective screening of higher risk infants, i.e. those with a family history, a breech position in utero, a suspicious hip examination or who exhibit other structural examination abnormalities such as metatarsus adductus or torticollis. The investigation can result in false negatives and especially false positives, revealing 'abnormalities' of uncertain significance and resulting in high treatment rates. While it is acknowledged that ultrasound examination is an unequivocally useful tool to evaluate the progress of unstable and dislocated hips, its role as a screening tool for DDH in the UK remains controversial and its cost

Fig. 29.12 Dislocated left hip with dysplastic acetabulum and small ossific nucleus.

effectiveness is questioned.<sup>14</sup> The National Screening Committee (NSC) in the UK currently recommends that every child should have a clinical examination based on the Ortolani Barlow maneuver within the first week of life and again at 6 weeks.<sup>15</sup> Those with a positive clinical examination should have an ultrasound. In July 2006 the NSC determined that population ultrasound screening should not be offered unless part of an ethically approved and externally funded research project (<http://www.library.nhs.uk/screening>).

In general terms, reduction of a dislocated hip becomes progressively more difficult the longer it has been dislocated. Treatment involves first reducing the hip and then keeping it in joint until it becomes stable. The chief complications of any treatment are re-dislocation and avascular necrosis (AVN) of the femoral head. The circulation of the femoral head is vulnerable and especially sensitive to pressure. It is known that forceful reduction or positioning of the hip in extreme flexion, abduction or internal rotation can apply excessive pressure to the femoral head and disturb the blood supply leading to AVN. In spite of avoiding these known causes, AVN remains a troublesome complication in the management of hip dislocation (Fig. 29.13).

From birth to about 3–4 months the dislocated or subluxed hip will often reduce with a gentle Ortolani maneuver and should then be maintained in a position of gentle flexion and abduction until it becomes stable when released. There are a wide variety of splints available to maintain this position but the Pavlik harness (Fig. 29.14), a dynamic splint affording the infant some movement within a safe arc, is probably the most widely used. The harness is worn 23–24 hours a day and

Fig. 29.13 Avascular necrosis after treatment for developmental dislocation of the hip.

Fig. 29.14 Infant in Pavlik harness.

requires regular scrutiny to ensure proper fitting. Hip development can be followed by repeated ultrasound examination at 2- or 4-weekly intervals until normal with a clinically stable hip. Harness treatment typically lasts 12–16 weeks if the dislocation is identified early. The Pavlik harness is not practical in children older than about 6 months.

When children present between 4 and 6 months of age it can be difficult to be certain of an adequate reduction, in the conscious patient, and these infants are often examined under anaesthesia. Radio-paque contrast is introduced into the hip joint during the examination and the resulting arthrogram outlines the cartilaginous femoral head and acetabulum so that a satisfactory reduction can be confirmed (Fig. 29.15). If there is any obstruction to proper location or extreme force or positioning is required to maintain satisfactory location, closed (nonsurgical) reduction is best abandoned in favor of later open (surgical) reduction when the obstruction or resistance to location can be addressed operatively. If closed reduction is possible, immobilization in a stable position of gentle flexion and abduction can be achieved by a plaster of Paris hip spica cast, once again avoiding extreme or forced positions. The reduction should be confirmed by a later CT scan of the hips in the spica cast. Typically such children remain immobilized for 6–9 months.

When children present after about 12–18 months successful closed reduction becomes unlikely. The later a child presents the more likely they are to require a surgical open reduction and further secondary operations either to the femur or to the acetabulum to correct secondary problems especially persistent acetabular shallowness (dysplasia). Late presentation increases the chance of secondary surgery and complications reducing the chance of a perfect outcome.

### Congenital dislocation of the knee

This presents at birth with the knee severely hyperextended instead of in the normal flexed position (Fig. 29.16). The etiology is unknown, but there is a high incidence of breech delivery indicating a role for intra-uterine positioning. Associated musculoskeletal abnormalities, especially subluxation or dislocation of the hip, are present in approximately 50%. Plain lateral radiographs reveal anterior subluxation or dislocation of the tibia on the femur.

Treatment begins soon after birth with serial casting to gradually flex the knee and is often successful within a few weeks of birth. If conservative treatment fails, there may be some underlying fibrosis of the quadriceps mechanism and open surgical release early in life can give good long term results.

Fig. 29.15 Arthrogram showing a satisfactory closed reduction of a dislocated hip.

Fig. 29.16 Congenital dislocation of the knee.

### Tibial bowing

Tibial bowing at birth can take four characteristic forms. Broadly speaking the convexity of the bow points to the four points of the compass namely anteromedial, anterolateral, posterolateral and posteromedial. The first three directions are associated with relatively severe problems namely fibula hemimelia, pseudoarthrosis of the tibia and tibia hemimelia respectively. Posteromedial bowing of the tibia is relatively benign.

#### *Posteromedial bowing of the tibia*

Posteromedial bowing of the tibia is associated with a severe calcaneovalgus deformity of the foot.<sup>16</sup> The appearance can be alarming at birth. Initial treatment is directed toward passive stretching of the foot deformity, sometimes with the addition of serial casting. The tibial bowing generally corrects in the first year of life, although tibial length inequality may persist and require later orthopedic intervention.

#### *Congenital fibula deficiency (fibula hemimelia)*

The fibula is the most frequently congenitally deficient long bone. The deficiency can be modest and isolated. Severe fibula deficiency is more common and is associated with a generally dysplastic limb and other deformities.

The choice of appropriate management can be extremely difficult. Modern prosthetics make amputation more acceptable and new methods of limb reconstruction, especially with the Ilizarov external fixator, make reconstruction more feasible. Amputation is recommended if the foot is nonfunctional, regardless of limb length, and if the length discrepancy is more than 30% even with a functional foot. Application of the appropriate management requires considerable clinical experience and should be tailored to the individual patient.

#### *Congenital tibial deficiency (tibia hemimelia)*

The child presents at birth with shortening of the tibia and a rigid equinovarus foot. The leg is bowed convex laterally. Other congenital limb abnormalities occur in up to 75%.<sup>17</sup> The tibia can be completely absent (Type I); absent in its distal portion but with a proximal portion remaining to form an articulation at the knee (Type II) (Fig. 29.17); or present but forming an abnormal distal tibiofibula diastasis or separation at the ankle (Type III).<sup>18</sup>

Management strategies range from prosthetics to reconstruction and once again, as in fibula hemimelia, considerable clinical experience is required to chart an appropriate course for each individual patient.

Fig. 29.17 Congenital tibial deficiency.

#### *Congenital pseudoarthrosis of the tibia*

Congenital pseudoarthrosis of the tibia presents with anterior or anterolateral bowing at the junction of the proximal two thirds and the distal one third of the tibia. Up to 80% of cases are associated with neurofibromatosis.<sup>19</sup> The bone and its covering periosteum are abnormal at the site of the bowing and the fibula may also be involved in the pathology. Spontaneous fracture at the abnormality can occur and subsequently leads to persistent nonunion or pseudoarthrosis.

Management should include the avoidance of fracture for as long as possible by the use of protective orthoses. Numerous methods have been used to encourage union at the fracture site with modest success. A Syme amputation of the foot followed by a below knee prosthesis remains a satisfactory long term solution, although modern reconstructive techniques especially using the Ilizarov external fixator offer new solutions. The abnormal bone and periosteum at the site of the pathology can be excised and the remaining healthy bone lengthened.

### Metatarsus varus

See section on 'Common orthopedic problems in childhood', page 1415.

### Congenital talipes calcaneovalgus

This foot posture is frequent in newborns and in the majority of children is within the spectrum of normality. The foot is dorsiflexed so that the dorsum touches the shin. If the foot can be fully plantarflexed the condition is termed postural, requires no treatment and will resolve spontaneously. Occasionally the foot cannot be fully plantarflexed. Physiotherapy and/or splintage should be commenced promptly to stretch the tight anterior structures and should be successful in most cases. In resistant cases, the possibility of an underlying neurological or skeletal abnormality should be considered.

### Congenital talipes equinovarus (CTEV; congenital club foot)

Congenital talipes equinovarus is a common foot abnormality with an incidence of 1–2/1000 live births (Fig. 29.18). It is twice as common in boys, bilateral in up to 50% and has a familial predisposition. Unaffected parents with an affected son have a 1:40 chance of having another son with the disorder. The pathogenesis is unknown.

Clinically the hindfoot is in equinus and varus (inversion) and the heel is difficult to feel. The forefoot is adducted and plantarflexed on the hindfoot giving a cavus or high arched appearance, and there is a deep transverse skin crease on the medial border of the foot. Internal tibial torsion is present and the foot and calf are often smaller than the opposite side. The navicular is medially displaced on the head of the talus. Passive correction to a neutral position is not possible.

A complete examination of the child is indicated to rule out potential neurological causes and associated conditions including DDH. Assessment of the severity and rigidity of the deformity at birth is difficult but helpful in determining the likely success of nonoperative treatment such as serial manipulation or casting versus the need for operative surgical correction. According to Harrold and Walker in 1983, if the foot can be passively returned to neutral, conservative treatment can be expected to be successful in 90%.<sup>20</sup> If fixed equinus is 0–20° degrees conservative treatment can be expected to succeed in 50% of cases; but if fixed equinus is more than 20° conservative treatment can only be expected to be successful in 10%.<sup>20</sup>

Fig. 29.18 Congenital talipes equinovarus.

More recently a serial manipulation and casting technique described by Ignacio Ponseti<sup>21</sup> has become the preferred method of management in many centers. Results indicate a higher success rate for this non-operative management technique, even in feet that are quite stiff from the outset. Children should be referred soon after delivery so that treatment can begin early. The technique involves a specific series of manipulative maneuvers to correct the underlying deformity followed by the application of a series of holding casts which are changed weekly. Typically after about six cast changes the forefoot and hindfoot are corrected but the foot remains in equinus. A percutaneous Achilles tenotomy is often necessary at this stage to allow correction of the equinus, followed by the application of the final cast which holds the position. The final cast is usually removed about 3–6 weeks later and thereafter the child must wear 'Denis Browne' boots and bar. This consists of boots that are connected by an adjustable bar holding the feet in external rotation, eversion and dorsiflexion. It is important for the success of the method that the patient and family comply with the proper use of this holding device. In the typical program the patient must wear the boots and bar continuously for 3 months following removal of the last holding cast and then for night time and naps for a further 3–4 years.

Although the Ponseti technique has changed the management of CTEV, some cases do not respond favorably and require surgical intervention although this is often less invasive than previously. It is important to warn parents of this potential from the outset and also to explain that some very resistant cases still require a more traditional surgical management. Recurrence of deformity is always a concern during the management of CTEV treated by any means and secondary surgery to correct recurring deformity, especially forefoot varus, is not uncommon. Sometimes repeated recurrence occurs in spite of secondary operations: this can be successfully managed using Ilizarov external fixator techniques.

### Congenital vertical talus

This is a rigid foot deformity that presents clinically as a 'rocker bottom' foot. In about 50%<sup>22</sup> the condition is associated with other congenital neuromuscular and genetic disorders like neural tube defects and arthrogyrosis. The head of the talus is dislocated from its normal articulation with the navicular and takes on a more vertical position. Diagnosis is made with a lateral radiograph and the foot stressed into maximal plantarflexion. If the navicular remains dorsally dislocated on the talus, the diagnosis is confirmed (Fig. 29.19).

Fig. 29.19 Congenital vertical talus.

In addition to the vertical position of the talus and the tight anterior structures causing dorsal dislocation of the forefoot, the posterior structures are also tight resulting in fixed equinus of the hindfoot as in CTEV. The hindfoot and forefoot are therefore essentially broken over the vertically disposed talus giving the foot the characteristic 'rocker bottom' in severe cases.

Initial treatment is directed toward passive stretching and splinting of the foot into plantarflexion to stretch the tight anterior structures. Surgery is frequently necessary later to lengthen the tight anterior and posterior structures and to restore the normal alignment and relationship of the talus with the other bones of the foot. Favorable results are emerging with a modification of the Ponseti technique used in CTEV.<sup>23</sup>

## INHERITED DISORDERS OF BONES AND JOINTS

Inherited disorders of bones and joints are a rare but important source of diagnostic confusion for the unwary as they may be easily confused with other disorders such as juvenile arthritis and Perthes disease. Most present with some combination of joint swelling or deformity; joint hypermobility or stiffness; and short stature. An awareness of these conditions will enable the correct diagnosis to be made, ensuring appropriate advice and genetic counseling is given.

This section is not intended to be an exhaustive review of a very complex area but describes some of the more common primary genetic disorders of bones and connective tissues, as well as identifying other genetic disorders in which bone and joint problems are a dominant feature. Many of these primary disorders of bones and connective tissues have been associated with identifiable genetic defects, particularly of the collagen genes. As these genetic defects are increasingly delineated it seems likely that the classification of these conditions will continually be updated and improved.<sup>24,25</sup>

## HYPERMOBILITY

Joint mobility follows a normal distribution in the population and is influenced by factors including age, sex and ethnicity. Infants and young children have joints that are more mobile than older children and adults but there are no good studies defining normal joint ranges in the very young. Females have a greater degree of joint laxity than males and hypermobile joints are much more common in certain ethnic groups, e.g. oriental. Hypermobility of the joints may be generalized or affect only one or two joints. Generalized joint hypermobility may occur as an isolated entity or as part of a number of well-recognized genetic syndromes.

The definition of hypermobility is based on clinical assessment. The criteria most frequently used are those defined by Beighton<sup>26</sup> which assess joint laxity based on a number of clinical maneuvers:

1. passive dorsiflexion of the 5th metacarpophalangeal joint to 90°;
2. apposition of the thumb to the flexor aspect of the forearm (Fig. 29.20a);
3. hyperextension of the elbow to greater than 10° (Fig. 29.20b);
4. hyperextension of the knee to greater than 10°;
5. forward flexion of the trunk to place the palms of the hands flat on the floor with the knees extended.

Those experienced in examining children will immediately realize that these measurements are not appropriate in the very young in whom these degrees of joint laxity are normal. There is a need to define age-related normal values but the Beighton scoring system has been shown to be valid in children over the age of 4 years when interpreted correctly.<sup>27</sup> More recently revised criteria have been developed<sup>28</sup> but have not been extensively used or validated in pediatric practice.

## Benign hypermobility syndrome

Joint hypermobility is a normal variant and causes no symptoms in most individuals. In others it is associated with a variety of musculoskeletal symptoms as part of the 'benign joint hypermobility syndrome' (BJHS).<sup>29</sup> Although labeled 'benign', affected individuals may have troublesome symptoms with significant morbidity and it may be impossible to differentiate from the milder variants of some of the genetic disorders such as Ehlers-Danlos syndrome.

BJHS occurs more commonly in females than in males and appears to have an autosomal dominant mode of inheritance. Affected children may have a variety of symptoms including arthralgia, joint effusions, widespread muscle pain, low back pain, flat feet and recurrent dislocations with many reporting significant functional difficulties.<sup>30</sup> Young children with hypermobility should be carefully assessed for associated coordination or proprioceptive difficulties which may contribute to their symptoms. Recurrent sports injuries, back pain and an increase in chronic musculoskeletal pain are reported in older children and adolescents with BJHS.

Despite much interest, the association between hypermobility and symptoms remains poorly understood.<sup>31</sup> Many hypermobile individuals remain asymptomatic while others have significant symptoms. Management consists of explanation of the condition, multidisciplinary input from physiotherapy, occupational therapy and podiatry together with appropriate pain management if required.

## INHERITED SYNDROMES WITH SIGNIFICANT HYPERMOBILITY

### Ehlers–Danlos syndrome

Ehlers–Danlos syndrome (EDS) consists of a group of disorders of connective tissue characterized by joint hypermobility plus fragility and laxity of the skin and other tissues. These conditions are characterized by abnormalities in collagen genes resulting in the production of abnormal collagens III and V and consequent tissue fragility. They vary both in severity and mode of inheritance and an accurate diagnosis is essential if patients are to be offered appropriate advice and counseling.

Over the years, 11 different types of Ehlers–Danlos syndrome have been described. A revised, simplified classification was agreed in 1997<sup>32</sup> with three major types being defined clinically. Although further refinement will occur this classification has been widely accepted and is helpful clinically and prognostically in clearly distinguishing between the vascular, potentially catastrophic, form of the condition and the others. The three major types are defined as follows.

1. 'Classical' EDS (previously types I and II): characterized by the classical skin hyperextensibility and associated joint hypermobility. In many cases this results from abnormalities of the COL5A1 and A2 genes.
2. Hypermobility EDS (previously type III): characterized predominantly by joint hypermobility and very difficult to distinguish from BJHS.
3. Vascular EDS (previously type IV): associated with vascular, intestinal and uterine rupture. This results from mutations in the COL3A1 gene which causes production of abnormal type III collagen. Although the inheritance is autosomal dominant, approximately one third are new mutations. The diagnosis can be confirmed by collagen studies of cultured dermal fibroblasts.

### Marfan syndrome

Marfan syndrome, also an inherited disorder of connective tissue, affects approximately 1 in 10 000 of the population. Inherited as an autosomal dominant trait it results from mutations in the genes encoding for the glycoprotein fibrillin, a component of elastin fibrils in the extracellular matrix.<sup>33</sup>

Marfan syndrome is characterized by tall stature, long extremities, fingers and feet, chest deformities, high arched palate and ocular abnormalities including lens dislocation. Joint hypermobility, although not diagnostic, is recognized frequently and there is a high incidence of spinal problems with the development of both scolioses and kyphoses. Mitral valve prolapse is common. Aortic valve disease and a tendency to sudden aortic rupture are of major concern.

Many individuals are only mildly affected and the diagnosis can be difficult. Diagnostic criteria are currently based on clinical features<sup>34</sup> but recent reports suggest that this can now be supported by molecular analysis.<sup>35</sup>

Individuals with type 1 homocystinuria may have tall stature, a high arched palate and resemble Marfan syndrome. Hypotonia occurs but the joints are stiff rather than hypermobile. Severe osteoporosis and mental retardation are characteristic.

### Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is a group of autosomal dominantly inherited collagen gene disorders typified by bone fragility and often associated with joint hypermobility.<sup>36</sup> The underlying defect in these conditions lies in the genes COL1A1 and COL1A2<sup>37</sup> which encode the peptide chains of type I collagen, the major structural protein of bone, ligament and tendon. Clinically the important features are those of an inherited osteoporosis. Radiological appearances range from mild osteoporosis with occasional fractures to a widespread skeletal abnormality with multiple fractures. In its most severe form, OI may be lethal in utero.

Types I and IV OI are the mildest forms of the condition, presenting with recurrent fractures in infancy and childhood (Fig. 29.21). Spinal involvement results in short stature which may be marked. There is a

Fig. 29.21 Osteogenesis imperfecta type I.

tendency for the fracture rate to reduce after adolescence but become more severe again in later adult life. Type I is distinguished by the presence of the characteristic blue sclerae. Associated dentinogenesis imperfecta and joint laxity occur with variable frequency.

Type II OI is a severe, crippling and frequently lethal disease. Multiple intrauterine fractures occur and early death results from chest infections and pulmonary restriction caused by the widespread fractures. Type III (Fig. 29.22) is the most severe nonlethal form causing severe bone fragility with marked joint hypermobility. Survivors of infancy are usually significantly disabled.

Until recently there has been no treatment for individuals with OI other than appropriate orthopedic management of fractures and supportive care. Expert physiotherapy and orthopedic input remain critical to optimal management of these children. The development of the bisphosphonate group of drugs offers new possibilities for treatment. Cyclical treatment with intravenous pamidronate has been shown to result in reduced bone pain, a significant increase in bone density, a

Fig. 29.22 Osteogenesis imperfecta type III showing recent fracture, severe osteoporosis and femoral deformity.

decreased number of fractures and an improved quality of life in many.<sup>38</sup> The role of oral bisphosphates remains unclear.

### Stickler syndrome

Stickler syndrome is an inherited disorder of connective tissues characterized by a typical facies with midface hypoplasia, high myopia with early onset, progressive hearing loss and arthropathy. Joint problems include both generalized joint hypermobility and early degenerative joint disease. Retinal detachment is a serious complication. Type I Stickler syndrome, the majority, has been associated with mutations in the COL2A1 gene encoding type II collagen and diagnostic criteria based on clinical features plus genetic confirmation have been developed.<sup>39</sup>

## INHERITED SKELETAL DYSPLASIAS

### Spondyloepiphyseal dysplasia (SED)

The spondyloepiphyseal dysplasias consist of a group of heritable disorders principally involving the spine and the epiphyses of the long bones. Several forms are described of varying severity. Type II collagen is the main protein component of articular cartilage and mutations of the COL2A1 gene are thought to result not only in the already mentioned Stickler syndrome but also in a number of other disorders including the spondyloepiphyseal dysplasias.

SED congenita is an autosomal dominant condition with its onset at birth. Affected children may have delay in walking, a waddling gait and short stature. Limitation of range of motion affects elbows, knees and hips. Radiological investigation shows flattening of the vertebrae (Fig. 29.23) and coxa vara.

SED tarda results in symptoms which seldom present before adolescence. Although usually X-linked recessive, autosomal recessive and dominant forms have also been described. Spinal and hip involvement occur and the course is usually benign. Early onset of osteoarthritis occurs in adult life.

Progressive pseudorheumatoid arthropathy is a variant of SED (Fig. 29.24) which presents between 3 and 11 years of age with painful, swollen joints especially affecting the hands. Progressive joint contractures and short stature develop and the condition is unresponsive to standard antiinflammatory medication.

### Multiple epiphyseal dysplasia

This is one of the more common skeletal dysplasias and is inherited as an autosomal dominant trait. It presents in childhood with pain and stiffness, usually progressing to joint contractures and associated short stature. At first sight it may be confused with juvenile arthritis, but the absence of signs and symptoms of inflammation can distinguish the two. Radiology demonstrates irregularities of the end-plates of the mid-thoracic vertebral bodies, shortening of the metacarpals and flattening, sclerosis and fragmentation of the epiphyses at the hips and knees (Fig. 29.25).

### Achondroplasia and hypochondroplasia

These disorders result from mutations of fibroblast growth factor receptor 3 (FGFR3) genes. Although inherited as an autosomal dominant trait, most cases of achondroplasia occur as new mutations. The classic form of achondroplasia causes severe disproportionate short stature. Affected individuals have normal or large heads with shortening of the limbs and an increased lumbar lordosis. The pedicles of the vertebrae are short which may lead to symptomatic spinal stenosis in adult life. Hypochondroplasia is a milder form resulting from different mutations in the FGFR3 gene.

### Trichorhinophalangeal dysplasia

This autosomal dominant disorder results from the deletion of multiple genes on chromosome 8. It is characterized by enlargement of the interphalangeal joints with characteristic facial features: a bulbous nose, hyperplastic nares, sparse, brittle hair and short stature.

Fig. 29.23 Spondyloepiphyseal dysplasia congenita showing abnormal vertebrae.

Fig. 29.24 Spondyloepiphyseal dysplasia tarda (progressive pseudorheumatoid arthropathy) affecting hands with obvious swelling of joints and bulbous ends to the phalanges.

Fig. 29.25 Multiple epiphyseal dysplasia with bilateral hip involvement.

Radiographic features include cone-shaped epiphyses with short metacarpals and metatarsals plus fragmentation of the epiphyses. Fragmentation of the femoral epiphyses may cause confusion with Perthes disease.

### Storage disorders: the mucopolysaccharidoses (MPS)

The MPS are genetically determined deficiencies of enzymes involved in the metabolism of glycosaminoglycans. All are inherited as autosomal dominant conditions and a prominent feature of most is a skeletal dysplasia affecting particularly the hands, feet and vertebrae and which may be the presenting feature. In the milder forms such as Scheie and Morquio syndromes the joint problems may dominate the clinical picture. In the more severe forms such as Hurler syndrome the characteristic coarsening of the facial features is striking but may be preceded by flexion deformities of the fingers.

An awareness that these conditions may present with skeletal symptoms will enable their early recognition, allowing appropriate genetic advice and counseling. For more detail see Chapter 26.

### OTHER INHERITED DISORDERS PRIMARILY AFFECTING THE MUSCULOSKELETAL SYSTEM

There are many other inherited disorders that primarily affect the musculoskeletal system and are currently difficult to categorize.

#### Osteopetrosis

This is a rare disorder resulting in frontal bossing, hypertelorism, exophthalmos and nasal obstruction which may be present from birth. It progresses during early childhood resulting in severe bleeding problems, recurrent fractures and early death. The disease is characterized by an increased density of the bones with metaphyseal flaring. Bone marrow transplantation may offer a cure.

#### Arthrogryposis

This refers to a number of disorders characterized by multiple congenital contractures.

#### Ollier disease

Ollier disease or multiple enchondromatosis becomes apparent during childhood when it presents with multiple juxta-articular outgrowths.

#### Idiopathic acro-osteolysis

This is inherited as an autosomal dominant trait and generally presents around 3 years with bony lysis which may affect the carpus or tarsus alone or occur in a more widespread pattern. The condition may

mimic juvenile arthritis in that affected areas are warm and swollen. Radiographs show progressive bone lysis and destruction of affected joints.

### Fibrodysplasia ossificans progressiva (FOP)

FOP is a rare autosomal dominant condition now known to result from dysregulation of the BMP-4 signaling pathway.<sup>40</sup> Painful inflammation of muscles and fascia, often triggered by minor trauma, is rapidly followed by fibrosis and calcification and the child presents with swelling in a muscle or the development of a contracture. Radiographs will show calcification in, and eventually ossification of, the muscles (Fig. 29.26a). The condition is characterized by congenitally short great toes (Fig. 29.26b), and sometimes thumbs, which may be diagnostic. The disease progresses to severe disability and to date no treatment has been shown to influence the natural disease progression.

(a)

(b)

Fig. 29.26 Fibrodysplasia ossificans progressiva showing (a) ossification of anterior neck muscles and (b) dysplastic great toes.

## OTHER INHERITED DISORDERS ASSOCIATED WITH MUSCULOSKELETAL PROBLEMS

Many inherited conditions may result in musculoskeletal problems. Some of the more important are outlined here. All are covered in more detail in other relevant chapters.

### Down syndrome (trisomy 21)

Down syndrome is associated with a variety of musculoskeletal problems. In infancy generalized muscular hypotonicity may be striking and many affected individuals remain significantly hypermobile with associated symptoms. Atlantoaxial instability is of major concern. An inflammatory arthropathy of unknown cause is well recognized in affected children.

### Velocardiofacial syndrome (22q11 deletion syndrome)

This syndrome is a common cause of congenital cardiac malformations and is associated with a variety of immunological abnormalities, particularly impairment of T cell function. Perhaps as a consequence of this it is now known to be associated with an inflammatory arthritis.<sup>41</sup>

### Cystic fibrosis (CF)

Many individuals with CF have arthralgias which may be troublesome but are not associated with any serious joint pathology. A few develop a recurrent acute arthropathy which can be extremely painful and distressing. Although the exact pathology is unclear it seems likely that this results from immune complex deposition and the cutaneous vasculitis that may occur is presumed to have a similar mechanism. Nonsteroidal anti-inflammatory drugs may be inadequate to control these acute symptoms and short courses of oral steroids may be helpful. In severe longstanding cystic fibrosis, hypertrophic pulmonary osteoarthropathy may develop as a cause for joint pain and swelling and should be considered in an individual with marked clubbing of the fingers and severe pulmonary disease. Plain radiography will demonstrate the characteristic periosteal reaction.

### Hemophilia

Hemophilia has previously been complicated by a destructive arthritis occurring as a consequence of recurrent intraarticular bleeds. It is a tribute to advances in care in hemophilia and the use of prophylactic factor VIII that chronic hemophilic arthropathy is now seldom seen in resource rich countries. Hemophilia must still be remembered in the differential diagnosis of a young boy presenting for the first time with a tense joint effusion. Joint aspiration demonstrates blood and abnormal coagulation will be found.

### Metabolic bone disease

Rickets usually presents with bone pain and bowing of the long bones. The most common cause is vitamin D deficiency (Fig. 29.27), but rickets may also result from a number of inherited disorders. Hypophosphatemic or vitamin D resistant rickets may be inherited as either an X-linked recessive or an autosomal disorder and is characterized by impaired parathormone-dependent proximal renal tubular reabsorption of phosphate. Hypophosphatasia is a rare autosomal recessive disorder characterized by severe rickets and reduced serum levels of alkaline phosphatase.

### Gout

Gout may result from either an increased production or a decreased excretion of urate and is extremely rare in childhood. It may result from a number of inherited disorders of purine metabolism; of these, familial juvenile hyperuricemic nephropathy is the most common.<sup>42</sup>

### Periodic fever syndromes

Familial Mediterranean fever (FMF) and other periodic fever syndromes may result in musculoskeletal symptoms including myalgia, arthralgia

(a)

(b)

Fig. 29.27 Dietary rickets in a breast-fed toddler: (a) clinical appearance; (b) radiological features with characteristic metaphyseal fraying.

and arthritis. These conditions are described in more detail in the section on the 'The differential diagnosis of systemic inflammatory disorders' (see p.1434).

## INFECTION IN BONES AND JOINTS

Bone and joint infections are relatively rare disorders in children, but may be associated with considerable skeletal morbidity and potential mortality unless rapidly recognized and adequately treated. A multidisciplinary approach to diagnosis and management, with

close collaboration between physician, orthopedic surgeon, microbiologist and radiologist, is necessary for optimal management and outcome.

### OSTEOMYELITIS AND SEPTIC ARTHRITIS

Frequently the result of hematogenous seeding of bacteria, osteomyelitis may also result from extension of local sepsis, iatrogenic inoculation (rare) or trauma. In osteomyelitis the vascular-rich metaphyses of long bones or vertebral bodies are the commonest sites involved. Fever and pain are frequent symptoms and the differential diagnosis includes trauma, rheumatic fever, septic arthritis, soft tissue infection, rheumatic disease (e.g. juvenile idiopathic arthritis), bone infarction secondary to hemoglobinopathy, leukemia and bony neoplasm.<sup>43</sup> Osteomyelitis may be acute, subacute or chronic. Subacute osteomyelitis has a longer duration than acute and tends to result from infection with less virulent organisms. Chronic osteomyelitis may result from failure to identify or ineffective treatment of acute osteomyelitis.

In neonates the clinical features may be nonspecific and include poor feeding, irritability and poor temperature control. An affected limb may become erythematous, tender and swollen, and there may be a paucity of spontaneous movement ('pseudo-paralysis'). Concomitant septicemia is commoner in this age group. In older children the features tend to be more localized when the peripheral skeleton is affected, but less so in the pelvis or spine.

As with osteomyelitis, the majority of cases of septic arthritis occur as a result of hematogenous seeding of the synovium during an episode of bacteraemia. Septic arthritis occasionally arises from contiguous spread from adjacent osteomyelitis, especially in the younger child in whom the metaphyseal-epiphyseal junction lies adjacent to the joint space.<sup>44</sup>

A septic joint will exhibit the classic features of inflammation: swelling, pain, warmth and erythema. An affected hip is held in flexion and external rotation for comfort; a knee in flexion. All passive movement will be resisted. The hip warrants specific consideration, as increased intracapsular pressure arising from septic arthritis may interrupt blood supply and lead to avascular necrosis of the femoral head.

Fever, malaise and anorexia are usually seen, and progression of symptoms is often rapid. In neonates, as with osteomyelitis, features may be nonspecific. Children with immunodeficiency states, including those on systemic corticosteroid therapy, should be evaluated with great care as clinical signs of inflammation may be masked.

The differential diagnosis includes traumatic effusion, hemarthrosis, transient synovitis, reactive arthritis, JIA, Lyme arthritis, malignant disease, slipper upper femoral epiphysis and Perthes disease. Local spread of infection may result in pyomyositis.

### Laboratory investigations

The full blood count may reveal thrombocytosis and neutrophil leucocytosis. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are both likely to be elevated, the CRP tending to mirror the course of the infection more closely.<sup>45</sup>

### Radiological investigations

Plain radiographs remain the primary initial imaging modality for suspected skeletal infections. In osteomyelitis soft tissue swelling and a periosteal reaction may be seen within a few days. Bony changes develop later (Fig. 29.28). In septic arthritis the early features are osteopenia of the epiphysis, increased joint space and soft tissue swelling (Fig. 29.29). Later in the disease destructive changes occur (Fig. 29.30).

Radionuclide bone scanning is sensitive at detecting areas of increased uptake, and may reveal multiple foci within the skeleton. However the specificity of this method is low and the features may not distinguish septic from nonseptic inflammatory lesions.

Fig. 29.28 Osteomyelitis of proximal humerus – 'moth eaten' appearance of bone and periosteal reaction.

(a)

(b)

Fig. 29.29 Septic arthritis of the hip: (a) soft tissue swelling of thigh; (b) subluxation of the hip.

Ultrasound (US) is a rapidly available and sensitive method for detecting effusions in the hip. Magnetic resonance (MR) imaging plays a particular role because of excellent delineation of anatomy including soft tissues and bone. T1-weighted fat-suppressed postcontrast images are recommended in both osteomyelitis and septic arthritis.

Fig. 29.30 Damage to ankle joint and distal fibula following disseminated staphylococcal sepsis with septic arthritis and osteomyelitis.

### Microbiological investigations

Isolation of the infecting organism will allow targetting of appropriate antibiotic therapy, so vigorous microbiological investigation is mandatory. Peripheral blood cultures must be taken. The suspicion of septic arthritis should prompt microbiological analysis of synovial fluid, with joint aspiration also helping to relieve pain. Typical synovial fluid features on microscopy and a comparison with noninfective inflammatory arthritis are shown in Table 29.4.<sup>46</sup> Bone biopsy may reveal the organism in osteomyelitis.

Approximately 75% of bone and joint infection in resource rich countries is currently caused by *Staphylococcus aureus*<sup>47</sup> and the primary source of the infection is rarely clear. The introduction of vaccination against *Haemophilus influenzae* type b (Hib) has virtually eliminated the incidence of septic arthritis caused by this organism in countries where the vaccination is available. In neonates Group B *Streptococcus* and Gram negative enteric bacteria are relatively common cause of skeletal infection. Group A beta-hemolytic streptococci (*Streptococcus pyogenes*) and *Streptococcus pneumoniae* are important causes at all ages. *Kingella kingae* skeletal infections are increasingly recognized and reported, especially in younger children and frequently after upper respiratory tract infections.<sup>48</sup>

Table 29.4 Comparison of synovial fluid analysis in children with infective and inflammatory arthritis. (Adapted from Shetty & Gedalia 1998<sup>46</sup>)

Characteristic	Normal	Juvenile idiopathic arthritis	Septic arthritis
Color	Yellow	Yellow	Serosanguinous
Clarity	Clear	Cloudy	Turbid
WBC count/mm <sup>3</sup>	< 200	15–20 × 10 <sup>3</sup>	40–300 000 × 10 <sup>3</sup>
PMN count (%)	< 25	60–75	> 75

PMN, polymorphic neutrophil; WBC, white blood cell

Tuberculous arthritis is insidious in onset, and there is a tendency to sinus formation. If tuberculosis is suspected, synovial fluid and biopsy of synovial tissue should be sent for specific culture and also for analysis by the polymerase chain reaction (PCR). A Mantoux test should be performed. Gonococcal arthritis must be considered in the adolescent presenting systemically unwell with a very acute arthropathy. Brucellosis and infection with *Mycoplasma pneumoniae* may both cause a low grade septic arthritis.

In the immunocompromised, Gram negative organisms, fungi or atypical mycobacteria need to be considered. Children with hemoglobinopathies are at increased risk of acute recurrent osteomyelitis with Gram negative bacteria such as *Salmonella*, *Shigella sonnei*, *Escherichia coli* and *Serratia* species.

### Treatment

Initial therapy is with empirical intravenous antibiotics for both osteomyelitis and septic arthritis. With concomitant septicemia supportive management on the neonatal or pediatric intensive care unit may be necessary.

The septic hip should be drained surgically to relieve pressure in the joint and minimize the risk of subsequent avascular necrosis. Surgical intervention is not always necessary in osteomyelitis<sup>47</sup> but may facilitate microbiological diagnosis. Subperiosteal or soft tissue abscesses and necrotic bone sequestra may need drainage.

The choice of antibiotic will depend upon the clinical context and local guidelines, but in the child with previously normal immune function must include adequate staphylococcal cover. Local incidence of methicillin-resistant *S. aureus* (MRSA) will determine whether antibiotic therapy should cover this possibility, and guidance from an expert microbiologist should be sought. Cefotaxime should be added if the child is not immunized against *Haemophilus influenzae*. A summary of empirical antibiotic therapy, by age, in an immunocompetent child is shown in Table 29.5.

In the immunocompromised, flucloxacillin plus cefotaxime are first line agents to provide adequate Gram positive and Gram negative cover. In the penicillin-allergic child cefradine is an alternative; with cephalosporin allergy vancomycin should be considered. Cefotaxime or ciprofloxacin may be used in *Salmonella* osteomyelitis.<sup>47</sup>

The duration of antibiotic therapy is controversial. There has been a move toward greater use of oral antibiotics beyond the initial stages of treatment in recent years. Intravenous antibiotic therapy should be continued for a minimum of 3 days, and then switched to oral for 3–4 weeks if fever has settled.<sup>49</sup> Switch to oral antibiotics should only be when the clinical condition of the child has improved, the fever has settled and the CRP is falling. Intravenous administration of antibiotics for longer periods is necessary in the immunocompromised or neonate.

### Outcome

With early recognition of the diagnosis and prompt treatment, the long term outcome of skeletal sepsis in children is good. Growth disturbance may follow if the epiphysis has been involved and these children will require prolonged follow-up. In the minority with articular damage permanent impairment of joint function and early osteoarthritis may ensue (Fig. 29.30). Inadequate or ineffective treatment of acute osteomyelitis may result in chronic osteomyelitis with necrosis and sequestration of the bone.

### DISCITIS

Infection in the intervertebral disc is a condition related to osteomyelitis, with infection arising from the vertebral end-plates, but without resulting in osteomyelitis of the vertebral body. The condition is believed by many to be secondary to infection,<sup>50</sup> the organism most commonly responsible being *S. aureus*. It is considered by others to have a non-infective inflammatory pathogenesis.

**Table 29.5** Guidelines for empirical parenteral antibiotic treatment of acute bacterial skeletal sepsis by age

Age	Antibiotic	Notes
Neonate	Cefotaxime and flucloxacillin	Alternative: flucloxacillin with gentamicin
Child < 5 years	Cefotaxime and flucloxacillin or cefuroxime	MRSA* use vancomycin and consider clindamycin if sensitive – beware resistance developing during treatment Flucloxacillin or cefradine monotherapy if methicillin sensitive <i>Staph. aureus</i>
Child > 5 years	Cefuroxime or flucloxacillin	MRSA* use vancomycin and consider clindamycin if sensitive – beware resistance developing during treatment Flucloxacillin or cefradine monotherapy if methicillin sensitive <i>Staph. aureus</i>

\* MRSA: Expert microbiologist advice should be sought

The condition is more common in preschool age children and any disc may be involved. The most striking clinical feature is the refusal of the patient to flex the lumbar spine. The older child may have difficulty walking or limp, will have a stiff back and will complain of back pain associated with constitutional upset. The younger child will frequently refuse to walk, often spontaneously adopting a prone position with extension of the lumbar spine for comfort. Discomfort may be reported when the child is traveling in an infant car seat.

The blood picture reveals a leucocytosis and raised ESR. Blood culture is usually negative although *Staph. aureus* may be identified in some. Culture of disc tissue is rarely indicated and frequently negative. Radionuclide bone scanning may highlight a 'hot' spot in the region of a disc space. MRI will demonstrate clearly the inflammatory lesion within the disc (Fig. 29.31a). Plain radiographs eventually reveal disc space narrowing and varying vertebral end-plate damage (Fig. 29.31b).

Most children respond quickly to antibiotic therapy, initially intravenous and then oral, without the need for surgical intervention. Pain is managed symptomatically with analgesics and sometimes a short term removable brace to unload the involved disc. Therapy is usually continued for 6 weeks. Failure to respond after a week or deterioration in spite of treatment should raise concerns regarding the potential of an abscess requiring surgical drainage or an unusual organism such as tuberculosis. The prognosis of juvenile discitis is generally good with no significant long term sequelae in the majority.

## VIRAL INFECTION AND ARTHRITIS

Arthralgia is a common symptom of viral infection. In some cases a true septic arthritis results, with virus particles being isolated in the joint fluid. In others arthritis occurs as a reactive process with no evidence of infection in the joint. Rubella, particularly 'natural infection' but also post vaccination, is associated with arthritis.<sup>51</sup> Parvovirus B19 (slapped cheek syndrome or Fifth disease) is occasionally associated with arthritis similar to that of rubella. Varicella may be associated with a benign reactive arthritis, but is occasionally complicated by a potentially fatal syndrome of necrotizing fasciitis and toxic shock syndrome as a sequelae of concomitant Group A streptococcus infection.<sup>52</sup> Paromyxovirus (mumps), adenovirus, ECHO virus and Coxsackie B virus may all be associated with arthritis.

Infection with the human immunodeficiency virus may be associated with a variety of rheumatological problems. These include arthralgias, septic arthritis (frequently fungal in origin), reactive arthritis, Reiter syndrome and a seronegative spondyloarthropathy.

## REACTIVE ARTHRITIS

### Transient synovitis of the hip

See section on 'Common orthopedic problems in childhood', page 1434.

### Reactive arthritis associated with bowel and genitourinary infections

In children, as in adults, a reactive arthritis may develop after enteric infections with *Salmonella*, *Shigella*, *Yersinia* and *Campylobacter*, and post-urethritis with *Chlamydia* in sexually active adolescents. The HLA-B27 antigen is commonly identified. There is usually a peripheral, asymmetrical lower limb arthritis. There may be associated dactylitis ('sausage digit' resulting from inflammation of both joints and tendon sheaths), tenosynovitis and involvement of the sacroiliac joints. There is usually a history of enteritis or urethritis within the preceding 4 weeks. Reiter syndrome, a triad of arthritis, conjunctivitis and urethritis, is uncommon in children.

Treatment requires nonsteroidal anti-inflammatory drugs in adequate doses. Occasionally systemic steroids are required to settle an acute arthritis. If the arthritis becomes chronic, intra-articular steroids and second-line agents including sulphasalazine and methotrexate may be considered.

### Rheumatic fever and poststreptococcal arthritis

(see Ch. 21)

Acute rheumatic fever remains prevalent in developing areas of the world. The disease arises as a complication of infection (pharyngotonsillitis) with Group A beta-hemolytic *Streptococcus pyogenes*. The modified Jones criteria are the basis for the diagnosis (Table 29.6).

Inflammation in various tissues may result in arthritis, carditis, a typical rash (erythema marginatum), subcutaneous nodules and a characteristic neurological syndrome, Sydenham chorea. Arthritis is a common clinical feature, tends to affect large joints and is flitting and self-limiting in nature. Erythema marginatum is an erythematous macular and nonpruritic lesion with serpiginous margins surrounding areas of normal skin. Sydenham chorea (also known as St Vitus dance) is caused by inflammation of the basal ganglia of the brain. It presents with involuntary movements of the extremities, muscular incoordination and emotional lability. Subcutaneous nodules may be seen on extensor surfaces of joints in the chronic phase of rheumatic heart disease. Rheumatic heart disease is discussed in more detail in Chapter 21.

Arthritis following Group A streptococcal infection is recognized in some children who do not fulfill the criteria for acute rheumatic fever. This poststreptococcal reactive arthritis differs from that of rheumatic fever in that it is nonmigratory and more persistent. As with rheumatic fever recurrent episodes are recognized.

Treatment of both rheumatic fever and poststreptococcal reactive arthritis involves antibiotics to eradicate the streptococcus. Penicillin V is the antibiotic of choice, and should be given as a 10-day course. In penicillin-allergic individuals, erythromycin is a suitable alternative. In rheumatic fever prophylaxis against streptococcal infection is indicated for at least 5 years after the initial attack, and into adulthood in patients with carditis.<sup>53</sup> There is no consensus regarding the use of prophylactic penicillin in those with poststreptococcal arthritis but if attacks are recurrent antibiotic prophylaxis may prove beneficial. Additional prophylaxis for surgical or dental procedures is necessary in the chronic stage of rheumatic heart disease (see Ch. 21).

In the acute illness nonsteroidal anti-inflammatory drugs (NSAIDs) may provide symptomatic relief from the arthritis. Steroids are reserved for patients with pancarditis associated with congestive cardiac failure.

### Lyme disease

The infectious spirochaete *Borrelia burgdorferi*, transmitted by the tick *Ixodes*, is responsible for Lyme disease. The regions where Lyme

Fig. 29.31 (a) MRI in discitis – abnormal signal in the L4 and L5 vertebral bodies with destruction of the intervening disc space; (b) plain radiograph showing narrowing of L4/5 disc space following resolution of acute illness.

Table 29.6 Modified Jones criteria for the diagnosis of rheumatic fever

Major criteria	Minor criteria
Polyarthritis common: flitting, large joints	Fever
Carditis common: pancarditis	Arthralgia
Chorea (Sydenham) uncommon: persistent	Prolonged P-R interval
Erythema marginatum uncommon: macules evolving to serpiginous	Elevated ESR/CRP, leucocytosis
Subcutaneous nodules uncommon: extensor surfaces	Previous rheumatic fever

The diagnosis of rheumatic fever is made in the presence of either two major criteria or one major plus two minor criteria together with evidence of recent group A streptococcal infection (positive throat swab, elevated antistreptolysin O titer (ASOT) or other antistreptococcal antibodies).

disease is seen most frequently are central Europe and northeastern United States. The disease is manifest by cutaneous, articular, neurological and other systemic features. The most typical skin manifestation is erythema chronicum migrans. Early lymphocytic

meningitis is commoner in children than in adults. The arthritis typically appears months to years after the original infection, and becomes chronic in up to 16%. In the majority there is an episodic monoarthritis, but occasionally polyarthritis develops. Treatment with antibiotics is necessary, with ceftriaxone recommended at a dose of 50 mg/kg/day for 14–28 days.<sup>54</sup> Amoxicillin at a dose of 50 mg/kg/day for 28 days is an alternative, but compliance may be poorer due to the dosage regimen. Some authors recommend doxycycline, but not in children below the age of 8 years. Intra-articular steroids should be avoided until completion of antibiotic therapy.

#### Arthritis associated with meningococcal infection

Meningococcal disease may be associated with both a true septic arthritis occurring in association with the acute septicemic illness or a reactive arthritis seen in the post-acute phase. With improved survival rates from severe meningococcal septicemia a post-infectious, immune complex mediated arthritis is seen with increasing frequency, often in association with a recrudescence of fever and the development of a vasculitic rash.

## JUVENILE IDIOPATHIC ARTHRITIS

Juvenile idiopathic arthritis (JIA) is not a single disease entity, rather a collection of heterogeneous diseases. JIA may be associated with significant morbidity, both articular and extra-articular, and may place a significant burden on child and carers alike. Mortality is rare and largely confined to the systemic onset subtype.

JIA is diagnosed according to a constellation of clinical features supported by the judicious use of relevant investigations (frequently to exclude other causes of arthritis). At the current time there are no pathognomonic diagnostic tests for JIA. A number of children with JIA will attain spontaneous remission, although rates vary according to disease subtype. Packham reported follow-up data on 246 adults with all subtypes of JIA and found that 43% had clinically active disease.<sup>55</sup> There is now a realistic expectation of disease control with modern therapeutic regimens delivered by an experienced multidisciplinary team. Future studies reporting the outcome of children treated since the advent of these newer therapeutic approaches are awaited, with an expectation that results will be improved. Nonetheless patients, families and professionals must remain realistic that no fundamental cure yet exists.

Significant advances made during the final decade of the 20th century and beyond include:

- Development and subsequent revision of a new classification system of JIA.
- Preliminary definition of improvement measures to evaluate outcome in drug studies (core set criteria).
- Further understanding of immunogenetic pathways.
- Drug studies exploring both optimal doses and routes of administration for conventional drug therapies such as methotrexate, and the new products of the biotechnology revolution, the so-called 'biologic' agents.
- Online resources: the British Society for Paediatric and Adolescent Rheumatology (BSPAR; [www.bspar.org.uk](http://www.bspar.org.uk)); Paediatric Rheumatology European Society (PREs; [www.pres.org](http://www.pres.org)); and the Pediatric Rheumatology International Trials Organization (PRINTO; [www.printo.it](http://www.printo.it)) have all developed websites providing useful sources of information for professionals, patients and parents on childhood rheumatic diseases of childhood with links to other relevant websites.

## DEFINITION AND CLASSIFICATION

JIA is defined as arthritis of unknown etiology that begins before the 16th birthday and persists for at least 6 weeks. Other known conditions must be excluded. For the purposes of defining arthritis, an inflamed joint is swollen, or limited in range of joint movement with joint pain or tenderness, which is not due to a primary mechanical disorder or to other identifiable cause.

In the final decade of the 20th century the International League of Associations for Rheumatology (ILAR) proposed and subsequently revised consensus guidelines for the classification of JIA.<sup>56</sup> The goal of this major work was to replace and unify previous historical classification criteria, namely juvenile rheumatoid arthritis and juvenile chronic arthritis. Although the ILAR criteria were proposed with the primary aim of defining and classifying clinically homogeneous subgroups within JIA for research purposes, they have been widely embraced and incorporated into clinical practice and are now in mainstream use as clinical diagnostic criteria despite awaiting full validation in further studies. The ILAR criteria define subtypes according to the onset pattern of the disease and associated clinical features. A summary of the clinical features of the JIA classification system is given in [Table 29.7](#).

## DIFFERENTIAL DIAGNOSIS

Juvenile idiopathic arthritis must always be considered a diagnosis of exclusion. Musculoskeletal symptoms are common in childhood, and in many cases are related to simple trauma. It should be possible to make a clinical distinction between inflammatory arthritis and arthralgia. If doubt exists, an expert pediatric rheumatology opinion should be considered before embarking on investigations that may be unpleasant for the child and potentially delay the diagnosis of JIA. As the nature of the differential diagnosis of inflammatory arthritis includes potentially life threatening disorders such as sepsis, malignancy and non-accidental injury, any child presenting requires careful assessment by means of thorough history taking, meticulous clinical examination and prompt, judicious use of appropriate investigations. Etiologies can be considered as follows: infection, trauma, autoimmune, neoplasia,

**Table 29.7** Clinical features of juvenile idiopathic arthritis

JIA subtype	Clinical features	Alerts
Systemic arthritis	Arthritis with or preceded by daily ('quotidian') fever for at least 3 days, accompanied by one or more of: evanescent erythematous rash; lymphadenopathy; hepatomegaly and/or splenomegaly; serositis	Arthritis may not be present early in course Mandatory exclusion of infective and malignant conditions
Oligoarthritis: Persistent	Arthritis of four or fewer joints within the first 6 months Affecting not more than four joints throughout the disease process. Frequently children below the age of 5 years	High risk of associated uveitis, especially if ANA positive
Extended	Affecting more than four joints after the first 6 months	
Polyarthritis RF positive RF negative	Arthritis of five or more joints within the first 6 months. Subdivided according to presence of RF	RF positive disease rare but equivalent to 'adult' rheumatoid arthritis
Psoriatic arthritis	Arthritis and psoriasis OR arthritis with at least two of dactylitis, nail pitting or onycholysis, psoriasis in first degree relative	Psoriasis and arthritis may not co-exist for many years
Enthesitis-related arthritis	Arthritis and enthesitis OR arthritis or enthesitis with two of: SI joint tenderness or inflammatory lumbosacral pain, HLA B27 antigen, onset after age 6 years in a male, acute (symptomatic) anterior uveitis, history of HLA B27 associated disease in a first degree relative	
Undifferentiated arthritis	Arthritis that fulfils criteria in no or more than two of the above categories	

Abbreviations: ANA, antinuclear antibody; RA, rheumatoid arthritis; RF, rheumatoid factor; SI, sacro-iliac.

hematological, metabolic, genetic, drug reactions, trauma (including non-accidental), mechanical/orthopedic. Such an approach should allow distinction of the many possible causes of arthritis, as shown in Table 29.8.

### CORE SET CRITERIA

To facilitate standardization of clinical measures of change in JIA, a core set of criteria have been developed by consensus primarily for the purposes of clinical trials,<sup>57</sup> although they may be useful within routine clinical practice. These criteria comprise:

- physician global assessment of disease activity (10-cm visual analogue scale);
- parent/patient assessment of overall well-being (10-cm visual analogue scale);
- functional ability (Childhood Health Assessment Questionnaire – CHAQ ([www.rheumatology.org/sections/pediatric/chaq](http://www.rheumatology.org/sections/pediatric/chaq));
- number of joints with active arthritis;
- number of joints with limited range of movement;
- erythrocyte sedimentation rate.

**Table 29.8** Differential diagnosis of inflammatory arthritis in childhood

Infection:
Acute septic arthritis
Viral arthritis
Reactive/post-infectious arthritis
Juvenile idiopathic arthritis.
Arthritis associated with inflammatory bowel disease
Other autoimmune rheumatic disorders:
Systemic lupus erythematosus
Juvenile dermatomyositis
Systemic sclerosis
Mixed connective tissue disease
Systemic vasculitis:
Henoch–Schönlein purpura
Kawasaki disease
Polyarteritis nodosa
Malignancy:
Leukemia
Neuroblastoma
Hematological:
Sickle cell anemia
Hemophilia
Immune deficiency syndromes
Genetic disorders:
Cystic fibrosis
Velocardiofacial syndrome
CINCA syndrome
Down syndrome
Stickler syndrome
Drug reactions
Trauma including non-accidental injury
Orthopedic:
Perthe disease
Pigmented villonodular synovitis
Miscellaneous:
Sarcoidosis
SAPHO syndrome
Familial Mediterranean fever

Abbreviations. SAPHO, synovitis, acne, pustulosis, hyperostosis and osteitis syndrome; CINCA, chronic infantile neurological cutaneous and articular syndrome.

### EPIDEMIOLOGY

Data describing incidence and prevalence of JIA are confusing and unclear. A detailed review of 34 studies beginning in 1966 showed the reported prevalence of JIA to vary from 0.07 to 4.01 per 100 000 children, while the reported incidence for JIA over the same period ranged from 0.008 to 0.226 per 1000 children.<sup>58</sup> This study highlights the need for standardization of diagnostic criteria, case definition, and case ascertainment and also the need to consider the clinical qualification and experience of participating researchers, health resources available within the study population, expectation of health and the size of the study cohort. Despite methodological differences between studies there does appear to be a true variability in disease occurrence according to geographical factors.

Overall, girls with JIA outnumber boys by approximately 2:1. There are important variations within disease subtypes with girls outnumbering boys in oligoarthritis, polyarthritis and psoriatic arthritis, but a more even sex distribution in systemic JIA<sup>59</sup> and boys outnumbering girls in the enthesitis-related arthritis subtype. In those with uveitis the ratio of girls to boys is higher, up to 6.6:1.<sup>60</sup>

### ETIOLOGY AND PATHOGENESIS

As with all autoimmune disease there is a complex interplay between genetic risk factors and environmental triggers. JIA has been referred to as a 'complex genetic trait', albeit one in which there are now several consistent and strong associations.<sup>61</sup>

Studies of genetic polymorphisms in both adult and childhood chronic arthritis have frequently, but not exclusively, involved the major histocompatibility complex (MHC). The MHC class II loci DR, DQ and DP are particularly associated with JIA. Age-related genetic susceptibility is suggested by the association of early childhood onset oligoarthritis with HLA A2, DR5, DR8 and DPB1\*0201.<sup>62</sup> Oligoarthritis in older boys is associated with HLA-B27, and to date this remains the only HLA association with any major relevance to routine clinical practice. Polyarticular JIA with a positive rheumatoid factor is associated with HLA DR4, as in adults with rheumatoid arthritis.

The British Paediatric Rheumatology Study Group demonstrated in a large multicenter study of 521 Caucasian patients with JIA the presence of multiple HLA class II associations. Differences were demonstrated between the seven subtypes defined by the ILAR classification criteria, which encouragingly lends support to this classification approach.<sup>63</sup>

There is growing evidence to support an etiological role for polymorphisms within individual genes coding for pro- and anti-inflammatory cytokines. In studies of synovial tissue from adults with rheumatoid arthritis, proinflammatory cytokines such as interleukin (IL)-1 and tumor necrosis factor (TNF)-alpha are elevated, and induce the release of tissue-destroying metalloproteinases.<sup>64</sup> There has been great interest in the role of cytokines as mediators of the inflammatory response in JIA, both to further the understanding of the pathogenesis of the disease and also as potential targets for biological therapies.

The pro-inflammatory cytokine TNF-alpha (TNF $\alpha$ ) occupies a central position in the cytokine network. TNF $\alpha$  is produced by several cells throughout the body, including synovial cells, T lymphocytes and mononuclear phagocytes, but in inflammatory arthritis it is mostly derived from activated macrophages. TNF $\alpha$ , with lymphotoxin-alpha (a related cytokine), is detected in synovial tissue in JIA and may amplify local inflammation and contribute to joint destruction.<sup>65</sup> TNF $\alpha$  stimulates further proinflammatory cytokine production including IL-1 and IL-6.

JIA is a heterogeneous disease. It is not surprising then that studies have revealed differences in cytokine profiles between JIA subtypes. Rooney et al demonstrated an imbalance between TNF $\alpha$  and its soluble receptor (sTNFR) in JIA, with different ratios in different subtypes, which may explain variations in disease patterns and resulting joint damage.<sup>66</sup>

## CLINICAL FEATURES

### Systemic arthritis

The systemic onset subtype accounts for 11% of all cases of juvenile arthritis, often occurring in younger children with a median age of onset of 4.3 years and a male to female ratio of 1:1.2 (data on percentages of each subclass is taken from Symmons 1996 which uses the historical classification, JCA;<sup>59</sup> percentages using the ILAR classification JIA may differ slightly from these, but data is not yet available).

Systemic JIA is defined as arthritis in one or more joints with or preceded by fever of at least 2 weeks' duration that is documented to be daily ('quotidian') for at least 3 days, and is accompanied by one or more of the following:

- evanescent (nonfixed) erythematous rash;
- generalized lymph node enlargement;
- hepatomegaly and/or splenomegaly;
- serositis.

The systemic features may precede the onset of arthritis. In toddlers, the arthritis may be subtle and difficult to confirm. Many will therefore require detailed workup to exclude sepsis and hematological malignant diseases.

The associated systemic manifestations of the disease are often much worse during the periods of fever, and the children are intensely miserable during these periods, with significant improvement when the fever settles. The rash is pale pink, macular (evanescent) and flitting in nature. It often occurs in linear streaks and it exhibits the Koebner phenomenon (Fig. 29.32). It most commonly occurs on the trunk, but can be generalized. Generalized lymphadenopathy occurs in the majority, and enlarged nodes are painless, rubbery and mobile. Hepatomegaly is common and splenomegaly occurs in approximately 50%. Serum transaminases are frequently elevated, and there is often hypoalbuminemia. Pericardial effusion on echocardiogram is common and usually asymptomatic, but a useful feature to aid diagnosis. Pleural effusion may co-exist with pericardial effusion, and either may occasionally require surgical drainage.

The pattern of arthritis associated with systemic JIA is variable. Approximately one third develop a polyarticular course with joint destruction within 2 years of disease onset (Fig. 29.33). Hepatosplenomegaly, serositis and low serum albumin are recognized as risk factors at disease onset, while later risk factors for an adverse outcome in systemic JIA are thrombocytosis, persistent fever or steroid dependency at 6 months.<sup>67</sup>

Three patterns of disease progression have been described:

1. monocyclic (systemic disease with a single episode);
  2. intermittent (recurrent fever and arthritis interspersed with periods of remission);
  3. persistent disease activity with systemic and polyarticular phases.
- Functional outcome is largely dependent on the course of the arthritis rather than on the systemic features.

Fig. 29.32 Rash of systemic juvenile idiopathic arthritis.

Fig. 29.33 Systemic juvenile idiopathic arthritis with polyarticular course – involvement of knees, ankles, hips, wrists and cervical spine.

### Oligoarthritis

This is defined as arthritis affecting between one and four joints during the first 6 months of disease and further subdivided into:

- persistent oligoarthritis: affects no more than four joints throughout the disease course;
- extended oligoarthritis: affects a cumulative total of five joints or more after the first 6 months of disease.

Oligoarthritis is the commonest onset pattern of JIA in Caucasian populations, accounting for approximately 50% of affected children.<sup>59</sup> Persistent oligoarthritis is commonest in preschool age girls (although does occur in boys) and in this age group is frequently associated with positive antinuclear antibodies (ANA) and an increased risk of silent, potentially blinding, uveitis.

Oligoarthritis most frequently develops asymmetrically in large lower limb joints, especially the knee (Fig. 29.34) and the ankle, and occasionally in the upper limb.

Oligoarthritis in preschool children is often insidious, but occasionally manifests acutely. The child may limp, especially after rest. The joint appears swollen and is warm, but rarely painful until passively moved through its full range. Examination of the knee may reveal a palpable effusion. With time, if unrecognized, flexion contractures may occur.

Fig. 29.34 Oligoarthritis showing marked swelling of R knee.

Bony overgrowth of the joint may be seen with leg length discrepancy (Fig. 29.35). Prompt recognition and treatment will prevent the development of such complications.

In a proportion of children with an oligoarticular onset there is an 'adding on' of involved joints beyond 6 months of disease – so-called extended oligoarthritis.

### Polyarthritis

This is defined as arthritis affecting five or more joints during the first 6 months of disease. This subtype is further subdivided on the basis of testing for IgM rheumatoid factor into:

- rheumatoid factor positive (seropositive);
- rheumatoid factor negative (seronegative).

Seronegative polyarthritis (Fig. 29.36) has a variable clinical expression ranging from low grade grumbling disease to an aggressive polyarthritis. An early peak age of onset is seen around 2 years, with a later peak around 8 years.<sup>60</sup> It varies in clinical expression ranging from low grade grumbling disease to an aggressive polyarthritis. Joints may be hot and swollen or simply tender with loss of function, without gross synovial swelling or palpable effusions (so-called 'dry synovitis'). Onset may be insidious but joint deformities, of both large and small joints, may develop rapidly.

Fig. 29.35 Oligoarthritis – plain radiograph showing overgrowth of right knee.

Fig. 29.36 Polyarthritis affecting wrists and the small joints of the hands.

Seropositive polyarthritis is rare, accounting for 3% of all children with JIA, compared to 17% for seronegative polyarthritis.<sup>59</sup> Children with seropositive polyarthritis typically are girls and develop disease in late childhood and adolescence. The arthritis is usually symmetrical affecting upper and lower limbs, in particular the small joints of the hands and feet. The test for IgM rheumatoid factor should be positive on at least two occasions 3 months apart.

### Psoriatic arthritis

Psoriatic arthritis is defined as arthritis and psoriasis (Fig. 29.37), or arthritis and at least two of the following:

- dactylitis;
- nail pitting and onycholysis;
- psoriasis in a first-degree relative.

In the UK, psoriatic arthritis accounts for 7% of all cases of JIA, is commoner in girls (male:female ratio 1:1.6) with a median age of onset 10.1 years.<sup>59</sup> Oligoarticular onset (asymmetrical involvement of large and small joints) is frequent and dactylitis (diffuse swelling of a finger or toe joint and periarticular tissues) is a hallmark feature (Fig. 29.38). The arthritis can be highly erosive. Nail abnormalities may be seen, including nail pitting and nail dystrophy (onycholysis). The arthritis precedes the psoriasis in as many as 75% of cases, and 45% of children develop psoriasis within 5 years of onset of arthritis.<sup>68</sup> The outcome in psoriatic arthritis is variable, with both oligo- and polyarticular courses described.

Fig. 29.37 Psoriatic arthritis.

Fig. 29.38 Dactylitis – swelling of third and fourth toes.

### Enthesitis-related arthritis

This is defined as arthritis and enthesitis (inflammation of tendon insertion into bone), or arthritis or enthesitis with at least two of the following:

- sacroiliac joint tenderness and/or inflammatory lumbosacral pain;
- presence of the HLA-B27 antigen;
- onset of arthritis in a male over 6 years of age;
- acute (symptomatic) anterior uveitis;
- history of ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome or acute anterior uveitis in a first-degree relative.

This subtype defines those with disease related to the HLA-B27 antigen, and avoids the term juvenile spondyloarthritis, inaccurate because of the rarity of spinal involvement in children. The commonest joints involved are the peripheral large joints of the lower limb, in an asymmetrical distribution. It is rare for children to present with axial skeleton symptoms or signs, although a minority develops arthritis of the sacroiliac joints in teenage years (Fig. 29.39) and subsequently ankylosing spondylitis in adulthood. There is a marked predominance of boys in this group, presenting after the age of 6 years. Enthesitis is a characteristic feature, often affecting the insertion of the Achilles tendon into the calcaneum, and may be distressingly painful resulting in significant functional impairment. The eye disease associated with enthesitis-related arthritis is an acute painful iritis (in contrast to the asymptomatic uveitis associated with other subtypes of JIA), and occurs in less than 20% of children.

### Undifferentiated arthritis

At present children who either fulfill criteria for no category, or who fulfill criteria for more than one of the other categories, are defined as undifferentiated.

### INVESTIGATIONS

Judicious investigation may serve to support the diagnosis of JIA. At presentation as a minimum full blood count, liver chemistry and a disease

Fig. 29.39 Gadolinium enhanced MRI showing right-sided sacroiliitis (note high signal on right compared to left).

activity measure, preferably erythrocyte sedimentation rate (ESR), are recommended for all JIA subtypes. A positive antinuclear antibody in oligoarthritis is a risk factor for silent uveitis and will help to guide the ophthalmology screening program. Rheumatoid factor is only of clinical significance in the context of those children with a polyarthritis. Serum ferritin may be disproportionately high in systemic JIA. Nonspecific hyperimmunoglobulinemia is often seen in polyarticular and systemic JIA. Hypoalbuminemia is common in systemic JIA, along with elevations of liver enzymes.<sup>67</sup>

### Radiological investigations

All imaging modalities may have a potential role in JIA:

- to aid diagnosis – particularly to exclude other musculoskeletal conditions;
- to document and define evidence of joint damage;
- to aid the assessment of complex joints, e.g. hip, subtalar, shoulder and temporomandibular joints;
- to detect subclinical or very early synovitis – magnetic resonance scanning with gadolinium contrast is a very sensitive technique;
- to distinguish synovitis from tenosynovitis;
- to facilitate intra-articular steroid injection.

Three stages of radiographic changes are seen on plain radiographs in JIA.<sup>69</sup>

- Early: soft tissue swelling, e.g. blurring of the infrapatellar fat pad on lateral knee radiograph and periarticular osteopenia.
- Intermediate: cortical erosions, joint space narrowing and subchondral cysts.
- Late: destructive joint changes with ankylosis, joint contractures, metaphyseal and diaphyseal changes and growth anomalies (Fig. 29.40).

Radionuclide bone scanning is sensitive in detecting areas of increased uptake within the skeleton, but will not differentiate between inflammation, infection or malignant disease. Ultrasound is a reliable method for detecting effusions, especially in the hip, guiding intra-articular injections and confirmation of popliteal cysts. In expert hands it is also increasingly useful as a method of documenting synovitis of joints and tendons. Intravenous contrast (gadolinium-DPTA) enhanced magnetic resonance sequences are exquisitely sensitive at detecting inflamed synovium and particularly valuable in the assessment of inaccessible joints such as the hip, and complex joints such as the ankle, where it may be difficult to distinguish clinically between the tibiotalar and subtalar joint. T1-weighted images with fat suppression are particularly recommended for demonstrating synovitis (Fig. 29.41).

(a)

(b)

**Fig. 29.40** Plain radiographs in juvenile idiopathic arthritis: (a) destructive changes of wrists with crowding of carpal bones; periarticular osteopenia and loss of joint space at proximal interphalangeal joints; (b) fusion in block of posterior elements of C2–C7.

### COMPLICATIONS: ARTICULAR

Articular complications are a direct result of synovial inflammation and can generally be minimized or prevented by optimizing control of the inflammatory process. Flexion contractures occur commonly and at a very early stage in JIA and if not treated intensively may become permanent. Overgrowth of affected limbs (Fig. 29.35) is a particular problem of oligoarthritis which may have serious long term complications

**Fig. 29.41** MR scan of left knee with fat suppression and gadolinium contrast. There is a small effusion with synovial thickening and enhancement.

e.g. a discrepancy in lower limb length resulting in a pelvic tilt and scoliosis in adult life. The temporomandibular joint (TMJ) may be involved in polyarthritis and specific features such as asymmetrical mouth opening and micrognathia may be noted during clinical examination. TMJ involvement may result in both cosmetic and functional difficulties and appropriate advice from an interested maxillofacial surgeon should be sought.

### COMPLICATIONS: EXTRA-ARTICULAR

#### Uveitis

The incidence of uveitis in JIA overall is approximately 10%, although it is commoner in ANA (antinuclear antibody) positive oligoarthritis.<sup>70</sup> Two patterns of ocular inflammation are seen in JIA. An acute, painful iritis is seen in children with enthesitis-related arthritis, and usually resolves rapidly with topical corticosteroid therapy. Chronic, asymptomatic anterior uveitis that may become sight threatening if not recognized and treated is especially common in preschool age girls with oligoarthritis. It is strongly associated with positive antinuclear antibodies. The diagnosis requires slit-lamp examination by an ophthalmologist.

To date no prospective randomized controlled data exist comparing immunosuppressive therapy in childhood uveitis. Visual complications (synechiae, band keratopathy, cataract or glaucoma) may develop in up to 30%, and significant visual loss has been reported in 11%,<sup>70</sup> highlighting the need for aggressive treatment.

In many cases uveitis in children with JIA can be controlled with topical corticosteroids and short-acting mydriatics. Early steroid-sparing therapy, to reduce the risk of steroid-related complications such as cataract and glaucoma, is indicated if it proves impossible to taper local steroid therapy because of persistent disease activity. Methotrexate is the commonest second line agent in use, with significant reduction in uveitis activity and steroid dependency being shown in a retrospective study.<sup>71</sup> If control cannot be achieved with

oral methotrexate alone, parenteral administration of methotrexate, or methotrexate in combination with ciclosporin, should be considered. Data from uncontrolled studies suggest benefit from infliximab in therapy-resistant uveitis.<sup>72</sup> Relapses and first presentation uveitis have been reported in patients receiving etanercept therapy, indicating more studies are needed to define any potential role for the biological agents in treating uveitis.

### Nutritional status and growth

Nutritional impairment and growth failure is a recognized complication of all subtypes of JIA. The etiology of nutritional impairment in JIA is not fully understood, nor is it clear how frequently it occurs. It may affect the general well-being of the child and contributes to the growth disturbance that is a serious consequence of JIA in some children.

### Osteoporosis

Osteoporosis is a significant long term complication of a variety of rheumatological disorders including JIA and occurs as a consequence of the underlying inflammatory process; of inactivity; and of steroid therapy.

### Psychosocial

Long term outcome studies have demonstrated a significant incidence of psychosocial difficulty in young adults with JIA. Attention to rehabilitation and early return to normal activities where possible is essential to minimize this. Families and schools must be encouraged to treat the child as normal and all should be in mainstream schooling. Good transitional care with an early focus on independence and career counseling is essential.

### Macrophage activation syndrome (MAS)/secondary hemophagocytic lymphohistiocytosis (HLH)

MAS/HLH is a rare but potentially life threatening complication of systemic JIA. Features in a child raising suspicion of MAS/HLH are fever, lymphadenopathy and hepatosplenomegaly, pancytopenia, low ESR, elevated liver enzymes and coagulopathy.<sup>73</sup> MAS/HLH may be triggered by an intercurrent infection or change in drug therapy. The pathognomic feature, macrophages actively phagocytosing hematopoietic elements, may be seen on the bone marrow aspirate but it must be noted that false negative bone marrow examinations may occur. Other laboratory features include hypertriglyceridemia and hyperferritinemia. Treatment of MAS/HLH consists of high dose corticosteroids and ciclosporin with good supportive care and vigorous treatment of concomitant sepsis. Such patients may require management in a pediatric intensive care setting.

## MANAGEMENT

As with all pediatric chronic diseases, optimal management of JIA is delivered by an experienced multidisciplinary team (Table 29.9). Adequate education of the child and family about the disease and possible therapeutic strategies is essential from the outset. The impact of JIA on patient and family may be significant and good results depend on considerable commitment from all. Information and encouragement will empower patients and families to be involved in and committed to their treatment with improved compliance and better results. The provision of appropriate written information is helpful; directing families to appropriate online resources is increasingly important.

### Physiotherapy and occupational therapy

The aim of physiotherapy is to maintain and restore joint function, and to increase muscle strength. This can only be achieved in association with medical therapy to control synovitis. An occupational therapist may provide adaptations at home or school. Many different strategies are available, but there is consensus that physical and occupational therapy early in the disease is associated with an improved outcome.<sup>74</sup>

**Table 29.9** Members of the multidisciplinary team involved in the care of a child with juvenile idiopathic arthritis

Medical	Professions allied to medicine	Community
Pediatric rheumatologist	Physiotherapist	Family
Pediatrician	Occupational therapist	Friends
Ophthalmologist	Psychologist	School teacher
General practitioner	Social worker	Parental employer
Orthopedic surgeon	Dietitian	
Dental practitioner	Orthotist	
Radiologist	Podiatrist	

## Medical management

The pharmacological management of JIA continues to evolve, in terms of specific drugs and strategies for their deployment. Early use of methotrexate (MTX) in polyarthritis, frequently at diagnosis or shortly after, is now standard practice in order to achieve and maintain disease remission. MTX is now regularly used in oligoarthritis resistant to local intra-articular corticosteroid injection therapy. MTX and other systemic immunosuppressive agents are frequently used in uveitis whether or not associated with JIA. Biological agents are now licensed therapies and appear effective and to date safe in treating JIA. There is the likelihood of further advances and new experimental therapies likely to follow rapidly. An algorithm showing an approach to pharmacological management of JIA is shown in Table 29.10.

### Nonsteroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are widely used at diagnosis, provide good symptomatic relief and contribute to the control of the inflammatory process although this takes time to achieve. Table 29.11 lists the commonly used NSAIDs and the doses required to achieve anti-inflammatory effect. Drugs with once or twice daily regimens are likely to have better compliance particularly in older children.

Side-effects are uncommon in children. Gastrointestinal upset is uncommon and may be relieved by the addition of a H<sub>2</sub> antagonist or proton pump inhibitor. Naproxen (and occasionally other NSAIDs) may be associated with scarring pseudoporphyria affecting the face and care should be taken in fair skinned children. Mood and behavior disturbances are occasionally reported by parents of young children on NSAIDs.

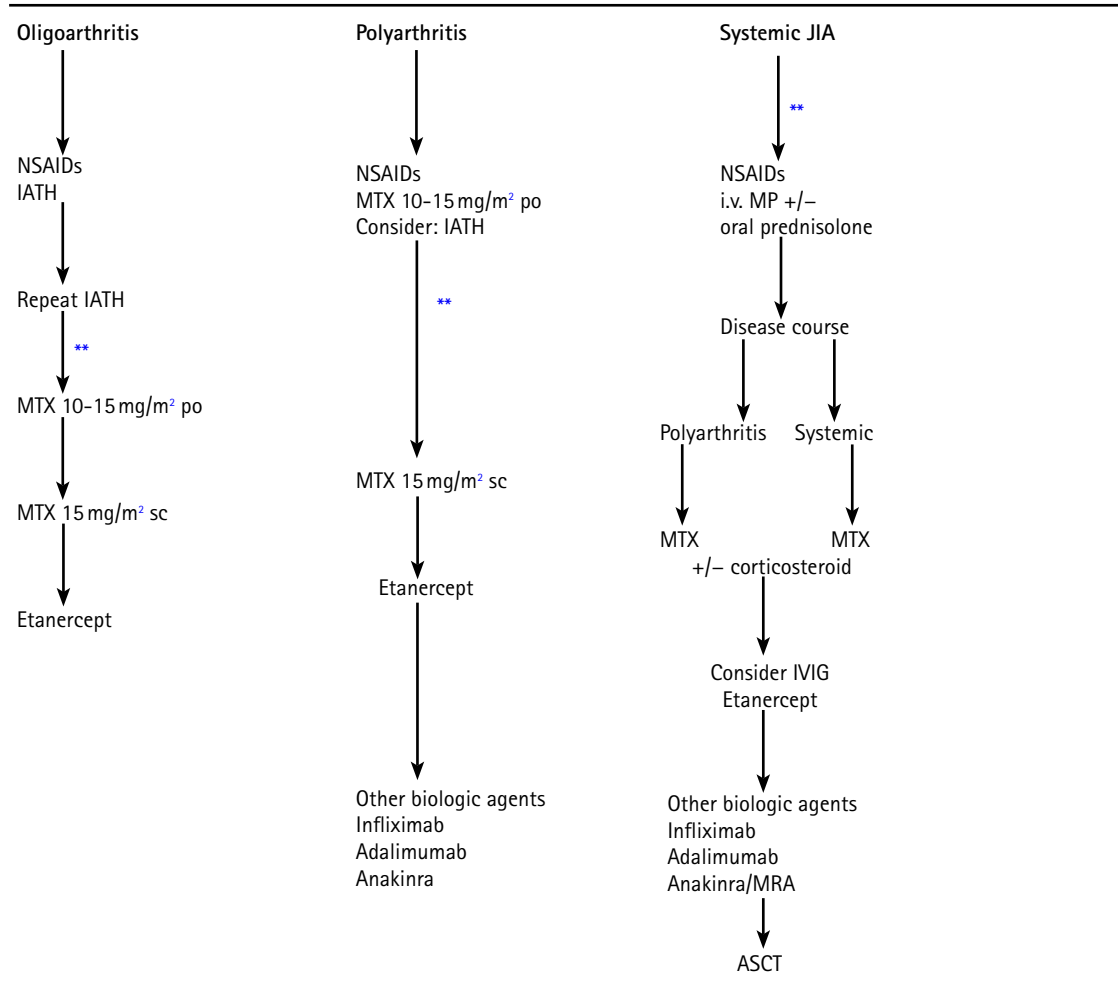

### Corticosteroid therapy

The early use of effective disease-modifying anti-rheumatic drugs (DMARDs), historically methotrexate and more recently anti TNF $\alpha$  agents, has dramatically reduced the dependency upon, and toxicity associated with chronic administration of systemic corticosteroids. Corticosteroids still have a role in the management of JIA, in particular for remission induction, and may be administered systemically by the intravenous and oral route, or locally by intra-articular injection.

**Local corticosteroid therapy.** Intra-articular steroid injections are effective, with a low risk of complications, in all subtypes of JIA, particularly oligoarthritis.<sup>75</sup> In polyarthritis, multiple intra-articular injections may be used simultaneously with the initiation of methotrexate therapy. The early use of intra-articular steroid injections and rapid resolution of synovitis relieves pain and facilitates early physiotherapy and rehabilitation thus preventing joint contractures. When used early, and if necessary repeatedly, intra-articular steroids may prevent leg length discrepancy in oligoarthritis.<sup>76</sup> Triamcinolone hexacetonide (TH) is the drug of choice for intra-articular injection in JIA, as shown in a randomized controlled trial with the alternative agent triamcinolone acetate.<sup>77</sup>

A typical regimen for dosage of triamcinolone hexacetonide is 1 mg/kg for large joints (knees, hips and shoulders) to a maximum

Table 29.10 Algorithm for the medical treatment of JIA by onset pattern

Key to algorithm: po—oral, sc—subcutaneous, NSAIDs—nonsteroidal anti-inflammatory drugs, iv MP—iv methylprednisolone, IATH—intra-articular triamcinolone hexacetonide, MTX TNF $\alpha$  methotrexate, IVIG—intravenous immunoglobulin; ASCT—autologous stem cell transplant. \*\* Indicates stage requiring management in conjunction with regional pediatric rheumatology center.

Table 29.11 Nonsteroidal anti-inflammatory drugs commonly used in children with juvenile idiopathic arthritis

Drug	Dose	Times daily	Notes
Diclofenac sodium	1 mg/kg	2–3	Max 150 mg/day SR available
Naproxen	5–10 mg/kg	2	Max 1 g/day
Ibuprofen	10 mg/kg	3–4	
Indometacin	0.5–1 mg/kg	2	Max 200 mg/day SR available
Piroxicam	< 15 kg 5 mg 16–25 kg 10 mg 26–45 kg 15 mg > 46 kg 20 mg	Once daily	Sublingual preparation available

SR, slow release.

of 40 mg, 0.5 mg/kg in smaller joints (ankles, wrists and elbows) and 2–4 mg/joint for the small joints of the hands and feet. The dose of triamcinolone acetonide is typically double that of triamcinolone hexacetonide. In young children with JIA or if multiple joints are to be injected, intra-articular injection will be performed using general anesthesia. In older children the procedure can be safely and effectively carried out using a 50/50 mix of nitrous oxide and oxygen (Entonox). Subcutaneous atrophy at the injection site is the only common adverse effect, with the highest incidence in a single study of 8.3% of patients.<sup>78</sup> A transient cushingoid state is reported with the use of triamcinolone acetonide, including occasionally after injection of a single joint.<sup>79</sup>

**Systemic corticosteroids.** Systemic corticosteroids, administered either as intravenous high dose ‘pulses’ (methylprednisolone 30 mg/kg usually for 3 consecutive days and repeated as necessary) or oral prednisolone may be considered as an adjunct in a defined course during the ‘lag’ phase while MTX becomes effective or may be used to control acute disease flares, again in strictly limited courses.

**Methotrexate**

Methotrexate (MTX) is currently the disease modifying agent of first choice in JIA. MTX is a dihydrofolate reductase inhibitor, although its

mechanism of action as an anti-inflammatory agent is not fully understood. In a double-blind placebo-controlled trial, MTX at a dose of 10 mg/m<sup>2</sup> was effective in polyarthritis (significant response in 63% of patients).<sup>80</sup> MTX is effective in extended oligoarthritis and systemic JIA.<sup>81</sup> Ruperto and colleagues for PRINTO reported in a randomized controlled trial that 28% of patients failed to respond to an oral dose of 8–12.5 mg/m<sup>2</sup>. Of those, a further 62.5% achieved a clinical response to subcutaneous administration at 15 mg/m<sup>2</sup>/week, but no additional benefit was seen at 30 mg/m<sup>2</sup>/week.<sup>82</sup>

Subcutaneous administration should be considered if oral administration fails to produce effective control, or is not tolerated. This can be self-administered at home by patients or carers. In the UK the Royal College of Nursing have produced guidelines regarding subcutaneous administration of MTX (<http://www.rcn.org.uk/publications/pdf/administering-methotrexate.pdf>).

Common side-effects of weekly low dose methotrexate include nausea and vomiting, which in some cases can be overcome by giving the MTX in two doses over 24 hours, use of an antiemetic agent or regular administration of folic acid. Mouth ulcers may also respond to folic acid supplementation. Transient elevations in liver enzymes are common, frequently associated with intercurrent viral infections, and resolving with temporary withdrawal of MTX. Significant liver toxicity and bone marrow suppression is rare.<sup>83</sup> Blood monitoring is mandatory while children take MTX. Monthly full blood count (FBC) and liver function tests (LFTs) initially, reduced to 2–3 monthly thereafter is satisfactory. There is no consensus on the use of folic acid to minimize adverse effects in children on weekly low dose MTX, although weekly administration in doses of 2.5–5 mg per week is standard in some centers.

Immunization with live vaccines is contraindicated during treatment with MTX. If circumstances permit, children known to be varicella zoster (VZ) susceptible should be immunised with VZ vaccine 2 weeks prior to starting MTX. Children known to be VZ susceptible and in contact with VZ, should be treated with either VZ specific immunoglobulin or prophylactic oral aciclovir according to local guidelines. A best practice statement on the immunization of the immunocompromised child is available.<sup>84</sup>

Methotrexate is teratogenic and liver toxicity may be increased with concomitant alcohol ingestion. Adolescents need specific counseling in these areas. A checklist prior to administration of MTX is given in Table 29.12.

### Biological therapies

Following publication of the previous edition of this text, there has been rapid growth in this form of therapy in JIA. Acute infection of any type mandates temporary interruption of therapy, and all live vaccines are contraindicated. A summary of anti-TNF agents used to treat JIA is given in Table 29.13.

**Etanercept.** In a multicenter clinical trial of children with polyarticular JIA who had previously failed to respond to therapy with low dose methotrexate, 74% improved with etanercept.<sup>85</sup> Adverse effects were similar to those in the placebo group, and included injection site

**Table 29.12** Information to be discussed prior to commencing methotrexate for JIA

Blood monitoring – FBC and LFTs monthly until dose stable and 2–3 monthly thereafter
Avoid all live vaccines
Miss a dose if acutely unwell with intercurrent infection – contact rheumatology team for advice
Ensure adequate contraception if sexually active
Limit alcohol intake to 5 units per week, and highlight the alcohol content of popular brands

reactions, headaches, minor upper respiratory tract infections, rhinitis, urticarial reactions, nausea and vomiting. Follow-on data have demonstrated safety and efficacy over a 4-year period, with the rate of serious adverse events being 0.13 per patient-year. The rate of serious infections was 0.04 per patient-year, in a total etanercept exposure of 225 patient-years.<sup>86</sup>

**Infliximab.** Efficacy similar to etanercept has been shown in an open label prospective pilot study of 24 patients.<sup>87</sup> In a randomized controlled trial, comparing infliximab at doses of 3 mg/kg vs 6 mg/kg, 75% of JIA patients responded to a dose of 6 mg/kg. Antibodies to infliximab were higher with the lower dose resulting in a higher incidence of allergic type infusion reactions and serious adverse events in the 3 mg/kg group compared to 6 mg/kg group (19% vs 9% respectively at weeks 14–52 of treatment).<sup>88</sup> Co-administration with weekly methotrexate is recommended to limit autoantibody production.

**Adalimumab.** Adalimumab is a recombinant human IgG1 monoclonal antibody, specific to human TNF. Theoretically there should be less risk of immunogenic reactions than with infliximab. Efficacy has been demonstrated in adult rheumatoid arthritis. At the time of writing JIA data are only available in abstract form, albeit with encouraging efficacy and safety at 1-year follow up.<sup>89</sup>

**Adverse effects of anti TNF agents.** Anti TNF agents have been shown to induce production of antinuclear antibodies, although the incidence of a lupus-like state remains low.<sup>90</sup> There have been reports of lymphoproliferative disease in adult patients with rheumatoid arthritis and Crohn disease treated with anti TNF agents,<sup>91</sup> although a causal link remains to be established. This highlights the need for further long term surveillance studies in JIA and a biologics registry has been established in the UK for this purpose (British Society for Paediatric and Adolescent Rheumatology Biologics and New Drugs Registry: [www.bsparreg.org](http://www.bsparreg.org)).

At the time of writing, etanercept is the only biological agent licensed for use in JIA in the UK. The National Institute for Health and Clinical Excellence (NICE: [www.nice.org.uk](http://www.nice.org.uk)) has recommended etanercept for children with active JIA in at least five joints, with inadequate response to MTX, or intolerable side-effects from MTX.

### Other biologic agents

Preliminary data suggests a role for two other agents in JIA. IL-1 is now known to play a role in systemic JIA.<sup>92</sup> Anakinra, an IL-1 receptor ana-

**Table 29.13** Biologic anti TNF agents for the treatment of JIA

Biologic agent	Structure	Mechanism of action	Administration	Red flags
Etanercept	Soluble fusion molecule of two human p75 TNF receptors	Binds and blocks TNF $\alpha$ and lymphotoxin $\alpha$	0.4 mg/kg twice weekly s.c. injection, maximum 25 mg per dose	Injection site reactions, infections
Infliximab	Chimeric human-mouse anti TNF $\alpha$ monoclonal antibody	Binds TNF $\alpha$	6 mg/kg at 0, 2 and 6 weeks, then 8 weekly thereafter by intravenous infusion	Infusion reactions, infection, TB reactivation, ANA and anti-dsDNA antibody formation
Adalimumab	Recombinant human IgG1 anti-TNF $\alpha$ monoclonal antibody	Binds TNF $\alpha$	24 mg/m <sup>2</sup> fortnightly by subcutaneous injection	Injection site reactions, infections

tagonist, has been used in adult RA and anecdotal evidence suggests that it may be effective in systemic JIA. An open label phase II clinical trial of anti-IL-6 receptor monoclonal antibody (MRA) has also shown promise in systemic JIA.<sup>93</sup>

### Other therapies

Intravenous immunoglobulin may be used in systemic arthritis<sup>94</sup> unresponsive to more conventional therapies. Dose regimens vary between 1 g/kg/day for 2 consecutive days and 400 mg/kg/day for 5 consecutive days, repeated monthly. Hydroxychloroquine may be of benefit in some seropositive patients. Sulphasalazine may be used in enthesitis-related arthritis. Leflunomide, an oral dihydroorotate dehydrogenase inhibitor, has shown efficacy in adults with rheumatoid arthritis. There is anecdotal evidence of benefit in JIA<sup>95</sup> but no controlled studies.

Autologous hemopoietic stem cell transplantation (ASCT) may be a possible option for patients with JIA refractory to conventional treatment and in whom the burden of drug toxicity is unacceptable. Early results have shown the potential for prolonged drug free remission, but a mortality rate of 9% was reported in a preliminary case series highlighting the importance of developing future protocols through collaborative multicenter studies.<sup>96</sup>

### Surgical management

Orthopedic surgery has an increasingly limited role in JIA. Joint replacement may ultimately be required in some cases, but should be deferred as long as possible. Newer techniques such as hip resurfacing may have a role in some, but detailed discussion is beyond the scope of this text.

### Transitional care

Young people with JIA entering transition into adulthood have specific medical and psychosocial needs, and many advocate that this process should be pro-actively managed. A multicenter study of a coordinated, evidence-based program of transitional care reported encouraging results.<sup>97</sup>

## OTHER ARTHROPATHIES IN CHILDHOOD

Infections and JIA are the only common causes of arthritis in childhood. The differential diagnosis of inflammatory arthritis in children (Table 29.8) is wide and other causes must be excluded as necessary. Many of these conditions are described elsewhere in the chapter.

## COMMON ORTHOPEDIC PROBLEMS IN CHILDHOOD

Children present to the clinician with a wide spectrum of problems ranging from complaints relating to form, posture and gait to complaints of localized pain at various sites. This section covers the more common orthopedic explanations for such presentations.

### COMMON PAINLESS COMPLAINTS

#### Normal variants

The shape and form of the lower limbs in children cause a great deal of parental anxiety. In spite of such concern, the majority of these children are normal and sound knowledge of normal variation cannot be overemphasized. The most common causes for parental concern are flat feet, bow legs, knock knees, and in-toe gait. The chief objective when presented with such children is to exclude a pathological explanation. In broad terms unilateral 'deformities' are more suspicious of pathology than bilateral which frequently reflect normal physiological variation.

#### Toe walking

The commonest explanation for this presentation is habitual or idiopathic toe walking although more serious explanations should be

considered and excluded. A thorough neuromuscular evaluation is mandatory since toe walking may be a feature of muscular dystrophy, cerebral palsy, a tethered cord or indeed any neuromuscular disorder. Children with habitual or idiopathic toe walking persistently walk on the toes, but can be encouraged to adopt a more normal heel strike. They should be able to stand still with the heels to the ground. Treatment is directed toward constant encouragement to reinforce the normal heel-toe gait pattern, but occasionally serial casting is helpful to break a persistent habit or if true tendo-Achilles shortening develops.

### Flat feet

Most children who are brought for assessment of flat feet are normal. The clinician's responsibility is to exclude potential pathological causes such as congenital vertical talus, tarsal coalition or juvenile idiopathic arthritis.

The clinical assessment aims to determine if the flat appearance is flexible or rigid. Rigid flat feet are never normal; flexible flat feet usually are. The feet should be observed weightbearing and walking. Many infants have 'fat feet' rather than flat feet, a pad of fat in the sole of the foot hiding the normal arch. Jack's test should be done. This requires the great toe to be dorsiflexed. As this is done a windlass mechanism tightens the plantar fascia and draws the flexible flat foot up into a normal arch (Fig. 29.42). The child should be asked to stand on tip-toe while the foot is observed both from behind and from the medial side. When standing, the heel of the flat foot is in valgus if viewed from behind. On tip toe the heel and hindfoot should swing into a varus posture and when viewed from the medial side an arch should develop. The flexible flat foot has a normal or even an increased range of movement as a result of a degree of ligamentous laxity. Limitation suggests pathology. Radiographs are not necessary in the evaluation of the flexible flat foot but should be included if there is any suspicion of inflexibility or symptoms of pain.

Flexible flat feet are rarely symptomatic and in most individuals represent an anatomical variant. They are occasionally associated with conditions where ligamentous laxity is a feature, such as Ehlers-Danlos and Marfan syndromes when they may persist into adult life. Treatment is rarely necessary. Footwear modifications do not alter the development of the foot although a simple arch support or a heel cup, to prevent the heel collapsing into valgus, can help to reduce symptoms of foot ache or minimize rapid shoe wear. In the rare cases where symptomatic flat foot persists into maturity, surgical correction can be considered.

### Bow legs and knock knees

Whilst the majority of children who present with bow legs or knock knees are physiologically normal, both presentations can be a manifestation of metabolic bone disease and consideration of such conditions is important.

#### Bow legs (*genu varum*)

Figure 29.43 charts the development of the tibiofemoral angle during growth. Varus angulation is normal in infants but usually resolves by 18–24 months.<sup>98</sup> Valgus angulation is normal in 3- to 5-year-olds, usually resolving by age 7–8 years. Clinical assessment should be made with

Fig. 29.42 Flexible flat foot – Jack's test.

Fig. 29.43 The tibiofemoral angle during growth. (Adapted from Salenius and Vankka 1975<sup>98</sup>.)

the child standing, if possible, and both patellae pointing forwards. The tibiofemoral angle can then be measured with a goniometer. This assessment is relatively crude but measurements more than two standard deviations from normal suggest further evaluation, to exclude a pathological explanation.

The principal pathological explanations for bow legs are metabolic bone disease, Blount disease and skeletal dysplasias. Radiographs are not usually helpful under 18 months of age but should be taken if there is a suspicion of pathology. Typical feature of rickets with widening and irregularity of the growth plate and trumpet-like flaring of the metaphysis (Fig. 29.27), or features of Blount disease or some skeletal dysplasia may be seen.

Infantile Blount disease can be difficult to distinguish from physiological bowing but is suggested by bowing that is severe or persisting beyond 24 months. Blount disease is the result of an idiopathic growth disturbance in the posteromedial part of the proximal tibial physis and is most common in people of Scandinavian or West Indian descent. Affected infants are often heavy and walk early and it is thought that increased pressure across the growth plate may play a role in the etiology. Differentiation from physiological bowing can be difficult and it is possible that the two conditions are part of a continuum. Radiographs can be helpful. In physiological bowing there is varus of the whole leg, both the distal femur and the proximal tibia, whereas in Blount disease bowing is principally at the proximal tibia, often with a sharp angulation in the medial metaphyseal region (Fig. 29.44). Early brace treatment may be effective in children under 3 years old.<sup>99</sup> A knee ankle foot orthosis (KAFO) is used to keep the knee in extension for 23 out of 24 hours a day in order to unload the posteromedial physis, but if the deformity continues to progress tibial osteotomy may become necessary.

### Knock knees (*genu valgum*)

As can be seen from Figure 29.43 genu valgum of around 8–10° is normal in 3- to 5-year-old children and gradually returns to adult values of 5–7° by around 7 years of age. Normal children, by definition, fall within two standard deviations of the mean and the normal distribution of the tibiofemoral angle is wide. Treatment of physiological knock knees is not necessary. The underlying cause of pathological cases should be addressed before attending to the limb deformity. Brace treatment is of little benefit and treatment often involves osteotomy or asymmetrical growth plate epiphyseodesis or stapling.

### In-toe and out-toe gait

We walk along a straight, imaginary line of progression, which stretches out before us. When the foot is placed on the ground, the line

of its long axis forms an angle with the line of progression and this angle is termed the foot progression angle. In-toe gait (internal foot progression angle) where the toes of each foot point inwards is a common cause for parental concern. Most patients who present with rotational problems in the lower limbs are normal. Occasionally rotational

Fig. 29.44 Blount disease.

problems may be pathological, representing part of a bone, joint or neuromuscular disorder.

The foot is at the end of the limb and an in-toe or out-toe gait may result from a twist or torsion in the femur, the tibia or the foot itself. Initial assessment of these children involves determining the site and magnitude of the torsion, by examining the rotational profile of the limb. The child should stand and walk so that the foot progression angle can be estimated. This is very variable in early childhood: most children under 4 years have a degree of in-toeing while most adults have a degree of out-toeing.

The rotational profile of the lower limbs should be evaluated (Fig. 29.45). The hips should be examined with the child prone on the examination couch and the knees flexed to  $90^\circ$ . External and internal rotation at the hip can then be assessed (Fig. 29.45AB,). This gives some indication of torsion within the femur but is also influenced by soft tissue tension about the hip capsule. With the child still prone and the knees flexed to  $90^\circ$  the limb can be viewed from above. The thigh-foot angle is the angle between the long axis of the thigh and the long axis of the foot (Fig. 29.45C). It gives some indication of torsion within the tibia. Care should be taken to encourage the patient to relax the foot for the examination while the examiner gently holds the foot in slight dorsiflexion. Soft tissue laxity about the knee can allow the foot to be twisted into internal or external rotation giving a spurious assessment. The sole of the foot should now be viewed from above. A line bisecting the center of the calcaneum should pass through the second toe or the second web interspace. This assessment helps to determine if deformity in the foot is contributing to the gait pattern.

### Femoral torsion

The long axis of the femoral neck is aligned slightly forwards of the transcondylar axis (or coronal plane) of the femur. The angle between the femoral neck axis and the transcondylar axis is the angle of femoral anteversion. At birth, femoral anteversion measures about  $40^\circ$  gradually falling to adult values of  $10\text{--}15^\circ$  during development. Infants have

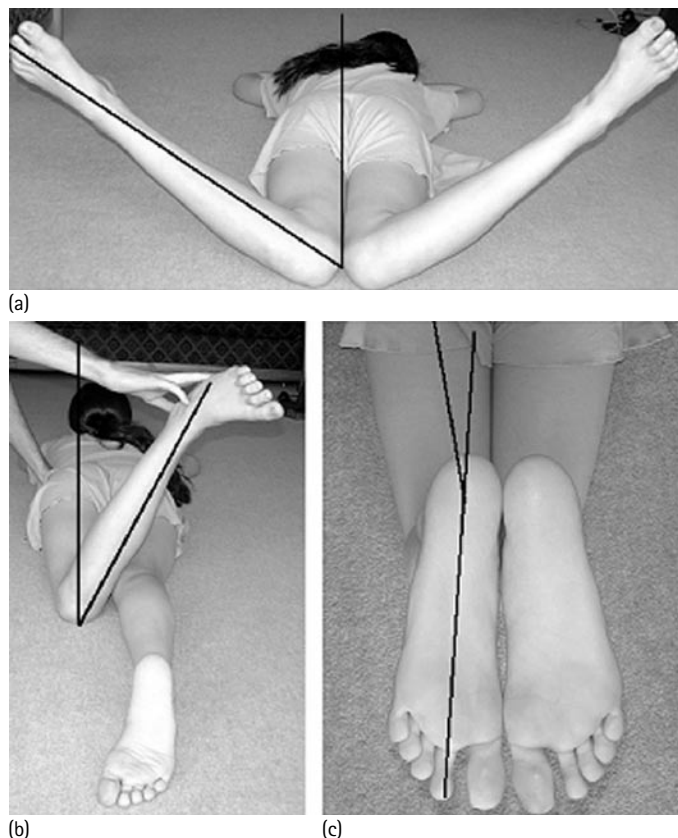

Fig. 29.45 Assessment of the rotational profile of the lower limbs.

the greatest degree of anteversion but do not normally demonstrate an excessive range of internal rotation at the hips because of soft tissue external rotation contracture which is normal in this age range. Femoral anteversion is the most common explanation for in-toe gait in children over 3–4 years and persistence of immature degrees of femoral anteversion is a frequent cause of in-toe gait in early adolescence particularly in girls. Patients present with various complaints especially awkwardness of gait and tripping. They sit in the 'W' position both because they can and because they find it comfortable.

Treatment is rarely necessary since most cases resolve during development. If the problem persists into late adolescence and is sufficiently severe, derotation osteotomy is effective. Sometimes especially in adolescent girls external tibial torsion coexists: this compensates for the internal femoral torsion so that the feet point forwards but the patellae are left 'squinting' medially toward each other (Fig. 29.46). If treatment proves to be necessary in such patients, it will involve bilateral femoral and tibial osteotomies. This is a considerable undertaking, not to be approached lightly.

Fig. 29.46 'Squinting' patellae.

### **Tibial torsion**

Internal tibial torsion is a common explanation for in-toe gait in the toddler age range. The degree of tibial torsion is assessed by measuring the thigh-foot axis, as already described, or by measuring the angle between the coronal (or transcondylar) plane and a line joining the tips of medial and lateral malleoli at the ankle. In the term infant at birth, the medial malleolus usually lies behind the lateral malleolus. By walking age the malleoli are level on the coronal plane and by the time walking is well established the lateral malleolus is behind the medial. In other words the infant normally has relative internal tibial torsion, which gradually rotates externally with growth. Internal tibial torsion often coexists with bowing of the legs in infants and young children and may exaggerate the appearance of the bowing. No treatment is necessary or effective for physiological internal tibial torsion.

Excessive external tibial torsion is less common than internal tibial torsion and more likely to persist into adolescence.<sup>100</sup> Once again the only effective treatment for tibial rotational abnormalities is tibial osteotomy. Serious thought needs to be given before offering operative solutions as neither internal nor external tibial torsion have been shown to be risk factors for later degenerative change.

### **Metatarsus varus**

Metatarsus varus or metatarsus adductus is medial deviation of the forefoot on the hindfoot. The subtalar and ankle joints are normal and the hindfoot is in neutral or slight valgus. This distinguishes the condition from clubfoot deformity where the hindfoot is stiff and in varus and equinus. The foot has a concave medial border which can be the cause of, or at least contribute to, an in-toe gait appearance.

The severity of the condition can be classified using the heel bisector as previously described. The condition is described as flexible if the forefoot can be passively overcorrected, partly flexible if it can be passively corrected to the midline and rigid if it cannot be returned to the midline. The natural history is of progressive spontaneous resolution. Consideration can be given to treatment if the deformity is rigid or partly flexible and serial casting has been shown to be effective.<sup>101</sup>

## **COMMON ORTHOPEDIC EXPLANATIONS FOR MUSCULOSKELETAL PAIN IN CHILDHOOD**

### **Growing pains**

Musculoskeletal pain in children is relatively common and usually benign. In evaluating children it is wise to remember that infection and neoplasia are amongst the myriad of potential explanations. Both commonly present in childhood as localized bone pain and must be given due consideration in the differential diagnosis.

The syndrome of benign 'growing pains' is common; usually presenting in children between 4 and 8 years. It can occur in the upper but more frequently the lower limbs. The typical history is of a child who, after a busy day, complains of aching pains in the limbs, frequently in the thighs, shins or around the front or the back of the knees. The pain can be severe, even disturbing sleep, and usually settles after a variable period of parental rubbing of the affected limbs. The next day the child is fine and there are no sequelae. The natural history is of resolution after 18–24 months but the course may be more protracted. The cause remains unknown but growth seems to have little to do with the symptoms. The likely explanation is muscle fatigue or cramp.<sup>102</sup> Treatment is primarily reassurance but can include stretching exercises if muscle fatigue is thought to be a factor.

### **Neck and back pain**

See later section, page 1437.

### **The painful or irritable hip**

The term irritable hip is not a diagnosis but the clinical presentation of hip pathology. The patient may present with symptoms ranging from severe pain with complete inability to weightbear to modest

pain, localized to the hip or referred to the knee, with virtually no limp.

The most sensitive sign of hip joint pathology is subtle limitation of internal rotation, which should be carefully sought. Clinical examination of the hip is equally important when patients present with localized hip pain or with isolated thigh or knee pain. The potential for knee pain to be referred from the hip is frequently overlooked.

The commonest cause for an irritable hip in childhood is transient synovitis, but the differential is wide and includes infections, acute and chronic, including septic arthritis and osteomyelitis, Perthes disease and slipped capital femoral epiphysis (SCFE). Less common causes include the inflammatory arthritides such as juvenile idiopathic arthritis, idiopathic chondrolysis and neoplasms. Transient synovitis, Perthes disease, SCFE and chondrolysis will be discussed here. The other disorders are discussed elsewhere in the chapter.

### **Transient synovitis**

This is the commonest cause for hip pain in children: it is estimated that about 3% of children will have at least one episode.<sup>103</sup> It is twice as common in boys and usually occurs between 3 and 8 years with a peak incidence around 6.<sup>104</sup> It is characterized by a transient period of hip joint irritability in a systemically well child. The etiology is unknown but hypotheses include trauma, allergic hypersensitivity or infection. In up to 70% of cases there is a history of either current or antecedent nonspecific upper respiratory infection, and the most widely accepted explanation is that the condition represents a transient reactive synovitis.

Hip joint ultrasonography is the most useful investigation, confirming that the hip joint is the source of complaint. The findings are nonspecific and do not necessarily exclude other causes of an irritable hip. Radiographs and laboratory tests are normal or nonspecific. Transient synovitis is essentially a diagnosis of exclusion and investigations are aimed at excluding other diagnoses. Pyogenic septic arthritis is the most important alternative diagnosis. The child with septic arthritis is usually systemically unwell with a high fever, a high white cell count and ESR and fails to improve with rest. The patient with an effusion due to transient synovitis may have a modest fever and mildly elevated ESR and improves with rest.

Treatment is symptomatic. Skin traction has been popular but is not now recommended because positioning the hip in extension increases intracapsular pressure and pain. If traction is to be used, the leg should be supported with the hip flexed. In practice it is more practical to let the child rest the limb in a position of flexion and external rotation for comfort, provided symptoms settle promptly.

Most cases resolve progressively over 5–10 days. Deterioration is more characteristic of septic arthritis and persistence of moderate or modest symptoms should raise suspicion of alternative explanations such as Perthes disease. Isotope bone scanning can be helpful in these circumstances to distinguish Perthes disease, characterized by reduced uptake, from transient synovitis and other inflammatory conditions where increased uptake is usual. A relationship between transient synovitis and the development of Perthes disease has been suggested but no direct causal correlation has ever been shown. It is safest to conclude that the only relationship is a similar mode of presentation, with an irritable hip.

### **Perthes disease (Legg–Calvé–Perthes disease)**

Perthes disease is avascular necrosis of the femoral head epiphysis due to a disturbance of the epiphyseal blood supply. The disturbance can affect part or all of the femoral epiphysis and the extent of involvement is related to the ultimate prognosis. Despite enthusiasm for the notion that thrombophilia or hypofibrinolysis may be involved in the pathogenesis, more recent work has proved less than encouraging and Perthes disease remains a condition of unknown etiology.<sup>105</sup> Eighty percent of cases occur between the ages of 4 and 9 years and the condition is five times more common in boys.<sup>106</sup> Children present insidiously with an irritable hip syndrome which persists and may deteriorate.

Initial radiographs may be normal. Radionuclide bone scanning shows decreased uptake, distinguishing Perthes from other causes of an irritable hip. MRI can reveal epiphyseal necrosis earlier than plain radiographs as well as defining the extent of involvement. Radiographs will ultimately reveal progressive changes in the hip joint and the femoral epiphysis.

The pathogenesis is reflected in sequential radiological stages. In the initial phase there is increased epiphyseal density which gives way to the fragmentation phase (Fig. 29.47a), sometimes heralded by the appearance of a subchondral radiolucent line or 'crescent sign' (Fig. 29.47b) and eventually characterized by the appearance of lucent areas fragmenting the epiphysis. The reparative or reossification phase supervenes and normal bone density slowly substitutes areas of previous lucency. The process continues from the periphery of the epiphysis to the center until the healed phase is reached. The bony epiphysis once again has the consistency of normal bone but may have become deformed to a greater or lesser degree.

Although Perthes disease can be bilateral in 10–12% of cases<sup>107</sup> radiographs characteristically reveal different stages of disease in the two sides. A similar appearance in both hips is very unusual and should raise suspicion of skeletal dysplasias such as multiple epiphyseal dysplasia (MED) (Fig. 29.25) and spondyloepiphyseal dysplasia (SED).

(a)

(b)

Fig. 29.47 Perthes disease: (a) stage of fragmentation and collapse; (b) crescent sign.

The progression from the initial phase to the end of the healed phase can take several years. During this time, especially during the fragmentation phase, the cartilaginous femoral head loses the support of its internal bony skeleton and becomes plastic, or able to change shape. The shape the femoral head becomes is determined by the extent of loss of support (or epiphyseal necrosis), and by the mechanical environment in which the plastic femoral head finds itself. The long term prognosis depends on how spherical the femoral head remains and how congruently it fits the acetabulum.

In early Perthes disease, when the femoral head remains plastic, the principle of treatment is the principle of 'containment'. The patient's own acetabulum is used as a template or mold to keep the femoral head spherical, or at least congruent. This can be achieved by the patient themselves if a good range of movement, especially abduction, is maintained. Alternatively, 'containment' treatment with an abduction brace or femoral or pelvic osteotomy is used to position the plastic part of the femoral epiphysis within the acetabulum. Clinical examination is a crucial part of patient assessment. If the patient maintains a good range of movement the soft femoral epiphysis will be constantly moving in and out of the acetabulum during day-to-day activity and will remain congruent. If, on the other hand, range of movement is limited especially abduction, the femoral epiphysis will not be contained within the acetabulum and weightbearing forces will lead to flattening of the epiphysis and incongruity. Loss of range of movement is therefore a sinister clinical sign.

Radiological evaluation is easiest using the Herring grading system. Herring divided the epiphysis as seen on an anteroposterior (AP) radiograph into medial, middle and lateral columns. Only the lateral column is evaluated. The hip is classified as Herring A if there is no necrosis involving the lateral column, Herring B if the lateral column is involved but retains more than 50% of its original height and Herring C if it has lost more than 50% of its original height. The prognosis deteriorates from grades A to C. In concept if the lateral column is intact, the remainder of the femoral head is protected from weightbearing forces, but if the lateral column fails the whole femoral head is exposed to forces from above and will flatten.

Patients under 5 years at the onset of Perthes disease have a good prognosis. In this age group patients frequently maintain an excellent range of movement, even in the face of extensive epiphyseal necrosis on radiographs, and they essentially contain their own femoral head. They rarely require intervention, but should be constantly reviewed to ensure that a good range of movement is maintained. The good prognosis in this age range is also a reflection of the immature acetabulum with much growth remaining. If the femoral head does become aspherical as a result of the Perthes process, the acetabulum will grow to match.

In older children the acetabulum has less growth remaining, is less able to accommodate an aspherical femoral head and incongruity becomes progressively more likely. Clinical signs reflect the radiological extent of epiphyseal necrosis. If there is clinical loss of range of movement in this age group radiographs will usually reveal Herring grade C or B lateral column involvement. These findings usually dictate 'containment' treatment. In the past a wide range of abduction braces have been used but more recent reports question their efficacy.<sup>108</sup> There is a growing inclination to offer surgical containment because of emerging evidence of improved outcome. Surgical containment is usually in the form of a varus femoral or pelvic osteotomy. It is common practice for surgical candidates to undergo an examination of the joint under anesthetic and hip joint arthrography, to ensure that the epiphysis is containable before embarking on surgical treatment. Patients should be followed to maturity, mainly to ensure a significant leg length discrepancy does not develop. A modest leg length discrepancy is common; one requiring treatment unusual.

Once the Perthes disease is over and the femoral epiphysis healed, it is no longer plastic. Hip pain can result if incongruity has developed. The objective of treatment now is restoration of functional congruity. Once again assessment commonly includes examination under

anesthesia and arthrography. The principal problem encountered in a deformed incongruent joint is 'hinge abduction'. Because the femoral head is too big to enter the acetabulum during abduction, it levers itself out of the joint with the 'hinge' at the lateral lip of the acetabulum. This limits the patient's functional abduction. The problem can sometimes be helped with a valgus femoral osteotomy.<sup>109</sup>

### Slipped capital femoral epiphysis (SCFE)

Slipped capital femoral epiphysis (SCFE) or slipped upper femoral epiphysis (SUFE) is the commonest hip disorder in the adolescent age range and is frequently the subject of medical negligence claims because of delay in diagnosis with potentially disabling consequences for the patient.

The capital femoral epiphysis is fixed to the femoral metaphysis by the proximal femoral growth plate or physis. If the cartilaginous physis is subjected to shear forces it can fail, usually through its hypertrophic zone, and the femoral epiphysis will then 'slip' posteriorly on the metaphysis, either progressively or suddenly. A SCFE occurs when the load applied exceeds the resistance of the physis to slip. This can occur because the load is too great, because the physis is vulnerable or, most often, because of a combination of these factors.

Hormonal events during normal adolescence lead to relative widening of the physis and its hypertrophic zone during periods of rapid growth. The threshold at which the widened physis fails is lower than a normal physis, making the adolescent vulnerable to SCFE. Any condition that widens the growth plate either because of increased growth or decreased ossification predisposes to SCFE and it has been associated with a variety of endocrine abnormalities including hypothyroidism, panhypopituitarism and hypogonadal conditions and treatment of short stature with growth hormone.<sup>110,111</sup> If a vulnerable physis is subjected to increased load, such as might occur in obesity, the risk of SCFE is further increased. Sixty-three percent of affected individuals are over the 90th percentile for weight.

The incidence of SCFE is around 2:100 000 and its peak presentation is 9–15 years in girls and 10–16 years in boys, i.e. during the adolescent growth spurt. The condition is more common in boys than girls in a ratio of 1.5:1.0. If a case presents in a child outside the expected age range or in a child with an unusual body habitus, more serious consideration should be given to an underlying endocrine or metabolic abnormality.

Careful radiographic interpretation is important for early detection. The AP radiograph is insufficiently sensitive and where a slip is considered possible a lateral radiograph should be obtained. Signs on the AP radiograph include subtle blurring and irregularity of the physis and slight loss of epiphyseal height. When the epiphysis slips a little further it is more obvious. A line, Klein's line,<sup>112</sup> drawn along the superior aspect of the femoral neck should cut off the lateral edge of the epiphysis but does not if the epiphysis has slipped. Minor degrees of slip are more easily seen on the lateral radiograph because the epiphysis primarily slips posteriorly (Fig. 29.48).

SCFE is classified into unstable (acute) or stable (chronic).<sup>113</sup> A third category of a stable slip suddenly becoming unstable also exists (acute on chronic). The distinction between the different types of slip is important because the clinical presentation and the prognosis differ significantly.

In the stable slip the femoral epiphysis gradually and progressively slips posteriorly on the femoral metaphysis. The patient may have a limp but can weightbear and the presentation is essentially that of an irritable hip. Referred knee pain may be the patient's only complaint and a futile search for a local explanation at the knee is a common cause for delayed diagnosis. Pain, discomfort or reluctance when the hip is internally rotated is a subtle indicator of hip pathology and should prompt further radiographic evaluation. Stable slips rarely if ever suffer the serious complication of avascular necrosis but can lead to significant proximal femoral deformity, limited range of movement, limb length discrepancy and premature degenerative change. If a stable slip remains undetected an unstable slip may supervene and seriously affect the

Fig. 29.48 Slipped capital femoral epiphysis: (a) AP radiograph; (b) frog lateral radiograph. Note the relative insensitivity of the AP radiograph – arrows demonstrate subtle difference in epiphyseal height.

prognosis. The keystone of management is early detection followed in most cases by fixation in situ with a cannulated screw. The principle of this treatment is to promote fusion of the growth plate to prevent further slippage and deformity. Osteotomies to correct deformity are controversial and are usually, though not always, deferred for 18–24 months to allow for remodeling. Persistent difficulties are unlikely to improve spontaneously thereafter.

There is usually no difficulty in diagnosing the unstable slip which occurs when the femoral epiphysis suddenly slips posteriorly off the femoral metaphysis. The patient presents in severe pain, unable to weightbear and the leg is held in external rotation. The rate of avascular necrosis in the unstable slip is around 47%.<sup>113</sup> The blood supply to the femoral epiphysis is vulnerable in the immature hip and the vessels passing along the femoral neck to the epiphysis are suddenly torn or stretched in the unstable slip. The avascular necrosis that follows may not be seen radiographically for some months, but if it occurs it is a devastating complication with no satisfactory treatment. The management of the unstable slip once again involves fixing the slipped epiphysis in situ to promote physeal fusion and to prevent further slippage and damage to the epiphyseal blood supply. No attempt is made to deliberately correct the unstable slip, for fear of further damage to the epiphyseal blood supply, but inadvertent reduction does take place during positioning for fixation in unstable slips and can be accepted. Once again the role of femoral osteotomies in the management of unstable slips is controversial.

The incidence of symptomatic bilateral SCFE averages around 25%, most contralateral slips occurring within 12 months of the original slip. Prophylactic fixation of the opposite side should be considered, especially in the child with an underlying endocrine or metabolic abnormality or some years of growth remaining. If the contralateral hip is not fixed the patient should be warned to return urgently at the first sign of hip or knee symptoms.

### **Idiopathic chondrolysis**

This uncommon condition is characterized by the rapid and progressive destruction of articular cartilage from both sides of the affected joint with subsequent pain and stiffness. It is five times more common in girls than boys and is typically a condition of adolescents. Radiographs reveal narrowing of the affected joint space. Chondrolysis of the hip is of unknown etiology in most cases but has been reported in association with SCFE,<sup>114</sup> trauma, prolonged immobilization and severe burns of the extremities.<sup>115</sup>

The natural history of chondrolysis includes an acute stage lasting 6–18 months with pain, inflammation, loss of range of motion and destruction of articular cartilage. Eventually the chronic stage emerges and can last from 3 to 5 years. During the chronic stage the hip may continue to deteriorate. Ultimately the hip may become pain free but stiff in a poor position, or pain free with partial or rarely complete return of motion and some restoration of the joint space.

The principles of treatment include control of any inflammation with therapeutic doses of NSAIDs and maintenance of motion with an aggressive physiotherapy program. Surgical release of persistent tendon contractures may be necessary in some patients and there are some encouraging results reported following aggressive subtotal capsulotomy and tendon release.<sup>116</sup> Some patients may ultimately come to hip arthrodesis in a functional position for the relief of pain.

### **Knee pain**

Complaints of knee swelling, mechanical symptoms (giving way and locking) or pain are common in both children and adolescents. A knee joint effusion indicates intra-articular pathology and mechanical symptoms often indicate joint instability, loose bodies or meniscal pathology. Pain is either localized or diffuse. There are numerous explanations for localized knee pain in children including a variety of overuse and sport-related problems (see later section, p. 1440). Referred knee pain is common and clinical examination of the hip is important in any patient presenting with unexplained knee pain.

### **Anterior knee pain (patellofemoral pain syndrome and chondromalacia)**

Anterior knee pain is a descriptive term for diffuse pain at the front of the knee. It is a very common complaint in the adolescent age range, typically affecting girls. The complaint is of a diffuse ache around the front of the knee at the patellofemoral joint (patellofemoral pain syndrome), which is worse after activity, after climbing up or down stairs and after sitting for prolonged periods with the knees in a flexed position. Chondromalacia is a term often used to describe this syndrome, but is really a pathological description of cartilage softening and degeneration, rarely present in young patients complaining of anterior knee pain.

The presentation of patellofemoral pain syndrome is fairly typical but evaluation should include reasonable steps to exclude other potential sources of pain. Lateral maltracking or subluxation of the patella is highly correlated with patellofemoral pain syndrome. Because the line of the quadriceps from the anterior superior spine to the tibial tuberosity passes to the lateral side of the knee joint, there is an inherent tendency for the patella to track to the lateral side of the trochlear sulcus in the anterior femur of the patellofemoral articulation. There are mechanisms to prevent such lateral maltracking, but these are sometimes inadequate. Pain at the lateral part of the articular surface of the patella can be a subtle consequence as can more overt subluxation or dislocation. Rotational malalignment also contributes to the problem and many patients will be found to have persistent femoral anteversion in association with compensatory external tibial torsion so that the feet point forwards but the patellae squint medially, the so-called 'miserable malalignment'.<sup>117</sup>

The natural history of anterior knee pain is of slow resolution and most cases respond to non-operative treatment.<sup>118</sup> For many, reassurance is all that is necessary. Physiotherapy is helpful and activity modification, especially the avoidance of provoking sports, may be necessary.

If there is evidence of maltracking some patients find a knee brace with a patella cut out, to hold the patella medially, is useful. An experienced physiotherapist can help with medial taping of the patella in combination with a program to stretch and strengthen quadriceps muscles. If symptoms are persistent and very troublesome in a patient with convincing maltracking, surgical intervention in the form of a lateral retinacular release can be successful in 75% of cases.<sup>119</sup>

### **Discoid lateral meniscus**

This is a congenital abnormality of the meniscus, which is the shape of a disc rather than the usual crescent. The discoid shape can be either complete, covering the whole lateral tibial plateau, or partial forming a rather wider crescent than usual. Children present with mechanical symptoms of giving way, locking or snapping similar to patients with a meniscal tear. Radiographs of the knee sometimes reveal a lateral joint space that is wider than usual, but MRI is the investigation of choice to demonstrate the extensive and thickened meniscus. Asymptomatic discoid menisci found incidentally should be left undisturbed. Symptomatic menisci can be successfully trimmed arthroscopically into a more normal crescent shape.<sup>120</sup>

### **Popliteal cyst**

This common condition presents as a fluctuant transilluminable swelling in the popliteal fossa. The usual reason for referral is parental concern. The cysts are asymptomatic although they may ache with activity and fluctuate in size. They are typically found subcutaneously along the medial side of the popliteal fossa and are simple synovial lined cysts arising from the semimembranosus sheath.

Plain X-rays of the knee are normal and the cyst is best confirmed by ultrasound scan examination. No treatment is required; spontaneous resolution over months or years is usual.

Occasionally, usually in association with an inflammatory arthropathy, popliteal cysts may rupture presenting with calf pain and swelling, the ruptured 'Baker cyst'. Ultrasound and MRI (Fig. 29.49) will distinguish this from other rare causes of calf pain and swelling in children.

### **Osteochondritis dissecans (OCD)**

Osteochondritis dissecans most commonly involves the knee joint, but can affect the articular surface of any joint. For reasons that remain unclear an area of subchondral bone undergoes avascular necrosis. Etiological theories include trauma, ischemia, a genetic predisposition or a combination of these. Symptoms are usually vague and develop insidiously over several months. The overlying cartilage is initially intact but may subsequently develop degenerative change and break into a flap or a loose body causing the onset of mechanical joint symptoms, including locking, snapping or giving way. The most commonly affected part of the knee is the lateral part of the medial femoral condyle, although it can affect any part of the articular surface including the patella.

Radiographs usually reveal a lucent fragmented area in the subchondral bone (Fig. 29.50). In addition to the routine anteroposterior and lateral views of the knee, a tunnel view is useful because it visualizes the intercondylar notch region and the lateral part of the medial femoral condyle where the condition is most common. Magnetic resonance imaging is the investigation of choice and not only delineates the bony abnormality but also provides some indication of whether the overlying cartilage is intact.

The prognosis of the condition is relatively good in young patients when the growth plate remains open but in adults and adolescents with a closed growth plate the prognosis is more guarded. Treatment should include activity modification to limit aggressive sporting activity, which may cause intact overlying cartilage to become loose. If there are no mechanical symptoms and MRI suggests that the overlying cartilage is intact, activity modification to limit symptoms is recommended until resolution which may take months or even years. If there are mechanical symptoms or the MRI suggests the possibility of a breach or flap of the overlying cartilage, arthroscopic examination is recommended. Large flaps, especially on the weightbearing

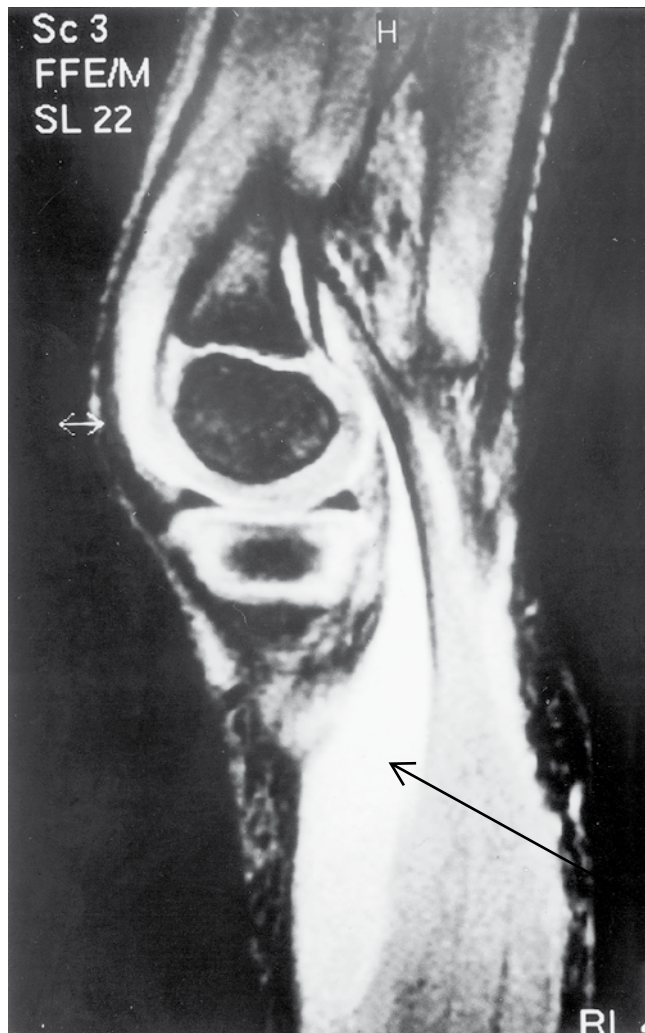

Fig. 29.49 MRI showing ruptured Baker cyst – arrow indicates inflammatory fluid collection extending from the popliteal fossa into the calf.

surface, should be fixed into position, although loose flaps are usually trimmed flush with the articular surface to prevent further mechanical symptoms and the base of the defect drilled to promote healing with fibrocartilage.

#### **Kohler disease**

Kohler disease or osteochondritis of the navicular presents in children around the age of 6 years. The radiographic appearance is that of fragmentation and flattening of the navicular (Fig. 29.51) but this radiological appearance may be a normal variant. The appearance is only considered pathological if there are associated symptoms of localized pain over the bone. Treatment of Kohler disease is symptomatic. There is no evidence of any long term sequelae.

#### **Freiberg disease**

Freiberg disease or osteochondritis of the metatarsal head is most common in the second metatarsal. It usually presents in adolescence with localized pain. Radiographs reveal flattening and fragmentation of the metatarsal head. It is believed to be an avascular necrosis developing in a stress fracture and is associated with local trauma as might occur in sport or in dancing. The condition is much commoner in girls. Treatment is initially conservative but persistent local pain and limited dorsiflexion of the metatarsophalangeal joint may necessitate surgical debridement.

Fig. 29.50 Osteochondritis dissecans of the knee.

#### **Tarsal coalition**

Tarsal coalition is an abnormal cartilaginous, fibrous or bony connection between two or more tarsal bones. It is surprisingly common with a reported incidence of 2%. The condition is inherited as an autosomal dominant trait and the incidence in first-degree relatives is 39%.<sup>121</sup> Fortunately the majority of coalitions are asymptomatic. If symptoms develop they usually present during the late juvenile or early adolescent years when the coalition, initially cartilaginous, begins to ossify. The condition is characterized by a painful, rigid valgus foot and peroneal muscle spasm which may be continuous or intermittent, exacerbated by activity and relieved by rest.<sup>122</sup>

Fig. 29.51 Kohler disease.

Fig. 29.52 Calcaneonavicular coalition.

The two commonest sites of coalition are between the calcaneus and the navicular (Fig. 29.52) and between the calcaneus and the talus, at the middle facet of the subtalar joint. Sixty percent of calcaneonavicular and 50% of talocalcaneal coalitions are bilateral.<sup>123</sup> Multiple coalitions can rarely coexist in the same foot. Calcaneonavicular coalitions begin to ossify between 8 and 12 years and talocalcaneal coalitions between 12 and 16 years.

Calcaneonavicular coalitions are most easily demonstrated radiographically with a 45° oblique radiograph of the foot. CT best demonstrates talocalcaneal coalitions. Secondary radiographic findings such as talar beaking should suggest the possibility of a tarsal coalition. Treatment is initially symptomatic with analgesia and immobilization. If conservative treatment fails, surgical resection of the abnormal coalition and interposition of fat or muscle to prevent recoalition has been shown to be successful in both calcaneonavicular<sup>124</sup> and talocalcaneal<sup>125</sup> coalitions. Generally, results are less satisfactory after talocalcaneal coalition resection and ultimately some patients come to a triple arthrodesis of the subtalar joint.

### Adolescent hallus valgus

Hallux valgus or 'bunions' in adolescents is usually familial rather than the result of poor footwear. It is girls that usually present because of the appearance rather than because of functional problems or pain. There is often an associated bunionette of the fifth toe and patients often have a characteristically broad forefoot with varus of the first metatarsal (metatarsus primus varus). Surgery is best deferred until skeletal maturity is reached. Surgical treatment gives good results for symptomatic feet with a painful bunion but caution should be exercised in the pain free patient who may be disappointed if surgery leaves a better looking but painful foot.

## VASCULITIS

Vasculitis is characterized by inflammation and necrosis of vessel walls. This may occur as a primary disorder, where the etiology remains unknown, or as a secondary phenomenon. Within the group of disorders known as the systemic vasculitides there are a variety of different conditions. Categorization of these conditions in childhood has been problematic and it is only recently that a specific pediatric classification system has been proposed<sup>126</sup> (Table 29.14). This is essentially a modification of the Chapel Hill criteria used in adults which classifies the systemic vasculitides based on vessel size.<sup>127</sup> Specific criteria are included for the diagnosis of the main childhood vasculitides.

There remain many children with a systemic vasculitis in whom categorization is difficult due to overlapping clinical features. The importance of attempting to classify these conditions relates to their variable prognosis. While some are self-limiting, others require aggressive immunosuppressive therapy to minimize morbidity and even mortality.

Table 29.14 Classification of childhood vasculitis. (Adapted from Ozen et al 2006<sup>126</sup>)

<b>I Large vessels</b>
Takayasu arteritis
<b>II Medium sized vessels</b>
Childhood polyarteritis nodosa
Cutaneous polyarteritis
Kawasaki disease
<b>III Small vessels</b>
a. Granulomatous:
Wegener granulomatosis
Churg–Strauss syndrome
b. Nongranulomatous:
Microscopic polyangiitis
Henoch–Schönlein purpura
Other (isolated cutaneous leucocytoclastic vasculitis; hypocomplementemic urticarial vasculitis)
<b>IV Other</b>
Behçet disease
Secondary vasculitis:
Infection
Connective tissue disease
Isolated CNS vasculitis
Cogan syndrome
Unclassified

Prompt recognition of those requiring such treatment is perhaps more important than an exact diagnostic label.

## PRIMARY VASCULITIS

The only primary vasculitides seen with any frequency in childhood are Henoch–Schönlein purpura and Kawasaki disease.

### Henoch–Schönlein purpura

Henoch–Schönlein purpura (HSP) is the most common of the childhood vasculitides with an estimated incidence of 20.4:100 000<sup>128</sup> peaking at around the age of 5. In the majority of affected individuals it is a benign, self-limiting condition but it can be associated with significant morbidity and occasionally mortality if serious organ involvement occurs. It has been estimated that approximately 1% of children with HSP develop persistent renal disease with less than 0.1% having serious disease.<sup>129</sup>

Pathologically HSP causes a leukocytoclastic vasculitis. The etiology remains uncertain but an infectious trigger is postulated in many cases. Although the pathology is poorly understood, there is much interest in the role of IgA. An elevated serum IgA may occur and the renal pathology overlaps with that seen in IgA nephropathy. Abnormalities in glycosylation of IgA1 have been identified in HSP and appear to be associated with renal involvement.<sup>130</sup>

HSP typically involves the skin, joints, GI tract and kidneys. The rash, characteristically a palpable purpura, affects the lower limbs (Fig. 29.53), buttocks, scrotum and elbows. More extensive involvement including rash affecting the face is not uncommon especially in younger children in whom the rash may be atypical.

Arthralgia and an acute, self-limiting arthritis are common. Gastrointestinal involvement with abdominal pain is one of the more troublesome symptoms of HSP and may be complicated by serious gastrointestinal bleeding, intussusception and rarely perforation of the bowel. Renal involvement occurs in around 50%<sup>131</sup> and ranges from mild asymptomatic hematuria and proteinuria to a nephrotic/nephritic picture with hypertension and a rapidly progressive glomerulonephritis. The importance of HSP lies in its potential for long term renal disease, and children with persisting urinary abnormalities require long term follow-up.

Fig. 29.53 Rash of Henoch-Schönlein purpura.

The diagnosis of HSP is clinical and usually straightforward. With an atypical course, the possibility of some other systemic vasculitis must be considered. Urinalysis should be monitored throughout in all affected children to identify nephritis. Other laboratory investigation is unhelpful and unnecessary in most cases. Abdominal ultrasound may be useful in the assessment of gastrointestinal involvement: characteristic thickening of the bowel wall can be seen and intussusception ruled out where necessary. Evidence of serious or persistent renal involvement may be an indication for renal biopsy to assess the pathology and guide appropriate therapy.

Management of HSP depends on its severity and the particular organ involvement in an individual. In most children it is mild and self-limiting although it may take a few weeks to settle. Recurrent attacks may be seen over a period of a few weeks or months. Most can be managed as outpatients with the parents being taught to test the urine for signs of renal involvement. Simple analgesia such as paracetamol may be adequate for joint and abdominal pain. More significant arthritis may require the use of NSAIDs although these must be used with caution if there is gastrointestinal or renal involvement. There is much anecdotal evidence to support the use of corticosteroids for severe abdominal pain in HSP but no controlled trials. Management of renal involvement depends on its severity. Asymptomatic renal disease requires monitoring but no active

therapy. There is uncontrolled evidence supporting the use of high dose steroids and immunosuppressive therapy where there is a rapidly progressive glomerulonephritis.<sup>132,133</sup> Debate continues around the issue of whether the incidence of serious renal sequelae can be reduced by the earlier administration of steroids. One recent controlled study suggests that in more severe disease early prednisolone therapy while not preventing renal involvement, may shorten its course.<sup>134</sup>

### Kawasaki disease

Kawasaki disease or Kawasaki syndrome, first described in Japan in 1967 by Tomisaku Kawasaki, is the other systemic vasculitis seen commonly in childhood, affecting medium sized vessels and with a particular predilection for involvement of the coronary arteries. This may lead to long term sequelae: Kawasaki disease has replaced rheumatic fever as the most common cause of acquired heart disease in children in the resource rich world.<sup>135</sup> Kawasaki disease predominantly affects children under 5 years with most serious sequelae affecting the under twos.

As with all forms of primary vasculitis Kawasaki syndrome is poorly understood and its etiology unclear. Susceptibility to the disease appears to vary with race, children of Asian origin having a higher incidence than Caucasian populations. Recurrence is unusual but reported in around 3%.<sup>136</sup> It occurs in mini-epidemics, its epidemiology suggesting a role for an infectious trigger but no single agent has been consistently associated with Kawasaki disease. There has been interest in the possible role of superantigens in view of clinical similarities to toxic-shock syndrome and the identification of superantigen positive bacteria (both *Staphylococcus aureus* and *Streptococcus*) from a number of individuals with the syndrome.<sup>137</sup> This theory remains unproven. Although the trigger remains uncertain, immunological abnormalities are well documented in Kawasaki disease. Elevated levels of pro-inflammatory cytokines (TNF- $\alpha$  and - $\beta$ , IL-1 and IL-6); upregulation of adhesion molecules (ELAM-1, ICAM-1 and VCAM-1) and elevated serum levels of macrophage colony-stimulating factor have all been demonstrated.<sup>138</sup>

The diagnosis is based on well-established clinical criteria (Table 29.15). The problem lies with those children, commonly the youngest, who have 'atypical' or 'incomplete' Kawasaki syndrome<sup>139</sup> and are at high risk of coronary artery involvement. The current criteria are insufficiently sensitive for diagnosis in this group and more comprehensive criteria are required.<sup>140</sup> A high index of suspicion is required to ensure that Kawasaki is not missed in the very young child.

The rash in Kawasaki syndrome is polymorphous, usually occurring early in the disease course. Crusting, petechiae and vesicle formation should prompt a search for an alternative diagnosis. An erythematous rash affecting the groin and perineal area and which peels within 48 hours is characteristic (Fig. 29.54a). Involvement of the hands and feet consists of diffuse swelling and/or erythema of the palms and soles. Peeling of the digits (Fig. 29.54b) is well known as a feature of Kawasaki but occurs relatively late in the subacute phase and is not diagnostically helpful. Kawasaki is a multisystem disease and can affect many organ systems. Extreme irritability is very typical of the younger child.

As with most of the vasculitides, laboratory features are nonspecific. Elevation of acute phase reactants, a mild hepatitis and sterile pyuria are common. Thrombocytosis may be marked in the subacute phase.

Table 29.15 Diagnostic criteria for Kawasaki disease

<b>Fever persisting for at least 5 days plus four of the following features:</b>
Changes in peripheral extremities or perineal area
Polymorphous exanthema
Bilateral conjunctival injection
Changes of lips and oral/pharyngeal mucosa
Cervical lymphadenopathy
<i>In the presence of confirmed coronary artery involvement and fever, less than four of the remaining criteria are sufficient to make the diagnosis</i>

(a)

(b)

Fig. 29.54 Kawasaki disease: (a) typical erythematous groin rash with peeling; (b) peeling of digits

A lumbar puncture may be indicated in the febrile, irritable child and will show a mononuclear pleocytosis.

Untreated Kawasaki disease goes through three phases, acute, sub-acute and convalescent, the whole process lasting 6–8 weeks. Mortality from coronary artery involvement is 2%. With treatment the process can be switched off in the acute phase and the mortality reduced to 0.3%.

The recognition that the clinical features of Kawasaki disease were the result of an immunologically driven process led to the use of immunoglobulin in treatment with dramatic benefit. Treatment of acute

phase Kawasaki disease with intravenous immunoglobulin has been clearly shown to reduce coronary artery involvement and hence mortality and morbidity.<sup>141</sup> A single infusion of 2 g/kg is now known to be the optimal regimen.<sup>142,143</sup> This is given with aspirin in high doses initially with reduction to an antiplatelet dose once defervescence occurs. Up to 20% of children with Kawasaki disease fail to settle following a first dose of intravenous immunoglobulin. Those refractory to a repeat dose are likely to benefit from treatment with high dose steroids.<sup>144</sup> The place of steroids earlier in the therapeutic regimen remains unclear.<sup>145</sup>

All children with a definite diagnosis of Kawasaki disease require cardiac assessment to look for evidence of coronary artery involvement which will necessitate long term cardiology follow-up. Guidelines are available for cardiac assessment and follow-up<sup>146</sup> and the reader is referred to Chapter 21 for further information.

### Polyarteritis nodosa

The other primary systemic vasculitides are rare in childhood. Polyarteritis nodosa (PAN) is the least uncommon.

Childhood PAN affects predominantly medium sized arteries. Involved vessels are affected by a necrotizing vasculitis with the formation of aneurysmal nodules in the vessel walls. It frequently presents very nonspecifically and a high index of suspicion is required to make the diagnosis. Presenting symptoms include unexplained malaise and fever, skin rash, abdominal pain, arthropathy and myalgia. Laboratory features are nonspecific with the presence of anemia and raised inflammatory markers. Antineutrophil cytoplasmic antibodies (ANCA) are not associated with classic PAN.

The diagnosis is based on the presence of typical clinical features plus either characteristic abnormalities on biopsy of an affected tissue or abnormal angiography.

Even with correct diagnosis and treatment this condition may have a significant mortality, although this varies considerably in reported series. Prompt treatment is essential in order to minimize damage from the vasculitic process (Fig. 29.55) and improve outcome. Unfortunately the rarity of this condition in childhood means that there are no controlled studies. A combination of high dose steroids plus some other immunosuppressive drug, usually cyclophosphamide, is required. Cyclophosphamide is the drug of choice in most cases and can be used either orally or via intravenous pulses. Once remission has been attained, azathioprine has been shown to be as effective as cyclophosphamide for maintenance and is associated with less long term toxicity. For those children who fail to respond to standard therapy with steroids and cyclophosphamide, anecdotal evidence supports the use of alternatives such as plasmapheresis, new immunosuppressants such as mycophenolate mofetil and biologics (anti-TNFs and rituximab).<sup>147</sup>

### Microscopic polyangiitis (MPA)

The microscopic variant of polyarteritis affects the smaller arteries and is less common than classic PAN in childhood. In adults this has a worse prognosis and outcome than classic PAN. It is not clear whether

Fig. 29.55 Gangrene of several toes in polyarteritis nodosa.

this applies to pediatric cases. Renal involvement dominates the clinical presentation and course of this condition. As with other small vessel vasculitides, ANCA may be detectable. Management is similar to that of classic PAN.

### Cutaneous polyarteritis

There are a group of children who present with a rash identical to that seen in PAN, sometimes associated with systemic upset, but with no evidence of major organ involvement. There is frequently evidence of previous streptococcal infection<sup>148</sup> and this is thought to play a role in the etiology. There is no evidence that this progresses to full blown PAN and it appears to be a separate entity. Prophylaxis with long term penicillin may prevent relapses.

### Wegener granulomatosis

Wegener granulomatosis is rare in childhood. Pathologically this is a necrotizing granulomatous vasculitis that affects the small vessels with a predilection for the upper and lower respiratory tract and kidneys. Although the exact pathophysiology is unclear, Wegener granulomatosis is strongly associated with the presence of autoantibodies directed against proteinase 3 (c-ANCA). Whether or not these antibodies play a pathogenic role in the condition remains unclear. Wegener granulomatosis may cause either localized or generalized disease. Steroids and cyclophosphamide are the mainstay of treatment in those with severe disease. With less serious involvement there may be a role for drugs such as methotrexate.

### Churg–Strauss syndrome

This vasculitis is exceptionally rare in childhood. The clinical picture is of variable vasculitic features associated with asthma, eosinophilia and infiltrates on chest X-ray.

### Takayasu arteritis

Takayasu arteritis, also known as 'pulseless disease', is rare in the UK but worldwide is one of the more common forms of systemic vasculitis affecting younger people. Pathologically it is a chronic giant cell arteritis which segmentally affects the large vessels particularly the aorta and its major branches. Following the initial inflammatory phase, stenosis of vessels leading to ischemia occurs.

During the active inflammatory phase of the disease, affected children may present with features of systemic upset such as fever, weight loss and myalgia. Often the disease presents with evidence of organ ischemia or hypertension.

The etiology of Takayasu arteritis is unclear but genetic factors are important with evidence of racial variations in both incidence and disease expression. Infections and especially tuberculosis have been thought to play a role in triggering the disease but this remains unproven. Management is difficult. Steroids and methotrexate have a role in the active inflammatory phase. Once stricture formation has occurred, angioplasty and reconstructive surgery may be necessary.

### Behçet syndrome

Behçet syndrome is an uncommon, poorly understood inflammatory condition in which at least some of the clinical features are the result of a vasculitis which can affect both arteries and veins. Behçet syndrome is characterized by aphthous oral ulceration, genital ulcers and uveitis. Rare in the UK, Behçet syndrome occurs much more commonly in eastern Mediterranean regions.

Behçet syndrome most commonly presents in early adult life and is rare in childhood. The diagnosis is based on clinical features. In children, recurrent oral ulceration may be the only manifestation for some years and until other features become apparent, it may not be possible to confirm the diagnosis. Painful oral ulcers occur in crops lasting up to 2 weeks. Genital ulceration occurs frequently. Uveitis, although common in affected adults, occurs less frequently in children. Arthralgia and arthritis are common in childhood Behçet syndrome as is recurrent fever. Skin lesions seen most frequently in children are folliculitis

and erythema nodosum. Gastrointestinal involvement may cause abdominal pain and diarrhea and is reported in approximately a fifth of affected children. CNS involvement, particularly meningoencephalitis, occurs in approximately 25%. Vascular involvement, which includes both venous and arterial thromboses and aneurysm formation, is potentially the most serious complication of Behçet syndrome. Pulmonary vasculitis, although rare in affected children, is associated with a high mortality.

Significant vascular involvement is associated with a poor outcome and merits treatment with systemic immunosuppressive agents.<sup>149</sup> Colchicine<sup>150</sup> and thalidomide<sup>151</sup> have been shown to be effective for Behçet syndrome where mucocutaneous lesions predominate.

### Cogan's syndrome

This systemic vasculitis is extremely rare. It is characterized by the association of vasculitic features with interstitial keratitis and vestibulo-auditory dysfunction.

## SECONDARY VASCULITIS

Secondary vasculitis occurs quite commonly in children. It may be seen in the context of a child known to have some other autoimmune rheumatic disorder such as juvenile idiopathic arthritis or systemic lupus erythematosus (Fig. 29.56). Treatment is that of the underlying disorder.

Vasculitis may also occur in association with a variety of infections. These include bacterial infections, viruses such as Epstein–Barr virus and infections such as tuberculosis. Vasculitis is seen not uncommonly in association with meningococcal disease.

Drugs may also be associated with vasculitis which usually remits when the offending agent is withdrawn.

Fig. 29.56 Secondary vasculitis in a child with systemic lupus erythematosus.

### ANTINEUTROPHIL CYTOPLASMIC ANTIBODIES (ANCA)

Antineutrophil cytoplasmic antibodies (ANCA) were first described in association with Wegener granulomatosis in 1985 and subsequently with MPA and Churg–Strauss syndrome. Cytoplasmic or c-ANCA gives coarse granular staining of the cytoplasm, is strongly associated with proteinase-3 and is characteristically found in Wegener granulomatosis. Perinuclear or p-ANCA gives staining of the nucleus and perinuclear area, is associated with antimyeloperoxidase and is more commonly seen in MPA. Atypical ANCA staining patterns are seen nonspecifically in many inflammatory conditions. Measurement of these antibodies has become part of the routine workup of a patient with suspected systemic vasculitis. Nonetheless these are not diagnostic tests and results must be interpreted with care. A strongly positive c-ANCA may support the clinical suspicion of a diagnosis of Wegener granulomatosis. A negative ANCA does not rule out the possibility of a systemic vasculitis.

### OTHER AUTOIMMUNE RHEUMATIC DISORDERS

#### SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a multisystem systemic inflammatory disorder most commonly seen in young adult women but well recognized in the pediatric age group. Rare in prepubertal children it occurs more commonly in the teenage years. Most pediatric series show a peak at 11–14 years but this may reflect referral bias, with older teenagers being referred direct to adult clinics. Females predominate in adult series, making up 85–90% of all cases. In childhood males make up a larger percentage of cases with a male to female ratio of 1:4.5. There are no good epidemiological studies of lupus in children: estimates of incidence are in the region of 10–20 per 100 000 children (under 18 years) but vary widely depending on the ethnic mix of the population. Lupus is more common in non-Caucasian races.

SLE has been regarded as the prototype autoimmune disorder with the recognition that one of the hallmarks of the disease is the production of a variety of autoantibodies. The presence of antinuclear antibodies (ANA) is virtually universal in children with lupus, a fact which can aid in making the diagnosis. Despite this recognition, the pathophysiology of lupus remains poorly understood. The presence of antibodies against double-stranded DNA is associated with the development of glomerulonephritis in lupus and the deposition of DNA–anti-DNA immune complexes may play a pathologic role. The role of other autoantibodies remains unclear.

Abnormalities in the functioning of many areas of the immune system have been documented in lupus, with recent interest in the role of dendritic cells<sup>152</sup> and abnormal apoptosis. A genetic predisposition to the development of lupus exists<sup>153</sup> and environmental triggers, including viruses, are thought to be important. Despite progress in our understanding of the widespread immune dysregulation seen in SLE its cause remains unknown. Nonetheless such progress is beginning to open up new therapeutic possibilities.<sup>154</sup>

Lupus is a multisystem disorder which can present in many different ways and with many different features making diagnosis difficult unless a high level of awareness of the condition exists. Delays in making the diagnosis are common, with the mean time to diagnosis being estimated at over a year in most pediatric series. The diagnosis is based on a combination of clinical and laboratory features (Table 29.16). Diagnostic criteria developed for use in adult patients<sup>155</sup> have been validated in a pediatric population.<sup>156</sup>

Lupus is extremely variable in both its clinical presentation and its severity, ranging from a relatively mild condition characterized by a facial rash, joint pains and fatigue to a severe life threatening illness. A wide variety of systems may be affected. General systemic symptoms such as fevers, weight loss, fatigue, arthralgia and general malaise are common throughout the disease course. The fatigue may be profound, disabling and difficult to treat. The characteristic skin rash is the facial butterfly rash which crosses the bridge of the nose and spares the nasolabial folds (Fig. 29.57). Other rashes (e.g. vasculitic)

**Table 29.16** Revised American College of Rheumatology criteria for the classification of systemic lupus erythematosus. (Adapted from Hochberg 1997<sup>155</sup>)

1. Malar rash
2. Discoid rash
3. Photosensitivity
4. Oral ulceration
5. Arthritis
6. Serositis:
  - a. Pleuritis
  - b. Pericarditis
7. Renal disorder:
  - a. Proteinuria >0.5g/24 h
  - b. Cellular casts
8. Neurological disorder:
  - a. Seizures
  - b. Psychosis (other causes excluded)
9. Hematological disorders:
  - a. Hemolytic anemia
  - b. Leukopenia <4×10<sup>9</sup>/L (two or more occasions)
  - c. Lymphopenia <1.510<sup>9</sup>/L (two or more occasions)
  - d. Thrombocytopenia <100×10<sup>9</sup>/L
10. Immunological disorders:
  - a. Raised antinative DNA antibody binding
  - b. Anti-5m antibody
  - c. Antiphospholipid antibodies:
    - i. Abnormal serum levels of IgG or IgM anticardiolipin antibodies
    - ii. Positive test for lupus anticoagulant
    - iii. False positive serological test for syphilis present for at least 3 months
11. Antinuclear antibody present in raised titer

A person shall be said to have SLE if four or more of the 11 criteria are present (serially or simultaneously).

may occur in SLE and many children with lupus exhibit marked photosensitivity. Alopecia is usually mild but can be severe with scarring. Raynaud phenomenon is common. Hematological involvement is frequent in pediatric lupus which may present initially with what appears to be idiopathic thrombocytopenic purpura. CNS lupus is a cause of long term morbidity and may manifest as seizure activity, psychosis, aseptic meningitis or headaches. Mood alteration is common and it

**Fig. 29.57** Typical facial rash in systemic lupus erythematosus – crossing the bridge of the nose and sparing the nasolabial folds.

may be difficult to separate organic CNS involvement from reactive symptoms due to coping with a chronic illness. Renal involvement is frequent in childhood lupus and one of the major causes of morbidity. When present it tends to dominate the clinical picture. It may present as asymptomatic hematuria and proteinuria, hypertension, nephrotic syndrome or a rapidly progressing glomerulonephritis. Renal biopsy has an important role to play in determining the severity and therefore the likely outcome of the renal disease. Children with lupus are at particular risk from infection which is now the most common cause of death. This is a result both of the disease process itself and of immunosuppressive treatment regimens. Pneumococcal sepsis is a particular risk and pneumococcal vaccination is recommended.

Laboratory investigations are helpful both in the diagnosis and monitoring of SLE. Anemia occurs as a result of chronic disease or hemolysis. Thrombocytopenia and leukopenia are common. Characteristically the ESR is elevated while the CRP remains normal. Renal function should be monitored in those with renal involvement. A mild transaminitis is common but serious liver abnormalities are rare. Serum complement levels are reduced in most patients while serum immunoglobulin levels are nonspecifically elevated. A positive antinuclear antibody (ANA) is found in virtually all patients and is a useful diagnostic tool. The ANA result must be interpreted in the light of the clinical picture as the specificity for lupus is low and children may have a positive ANA for many reasons. Antibodies against double-stranded DNA and Sm (Smith antigen) are of greater specificity. Other autoantibodies such as anti-Ro, La and RNP may occur.

Management of lupus requires regular monitoring and attention to detail. Optimal management is in a multidisciplinary team setting with input from both a pediatric rheumatologist and a pediatric nephrologist. Drug therapy depends on disease severity and organs involved. Mild lupus can be managed with NSAIDs, hydroxychloroquine and low dose methotrexate. Avoidance of sun exposure and the use of sunblock are important. Thalidomide has been used for severe mucocutaneous disease. More significant organ involvement will require the use of moderate doses of steroids while severe disease which is life or organ threatening will require treatment with high dose steroids and immunosuppressive agents such as azathioprine and cyclophosphamide. Controlled studies in adults have shown the superiority of combinations of steroids and immunosuppressants over steroids alone<sup>157,158</sup> but there are no controlled studies in pediatric SLE. Treatment must be sufficient to suppress disease activity but aim to minimize toxicity. The long term toxicity particularly of high dose steroid regimens is very significant and steroid side-effects are particularly unacceptable to teenage girls who are the group most affected by lupus. Recently there has been interest in the use of mycophenolate mofetil a potentially less toxic alternative to cyclophosphamide.<sup>159</sup> Rituximab, a biologic drug which targets B cells, has been shown to be effective in individuals with disease resistant to more conventional therapies.<sup>160</sup> There are no pediatric studies to date and concern from some anecdotal reports regarding the frequency of side-effects.<sup>161</sup>

The ESR, urine protein level, levels of C3 and C4 and ds-DNA titer may all be used in monitoring disease activity and response to treatment but clinical assessment of disease activity remains the gold standard. A variety of assessment tools have been developed to allow quantitative assessment of disease activity in lupus and have been validated for pediatric use.<sup>162</sup> PRINTO (The Pediatric Rheumatology International Trials Organization) has developed and validated both a disease activity core set and a definition of improvement for use in pediatric lupus.<sup>163,164</sup>

SLE is a serious disease and those who present in childhood have a high incidence of major organ involvement. Current treatment has markedly reduced the mortality but the long term morbidity remains high. Infection is the most common cause of death but renal death with the consequent need for dialysis and transplantation continues to occur in those with aggressive nephritis. Early diagnosis and optimal management should reduce this but the need for improved treatment protocols remains.

As survival rates from childhood lupus have improved it is clear that there is a high incidence of serious long term morbidity.<sup>165</sup> CNS disease results in long term psychological sequelae in many. Osteoporosis results both from the disease and its treatment. Lupus is known to cause a dyslipoproteinemia<sup>166</sup> and early onset coronary artery disease is a major complication of childhood lupus. Whether this can be altered by treatment of the lipid abnormalities is unknown.

### Drug-induced lupus

A number of drugs are well known to cause a lupus-like syndrome. The best known in children are the antiepileptic drugs phenytoin and carbamazepine and the antihypertensives hydralazine and captopril. An addition to the list, of importance in teenagers, is minocycline commonly prescribed for acne.<sup>167</sup>

### Antiphospholipid syndrome

As with other autoantibodies such as ANA, low titer antiphospholipid antibodies are seen not uncommonly in children, and are frequently thought to be epiphenomena of no clinical significance. Low titer antiphospholipid antibodies occur in around 30% of children with SLE but are of dubious clinical significance. The antiphospholipid syndrome occurs where higher titers of antibodies are associated with coagulation abnormalities and thromboembolic events.

Antiphospholipid syndromes are usually secondary, frequently in association with SLE. Primary antiphospholipid syndromes have been described in childhood but are rare.

These antibodies should be looked for in any child presenting with unexplained thromboembolic phenomena. Anticoagulation is required where there is evidence of an associated thrombotic problem. The role of prophylaxis, with either low dose anticoagulation or aspirin, in children is unclear.

### Neonatal lupus erythematosus

The neonatal lupus syndrome is defined by the presence of maternal autoantibodies to Ro and La which cross the placenta causing clinical abnormalities in the fetus and neonate. The characteristic skin rash, thrombocytopenia and hepatic abnormalities are usually self limiting. The importance of the syndrome lies in its association with congenital heart block which may cause intrauterine bradycardia, cardiac failure and death. This syndrome usually affects pregnancies of women with only mild lupus or of healthy women subsequently found to have anti-Ro and La antibodies.

### JUVENILE DERMATOMYOSITIS AND POLYMYOSITIS

The idiopathic inflammatory myopathies comprise a group of conditions characterized by unexplained inflammation of the muscles. In childhood, dermatomyositis is ten times more common than polymyositis.

Juvenile dermatomyositis (JDM) is a rare condition with an incidence of 1.9 per million children under 16 years in the UK.<sup>168</sup> Juvenile dermatomyositis occurs at all ages throughout childhood but with two peaks of presentation at 5–9 years and at 11–14 years. The condition is more common in females than males.

The etiology of JDM remains unknown. In children, unlike adults, there is no association with malignancy. Studies have shown a strong association with HLA-DQ1\*0501<sup>169</sup> confirming a role for genetic factors. There has been interest in the role of TNF in the inflammatory myopathies and an overrepresentation of TNF- $\alpha$ -308A allele has been demonstrated in a population of children with JDM.<sup>170</sup> A number of epidemiological studies have documented clustering of onset of cases, stimulating interest in the role of infectious agents as triggers. No single agent has been identified.

Once established, a variety of immunological abnormalities occur in children with JDM. Antinuclear antibodies are found in approximately 60%. Their specificity is for the most part unknown and in contrast to adults, myositis-specific antibodies (e.g. Jo-1; Mi) are seldom present. Active disease is associated with elevation of serum immunoglobulin

levels, evidence of complement activation, lymphopenia and an increase in the percentage of B lymphocytes.

The diagnosis of JDM is based on criteria published by Bohan and Peters in 1975.<sup>171</sup> A child is considered to have JDM if, having excluded other known causes, they have a characteristic rash plus three of the following four criteria: symmetrical proximal muscle weakness, elevated muscle enzymes, abnormal muscle histology and EMG changes. The increasing use of modalities such as MRI to demonstrate inflammatory muscle changes is replacing more invasive investigations in many patients and there is a need for a revision of these diagnostic criteria.<sup>172</sup>

The rash in JDM is the first symptom in approximately 50%. A further 25% report a simultaneous onset of the rash and weakness while in the last 25% weakness precedes the rash. The typical rash affects the eyelids, knuckles and extensor aspects of the knees and elbows (Fig. 29.58). Erythema affecting the face and upper trunk may also be seen. The eyelid rash is violaceous in hue, while the lesions over the knuckles may have a hypertrophic appearance (Gottron papules) (Fig. 29.59). Marked nailfold erythema occurs and is indicative of the vasculopathy that characterizes JDM. Examination of the nail fold capillaries will show typical changes with capillary dilatation and areas of thrombosis (Fig. 29.59).

The other major feature of JDM is an inflammatory myopathy. This affects the proximal limb muscles, often first noticed by difficulty with climbing stairs or brushing hair. Muscle weakness may be severe and involvement of the neck flexors and abdominal muscles occurs in addition to those in the limbs. Weakness is frequently associated with complaints of muscle pain and tenderness. Myositis is confirmed by documenting abnormalities of muscle enzymes such as creatine kinase, aspartate aminotransferase (AST), alanine aminotransferase (ALT), aldolase and lactate dehydrogenase (LDH). It should be remembered that muscle enzymes may be normal despite active disease. EMG,

Fig. 29.59 Juvenile dermatomyositis showing Gottron papules and typical nailfold changes.

(a)

(b)

Fig. 29.58 Typical rash of juvenile dermatomyositis with erythema over: (a) extensor aspects of metacarpophalangeal and proximal interphalangeal joints; (b) knees.

muscle biopsy and MRI will show characteristic inflammatory change (Fig. 29.60).

JDM is a multisystem disease and although the main features are of skin and muscle involvement, many organ systems can be affected by the widespread vasculopathy. Dysphagia occurs as a result of disease affecting the esophagus, while dysphonia results from involvement of the soft palate. Cardiac abnormalities are reported in up to 50%. Most are minor but cardiomyopathy can occur. Interstitial lung disease is uncommon but carries a poor prognosis.

Before the advent of steroids, JDM had a very poor prognosis. Thirty percent of affected children died, 30% had severe chronic disease and

Fig. 29.60 Muscle MRI in juvenile dermatomyositis showing patchy, heterogeneous texture of the muscles typical of an inflammatory myopathy.

only 30% recovered. Steroids and more recent developments in therapy have dramatically changed the outlook but this is still a disease with an associated mortality and significant morbidity. Three characteristic disease courses are recognized. Some children have an acute monocyclic course which resolves with treatment; others a relapsing, remitting course while a third group have severe, unremitting chronic disease. In addition it is now recognized that there is a wide variety of clinical patterns seen within the overall label of JDM. Some children have predominantly muscle disease, others cutaneous. Some have both while a further group have evidence of a widespread vasculopathy with cutaneous ulceration (Fig. 29.61) and serious organ involvement.

Calcinosis of the muscle is a well-recognized complication of JDM (Fig. 29.62). It is at least in part related to disease severity and duration and its incidence can be reduced by prompt and appropriate treatment. Lipodystrophy may complicate JDM (Fig. 29.63) and in some is associated with the development of insulin resistance. As with lupus, osteoporosis is a complication both of the disease and its therapy.

Treatment of JDM remains controversial. There is no consensus on the type, route of administration and duration of treatment and there are no randomized controlled trials. In uncomplicated JDM, oral prednisolone is the most commonly used treatment in a dose of 1–2 mg/kg/day, tapering over 12–18 months. In an attempt to get more rapid disease control and minimize toxicity from oral steroids, many now advocate initial treatment with pulsed intravenous methylprednisolone. Other drugs were traditionally reserved for those with severe or steroid resistant disease but it is now recognized that early use of an additional drug, usually methotrexate,<sup>173</sup> results in reduced morbidity and a reduction

in the total steroid dosage required. Intravenous immunoglobulin may play a role in some patients and cyclophosphamide may be indicated in refractory disease.<sup>174</sup> There is interest in the use of new therapeutic options such as mycophenolate mofetil, the anti-TNF drugs or stem cell transplantation in children who fail to respond to other therapies but these must still be regarded as experimental.

Treatment is adjusted depending on the clinical response but monitoring may be difficult. Levels of muscle enzymes are not a good guide to activity and should not be used to plan treatment. Clinical assessment is the gold standard and there have been various attempts to try and improve methods of doing this. The childhood myositis assessment scale<sup>7</sup> is a useful method for objectively assessing muscle strength, serial scores then being used to quantify changes in the disease process. MRI is being used as a non-invasive method of assessing muscle inflammation and again may be used serially to document progress. A core set of criteria for the assessment of disease activity has been proposed by PRINTO but remains to be validated.<sup>175</sup>

## SCLERODERMA IN CHILDHOOD

The scleroderma group of disorders is characterized clinically by thickening of the skin. This can occur in both localized and systemic forms, the former occurring much more commonly in pediatric practice.

### Localized scleroderma

Localized scleroderma may be subdivided into morphea and linear scleroderma. Morphea lesions most commonly occur on the trunk

(a)

(b)

Fig. 29.61 (a,b) Ulcerative vasculopathy in juvenile dermatomyositis.

(a)

(b)

Fig. 29.62 Juvenile dermatomyositis with extensive calcinosis affecting: (a) lower limb (plain radiograph); (b) chest wall (CT scan).

and present as pale patches of thickened skin. When active there may be surrounding erythema and with time they become hyperpigmented (Fig. 29.64). They usually occur as isolated lesions and, although they may be cosmetically unpleasant, seldom cause other problems.

Linear scleroderma is of much greater concern. In this condition the child or parent may notice a band of skin discoloration in a linear distribution on a limb or on the face/scalp (when it is known as 'en coup de sabre'; Fig. 29.65). These lesions do not follow a dermatomal distribution and they are poorly understood. As with morphea, an erythematous color may indicate an active lesion: with time they become hyperpig-

Fig. 29.63 Lipodystrophy in juvenile dermatomyositis – absence of subcutaneous fat in lower limbs.

mented. These lesions may be associated with atrophy and undergrowth of surrounding structures or the affected limb (Fig. 29.66) causing significant cosmetic and functional difficulties.

In a large collaborative data collection, 40% of children with localized scleroderma were found to be ANA positive. In a percentage of affected children extracutaneous manifestations (e.g. arthritis, neurological) occur but progression to systemic sclerosis does not.<sup>176</sup>

Our lack of understanding of the underlying process in these conditions makes treatment difficult. Methotrexate is now widely used to treat active lesions<sup>177</sup> and there is anecdotal evidence supporting the use of steroids and methotrexate in combination. Where a band of scleroderma crosses a joint, vigorous physiotherapy is helpful in maintaining joint range.

### Systemic sclerosis

The systemic sclerosis disorders are extremely uncommon in pediatric practice. In adults, systemic sclerosis can be subdivided into

Fig. 29.64 Morphea.

Fig. 29.66 Limb atrophy in linear scleroderma.

Fig. 29.65 En coup de sabre lesion.

diffuse cutaneous systemic sclerosis (formerly known as progressive systemic sclerosis) and limited cutaneous systemic sclerosis (formerly CREST syndrome). Diffuse disease, characterized by cutaneous involvement extending to the proximal limbs and trunk, progresses rapidly over the first few years and is associated with the presence of anti-Scl 70 antibodies. The hallmark of limited disease is skin involvement of the distal extremities and face only. These categories appear less clearcut in childhood, many having features that overlap between the two

Raynaud phenomenon is usually the first feature of these conditions and if not present the diagnosis is unlikely. A history of Raynaud phenomenon may be difficult to obtain in a young child. The earliest clinical finding is cutaneous edema usually affecting the hands which consequently feel firm on palpation. Biopsy at this stage will show inflammatory change in the subcutaneous tissue which becomes thicker and tighter. This results in stiffness of the extremities and the characteristic pinched appearance of the face. Joint contractures develop and the skin is very susceptible to minor trauma. Ischemia results in loss of the finger pulp and the typical digital pitting scarring (Fig. 29.67). Severe ischemia may result in the loss of digits. Subcutaneous calcification, pulmonary hypertension and esophageal disease are common in the limited form of the disease. Diffuse disease is characterized by early interstitial lung disease, gastrointestinal involvement, cardiac abnormalities due to small vessel obliteration and renal disease. The scleroderma renal 'crisis' which results from a critical reduction in renal blood flow causing cortical ischemia, activation of the renin-angiotensin system and malignant hypertension, was previously a fatal event but can now be treated with angiotensin converting enzyme (ACE) inhibitors.

Fig. 29.67 Digital pitting scars in systemic sclerosis.

Renal disease is less common in the childhood form of the disease and the outcome is generally better than in adults.<sup>178</sup> Cardiac disease is the most common cause of death in affected children.

Management requires meticulous attention to detail. Protective measures (avoidance of cold exposure, use of warm mittens and avoidance of smoking) are important in reducing ischemia of the digits. Nifedipine, in a long-acting preparation, is the drug of choice. Occasional patients with severe digital ischemia and impending gangrene will benefit, often impressively, from the use of intravenous prostaglandin. Emollients are helpful for dry skin while physiotherapy and splinting may benefit joint disease. Gastrointestinal symptoms may be helped by the use of omeprazole together with a prokinetic agent such as cisapride. Broad-spectrum antibiotics may help malabsorption secondary to bacterial overgrowth. ACE inhibitors given where there is any evidence of renal involvement will reduce the risk of a scleroderma crisis.

Immunosuppressive therapy is used early where there is evidence of serious organ involvement and may influence the course of the disease. Once fibrosis is well established it is likely to be irreversible. Monitoring to detect signs of early organ involvement is therefore essential. Traditionally, treatment was with d-penicillamine but there is no evidence of benefit and the drug is associated with significant toxicity. Interest now lies in the use of powerful immunosuppressive regimens. Steroids, methotrexate, ciclosporin, cyclophosphamide, mycophenolate mofetil and antithymocyte globulin may all have a role. There is some anecdotal evidence suggesting that if used early, steroids and cyclophosphamide will halt progression of the lung disease which is one of the major determinants of mortality. There are no controlled studies to date and little hard evidence on which to base treatment plans.

### MIXED CONNECTIVE TISSUE DISEASE

Mixed connective tissue disease (MCTD) is an entity characterized by Raynaud disease, swollen fingers and hands, myositis and a strongly positive antibody against RNP. Whether this is truly a separate disease or a subset of some other condition such as SLE is a matter of continuing debate. Many individuals with MCTD would also fulfill diagnostic criteria for the diagnosis of SLE.

### OVERLAP SYNDROMES

A number of patients are seen with features of more than one autoimmune disorder and are classed as having overlap syndromes. The most commonly seen in pediatric practice are overlaps between JDM or polymyositis and scleroderma.

### UNDIFFERENTIATED CONNECTIVE TISSUE DISORDERS

A number of children and adolescents will present with some features of this group of conditions, often associated with a positive antinuclear antibody, but insufficient to be defined as one of the well-characterized conditions already described. Some will evolve with time into one of the clearly defined conditions while others will remain undifferentiated.

### SJÖGREN SYNDROME

Sjögren syndrome is a chronic inflammatory disorder characterized by lymphocytic infiltration of the exocrine glands and resulting in sicca symptoms, i.e. dry eyes and dry mouth. Sjögren syndrome may be primary or secondary, occurring in association with some other autoimmune rheumatic disorder. Conditions known to be associated with Sjögren syndrome include SLE, rheumatoid arthritis, MCTD, systemic sclerosis, dermatomyositis and primary biliary cirrhosis. Recognition is important as there is a significant risk of a lymphoid malignancy developing in the affected glands.

Although uncommon in pediatric practice, Sjögren syndrome does occur. Secondary Sjögren syndrome is more common than primary and usually develops in the context of a patient with a known autoimmune rheumatic disorder. Sjögren syndrome in childhood generally presents with parotid swelling which may be troublesome, recurrent and painful (Fig. 29.68a). The most important differential diagnosis is viral sialadenitis. If the problem is recurrent then Sjögren syndrome should be considered.

Although there are established criteria for the diagnosis of Sjögren syndrome in adults these are difficult to apply in children. Parotid imaging may be difficult to interpret. Ultrasound may be the most useful imaging procedure as it is inexpensive, well tolerated and shows characteristic abnormalities (Fig. 29.68b). For the diagnosis to be made the parotid swelling should be accompanied by evidence of dry eyes, dry mouth and the presence of autoantibodies.

Management of Sjögren syndrome consists firstly of management of the underlying disorder. Artificial tears are used for dry eyes and a variety of preparations are available to relieve the dry mouth. Dental care must be meticulous as the lack of saliva predisposes to severe dental caries. Monitoring for the development of malignancy in the salivary glands is important.

### RAYNAUD PHENOMENON

Raynaud phenomenon was first described in 1862 as episodic digital ischemia provoked by factors such as cold or emotion. Classically in Raynaud syndrome there is a triphasic color change. The digits initially blanch followed by cyanosis and then erythema on rewarming. For the diagnosis to be considered at least two of these phases must be present. In addition to the digits, changes may be seen in the ear lobes, tip of the nose and around the mouth.

Primary Raynaud syndrome, where the phenomenon occurs in isolation in an otherwise healthy individual, is common in young women and frequently familial. Secondary Raynaud syndrome occurs in conditions such as SLE, systemic sclerosis and MCTD and may be the presenting feature of such illnesses. All young people presenting with Raynaud syndrome should have a careful evaluation to exclude an underlying disorder. Any atypical features (year-round symptoms, digital ulceration) or the presence of antinuclear antibodies raise the possibility of secondary Raynaud syndrome and the child or teenager should be followed up to ensure no further problems develop.

Primary Raynaud syndrome will usually be controlled by symptomatic measures and protection from the cold. Unfortunately the use of warm gloves or mittens is unpopular in teenage years when primary Raynaud syndrome may be troublesome. Nifedipine will often improve symptoms, the dose being titrated to clinical response and the development of side-effects.

### ERYTHEMA NODOSUM

Erythema nodosum is seen not infrequently in children. The typical story is of the sudden onset of one or more tender, erythematous raised nodules or plaques on the anterior surface of the tibia. Pathologically this represents a septal panniculitis (inflammation within the subcutaneous

fat). The nodules lie deep and may be easier to feel than to see. As they resolve they develop an ecchymotic appearance and lesions at varying stages of development are frequently seen. Resolution usually occurs over a 4- to 6-week period.

In the majority of cases, erythema nodosum is an acute process occurring in response to an infectious trigger. Recurrent or chronic erythema nodosum merits investigation for some underlying cause.

Most cases in children occur as a post-streptococcal phenomenon and are associated with markedly raised ASO titers. Other infections such as mycoplasma, viruses and tuberculosis must be remembered. Drugs including antibiotics and oral contraceptive pills may cause erythema nodosum. Rarely, but importantly, it may be the presenting feature of some systemic disorder such as inflammatory bowel disease, sarcoidosis or an autoimmune rheumatic disorder.

### THE DIFFERENTIAL DIAGNOSIS OF SYSTEMIC INFLAMMATORY DISORDERS

A chronic systemic inflammatory process in a child may result from chronic infection, malignancy or a rheumatological disorder such as systemic onset juvenile idiopathic arthritis, SLE, JDM or a systemic vasculitis. There are a number of unusual conditions of unknown etiology that may present in this fashion and must be remembered in the differential diagnosis. Some are outlined in this section.

#### Familial Mediterranean fever and other periodic fever syndromes

The periodic fever syndromes are a group of disorders characterized by unprovoked inflammation. Many have now been associated with gene mutations affecting the IL-1 and TNF $\alpha$  pathways enabling both genetic diagnosis and possible therapeutic options.<sup>179</sup>

Familial Mediterranean fever (FMF) principally affects individuals of eastern Mediterranean origin especially Sephardic and Iraqi Jews, Armenians and Levantine Arabs and is inherited as an autosomal recessive trait. It results from mutations of a gene on chromosome 16 that influences the production of a protein known as pyrin or marenostrom.<sup>180</sup> It is characterized by recurrent episodes of fever, serositis, arthralgia and synovitis of the large joints. Between attacks the joints return to normal. Untreated, it is associated with a high incidence of amyloidosis, the risk of which can be minimized by treating with colchicine.

Other periodic fever syndromes include the hyper-IgD syndrome which is characterized by recurrent fevers and an elevated immunoglobulin-D level. Mutations of the gene encoding mevalonate kinase have been identified in this condition.<sup>181</sup> An autosomal dominant syndrome characterized by periodic fever has been found to result from a mutation of the TNF receptor 1.<sup>182</sup>

#### Chronic infantile neurological, cutaneous and articular (CINCA) syndrome

This syndrome is characterized by the triad of rash, joint abnormalities and CNS involvement.<sup>183</sup> The rash which is urticarial and migratory appears in the first few months of life. Joint manifestations result from a disordered growth of cartilage (Fig. 29.69) and range from arthralgia and intermittent swelling to severe overgrowth of the epiphyses with loss of range of motion. Severe overgrowth of the patella is characteristic. Abnormalities of the CNS are universal and include chronic meningeal irritation, impairment of cognition and sensorineural deafness. Laboratory examination shows nonspecific elevation of inflammatory markers. Affected individuals have a characteristic facial appearance with frontal bossing, a hypoplastic midface and blond hair. This rare disorder is now known to be associated with dominantly inherited mutations in the CIAS1 gene, involved in the processing of IL-1 $\beta$ .<sup>184</sup> This has led to the therapeutic use of IL-1 blockade in the form of anakinra with dramatic benefit in many patients.

Fig. 29.69 Chronic infantile neurologic cutaneous and articular syndrome showing abnormal bone development.

### Sarcoidosis

Sarcoidosis is an uncommon disorder in children and is characterized by a multisystem inflammatory process of unknown etiology. Two distinct disease patterns are seen although there are many cases where features overlap. In older children the pattern is very similar to that seen in adults with constitutional symptoms, lymphadenopathy and lung disease. In infants and young children a different pattern of disease is described with cutaneous involvement, arthropathy and uveitis. Histologically the disease may result in the formation of granulomata. There is no single diagnostic test: serum levels of angiotensin converting enzyme are elevated in 80% but it should be remembered that levels are higher in normal children than in adults and pediatric standards are required. The Kveim test is no longer used.

### SAPHO syndrome and chronic recurrent multifocal osteomyelitis (CRMO)

The SAPHO syndrome is an inflammatory disorder of unknown etiology characterized by synovitis, acne, pustulosis, hyperostosis and osteitis. Many cases only have a few of these features and CRMO, which is characterized by multifocal osteitic lesions, is thought to be part of the same spectrum of disease. The etiology is unknown. A family history of psoriasis is associated with SAPHO and an infectious trigger has been postulated, although no infecting organism is identified in most individuals. Radionuclide bone scanning is useful for demonstrating the multifocal nature of the problem (Fig. 29.70a). Biopsy may be necessary to exclude infection or malignancy. The hyperostotic clavicular lesions (Fig. 29.70b) may be both painful and cosmetically unsightly. Laboratory

(a)

(b)

Fig. 29.70 SAPHO syndrome: (a) radionuclide bone scan demonstrating lesions in clavicle, rib and vertebra; (b) hyperostotic lesion of right clavicle.

investigations may show mildly elevated inflammatory markers. Steroids and methotrexate are used to suppress the inflammatory process and bisphosphonates may also have a role.

### CHRONIC PAIN SYNDROMES

Musculoskeletal pain is common in children and adolescents but generally shortlived and easily explained. A small group will develop unexplained disabling chronic musculoskeletal pain which poses a challenging diagnostic and management problem.

Pain is a universal phenomenon and in most cases a useful symptom, alerting the individual to tissue damage. Chronic pain differs in serving no useful function. Chronic pain occurring with no underlying physical disorder, or disproportionate chronic pain where the pain is out of all proportion to any known disease (the idiopathic pain syndromes), are perplexing conditions. Pain is by definition subjective and must

therefore be accepted at face value.<sup>185</sup> The International Association for the Study of Pain<sup>186</sup> defines pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage ... It is unquestionably a sensation in part of the body but is always unpleasant and therefore also an emotional experience.'

In all reported series, idiopathic pain syndromes predominantly affect girls. The age of onset peaks in the early adolescent years and these conditions are uncommon under 8 years.<sup>187</sup> Recent data suggest that the prevalence of these conditions in childhood is increasing.<sup>188</sup>

Children with idiopathic pain syndromes are among the most disabled children seen in pediatric rheumatology and orthopedic clinics. They complain of severe pain unresponsive to standard therapies and frequently have major functional limitations. It is often difficult for both the family and pediatrician to accept that there is no organic pathology and the diagnosis is often delayed while a prolonged series of investigations is undertaken. With the correct diagnosis and management many will do well and it is therefore important to recognize these conditions as early as possible. The diagnosis is by definition one of exclusion of underlying pathology. In most cases this can be done on the basis of a careful history and clinical examination and few investigations are necessary or helpful.

The terminology and classification system used to define the idiopathic pain syndromes in the literature is confusing and generally unhelpful in children. Pain syndromes in children differ in many respects from those described in adults and frequently fail to meet criteria required for clearly defined syndromes. Children with pain syndromes seem to divide into two distinct groups: those with localized pain and those with diffuse or generalized pain.<sup>189</sup>

### LOCALIZED IDIOPATHIC PAIN SYNDROMES

The best example of a localized pain syndrome in children is reflex sympathetic dystrophy (RSD) also known as complex regional pain syndrome type 1, reflex neurovascular dystrophy, algodystrophy and Sudeck atrophy. RSD is characterized by localized pain associated with evidence of autonomic dysfunction. In adults this syndrome usually follows immobilization of a limb following trauma. In children any preceding trauma is usually insignificant. It is presumed that the child stops using the limb in response to minor trauma and that subsequent changes are secondary to immobility, but the condition is poorly understood. Psychological factors are thought to be significant in the majority of children with the condition.<sup>190</sup> The child develops severe pain in the affected limb and rapidly becomes unable to use it. Hyperesthesia (an increased sensitivity to stimulation), allodynia (pain due to a stimulus that does not usually cause pain) and dysesthesia (an unpleasant abnormal sensation) are characteristic. The limb becomes cold, blue, diffusely swollen and at times may adopt bizarre postures (Fig. 29.71). Rarely, wasting and trophic changes occur.

Fig. 29.71 Bizarre posturing of the hand in reflex sympathetic dystrophy.

The diagnosis in most cases is straightforward as long as the physician is aware of the condition and considers it. The child presents with a single cold, extremely painful limb and complains of severe pain on even light touch. Frequently they are unable to tolerate even a sock on the affected foot. Despite their predicament many seem remarkably unconcerned (la belle indifference) unless asked to touch or use the painful limb. With an atypical history or a younger child, care must be taken to ensure that no underlying pathology (particularly malignancy) is missed. A blood count, ESR, plain radiograph and radionuclide bone scan are usually sufficient, the typical bone scan in established RSD showing reduced uptake in the affected limb (Fig. 29.72).

The management of these children depends on establishing trust. Many have seen multiple health professionals before a diagnosis has been reached;<sup>191</sup> this frequently leads to increasing psychosocial difficulty and a loss of faith in the medical profession. It is essential to successfully reassure both child and family that there is no underlying organic pathology while accepting their pain at face value. Once the diagnosis is made a simple explanation of the effect of immobilization on a limb is usually easily accepted and the role of 'stress' in contributing to this condition can be discussed. A combination of an individualized program of physiotherapy together with attention to psychological factors leads to full recovery in the majority.<sup>187,192</sup> Sympathetic blockade and other treatment modalities used in affected adults are neither necessary nor helpful in the management of children and young people with RSD.

RSD is only one form of localized pain syndrome. Other individuals may have chronic musculoskeletal pain localized to one area of the body but without associated autonomic dysfunction. These syndromes are not clear cut and there is an overlap between such groups of patients.

### DIFFUSE CHRONIC PAIN SYNDROMES

Widespread musculoskeletal pain affects a further group of young people, again predominantly female. The mean age tends to be slightly older than those with RSD with a peak at around 15 years. These patients can be subdivided into those with multiple tender points who meet criteria for the diagnosis of fibromyalgia and those without specific tender points. In our experience it is unhelpful to differentiate between

Fig. 29.72 Radionuclide bone scan in reflex sympathetic dystrophy showing reduced uptake in (R) affected compared to the (L) normal limb.

the two groups. There are no significant differences between them and they differ in many ways from adults with fibromyalgia. It is more helpful to class all as simply having a diffuse chronic pain syndrome.

In association with their pain many of these young people complain of fatigue, poor sleep and, in some, feelings of depression. There appears to be an overlap between this group of teenagers and those with chronic fatigue syndrome, the exact diagnosis depending on whether the pain or the fatigue predominates.

The etiology of this group of disorders is unknown. An association with hypermobility has been noted and psychosocial factors are contributory.<sup>193,194</sup> Management of these young people is similar to those with localized pain, although the outcome is generally less good with a higher incidence of relapse. An exercise regimen will often result in significant improvement but relapse when this is withdrawn is frequent. Attention to psychological factors is essential. In some, particularly those with poor sleep, the use of drugs such as tricyclic antidepressants may be helpful. Recent interest has focussed on improving methods and developing tools for assessing the impact of chronic pain on these young people.<sup>195</sup>

## BACK PROBLEMS IN CHILDHOOD AND ADOLESCENCE

Neck or back pain is unusual in the young child and must be taken seriously. Persistent or deteriorating pain is an important complaint and tumors and infections should always be considered in the differential diagnosis. Localized pain is usually more suggestive of significant pathology than ill-defined pain, but young children are often unable to give a history of local pain and some conditions such as discitis may present with odd symptoms such as a gait abnormality or even abdominal pain.

In the adolescent population complaints of ill-defined pain without pathological explanation are common.<sup>196</sup> Nevertheless careful evaluation is important. Additional signs and symptoms such as torticollis, scoliosis or neurological radicular symptoms will direct the approach to appropriate investigations.

As a rule of thumb, while pain, or pain provoking pathology, may cause abnormal spinal postures like torticollis or scoliosis, it is unusual for congenital or developmental explanations for spinal deformity to be responsible for pain.

## TUMORS

Malignant neoplasms, primary or secondary, though rare, are a potential source of back pain in children. Primary tumors can arise from the bone, such as Ewing sarcoma; from the hemopoietic tissue, such as the leukemias; or from the contained neurological tissue or its coverings. Only 3% of primary bone tumors occur in the axial skeleton and in children 60% of these are benign.<sup>197</sup> The most common benign lesions include osteoid osteoma or osteoblastoma, eosinophilic granuloma and aneurysmal bone cysts.

Osteoid osteomas typically involve the posterior elements and characteristically present with pain, especially night pain classically relieved by NSAIDs. Radiographs may show an area of sclerosis; radionuclide bone scanning will reveal intense focal uptake in the lesion. Subsequent CT scanning will identify a discrete lesion with a thick sclerotic rim and a lucent nidus of osteoid material at the center. Osteoblastoma is similar histologically to osteoid osteoma but larger. Aneurysmal bone cysts are typically expansile lytic lesions with a thin rim of cortical bone. Once again they usually occur in the posterior elements but may involve the adjacent pedicle or body. Eosinophilic granuloma usually affects the body of the vertebra which subsequently flattens, giving the characteristic vertebra plana of Calvé disease.

## INFECTION

See section on 'Infection in bones and joints', page 1401.

## TORTICOLLIS

Torticollis secondary to congenital and developmental problems is not usually accompanied by pain. In practice the commonest cause of painful torticollis in children is atlantoaxial rotatory displacement, but it is important to bear in mind that there are other explanations including infections, tumors, CNS abnormalities like syringomyelia, and ocular dysfunction.<sup>198</sup>

### Atlantoaxial rotatory displacement

Typically the child awakes with a 'wryneck'. This commonly resolves without treatment over the course of a week but occasionally the posture persists when it is best described as atlantoaxial rotatory fixation. There is often associated muscle spasm of the long sternocleidomastoid muscle because of its attempts to correct the deformity, unlike congenital muscular torticollis where the contracted muscle is responsible for the deformity.

In most cases the etiology is not apparent although the condition can be caused by trauma or occur in association with recent upper respiratory tract infection. When subluxation occurs in association with inflammation of adjacent neck tissues or upper respiratory tract infection it is known as Grisel syndrome. It is postulated that hyperemia of the atlantoaxial joints leads to variable ligament laxity and synovitis. Thickened synovial folds may subsequently impinge during rotation and lead to fixation.

Diagnosis in the acute stage is based on the history. Radiological assessment is difficult because of the head posture, but in the anteroposterior film the anteriorly rotated lateral mass of C1 appears wider and closer to the midline than the posteriorly rotated lateral mass. Because of the difficulty in interpretation of plain radiographs, CT scanning or dynamic MRI is usually of more value for definitive diagnosis.

Atlantoaxial rotatory displacement with minimal subluxation and no encroachment of the vertebral canal is relatively benign. Greater degrees of subluxation are rare but do have potentially serious neurological complications because of increasing encroachment of the vertebral canal. Most cases resolve spontaneously with simple analgesia and a soft collar for support. If persistent the patient should be admitted for halter traction with analgesia and muscle relaxation. Halo traction is occasionally required, especially if presentation is delayed. If the displacement is fixed and significant there is potential compromise of the vertebral canal and surgical fusion is a consideration.

### Paroxysmal torticollis of infancy

Paroxysmal torticollis of infancy is a rare episodic torticollis of unknown etiology. Episodes last for minutes to days with eventual spontaneous recovery. Two thirds of affected children are girls, with an average age of onset of 3 months. Attacks usually occur in the morning, occurring 1–4 times each month and can be associated with trunk curvature, eye deviations and torticollis which may alternate sides on different episodes. The condition usually resolves over 12–24 months and requires no treatment.

### Sandifer syndrome

This syndrome is the association of infant gastroesophageal reflux with posturing of the neck and trunk. It is believed that the torticollis is the child's attempt to decrease the discomfort resulting from reflux.

## JUVENILE DISCITIS

See previous section on 'Infection in bones and joints', page 1401.

### Calcific discitis

This condition occurs in children with an average age of onset of 8 years. It is most common in the cervical spine and usually presents with the acute onset of neck pain and sometimes torticollis. Radiographs reveal calcified deposits in the affected nucleus pulposus. The etiology of the condition is unknown and treatment is symptomatic. The calcific deposits disappear in most patients by 6 months.

### SCHEUERMANN KYPHOSIS

This condition can be responsible for a painful kyphosis. Patients present either with pain or an increasing round back deformity during adolescence (Fig. 29.73). The condition is more frequent in the thoracic but can also occur in the lumbar spine. There is usually a clear apex to the spinal deformity, which is relatively rigid distinguishing the condition from benign postural round back, which is flexible on extension. Lateral radiographs show vertebral wedging, end-plate irregularity and Schmorl node formation (herniation of intervertebral disc into the end-plate of an adjacent vertebra).

Treatment of the deformity with extension exercises and occasionally extension bracing is usually successful. Surgical intervention for severe deformities is seldom required.

### SPONDYLOLISTHESIS AND SPONDYLOLYSIS

Spondylolisthesis is the slipping forward of a vertebra on its neighbor below. It is classified into five types. Isthmic and dysplastic types are most common in children; degenerative, traumatic and pathological types are unusual.

Isthmic spondylolisthesis occurs when a defect or lysis develops in the pars interarticularis (spondylolysis) and is most common in L5 and L4 (Fig. 29.74). This defect is usually the result of a stress fracture at the pars. Affected patients often give a history of sporting activity. The vertebra concerned, having lost its 'bony hook' on the vertebra below, is able to slip forward, although this probably only occurs in about 20% of cases of spondylolysis. Clinical examination of a significant slip reveals a step on palpation of the lumbar spine and so-called 'heart shaped buttocks' because of the deformity.

Fig. 29.73 Scheuermann kyphosis.

Neurological radicular symptoms are rare but there is often associated hamstring spasm. The defect can be seen on oblique radiographs (the classic 'collar on the Scottie dog') but is best seen on reverse gantry CT scanning. If the slip is translated less than 50% symptoms can be treated by activity modification, analgesia and bracing. If symptoms settle the patient can be observed. Persistent symptoms, a slip of more than 50% or progressive slippage are all indications for surgical intervention. There are various surgical techniques but the principle is to fuse the unstable vertebra to its neighbor below.

Dysplastic (or congenital) spondylolisthesis is due to hypoplasia of the L5/S1 facet joint. This leads to instability of the L5 vertebra, which may subsequently slip.

### ADOLESCENT DISC PROLAPSE

Disc prolapse is infrequent in children but occurs occasionally in adolescents when its presentation is somewhat different from adults. Stiffness is a more common symptom than back pain. There is commonly severe hamstring spasm with very limited straight leg raising and a spinal list (or tilt) is often present. The majority resolve without need for surgical intervention. If MRI shows a large sequestered fragment of disc material with significant symptoms, surgical excision may be considered.

### OSTEOPOROSIS

Osteoporosis is a major health problem in the modern world and of major consequence in terms of its associated morbidity, mortality and health economics. The formation of bone structure occurs primarily during childhood and adolescence, with 90% of the peak bone mass being accumulated during the years of longitudinal growth. At any given age,

Fig. 29.74 Spondylolysis of L5.

bone mass is the result of both the peak bone mass, i.e. that acquired during the growth years, and the rate of age-related loss which starts from around 30 years and accelerates in women after the menopause. Optimization of skeletal development during childhood and adolescence therefore has a role in the longer term reduction in osteoporosis. This becomes particularly important when caring for children with chronic diseases which may adversely influence bone formation.

Bone exists in a constant state of remodeling during which old bone is removed and replaced by new bone. Bone gain during childhood and adolescence, and bone loss in later life, is therefore the result of a positive or negative balance between these two processes. This balance can be altered or disrupted by a variety of other factors. Bone structure is influenced by both genetic and lifestyle factors. It has been estimated that up to 80% of bone mineral density (BMD) can be accounted for by genetic factors, with gender, race and body size being important determinants. A number of candidate gene polymorphisms have been identified that are significant in relation to bone mass. Of particular importance appear to be polymorphisms of the vitamin D receptor, estrogen receptor and collagen type 1 alpha-1 genes. Other polymorphic genes encoding for bone proteins, hormones and cytokines may prove significant and it seems likely that a great variety of genes are involved in determining bone mass and strength. Lifestyle factors have an important contribution to make, with diet and physical activity being particularly important. There is a relationship between the amounts of muscle and fat in the body and the amount of bone: any dieting that results in an excessive weight loss will be associated with bone loss. Nutritional factors such as dietary calcium and vitamin D are contributory and ensuring an adequate intake will optimize bone development. Physical activity has an important influence on bone density and an adequate amount of weightbearing activity is essential for optimal bone growth.

The World Health Organization defines osteoporosis as 'a disease characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increased risk in fracture'. Categories of disease are based on the measurement of BMD, with osteoporosis being defined as BMD more than 2.5 SD below the young adult mean value. Severe or established osteoporosis is defined as more than 2.5 SD below the young adult mean value in the presence of one or more low-trauma or fragility fractures.

These diagnostic criteria for osteoporosis have limitations. It must be remembered that they were developed in postmenopausal women and their applicability to other groups such as males and younger patients remains unclear. For such groups the relationship between BMD and fracture risk may be different and it is the fracture risk that is ultimately of importance. There are also difficulties inherent in the measurement of BMD in the growing child (see below) which may make the use of such definitions inappropriate. The definition of osteoporosis where fractures have not yet occurred is therefore somewhat arbitrary at present in children and young people. Further work is needed in this area.

### ASSESSMENT OF BONE DENSITY IN PEDIATRIC PRACTICE

Conventional radiography is a relatively insensitive method of assessing bone mass and significant osteoporosis can only be diagnosed confidently when associated with a typical fracture. There has been interest in the use of ultrasound to assess bone density<sup>199</sup> and its acceptability in pediatric practice may lead to further interest in this method in the future. Quantitative methods of CT scanning can be used to assess bone density but the tool most frequently used now, and generally regarded as the gold standard, is DEXA (dual energy X-ray absorptiometry) scanning.

DEXA scanning can be used to assess muscle mass, total and percent body fat and bone mineral. DEXA measures both the bone mineral content and the bone mineral density. This has a number of pitfalls in pediatric practice and results must be interpreted with care.<sup>200</sup> The amount of bone mineral content is directly related to body size and it is necessary to correlate values with skeletal size. Reference standards for children in different populations are not widely available, while genetic

and racial difference in bone density make population-based reference values essential. In addition, machines vary considerably and calibration is important. With these provisos DEXA appears at present to be the method of choice for the assessment of bone density. Measurements are generally taken from the lumbar spine and proximal femur. Results should be expressed in terms of the number of standard deviations above or below the mean of an age-related control population (Z-score). DEXA provides a quantitative method that can be repeated serially to monitor change and assess the effects of treatment, provided the results are interpreted with caution in the growing child or adolescent.

### PRIMARY OR IDIOPATHIC JUVENILE OSTEOPOROSIS

Primary osteoporosis is rare in childhood. Juvenile osteoporosis occurs before or around puberty, affects both sexes and is of unknown pathophysiology. The child will present with pain in the back, hips and feet with evidence of fractures including vertebral crush fractures (Fig. 29.75). This is a self-limiting condition which resolves with puberty but treatment with pamidronate to reduce pain and increase bone density during the active phase may be helpful.

### SECONDARY OSTEOPOROSIS IN CHILDHOOD

Osteoporosis in children usually occurs in relation to some underlying chronic disease or as a consequence of treatment with glucocorticoids.

#### Disease related

Osteoporosis is increasingly recognized as an important sequel of a number of chronic childhood disorders, contributing greatly to the long term morbidity. In the childhood rheumatic disorders such as

Fig. 29.75 Idiopathic juvenile osteoporosis – plain radiograph showing osteoporotic collapse of thoracic vertebrae.

juvenile idiopathic arthritis, dermatomyositis or systemic lupus erythematosus, osteoporosis occurs as a direct result of the underlying inflammatory process and prevention depends on optimal control of the disease process. Nutritional impairment, immobility or even relative inactivity in children with chronic ill-health are all contributory. Other unknown factors which are disease specific are clearly of importance, e.g. individuals with JDM or SLE appear more vulnerable than those with juvenile arthritis.

### Drug related

Glucocorticosteroids are widely used in the treatment of a number of common diseases in childhood including the rheumatic disorders, inflammatory bowel disease, asthma and nephrotic syndrome. Although clearly necessary for treatment their effect on bone mineral density can be significant. The adverse effects of steroids on bone metabolism are well known and result from a variety of actions of these drugs. They are known to induce renal calcium efflux and inhibit calcium uptake from the intestine, leading to a fall in serum calcium and secondary hyperparathyroidism. This increases bone resorption and reduces bone formation and is well documented immediately after commencement of treatment. The increase in bone resorption does not usually continue but the amount of new bone formation is reduced as a result of increased apoptosis of osteoblasts and contributes to ongoing bone loss. The bulk of the bone loss in steroid-induced osteoporosis occurs in the first 6 months of treatment but overall the effect is related both to the total dose used and to the duration of therapy. There is considerable individual variation in the effect of steroids on bone density presumably as a result of genetic factors. Some individuals will tolerate a significant dose with no adverse effect whereas others will become significantly osteoporotic with minimal dosage regimens.

Other drugs such as methotrexate, heparin and thyroxine are known to reduce bone mineral density but none has been shown to have significant clinical effect in pediatric practice.

### PROPHYLAXIS OF OSTEOPOROSIS IN CHILDHOOD

There is ongoing debate regarding the use of prophylactic measures to prevent osteoporosis in childhood. General advice regarding exercise and nutrition are important. Weightbearing exercise is clearly beneficial and with an increasingly sedentary lifestyle for many it is important to advise patients regarding this. The avoidance of severe weight loss is also important.

A diet with an adequate calcium intake is frequently lacking in adolescents. There has been much interest in the relationship between calcium intake and bone mineral acquisition and some evidence that calcium supplementation can increase bone mineral density. Any benefit shown in children and adolescents is transient and disappears when the supplementation is discontinued, making it seem unlikely that this is of any longer term benefit. Current evidence supports the use of calcium supplements to improve bone mineralization where the diet is deficient<sup>201</sup> but the benefits of supplementing above the normal dietary recommended intake are unproven.

Current recommendations for adults are that patients on steroids should receive prophylactic treatment for bone loss. There are no recommendations for children. A recent survey of pediatric rheumatology units in the UK (unpublished data) showed no consensus on the use of prophylactic measures in the prevention of steroid-induced osteoporosis. Some units advocate general advice only, some prescribe calcium supplements and others calcium and vitamin D for all children going on to long term steroids. At the moment there is no clear evidence on which to base a decision.

### TREATMENT OF OSTEOPOROSIS IN CHILDHOOD

Until relatively recently, no specific treatments were available for osteoporosis. The advent of the bisphosphonates has altered our approach to the investigation and identification of at-risk children as there is now an effective treatment that can be used to reduce fracture risk.<sup>202</sup>

The bisphosphonates are synthetic compounds whose main action consists of the inhibition of osteoclastic bone resorption. The newer bisphosphonates are thought to act directly on the osteoclast to induce apoptosis. There were initial concerns about the use of these drugs in children with rapidly growing bones and in women of child-bearing potential. They are of low molecular weight and therefore likely to be able to cross the placenta. Fetal bone turnover is high and these drugs could potentially cause substantial effects on skeletal development. Nonetheless the cost of untreated osteoporosis is such that these drugs are now well established for use in pediatric practice.

The first generation bisphosphonates such as etidronate have been associated with bone mineralization defects and have generally been superseded in pediatric practice by the newer drugs such as pamidronate and alendronate. Pamidronate is the established treatment for osteoporosis in children and adolescents and is generally well tolerated. It has the disadvantage of requiring to be given by intravenous infusion and there is therefore increasing interest in the use of an oral alternative such as alendronate.<sup>203</sup>

Where there is established osteoporosis with evidence of a fracture there seems little doubt that the use of these drugs is appropriate. With reduced BMD but no fracture, there is no clear agreement as to when children should be treated as the relationship between BMD and fracture risk is not clearly established. Most clinicians would agree that a BMD measurement more than 3 SD below the mean is likely to represent an increased fracture risk and would therefore merit treatment.

### OVERUSE AND SPORT-RELATED PROBLEMS IN CHILDREN

Active children frequently present with a variety of musculoskeletal symptoms that are a consequence of their activity. Such overuse syndromes can present in any child but become more common in the participants of organized competitive sport. While children are subject to the same injuries as adults, their immature musculoskeletal system responds somewhat differently. Submaximal loading of musculoskeletal structures leads to tissue damage, followed by repair. Repeated submaximal loading results in tissue hypertrophy. Overuse syndromes are characterized by the development of inflammatory pain when tissue damage exceeds the rate of tissue repair. The structures involved can be the bones, the soft tissues or, most commonly the junctions where they converge. In children these junctions are weaker than either the tendons or ligaments: apophysitis and avulsion fractures are therefore more common than ligament or tendon rupture. In children tendon rupture is also rare because overuse typically results in inflammation of the tendon sheath (tenosynovitis) rather than the tendon itself (tendonitis), and tendon degeneration is rare in the young.

### STRESS FRACTURES

Stress fractures are undisplaced fatigue fractures, which develop as a result of repeated loading. The lower limbs are most frequently affected especially the metatarsals (march fractures) and the tibia.

Younger children and even toddlers can present with stress fractures but they are more common in adolescents where the proximal third of the tibia is the most frequent site, and running the most common explanation.<sup>204</sup> Symptoms of localized pain develop insidiously and are usually relieved by rest. Plain radiographs eventually show a localized periosteal reaction and increased density, but are frequently unhelpful at presentation. Radionuclide bone scanning is a more sensitive investigation. Infection and tumors can present with similar features and should always be considered in the differential diagnosis.

Treatment involves protection from further trauma, which sometimes involves immobilization and always involves abstinence from the causative stress, usually running. Once symptoms have resolved a gradual return to activity can be begun.

## EPIPHYSEOLYSIS

Repeated traction, compression, torsion and angular stress on the growth plate (physis) can lead to stress injury resulting in localized peri-articular pain. Radiographs reveal widening of the growth plate and irregularity of the metaphyseal margin (Fig. 29.76). Involvement of the proximal humeral physis has been reported in baseball pitchers,<sup>205</sup> while female gymnasts have involvement of the distal radius.<sup>206</sup> Treatment involves modification of activity. Severe cases can be slow to resolve and premature physeal closure with subsequent wrist problems have been reported in gymnasts.<sup>207</sup>

## OSTEOCHONDRITIS DISSECANS

See 'Common orthopedic problems in childhood', page 1415.

## APOPHYSITIS

In the growing skeleton tendons join long bones at sites of ossification called apophyses. Apophysitis is inflammation at these junctions as a result of traction injury caused by the repeated pull of the attached tendon. Radiographs often reveal fragmentation and sclerosis of the apophysis with small, avulsed ossified fragments. Patients are usually in the adolescent age range from about 10 to 16 years. Symptoms usually begin insidiously, are made worse by activity and better by rest. Eponymous names are associated with the condition at some sites, but all are benign self-limiting conditions. The usual natural history is resolution by maturity. Treatment includes activity modification and symptomatic treatment. Occasionally in young athletes, explosive contraction of a muscle causes a tendon to pull off its whole attachment with a significant fragment of bone.

### Pelvic apophysitis and avulsion fractures

The hip and pelvis can be the source of symptoms at the site of several apophyses. Sudden explosive contraction of the attached muscles can result in acute avulsion fractures of these apophyses and repeated submaximal trauma can result in the insidious development of symptoms. The iliac crest is the site of insertion of the abdominal muscles and can become painful as a result of trunk rotation such as when running. Other sites of apophysitis around the hip and pelvis include the insertion of sartorius at the anterior superior iliac spine (Fig. 29.77), the insertion of the rectus femoris at the anterior inferior iliac spine, the insertion of the gluteal muscles at the greater trochanter, the insertion of the psoas muscle at the lesser trochanter and the insertion of the hamstrings at the ischial tuberosity. Each of these conditions can explain pain in and around the hip region, but in the adolescent age range more serious explanations such as a slipped capital femoral epiphysis must be considered.

Fig. 29.76 Epiphyseolysis of distal tibia.

Fig. 29.77 Avulsion of anterior superior iliac spine.

### Osgood–Schlatter disease

Osgood–Schlatter disease of the tibial tuberosity is the most common apophysitis, presenting in approximately 15% of teenage boys and 10% of teenage girls.<sup>208</sup> There is localized pain and swelling at the tibial tuberosity. Radiographs typically show fragmentation of the tibial tuberosity with avulsed fragments (Fig. 29.78). Symptoms usually respond to activity modification. In the enthusiastic young athlete sport need not be prevented but simply modified. Occasionally symptoms do persist after maturity with up to 20% of mature patients complaining of discomfort when kneeling.<sup>209</sup> Treatment is seldom required or helpful, except if a loose ossicle persists, when excision can be curative.

### Sinding–Larsen–Johansson disease

Sinding–Larsen–Johansson disease is apophysitis at the lower pole of the patella. It is similar to Osgood–Schlatter disease and the two conditions can coexist (Fig. 29.78). Treatment follows a conservative activity modification approach.

### Sever disease

Sever disease is inflammation of the calcaneal apophysis, at the insertion of the tendo-Achilles. Radiographs show increased density and fragmentation of the calcaneal apophysis, but this appearance is non-specific and can be seen in asymptomatic subjects. Treatment is conservative and a heel lift is sometimes helpful.

### Iselin disease

Iselin disease is apophysitis at the insertion of peroneus brevis at the base of the fifth metatarsal. It should not be confused with fractures in the vicinity, which can follow acute trauma.

## VALGUS OVERLOAD OF THE ELBOW

Valgus overload of the elbow occurs in a variety of throwing and batting sports and in activities where the upper limb is required to bear heavy loads such as in gymnastics. Perhaps the best example is the

Fig. 29.78 Knee with coincidental Osgood-Schlatter and Sinding-Larsen-Johansson disease.

junior baseball pitcher – ‘Little Leaguer’s elbow’. Valgus stress of the elbow generates tension and distraction of the medial structures, including the medial collateral ligament and the medial epicondyle and compression of the lateral structures, namely the capitellum and the radial head. The young athlete can develop problems in any of these areas.<sup>210</sup> The medial epicondyle may become painful and prominent in a typical apophysitis-like presentation. Occasionally the medial epicondyle can be completely avulsed and if significantly displaced it should be reduced and fixed. The ossific nucleus of the capitellum may become fragmented with appearances similar to Perthes disease when the condition is referred to as Panner disease. If the patient is young the prognosis for complete resolution is good. Older and adolescent patients can also develop subchondral defects, which are considered to be a form of osteochondritis dissecans. Loose flaps or loose bodies can develop causing mechanical symptoms including elbow locking as well as pain. Treatment of the painful elbow usually involves activity modification but surgical debridement may be necessary if mechanical symptoms secondary to a loose body occur.

### SNAPPING TENSOR FASCIA LATA SYNDROME

The iliotibial band is a broad condensation of the fascia on the lateral side of the leg running from the tensor fascia lata muscle at the iliac crest, across the greater trochanter of the hip and across the lateral side of the knee. When the leg is adducted at the hip and internally and externally rotated the iliotibial band can be pushed backward and forward by the passing greater trochanter beneath. The band is put under tension and then suddenly snaps back with a disconcerting clunk. If this occurs repeatedly a tender secondary trochanteric bursitis develops. The condition is more common in girls and the clunking is sometimes

voluntary. Management includes stretching exercises, avoidance of the provoking movements and reassurance because some patients believe that their hip is dislocating. The condition sometimes presents in runners and if refractory to conservative management the iliotibial band can be lengthened by ‘Z’ plasty.

### ILIOTIBIAL BAND FRICTION SYNDROME

This condition is caused by rubbing of the iliotibial band against the lateral epicondyle at the distal femur during repetitive knee flexion and extension. It usually affects runners and most cases are associated with a recent increase in activity.<sup>211</sup> Activity modification sometimes including stretching exercises, is the mainstay of treatment.

### ANTERIOR KNEE PAIN, PATELLOFEMORAL PAIN SYNDROME AND CHONDROMALACIA

See ‘Common orthopedic problems in childhood’, page 1415.

### MENISCAL INJURIES OF THE KNEE

Meniscal tears are unusual in young children unless there is an underlying meniscal anomaly such as a discoid meniscus (see ‘Common orthopedic problems in childhood’, p. 1415). In adolescence the incidence of meniscal tears begins to increase and are usually related to sport. Meniscal tears usually result from a twisting injury when a ‘pop’ is sometimes heard or felt, followed by knee swelling. There are few specific and reliable clinical tests but the patient may give a history of giving way and ‘true’ knee locking. ‘True’ locking specifically implies a block to full extension. If a tear is suspected, MRI is a sensitive investigation. In young patients the meniscus is more vascular than in the adult and is more likely to heal following injury. In recent years the vital role of the meniscus in load distribution and proper knee function has become recognized and preservation or repair of the injured meniscus, especially in young patients, is important. Fortunately children and adolescents have a higher incidence of peripheral tears which, because of a good peripheral blood supply, are more amenable to successful repair.<sup>212</sup>

### COLLATERAL AND CRUCIATE LIGAMENT INJURY OF THE KNEE

Ligament injury of the knee, and indeed of other joints, is rare in young children, becoming increasingly common as maturity is approached. Rupture of collateral and cruciate ligaments does sometimes occur, the mechanism of injury being similar to that in the adult. In the child ligaments are stronger than the bone to which they are attached, and mechanisms that would lead to rupture of a ligament in an adult lead to avulsion of the underlying bone. The best example is an avulsion fracture of the tibial eminence, the site of insertion of the anterior cruciate ligament. In general terms if avulsion fractures are significantly displaced from their origin, management includes reduction and sometimes fixation.

### BREASTSTROKER’S KNEE

Competitive breaststrokers can develop medial knee pain along the medial collateral ligament. The ‘whip kick’ technique, a modified frog kick, has been associated with the problem. Rest and avoidance of the technique is helpful.

### ‘SHIN SPLINTS’

‘Shin splints’ is a term that has emerged to describe exercise-induced shin pain in the athlete. It is a nonspecific clinical presentation with a number of underlying pathological explanations. Radiographs are important to exclude serious explanations for bone pain such as infection or tumor and may identify other explanations such as stress fractures.

## Periostitis

Inflammation of the tibial periosteum or periostitis is a common cause for shin splints syndrome. It is characterized by pain along the postero-medial edge of the distal third of the tibia where the soleus muscle and its investing fascia originate. It is presumed to be a traction phenomenon and a variety of anatomical alignment variations such as forefoot pronation, genu valgum, femoral anteversion and external tibial torsion have been implicated as potential causes as well as poor footwear and training regimens.<sup>213</sup>

Radiographs sometimes show periosteal new bone along the postero-medial tibia and radionuclide bone scanning shows increased uptake in a longitudinal distribution in contradistinction to the transverse pattern of increased uptake seen in stress fractures.<sup>214</sup> Management should first involve an attempt to identify the underlying cause followed by conservative measures including footwear and activity modification to address the symptoms. Surgical treatment should only be considered as a last resort.

## Chronic compartment syndrome

Chronic compartment syndrome develops when muscle volume increases as a result of increased blood flow during exercise. The relatively unexpandable osseofascial compartment cannot accommodate the extra volume, and pressure within the compartment increases.

When the intracompartmental pressure exceeds capillary filling pressure the muscles within the compartment develop ischemic pain. This usually resolves a short time after exercise stops. Some patients may experience a transient foot drop. Chronic compartment syndrome can present with 'shin splints' symptoms indistinguishable from periostitis.<sup>215</sup> Diagnosis depends on measuring compartment pressures during exercise on a treadmill. All four compartments in the leg should be assessed although the most commonly affected is the anterior compartment. Initial treatment involves a conservative approach with footwear and activity modification. Surgical treatment in the form of fasciotomy is reported to be successful in 90%.<sup>216</sup>

## Superficial peroneal nerve compression

Superficial peroneal nerve compression can also give rise to activity-related shin pain. The superficial peroneal nerve emerges from the fascia of the lower third of the anterolateral part of the leg to the subcutaneous plane where it travels distally, to supply sensory innervation to the dorsum of the foot. During exercise increased muscle pressure can compress the superficial peroneal nerve against the edge of the fascial hiatus where it emerges. This leads to exercise-induced leg pain, sometimes with associated local pain at the hiatus in the fascia and altered sensation on the dorsum of the foot. In troublesome cases limited fasciotomy at the fascial hiatus is effective.

## INTRODUCTION

The skin comprises roughly 15% of the body weight. It is a complex organ which undergoes constant repair. Its main functions are:

1. a barrier to absorption and loss of fluid and electrolytes;
2. a barrier to external injurious agents and mechanical stress;
3. protection against ultraviolet light;
4. protection against pathogenic microorganisms;
5. regulation of body temperature;
6. as a sensory organ;

7. synthesis of vitamin D;

8. social (and sexual) communication.

To perform these functions, the skin requires a complicated structure. It consists of three layers:

1. epidermis, derived from ectoderm;
2. dermis, derived from mesoderm;
3. subcutis, derived from mesoderm.

The main function of the outermost horny layer of the epidermis is to act as a barrier to fluid and electrolyte loss as well as to external injurious agents. Ninety five percent of the epidermis is made up

of *keratinocytes* which originate from the basal layer of the epidermis and progress towards the exterior. *Melanocytes* are also found in the basal layer, and are differentiated from keratinocytes by darkly staining nuclei and clear cytoplasm: their main function is protection against ultraviolet radiation by distributing melanin throughout the basal layer. The amount of melanin determines the racial color. The *Langerhans' cell*, located in the mid epidermis, is a dendritic antigen-presenting cell that plays an important role in allergic contact eczema and forms part of the immune defense in the skin. The exact function of a fourth cell, the *Merkel cell*, has not been determined, but present evidence suggests a mechanoreceptor role.

The dermoepidermal junction is the interface between the epidermis and dermis. Its major component, the basement membrane zone, has many functions including adhesion, signaling and barrier.

The dermis is composed of collagen and elastic fibers within a matrix of ground substance. Blood vessels, sensory and autonomic nerves and nerve endings, hair follicles (pilosebaceous units) and sweat glands traverse the dermis. Temperature is regulated mainly by autonomic control of blood shunting between the superficial and deep arteriolar and venular plexuses. Secondary temperature regulation, which is particularly important where the ambient temperature exceeds 37°C, depends on evaporation from the eccrine sweat glands which are under adrenergic control.

The subcutis consists mainly of adipose tissue, whose main function is insulation of the body. In sites such as the sole of the foot, fibrous bands within the subcutis have a buffering and protective effect.

The skin appendages such as hair and nails are largely vestigial in the human; loss of either does not constitute any threat to the survival of the individual.

## MANAGEMENT OF A SKIN PROBLEM IN A CHILD

It is important to take a detailed history either from the child or from the parents. History taking is similar to that in internal medicine, though the emphasis is different. Of particular importance are the following:

1. family history – many skin diseases are hereditary;
2. past history of the skin disease – conditions such as psoriasis and atopic eczema tend to be intermittent;
3. general health – some diseases (e.g. connective tissue diseases) are multiorgan problems;
4. previous treatment – both oral and topical: treatment may have modified the clinical picture (for better or for worse).

## Examination of the child

The child should be undressed completely to allow full assessment of the condition. A general medical examination should also be performed. If a rash is present, note should be taken of the following points: (1) color, nature and distribution; (2) relationship of the rash to skin appendages, such as hair follicles and sweat ducts; (3) mucous membranes: some skin diseases have a banal appearance in the skin, but a characteristic appearance in mucous membranes, e.g. lichen planus, congenital syphilis; (4) examination of the hair and nails, as changes may give a clue as to the diagnosis.

## TREATMENT OF SKIN DISEASES

As the skin is so accessible, it is sensible where possible to treat skin diseases with topical preparations. It is also important to introduce the active agent (e.g. steroid, antibiotic) in a suitable form or vehicle:

1. Lotions (solutions) are very useful for exudative rashes as 'wet dressings', where ointments and creams would 'float off', e.g. potassium permanganate. They are also useful for hairy areas, e.g. scalp. Shake lotions contain insoluble powders, e.g. calamine lotion.
2. Creams (oil–water emulsions). Bases such as cetomacrogol or aqueous cream are very acceptable to the patient, e.g. topical steroid creams.

3. Ointments such as petrolatum have a greasy base. They are useful for dry skin conditions, such as atopic eczema, e.g. steroid and antibiotic ointments.
4. Gels (semicolloids in alcohol base, which dry on the skin). Useful for scalp conditions.
5. Pastes (ointments + 15–30% powdered solids). Used on linen dressings, e.g. tar paste.
6. Powders, e.g. antifungal foot powders, miticides.

## Topical corticosteroids

These are useful for treatment of symptoms and signs of inflammatory dermatoses, in particular eczema. Factors to be considered when prescribing include age of child, site of application and type of preparation. The fingertip unit (FTU) technique provides guidance for the quantity of corticosteroid to be applied.<sup>1</sup> One FTU is the amount of topical steroid that is squeezed out from a standard tube along an adult's fingertip. One FTU is used to treat an area of skin on a child equivalent to twice the size of the flat of an adult's hand with the fingers together. The weakest corticosteroid that controls the skin condition should be used. Preparations should be applied no more than twice daily. In general the more potent corticosteroids are not recommended in infants under 1 year but can be used on the trunk and limbs in severe cases for up to 2 weeks.

## NEVI AND OTHER DEVELOPMENTAL DEFECTS

### MELANOCYTIC NEVI

#### Congenital melanocytic nevi (CMN)

These occur in 0.5–2% of the population (Figs 30.1 and 30.2). They are arbitrarily classified as small (less than 1.5 cm), medium (1.5–20 cm) or large/giant (greater than 20 cm or 5% or more of body surface), in estimated adult size. They occur at birth as raised, verrucose or lobulated nodules or plaques of varying shades of brown to black, sometimes with blue or pink components. They have an irregular margin and often long dark hairs and may become increasingly lobulated and hairy with time. Giant-sized lesions may produce considerable redundancy of skin and often occur in a 'garment' or 'bathing trunk' distribution on the trunk and adjacent limbs. The very small CMN initially may be difficult to distinguish from café-au-lait macules. In patients with multiple large nevi an eruption of smaller ones (satellite nevi) may occur over the first year of life. Once established, the nevi increase in size in proportion to the patient's growth. Although rare, large CMN on the scalp or dorsal spine, especially with satellite nevi, may be associated with symptomatic leptomeningeal melanocytosis (neurocutaneous melanocytosis) with a median age of onset of neurological symptoms at 2 years.<sup>2</sup> Furthermore, magnetic resonance imaging (MRI) scans detect

Fig. 30.1 Congenital melanocytic nevus.

Fig. 30.2 Congenital melanocytic nevus.

Fig. 30.3 Halo nevus.

leptomeningeal involvement in 5–30% of asymptomatic children with CMN in this distribution.<sup>3–5</sup>

Considerable controversy remains regarding the risk of development of malignant melanoma in CMN and hence the approach to management. Malignancy can arise from the dermal as well as the junctional component of CMN. The incidence of malignancy in large nevi has varied from 2 to 31% in different series but most studies have been retrospective and biased. A long term prospective study based on the Danish birth register is probably the most reliable and a lifetime risk of 4.6% is calculated from it.<sup>6</sup> In a retrospective study which included a review of the world literature primary cutaneous malignant melanoma was diagnosed within a large CMN before the age of 5 years in 50% of cases. No melanoma developed in the satellite nevi. Melanoma also occurs in medium-sized and small CMN<sup>7,8</sup> but the exact incidence for small lesions is not known, though it is definitely lower than for large nevi. A single follow-up study does not support the view of a significantly increased risk of melanoma in banal-appearing, medium-sized CMN, although median follow-up was short at 5.8 years.<sup>9</sup>

While small lesions, in which the malignancy risk is low and is usually postpubertal, can be easily excised, removal of large lesions in which the risk is much more significant is more difficult and with giant lesions may be impossible. In all cases the risk must be weighed against possible functional impairment and the morbidity of multiple operations. Many surgical procedures are available and are chosen depending on the site and extent of the lesions. Dermabrasion and laser therapy may improve the appearance of the nevus by removal of superficial pigment cells but the bulk of the lesion remains and the malignancy risk is not substantially reduced.

### Acquired melanocytic nevi (AMN)

In a longitudinal study, 0.5% of babies had a CMN at birth and the number of melanocytic nevi in the same cohort at 1 year had risen to 35%.<sup>10</sup> These nevi continue to increase in number throughout childhood. They commence as brown or black macules, some of which become raised and enlarge laterally as they develop. They are usually of uniform color and well circumscribed. Histologically the flat lesions show clustering of nevus cells at the dermoepidermal junction (junctional nevus) and the raised ones also show intradermal nevus cells (compound nevus). Pure intradermal nevi are rare in children. The risk of melanoma arising from acquired melanocytic nevi is very low (less than 0.1%) and so their prophylactic removal in young patients is not justified.

### Halo (Sutton's) nevi

A nevus may develop a depigmented halo (Fig. 30.3). The lesions are often multiple and are relatively common. The nevus may appear

inflamed and often disappears leaving a white spot which may repigment years later. This is a completely benign change.

### Atypical (dysplastic) nevi

Atypical nevi is the preferred term as dysplasia relates to histological features only. They are a subtype of acquired melanocytic nevi with characteristic clinicopathological features. They are a marker for the development of malignant melanoma, occurring in over 90% of patients with familial melanoma and over 10% of those with sporadic melanoma. These nevi differ from more typical AMNs by being larger (more than 5 mm diameter), having irregular and indistinct margins and irregular tan brown coloration, often with an erythematous component. They are predominantly macular, sometimes with a central elevated portion. They may appear in childhood as small typical appearing nevi which after puberty develop the atypical features. In adolescence and early adult life new atypical lesions may appear de novo. Atypical nevi may appear on the scalp in childhood. The final confirmation is based on the finding of some or all of a constellation of histopathological features of which the most important are nuclear atypia and a lymphocytic infiltrate. Familial atypical nevus syndrome is present when an individual has greater than 50 atypical nevi and a history of melanoma in a first or second degree relative.

Patients with multiple atypical nevi should be monitored with serial photography. Any mole showing significant alteration should be excised. Family members should be checked for the presence of atypical nevi or melanoma.

### EPIDERMAL NEVI

Epidermal nevi are hamartomas arising from the basal layer of the embryonic epidermis that gives rise to skin appendages and keratinocytes. These nevi have been conventionally classified according to the main tissue of origin (keratinocytic, sebaceous and follicular) although this is somewhat arbitrary as more than one cell type may be present.

Epidermal nevi can involve any area of skin and may be present at birth (particularly those on the head) or appear in the first few years of life (or exceptionally later). They may simply grow with the patient or can extend well beyond their original distribution over months or years. Extension occurs less often with nevi on the head and with nevi present at birth, whatever their location. It is now clear that the linear and swirled patterns taken by epidermal nevi follow the lines of Blaschko, which define the tracks of clones of genetically identical cells. All epidermal nevi can be explained on the basis of genetic mosaicism<sup>11</sup> with each type of nevus representing the cutaneous manifestation of a different mosaic phenotype. In most patients the nevus is the only detectable

manifestation but in some patients there are associated abnormalities in other organ systems, particularly skeletal, neurological and ocular.<sup>12,13</sup> This association has been called the 'epidermal nevus syndrome'.<sup>11</sup>

Keratinocyte nevi often start as lightly pigmented streaks that thicken and darken with time to become verrucous. They usually spare the face and scalp. Up to 10% may show histological features of epidermolytic hyperkeratosis and biopsy is therefore recommended, if possible, due to the risk of parenting a child with bullous ichthyosis. Inflammatory linear verrucous epidermal nevi (ILVEN) usually present after 6 months of age with a linear pruritic and inflamed lesion often on the lower limb.

Sebaceous and verrucous nevi are closely related. The former most commonly occur on the scalp and face and have a yellowish color due to prominent sebaceous glands. They present as a hairless, often solitary linear plaque, usually flat in infancy and childhood and becoming verrucous at puberty. Sebaceous nevi (Fig. 30.4) are rarely (< 5%) complicated in adult life by basal cell or squamous cell carcinoma.

The follicular or comedonal nevus presents as linear plaques with dilated follicular pores with comedones. The face is the commonest site but any involved site can be complicated in adolescence with acne-like cyst formation and scarring.

Skeletal abnormalities occur particularly with nevi of keratinocytic type on the limbs, and neurological and ocular abnormalities with nevi of sebaceous type on the head. The major clinical neurological features are seizures, developmental delay and hemiparesis. All patients with epidermal nevi should have a careful physical examination at presentation. Patients with linear nevi on the head who present in infancy and are normal on initial examination should be followed for several years. Most centers embark on imaging studies only in patients with clinical abnormalities.

Therapy of these lesions is difficult. Topical retinoic acid may temporarily flatten very thick areas. There are a few reports of improvement of gross lesions with oral retinoids but the effect depends on continued use of the drug. Recurrence is almost invariable following diathermy and cryotherapy. Carbon dioxide, argon and more recently erbium:YAG lasers have been used in some cases with good results though these may be temporary. Excision is appropriate for small and linear lesions and for irritating or cosmetically troubling areas of more widespread nevi.

## VASCULAR NEVI

These can be divided into hemangiomas, which are proliferative vascular tumors, and vascular malformations which represent fixed collections of dilated abnormal vessels.<sup>14</sup>

### Hemangiomas

Hemangiomas (Fig. 30.5) are usually not present at birth, undergo a fast growth phase and then, over a long period, tend to spontaneous

Fig. 30.4 Sebaceous nevus.

Fig. 30.5 Capillary (strawberry) hemangioma.

resolution. Emerging evidence shows that hemangiomas share unique tissue-specific markers (e.g. GLUT-1) with placental microvessels suggesting a possible common origin.<sup>15</sup> The terms capillary (strawberry), cavernous and capillary-cavernous are misleading and should be abandoned in favor of the simple term hemangioma.

### Clinical features

Superficial hemangiomas are usually not present at birth but appear in the first weeks of life as an area of pallor followed by a telangiectatic patch. They then grow rapidly into a lobulated, well-demarcated, bright red tumor. Rapid growth continues over the first 6 months; the growth rate then slows and further growth after 10 months is unusual. After a stationary phase signs of involution appear with the appearance of gray areas which enlarge and coalesce. The tumor becomes softer and less bulky and then disappears in 90% of cases by 9 years of age.

Deeper hemangiomas may occur alone or beneath a superficial lesion. They also usually appear after birth and undergo a growth phase which however may be less striking than that of the more superficial lesions. The overlying skin is normal or bluish in color. As they resolve they soften and shrink and complete disappearance occurs in many cases: occasionally some redundant tissue remains in the place of large lesions. Apparent deep hemangiomas which show no sign of resolution are now recognized as vascular malformations, usually of venous type, and are not hemangiomas at all.

### Complications

Ulceration may occur during the rapid growth phase of superficial hemangiomas. If secondary infection is controlled the ulcers usually heal in a few weeks but some scarring is inevitable. Ulceration of lesions on eyelids, lips or ala nasae can lead to full thickness tissue loss. Scarring following ulceration of lesions on or near the eyelids can result in a cicatricial ectropion and alopecia may be permanent after scalp ulceration.

Hemangiomas may encroach on vital structures. A hemangioma closing the eye for as little as 4 weeks in infancy can produce amblyopia. However, even without occluding the pupil an eyelid lesion, by pressing on the eye and producing a refractive error, can lead to failure of development of binocular vision and partial amblyopia. Large hemangiomas around the mouth may interfere with feeding and one blocking both nares can lead to respiratory difficulties while the child is being fed. A large deep hemangioma around the neck may displace the pharynx or trachea; the upper respiratory tract may also be directly involved with the hemangioma. The possibility of laryngeal involvement should be considered whenever there is a fast growing extensive lower face or neck hemangioma, particularly when there is accompanying intraoral involvement, and a lateral airways X-ray or MRI should be arranged. If there is stridor, an urgent laryngoscopy is mandatory. Even when traumatized, uncomplicated hemangiomas rarely bleed significantly.

### Management

Simple observation and reassurance while awaiting natural resolution is the ideal approach for most hemangiomas. Serial photography and showing photographs of other resolving lesions are encouraging. Indications for active intervention are: an alarming growth rate; threatening ulceration in areas where serious complications could ensue; interference with vital structures; and severe bleeding. Oral corticosteroids are the treatment of choice. The optimal dose is not known but a meta-analysis suggests that 3 mg/kg or more for 6–8 weeks may give the best response.<sup>16</sup> Repeated courses should be avoided wherever possible. Intralesional steroids may shrink localized hemangiomas which fail to respond to systemic steroids, and interferon-alpha has been effective in some life threatening cases although severe neurotoxicity, including spastic diplegia, has been reported.<sup>17</sup> Laser therapy became an increasingly popular treatment modality for uncomplicated hemangiomas but without good evidence for effectiveness. A randomized, controlled study of early pulsed dye laser treatment has shown no benefit of treatment at 1 year follow-up.<sup>18</sup> Life threatening hemangiomas have been treated with variable success with oral vincristine.<sup>19</sup> Cosmetic surgical procedures can improve the appearance when loose tissue remains.

### Congenital hemangioma

Two types of this rare hemangioma are recognized.<sup>20</sup> Both are usually solitary lesions and account for about 3% of all hemangiomas. Rapidly involuting congenital hemangioma (RICH) is similar to infantile hemangioma but differs in that it is fully developed at birth, with subsequent rapid involution and regression. Non-involuting congenital hemangiomas (NICH) are usually plaque-like or bossed and as the name implies do not resolve spontaneously. Unlike infantile hemangiomas they are GLUT1 negative.

### PHACE syndrome

PHACE is an acronym to describe a constellation of features: posterior fossa brain malformations, facial hemangioma, arterial anomalies, cardiac anomalies (including aortic coarctation) and eye abnormalities. If ventral developmental defects such as sternal clefting or supraumbilical raphe are present the association is referred to as PHACES. This syndrome should be considered in any infant presenting with an extensive facial hemangioma.<sup>21</sup>

### Kasabach–Merritt syndrome (hemangioma – hemorrhage syndrome)

This is the rare association of thrombocytopenia with vascular tumors (Fig. 30.6). In children these are usually either large, deep hemangiomas, especially on limbs and around limb girdles, or diffuse hemangiomas. Thrombocytopenia is caused by entrapment of platelets within the lesions and is sometimes followed by disseminated intravascular coagulation (DIC). At first there may be bleeding into the

Fig. 30.6 Kasabach–Merritt syndrome.

hemangioma, which rapidly enlarges; widespread life threatening hemorrhage may follow. When bleeding is confined to the hemangioma the approach should be conservative; in severe cases high dose systemic corticosteroids are indicated together with resuscitation, transfusion, and management of the DIC.

### Diffuse infantile hemangiomatosis

This is a condition with multiple small hemangiomas in a widespread distribution. A benign form has lesions limited to the skin but a potentially serious systemic form may occur with lesions in many organs, particularly liver (64%), gastrointestinal tract (52%), lungs (52%) and central nervous system (52%) with or, rarely, without cutaneous lesions.<sup>22</sup> All patients with multiple cutaneous lesions should be carefully assessed with full blood count, chest X-ray, and examination for cardiac failure due to arteriovenous shunts and for bleeding from the gastrointestinal tract. An ultrasound or abdominal computerized tomography (CT) scan should be performed to exclude hepatic involvement and other organs may need to be further investigated. Angiography and technetium-labeled red blood cell scans can delineate further the extent of internal involvement.<sup>23</sup> With severe systemic involvement high dose corticosteroids are required along with management of cardiac failure and other complications, and active surgical intervention may be necessary in selected cases.

### Vascular malformations

Vascular malformations are structural abnormalities and as such are present at birth, grow in proportion to the patient's growth and have no tendency at all to resolution. They can be further divided into fast flow, e.g. arteriovenous, or slow flow, e.g. venous, lymphatic or capillary malformations.

### Capillary malformation (port-wine stain, nevus flammeus)

This is a vascular malformation composed of dilated mature capillaries. It is present at birth and shows no involution. Lesions may be unilateral or, less often, bilateral, and occur anywhere on the body, though they are most commonly found on the face. They are deep pink in infancy becoming more purple later. After puberty they may become raised and nodular. Good results can be achieved with the pulsed dye laser. Port-wine stains (PWS) must be distinguished from salmon patches at the nape of the neck (stork bite) and lesions on the eyelid or forehead (angel kiss). The vast majority of facial lesions resolve in months whilst the occipital ones persist.

It is important to be aware that, even in the absence of Sturge–Weber syndrome, ocular complications can occur. If the PWS encroaches the upper eyelid glaucoma may occur. The incidence increases to over 30% if the lower eyelid is also involved.<sup>24</sup>

### Sturge–Weber syndrome

This is the association of a facial capillary malformation and a vascular malformation of the ipsilateral meninges and cerebral cortex. The cutaneous lesion always involves the skin in the distribution of the first division of the trigeminal nerve.<sup>25</sup> In 20% of infants the neurological manifestations of the syndrome include convulsions, hemiparesis and mental retardation.

Patients presenting with a capillary malformation in the appropriate distribution should have early neurological and ophthalmological consultation and continued close follow-up. A CT scan may demonstrate the intracranial malformations in the first few months of life. Parallel streaks of calcification may be demonstrated radiologically after about 2 years of age.

### Vascular malformations with limb hypertrophy

Klippel–Trenaunay syndrome refers to a Parkes–Weber syndrome (PWS), associated with ipsilateral overgrowth of a limb, with soft tissue and/or bony hypertrophy and venous varicosities. The condition arises predominantly due to venous malformations whereas PWS, with similar

clinical features, is caused by arteriovenous fistulae. In both instances, deeper lymphatic abnormalities may also be present. In 15% of cases of Klippel–Trenaunay syndrome involvement may be bilateral. Treatment is generally unsatisfactory with few cases being amenable to surgical correction. Compression bandaging may help to some extent with the increased girth of a limb.

### CONGENITAL APLASIA CUTIS

Aplasia cutis congenita (ACC) is a congenital absence of skin and in 70% of patients is located as a solitary lesion on the scalp. The commonest form is a localized oval, stellate or linear area at or near the midline of the scalp which presents as an ulcerated area which crusts (Fig. 30.7). Resolution occurs after some months to leave a scar that is usually atrophic but is occasionally hypertrophic. There is permanent alopecia at the site. Rarely the lesion is already scarred at birth. The defect may involve not only skin but also subcutaneous fat and even bone. The bony defect will eventually heal but until it does there is a risk of meningitis. Deep aplasia may erode large vessels producing serious hemorrhage. A skull X-ray should be performed in all cases unless the lesion is obviously very superficial. Early management of scalp ACC is conservative with protection of the area and early treatment of secondary infection. Very deep lesions, however, may require skin and/or bone grafting. In later life scalp reduction techniques can be used to deal with the area of alopecia.

After the scalp the next commonest site is the lower limbs. When multiple lesions occur their distribution is often strikingly symmetrical and they may be covered with a shiny transparent membrane rather than being open erosions. Cases with extensive truncal and limb ACC are often associated with a fetus papyraceus at delivery, indicating the death of a twin early in the second trimester.

ACC-like lesions can occur on the lower limbs of patients with several types of epidermolysis bullosa probably resulting from intrauterine mechanical trauma. ACC may occur in a number of syndromes including trisomy 13, 4p-syndrome, 46XY gonadal dysgenesis and the Johanson–Blizzard syndrome. It may also be associated with a number of morphological abnormalities, particularly those involving the limbs.

### DERMOID CYSTS

Congenital inclusion dermoid cysts typically present as asymptomatic subcutaneous swellings. Approximately 40% are present at birth with the rest appearing over the next 5 years. They arise due to entrapment of epithelium along embryonic fusion lines and occur particularly on the head and neck with predilection over the lateral eyebrow and dorsum of the nose. It is essential that adequate imaging investigations are performed prior to surgery as they may form deep tracts into underlying tissue.

Fig. 30.7 Aplasia cutis.

## HEREDITARY DISEASES

### THE ICHTHYOSSES

These are a group of inherited conditions with dry thickened skin of varying severity. The major ichthyoses comprise:

1. ichthyosis vulgaris (IV);
2. X-linked recessive ichthyosis (XLRI) (Fig. 30.8);
3. lamellar ichthyosis (LI);
4. congenital ichthyosiform erythroderma (CIE) (Fig. 30.9);
5. bullous ichthyosis (BI).

The histopathological and clinical features of the major ichthyoses are listed in Table 30.1. They are life-long disorders with little tendency to spontaneous improvement.

#### Management

Simple emollients such as aqueous cream may be adequate in IV. Keratolytics containing urea, propylene glycol or alpha-hydroxy acids may be more effective and useful in IV and XLRI but they may sting on fissured skin. The more severe ichthyoses often show little improvement with these topical agents. Oral retinoids may be very helpful in CIE but their effectiveness must always be weighed against their potential

Fig. 30.8 X-linked ichthyosis.

Fig. 30.9 Lamellar ichthyosis (congenital ichthyosiform erythroderma).

Table 30.1 Classification and features of the major ichthyoses

	Onset (and inheritance)	Clinical features	Complications and associations	Chromosomal/gene loci
Ichthyosis vulgaris	After birth but within the first year of life (AD)	Fine pale branny scales especially on extensor surfaces of limbs. Wide sparing of flexures of limbs. Trunk less severely involved. Face usually spared. Hyperlinear palms	Rarely corneal dystrophy, keratosis pilaris, atopy	Loss of function of filaggrin
Recessive X-linked ichthyosis	Appears within the first 3 months of life. Sometimes congenital with a thin shiny covering membrane (XLR)	Large dark adherent scales mainly on extensor surfaces of limbs. Scaling encroaches on limb flexures and axillae with narrow sparing. Trunk is diffusely involved. Sides of face often involved. Usually severe involvement of neck and thick scalp scaling. Palms and soles are uninvolved	Frequent corneal dystrophy (also in carriers). Cryptorchidism. Steroid sulfatase deficiency in most tissues including the amnion (which is derived from fetus). This placental steroid sulfatase deficiency may result in a failure of spontaneous onset of labor	Steroid sulfatase gene deletion (Xp22.3)
Lamellar ichthyosis	Usually at birth as 'collodion baby' (AR/AD)	Large dark plate-like scales. Mild to moderate erythroderma. The whole body surface is involved, including palms and soles	Ectropion. Blockage of external auditory meatus with scale resulting in hearing loss. Block of nares with scale. Pyrexia from sweat duct obstruction. Failure to thrive. Alopecia	TGM1 gene mutations (14q11.2); also 2q33–35, 19p12–q12
Congenital ichthyosiform erythroderma	Usually at birth as 'collodion baby' (AR)	Fine white scale in most areas, sometimes larger and darker on lower legs.  Mild to very severe generalized erythroderma. Whole body surface is involved including palms and soles	Similar to those of lamellar ichthyosis but of lesser extent	TGM1 gene mutations (14q11.2); also 3p21
Bullous ichthyosis (epidermolytic hyperkeratosis)	At birth with erythroderma and widespread blistering. After a few days the redness subsides and over early months the blistering tendency reduces (AD)	Thick dark warty scales from time to time to leave denuded areas with a red base. Blistering is rare after 1 year. The condition may be localized to extensor surfaces but is usually widespread although the face is usually spared. Palm and sole involvement is variable	Bacterial superinfection is a recurrent problem. Heavy bacterial colonization is inevitable. Maceration and offensive odor are major problems	K2e gene mutations (12q11–13)

AD, autosomal dominant; AR, autosomal recessive; XLR, X-linked recessive.

side-effects, especially skeletal abnormalities and teratogenicity. In BI their usefulness is limited by their tendency to increase skin fragility. Detection and treatment of secondary bacterial infection is important in BI and topical disinfectants may reduce bacterial colonization and malodor.

### Collodion baby

This is a descriptive term for the child who is encased at birth in a shiny tight membrane resembling collodion or plastic skin, producing ectropion and eclabium and fissuring (Fig. 30.10). The skin peels off in days or weeks. This may be a presentation of various conditions, particularly CIE (which overlaps with lamellar ichthyosis), chondrodysplasia punctata, trichothiodystrophy and rarely Netherton syndrome. In approximately 10% of collodion babies the membrane peels off to leave normal skin: this condition is called lamellar ichthyosis of the newborn. Collodion babies show temperature instability and excessive fluid loss. Corneal exposure may result if the eyes are not covered and the eclabium may necessitate squeeze bottle, tube or dropper feeding. As the fissures appear, secondary infection becomes a risk. The child should be nursed in a humidicrib with aseptic handling.

Fig. 30.10 Collodion baby.

## Harlequin ichthyosis

This is a rare, potentially lethal, autosomal recessive disorder. Causative mutations in the ABCA12 gene, which is a member of the ATP-binding (ABC) transporter family, have recently been identified.<sup>26</sup> ABCA12 is an epidermal lipid transporter and loss of the skin lipid barrier is thought to lead to abnormal keratinization.

At birth the child is covered in large dark plates of scale with deep fissures. Severe ectropion and eclabium, deformed ears and claw hands and feet are present. Most used to die as neonates due to secondary infection, anemia, circulatory disturbances or renal failure but the few who have survived have had a severe ichthyosiform erythroderma. (Note – this is different from the harlequin color change.)

## Ichthyosis as part of other syndromes

Some of the syndromes of which ichthyosis is a part are listed in Table 30.2.

## EPIDERMOLYSIS BULLOSA (EB)

This is a rare group of inherited diseases characterized by trauma-induced blistering of skin and mucosae. The prevalence is between 1/50 000 and 1/2 000 000 for the more common and rarer forms, respectively. Over 20 types are now identified, separated on the basis of inheritance, clinical features, immunohistochemistry, electron microscopic (EM) and molecular pathology. The split may be within the epidermis, at the dermoepidermal junction in the lamina lucida (junctional; Figs 30.11 and 30.12) or in the upper dermis (sublamina densa; Fig. 30.13). A classification is given in Table 30.3. The structure of the cutaneous basement membrane zone and the gene defects in epidermolysis bullosa are shown in Figure 30.14.

A firm diagnosis should be established as soon as possible by EM and immunohistochemical analysis from an unaffected area of skin in which the split is induced by prior rubbing. This enables a prognosis to be given and a management plan to be established for present and future.

## Epidermolysis bullosa simplex (EBS)

### Localized EBS (Weber – Cockayne)

The blisters are often not noticed until the child starts to walk. It may be so mild that it does not present until adult life. However, morbidity can be such that daily activities are affected. Blisters develop on hands and feet and, as with all forms of EBS, they are often worse with increased temperatures in the summer months. Very occasionally other body sites are affected.

### Generalized EBS (Koebner)

The onset of blisters is at birth or early infancy. They may be widespread but affect particularly areas of trauma such as hands, feet, knees and elbows. The oral mucosa is occasionally involved. Nails are not affected and there is no scarring. As with localized EB, secondary infection is the main complication. Life expectancy is normal.

### Herpetiform EBS (Dowling – Meara)

Widespread blistering can be present at birth and severe cases may be mistaken for junctional EB. Transient milia develop at sites of grouped blisters. The hands and feet are especially affected, often leading to a palmoplantar keratoderma. Nail thickening is common. Oral, laryngeal and esophageal mucosal involvement is sometimes seen. Although blistering may persist through adult life the tendency is for considerable improvement.

## Junctional EB

### Generalized severe (Herlitz) EB

Blistering is present at birth and may be relatively minor at first. Slow wound healing is seen particularly on the face and around the nails. Typically affected babies have a hoarse cry due to mucosal involvement which is extensive and severe involving nasal, oral, esophageal as well as anogenital and urinary epithelium. Many infants die due to overwhelming sepsis. Survival to adolescence is rare but older children suffer from chronic sepsis, anemia and growth retardation.

Table 30.2 Syndromes associated with ichthyosis

Syndrome	Inheritance	Type of ichthyosis	Other major features	Molecular defects
Chondrodysplasia punctata	XLR	Onset may be as 'collodion baby'. Initially occurs as a diffuse redness and scaling. Later occurs in a whorled patchy distribution	Epiphyseal dysplasia, cataracts, follicular atrophoderma	XLR: Emopamil binding protein gene mutations
	XLD			XLD: Arylsulfatase E gene mutations
Sjögren–Larsson syndrome	AR	Generalized ichthyosis at birth. Later large dark scales most prominent in flexures	Mental retardation, spasticity	Aldehyde dehydrogenase family mutations
Chanarin–Dorfman syndrome (neutral lipid storage disease with ichthyosis)	AR	Ichthyosis simulating mild to moderate congenital ichthyosiform erythroderma	Lipid vacuoles in almost all cells. Normal serum lipids. Cataracts, deafness, developmental delay	Unknown
Refsum syndrome	AR	Delayed onset of ichthyosis of mild form, simulating ichthyosis vulgaris	Failure to degrade phytanic acid. Retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia	Phytanoyl–CoA hydroxylase gene mutations
Netherton syndrome	AR	Erythroderma at birth. Late development of circinate migratory scaly lesions (ichthyosis linearis circumflexa) in widespread distribution. Some cases simulate congenital ichthyosiform erythroderma	Alopecia due to hair shaft abnormalities, especially trichorrhexis invaginata, atopic diathesis, developmental delay, generalized aminoaciduria	Serine proteinase inhibitor (SPINK 5) gene mutations

AR, autosomal recessive; XLD, X-linked dominant; XLR, X-linked recessive.

Fig. 30.12 Junctional epidermolysis bullosa.

Fig. 30.13 Dystrophic epidermolysis bullosa.

Table 30.3 Classification of major types of hereditary epidermolysis bullosa

	Inheritance
<b>Intraepidermal blister</b>	
Epidermolysis bullosa simplex (EBS)	
Localized (hands and feet) EBS (Weber–Cockayne)	AD
Generalized EBS (Koebner)	AD
Herpetiform EBS (Dowling–Meara)	AD
EBS with muscular dystrophy	AR
<b>Lamina lucida blister</b>	
Junctional epidermolysis bullosa (JEB)	
Generalized severe (Herlitz)	AR
Generalized atrophic benign (GABEB)	AR
JEB with pyloric atresia	AR
<b>Sublamina densa</b>	
Dystrophic epidermolysis bullosa (DEB)	
Dominant DEB	AD
Recessive DEB (Hallopeau)	AR

AD, autosomal dominant; AR, autosomal recessive.

### **Generalized atrophic benign EB (GABEB)**

Although in the initial stages the blistering has a similar pattern to Herlitz EB the child survives with a decreasing tendency to blister. Mucous membranes are involved but less so than the Herlitz form. The major feature of GABEB is alopecia which follows the blistering. Lesions may also heal with hyperpigmentation. The life span of the affected individual is normal.

### **Dystrophic EB**

Dystrophic EB is characterized by skin fragility, blisters, scarring with milia formation and nail changes. The autosomal recessive form is more severe than the dominant disease with greater skin fragility and therefore more widespread blistering. Repeated blistering and scarring can lead to syndactyly of fingers and toes and club-like deformities of hands and feet with several digits encased together in a scar. Severe involvement of oral mucosa may lead to stricture formation in autosomal recessive patients. Laryngeal and tracheal involvement may threaten the airway. Hypoproteinemia is caused by constant loss of protein in blister fluid, malabsorption and malnutrition. In all cases the nails are thickened and often lost. Aggressive squamous cell carcinomas may arise in the scar tissues and metastatic disease is a major cause of death in adult patients with severe disease.

### **Management**

In mild epidermolysis bullosa simplex and dominant dystrophic cases advice is required regarding avoidance of trauma, a reduction of friction, appropriate clothing and footwear. New blisters should be pricked to drain them but not deroofed and various dressings of non-stick material are appropriate. Secondary bacterial infection is treated with topical or oral antibiotics.

In the severe forms with extensive neonatal blistering extreme care is necessary to avoid further skin damage. The infant should initially be nursed naked in a humidicrib lying on non-adherent material with barrier nursing to prevent infection. Blisters should be drained and antibacterial creams such as silver sulfadiazine applied to large erosions. Vaseline gauze or non-adherent plastic dressings should be used as required, secured with tubular gauze or by other means but never taped to the skin with adhesive. A nasogastric tube should never be passed.

Severe complications may require a multidisciplinary approach. In the UK advice, both medical and nursing, should be sought whenever appropriate early in management from regional centers with a particular expertise in EB. Where possible, one physician should coordinate the entire management program to provide stability and continuity. The family should be directed towards support organizations, which can offer practical advice, emotional support and companionship. Finally, genetic counseling of the parents and later the patient should be arranged at an appropriate time.

Fig. 30.14 Structure of cutaneous basement membrane zone and gene defects in epidermolysis bullosa.

## ECTODERMAL DYSPLASIAS

The ectodermal dysplasias (Fig. 30.15) are a heterogeneous group of inherited conditions with a primary defect in two or more of the following: teeth, nails, hair, sweat glands or abnormalities in tissues of ectodermal origin, including eyes, ears, oral and nasal mucosa, melanocytes and central nervous system. Molecular genetics is increasingly yielding more insight into the abnormal regulatory mechanisms in ectodermal dysplasias and this is leading to revised classifications according to the function of the involved mutated genes.<sup>27</sup>

The major features of some of the more important ectodermal dysplasias are documented in Table 30.4.

### Management

As these are disorders manifesting very diverse features, a multidisciplinary approach is essential.

If the scalp hair is very sparse the cosmetic benefit of a good wig may be invaluable. Primary and secondary dentitions can be assessed with

dental X-rays in infancy in conjunction with a pediatric dentist experienced in these conditions. Early use of prostheses may prevent development of some of the structural facial abnormalities. Newer techniques include osseous implants into which prosthetic teeth can be fitted.

If hypohidrosis is extreme hyperthermia may result and may be severe and life threatening. Advice regarding activities, clothing and methods of cooling may be required.

Atopic eczema often accompanies hypohidrotic ectodermal dysplasia and will require the usual treatment. Many patients have dry skin and require emollients, and keratolytics may improve palmoplantar keratoderma.

All patients with eye abnormalities should be managed in conjunction with an ophthalmologist. Artificial tears are essential for dry eyes to prevent corneal damage. Reconstructive procedures will be required for atresia of nasolacrimal ducts and canaliculi. Severe respiratory infections complicate some of these syndromes and need antibiotics, physiotherapy and regular pediatric follow-up.

## TUBEROUS SCLEROSIS

The tuberous sclerosis complex (TSC) is an autosomal dominant, neurocutaneous disorder characterized by the formation of hamartomata in many organs. Mutations in the hamartin gene (9q34) account for approximately half of the cases (TSC1) and the other half arise due to mutations in the tuberin gene (16p13) (TSC2).<sup>28</sup> Both act as tumor suppressor genes and around 60% arise due to spontaneous mutations. A small number of families are unlinked to either gene. Epilepsy occurs in 80% and mental retardation in 70%. Up to 20% of patients with infantile spasms will have TSC and should therefore have their skin examined. Other systemic abnormalities include retinal phacomata and a variety of hamartomata in renal tract, heart and other organs.

### Dermatological features

The most pathognomonic features are angiofibromas (adenoma sebaceum), periungual fibromas, shagreen patches and ash leaf macules (Figs 30.16 and 30.17). The angiofibromas appear as 1–4 mm bright red papules in a centofacial distribution. Sometimes they coalesce to form cauliflower-like masses. Their onset is usually between the ages of 3 and 10 years and they may become more extensive at puberty. Numbers vary from a few to several hundred. Periungual fibromas appear around puberty as

Fig. 30.15 Ectodermal dysplasia.

Table 30.4 The ectodermal dysplasias

	1. Hypohidrotic ectodermal dysplasia (Christ–Siemens–Touraine syndrome)	2. Hidrotic ectodermal dysplasia (Clouston syndrome)	3. Rapp–Hodgkin syndrome	4. EEC syndrome (ectrodactyly, ectodermal dysplasia and clefting)	5. AEC syndrome (ankyloblepharon, ectodermal dysplasia and clefting) (Hay–Wells syndrome)
Inheritance	X-linked recessive*	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal dominant
Hair	Hypotrichosis of scalp, body hair, eyebrows and lashes. Beard normal. Hair fine and fair	Hypotrichosis. Hair fine and dry	Sparse, coarse and stiff with hair shaft abnormalities	Sparse wiry hair	Severe hypotrichosis
Teeth	Hypodontia. Conical teeth	May be normal. Hypodontia, caries, widely spaced teeth	Hypodontia, abnormally shaped teeth. Early caries	Hypodontia, abnormally shaped teeth	Variable hypodontia, abnormal shape, delayed eruption
Nails	Often normal. Sometimes fragile and occasionally dystrophic or absent	Thick, striated, discolored. Paronychia and nail loss. Rarely thin and brittle	Small and dysplastic	Thin, pitted and striated	Severe dystrophy. Short due to absence of distal nail plate
Sweating	Hypohidrosis often with hyperthermia	Normal	Hypohidrosis	Occasional hypohidrosis	Variable hypohidrosis
Skin	Smooth and dry, loss of dermatoglyphics, wrinkled and hyperpigmented around eyes, atopic dermatitis	Thick over finger joints, knees and elbows. Palmoplantar keratoderma	Dry and coarse. Thick over elbows and knees. Reduced dermatoglyphics	Dry and thin. Palmoplantar keratoderma	Large weeping areas at birth, later dry and scaly. May be recurrent scalp crusting. Palmoplantar keratoderma
Eyes	Hypoplasia of nasolacrimal duct, decreased lacrimal gland secretion, dry eyes, photophobia and corneal opacities	Usually normal. Occasionally premature cataracts	Atresia of lacrimal puncta producing epiphora, corneal opacities	Nasolacrimal duct stenosis, dacryocystitis, corneal scarring	Ankyloblepharon filiforme adnatum, nasolacrimal duct atresia
Facies	Variable. Thick lips, saddle nose, frontal bossing, maxillary hypoplasia. Occasionally abnormal ears	Normal	Cleft lip, hypoplastic maxilla. Microstomia. Prominent malformed ears	Cleft lip	Cleft lip often, microstomia, broad nasal bridge, sunken maxilla, abnormal pinnae
Mucosae	Poor development of mucous glands in gastrointestinal and respiratory tracts. Atrophic rhinitis, thick nasal secretion, recurrent chest infections, dysphagia. Dry mouth	Normal	Chronic rhinitis	Hoarseness due to abnormality of laryngeal mucosa	Filamentous bands in vagina, anal fissure
Miscellaneous	Absent or supernumerary nipples. Absent breast tissue in carriers. Asthma	Tufting of terminal phalanges with finger clubbing. Thickening of skull bones	Short stature. Cleft palate. Syndactyly	Cleft palate. Ectrodactyly (split hands and feet). Syndactyly	Cleft palate. Syndactyly

\* Autosomal recessive variant is difficult to distinguish phenotypically.

firm smooth flesh-colored papules in a periungual or subungual location. The shagreen patch is a connective tissue nevus comprising an accumulation of collagen as an irregularly thickened yellow-white plaque, usually in the lumbosacral area. It develops between the ages of 2 and 5 years. Ash leaf macules are depigmented macules, usually 1–3 cm in diameter but occasionally much larger. They are usually oval in shape, with a minority truly ash leaf shaped. They may be present at birth or appear during the first year. Large numbers may be present and they are best visualized under Wood's (ultraviolet) light.

Other dermatological features include fibromatous plaques on brow or scalp, intraoral fibromas, multiple fibroepithelial polyps around the neck and in the axillae and a variety of other depigmented lesions

including numerous guttate macules and large dermatomal lesions. Poliosis and canities may also occur.

Patients who present with these characteristic skin signs should be referred for neurological assessment and computerized axial tomography to demonstrate any intracranial lesions. Laser therapy may improve the cosmetic appearance of the angiofibromas.

## INCONTINENTIA PIGMENTI

Incontinentia pigmenti (IP type 2) is a multisystem disorder inherited as an X-linked dominant trait and is usually prenatally lethal in males (Figs 30.18 and 30.19). It arises due to mutations (usually genomic

Fig. 30.16 Adenoma sebaceum: tuberous sclerosis.

Fig. 30.17 Ash leaf patch: tuberous sclerosis.

rearrangement) in the NEMO gene (Xq28) and lesions probably occur through apoptosis of cells carrying the mutant gene.<sup>29</sup> There is increasing evidence that the 'sporadic type of IP' (IP type 1) represents a distinct disorder, hypomelanosis of Ito (q.v.), linked to Xp11. Neurological abnormalities occur in about 30% of cases and include epilepsy, mental retardation and spastic diplegia and tetraplegia. Ocular abnormalities are seen in 30% and include strabismus, cataracts, retinal vascular proliferation and retinal detachment. Over 80% of patients have dental abnormalities with partial anodontia and peg-shaped or conical teeth. A variety of skeletal abnormalities including limb reduction defects occur, and rarely cardiac abnormalities are seen.

### Cutaneous lesions

The four cutaneous stages of this disease may follow each other in an orderly progression; however, overlap may occur, particularly in the earlier stages. Stage one comprises linear groups of vesicles which appear mainly on the limbs at birth or in the first days of life accompanied by a peripheral blood eosinophilia. They clear spontaneously over several weeks. Stage two is the verrucose stage with linear warty lesions appearing between 1 and 4 months of age: they occur particularly on the limbs, especially on dorsa of hands and feet, and resolve spontaneously after

Fig. 30.18 Incontinentia pigmenti: pigmented stage.

Fig. 30.19 Incontinentia pigmenti: vesicular stage.

weeks or months. Stage three comprises streaks and whorls and splattered patterns of macular hyperpigmentation which appear on both limbs and trunk at 12–24 months of age. Lesions persist to early adult life. Stage four is typically seen in affected female adults as linear, hypopigmented, atrophic streaks on the lower legs. These lesions are permanent.

Other dermatological features of incontinentia pigmenti are cicatricial alopecia over the vertex of the scalp and nail dystrophy in 40%.

### ACRODERMATITIS ENTEROPATHICA AND NUTRITIONAL ZINC DEFICIENCY

Acrodermatitis enteropathica is an autosomal recessive condition in which there is a defective absorption of zinc, possibly due to the absence of a specific carrier protein. An identical condition occurs in infants with nutritional zinc deficiency. This may occur as a result of prematurity with low zinc stores, particularly in bottle-fed babies (as there is a lower bioavailability of zinc in bovine milk as compared to breast milk), or as a result of low breast milk zinc. Zinc deficiency also occurs in acquired immunodeficiency disease, cystic fibrosis and other causes of malabsorption and in infants on parenteral nutrition solutions not containing adequate zinc.

#### Clinical features

The onset in the primary form occurs usually when the child is weaned or in the first few weeks of life in a bottle-fed infant. In the children with nutritional zinc deficiency the onset is usually at the time of the first growth spurt. Erythematous and crusted, sometimes vesicular and pustular lesions appear in an acral distribution particularly around nose, mouth and eyes (Fig. 30.20) and sometimes on tips of digits and the paronychia areas. An anogenital rash (Fig. 30.21) is also common and psoriasiform

Fig. 30.20 Acrodermatitis enteropathica: mouth.

Fig. 30.21 Acrodermatitis enteropathica: buttocks.

lesions may occur on knees and elbows and occasionally elsewhere. Secondary bacterial and candidal infection is common. In the primary form mucosal involvement with glossitis, cheilitis and conjunctivitis may occur, a nail dystrophy is usual, and alopecia and diarrhea may occur.

The diagnosis is confirmed by finding a low serum zinc. The condition responds rapidly to the administration of high doses of oral zinc as either zinc gluconate or zinc sulfate. This is required life-long in the primary form but only for a few weeks in the secondary variety.

## NEUROFIBROMATOSIS

Neurofibromatosis is a very variable multisystem disorder which is described in detail in Chapter 22. Only the dermatological features will be considered here.

### Pigmented lesions

The café-au-lait macule is the most common of these: most prepubertal individuals with neurofibromatosis have at least six macules of greater than 0.5 cm in diameter increasing to at least 1.5 cm post puberty. Eventually hundreds of macules may be present.

In 20% of cases small freckle-like pigmented macules occur in the axillae. These occur only in the presence of café-au-lait macules and the combination is of great diagnostic significance. Similar small pigmented macules may occur in a widespread distribution, especially in patients with large numbers of café-au-lait spots. Larger pigmented patches 10 cm or more in diameter may overlie plexiform neuromas.

## Neurofibromas (mollusca fibrosa)

These are soft pink or skin-colored tumors, often sessile or pedunculated and characteristically indentable. They usually develop after puberty. Their distribution is widespread and up to thousands of tumors half to several centimeters in diameter may occur. Small firmer discrete nodules occur along the course of peripheral nerves. The plexiform neuroma is a larger diffuse elongated neurofibroma along the course of a peripheral nerve. These may be present at birth or develop later. There may be an overgrowth of skin and subcutaneous tissue associated with these lesions producing gross disfigurement as a giant pendulous tumor with a wrinkled surface.

## HEREDITARY PHOTOSENSITIVE DISORDERS (Table 30.5)

Photosensitivity is the cardinal feature of most of the porphyrias although some types may present with chronic nonspecific abdominal or musculoskeletal pain.<sup>30</sup> Photosensitivity occurs in other metabolic diseases such as phenylketonuria and Hartnup disease and severe photosensitivity also occurs in oculocutaneous albinism.

## SKIN DISEASES OF THE NEONATE

### ERYTHEMA TOXICUM NEONATORUM

This is a transient condition of unknown etiology occurring in up to 70% of neonates. The onset is from birth to 14 days but most cases start between day 1 and day 4. The commonest lesions are erythematous macules and papules but in some cases pustules appear. Lesions occur anywhere on the body surface except palms and soles but with a predilection for face and trunk. In cases present at birth, lesions are more acraly distributed and are often pustular. A peripheral blood eosinophilia is present and smears from pustules demonstrate sheets of eosinophils. The condition usually resolves in 2–3 days but, rarely, may persist for several weeks.

Recognition of this entity is important to avoid unnecessary investigations of serious neonatal infections.

### TRANSIENT NEONATAL PUSTULAR DERMATOSIS

This is a benign condition in which superficial pustules are present at birth; it is rare for further lesions to develop postnatally. The pustules rupture within 24 h, developing a brown crust that separates after a few days to leave normal skin or a hyperpigmented macule in dark-skinned individuals. Lesions occur mainly on chin, upper anterior trunk, lower back and buttocks. They are asymptomatic and the infant is otherwise well. Lesions are sterile on culture enabling differentiation from important neonatal infections. If hyperpigmented macules occur, they resolve over 3–4 months.

### ACROPUSTULOSIS OF INFANCY

This is a benign condition of unknown etiology occurring in otherwise healthy infants. The onset is usually in the neonatal period but may be delayed for some months. Recurrent crops of papules which quickly evolve into 2–4 mm vesicopustules occur, most commonly on the palms and soles and dorsa of hands and feet. Initially each crop takes 1–2 weeks to settle and new crops occur every 2–3 weeks. As time goes on the crops occur less frequently and the episodes are less severe and of shorter duration. Lesions are pruritic and finally resolve by 2–3 years.

The disease must be differentiated from other neonatal pustular conditions including herpes simplex, impetigo, scabies and candidiasis. Cultures of the lesions of infantile acropustulosis are sterile. A clinically identical condition can occur also as a postscabetic reaction in infants who have been successfully treated for scabies.

Topical therapy is usually ineffective. Oral antihistamines can be used if pruritus is severe.

### MILIA

These represent retention cysts of the pilosebaceous follicles. They occur in approximately 50% of neonates as firm pearly white 1–2 mm

Table 30.5 Hereditary photosensitivity disorders

	Xeroderma pigmentosa	Bloom syndrome	Cockayne syndrome	Rothmund–Thomson syndrome	Erythropoietic protoporphyria	Congenital erythropoietic porphyria (Gunther disease)
Inheritance	AD	AR	AD	AR	AD	AR
Cutaneous features	Freckling initially, telangiectasia, spider nevi (angioma), subsequently atrophic hypopigmented guttate macules	Reticulate telangiectasia at sun-exposed sites. More than 50% have variable numbers of café-au-lait macules	Scaling and erythema at sun-exposed sites. Subsequently hyperpigmentation and atrophy	Mild photosensitivity only. Poikiloderma of cheeks and hands. Hyperkeratosis of palms and soles in adults	Relatively mild photosensitivity. Burning sensation after exposure to sunlight. Subsequently small scars on nose and cheeks	Severe photosensitivity in infancy. Blistering. Pink urine and brown discoloration of teeth. Hypertrichosis
Other features	Photophobia, conjunctivitis. Short stature, hypogonadism, microcephaly, mental retardation, deafness, ataxia	Dwarfism, hypogammaglobulinemia	Dwarfism. Disproportionately large limbs. Delayed psychomotor development. Optic atrophy, retinal degeneration and progressive deafness	Short stature. Sparse hair, cataracts, hypogonadism	Gallstones and hepatic cirrhosis	
Molecular defect	Defective DNA repair mechanisms	Chromosomal breakage disorder	Pathogenesis unknown	Mutations in RECQL4	Ferrochelatase deficiency	Uroporphyrinogen III synthase deficiency
Malignancy risk	Cutaneous melanoma and non-melanoma skin cancers	Cutaneous squamous cell carcinoma, leukemia, lymphoma, nephroblastoma		Cutaneous squamous cell carcinoma		
Other			Mean age of death 12 years due to renal failure, infections, neurological complications		Diagnosis confirmed by raised erythrocyte protoporphyrin. Beta-carotene may be helpful treatment	Diagnosis confirmed by elevated porphyrins in erythrocytes, urine and feces. Fatal outcome usually by second or third decade due to anemia, hepatic or renal failure. Successful cure following bone marrow/stem cell transplant

AD, autosomal dominant; AR, autosomal recessive.

papules particularly on the face. They usually disappear by 4 weeks of age. Epstein's pearls are epidermal cysts on the palate present in the majority of newborns. Persistent milia may be a marker for certain syndromes including Bazex syndrome, orofaciocigital syndrome type I and Marie – Unna hypotrichosis.

### MILIARIA (PRICKLY HEAT)

This is a sweat retention phenomenon common in young infants. Unlike the equivalent condition in older persons it can occur in the absence of fever or significant occlusive factors. An obstruction of unknown etiology occurs within the intraepidermal portion of the eccrine sweat duct with retention of sweat behind the block. Lesions commence as red macules on which are superimposed 2–3 mm papules, vesicles or pustules (Fig. 30.22). Secondary infection can occur but most commonly these pustules are sterile. Characteristically the pattern and severity of the condition alter significantly from day to day enabling differentiation from infantile acne and infective conditions. Lesions occur most commonly on the face but scalp, neck and upper

trunk are other common sites. The condition is also prone to occur under plastic napkins and napkin covers.

Management involves keeping the child as cool as practicable and avoidance of contact with non-porous materials such as nylon and plastic, and of occlusive topical agents. The parents should be reassured that this is a transient condition and is uncommon after 6 months of age.

### SUBCUTANEOUS FAT NECROSIS OF THE NEWBORN

This is a necrosis of subcutaneous fat in the newborn probably induced by ischemia. It occurs usually in healthy full-term infants. Often, however, there is a history of a difficult labor and delivery with such complications as prolonged labor, fetal distress, perinatal asphyxia due to meconium aspiration or other cause and forceps delivery. The condition has also been reported in several cases following hypothermic cardiac surgery.

The lesions appear between the second and third weeks of life as non-tender, firm, skin-colored or red–purple nodules or plaques occurring particularly on buttocks, shoulders, upper back, proximal limbs and cheeks. New nodules may develop over several weeks. They usually disappear

Fig. 30.22 Pustular miliaria (prickly heat).

spontaneously without complication in several months leaving no trace. However, sometimes they become fluctuant, ulcerate or calcify.

Metabolic complications include hypercalcemia, hypoglycemia, thrombocytopenia, anemia and hypertriglyceridemia. Fluctuant lesions should be aspirated, secondary infection should be dealt with if it complicates ulcerated lesions, and serum calcium levels should be monitored, particularly in the presence of calcified lesions, for up to 6 months. Otherwise management involves observation and reassurance.

### CUTIS MARMORATA (CONGENITAL LIVEDO RETICULARIS)

This term usually refers to a transient benign physiological vascular reaction occurring in both premature and full-term infants as a response to minor cooling. A blue or purple discoloration in a marbled or reticulate pattern occurs on trunk and limbs. It lasts minutes to hours but reverses quickly on warming the infant. The tendency to the condition lasts for weeks or months.

There are a number of important conditions which may be associated with more severe and persistent cutis marmorata. These include Down syndrome, trisomy 18, homocystinuria, de Lange syndrome, neonatal lupus and congenital hypothyroidism. A nevus vascular disorder, cutis marmorata telangiectatica congenita (CMTC), presents with reticulate purple lesions but the distribution is often segmental rather than generalized and atrophy and ulceration may occur in the affected areas. Musculoskeletal, neurological and vascular anomalies may be seen with CMTC.<sup>31</sup>

### HARLEQUIN COLOR CHANGE

This vascular phenomenon is probably caused by an immature autonomic regulatory mechanism. It does not indicate any significant neural or vascular abnormality. When the neonate lies on one side the lower half of the body is red and the upper half is pale with a clear midline separation. This color change is transient and can be reversed by altering the infant's position. It is rarely seen after the first few days of life.

### INFANTILE ACNE

This condition commences at about 3 months of age with lesions particularly on the cheeks. Open comedones predominate but closed comedones,

papules, pustules and even cysts can occur. Deeper lesions may produce significant scarring. Untreated the condition usually lasts 2–3 years. In patients with a strong family history of acne the condition may be more severe and there may be difficult acne at puberty. Hormonal abnormalities are rarely found in these patients and investigation is indicated only in cases which are unusually severe, prolonged or unresponsive to therapy. Most patients with mild acne respond well to topical therapies (benzoyl peroxide, erythromycin or retinoids). Oral antibiotics (erythromycin or trimethoprim) may be required for moderate/severe cases. Isotretinoin has also been successfully used in severe cases.

## INFECTIONS AND INFESTATIONS OF THE SKIN

### VIRUS INFECTIONS

#### Herpes simplex

Herpes simplex virus (HSV) infections are extremely common in children, and serological studies confirm that more than 90% of the population have been infected by adulthood (Fig. 30.23). The commonest type is HSV1, though HSV2 is more important in adulthood, being the cause of genital herpes. Four distinct presentations are recognized in childhood.

#### *Neonatal herpes simplex virus infection*

This is a potentially devastating infection usually contracted during delivery from infected vaginal secretions (HSV2) (Fig. 30.24). However, intrauterine and postnatal infection may occur. Approximately 50% of infected infants have skin lesions which are manifested as grouped blisters localized initially on the presenting part, usually the head, with the onset usually between the 4th and 8th days of life. The eruption may

Fig. 30.23 Perineal herpes simplex.

Fig. 30.24 Neonatal herpes on scalp.

become widespread with individual lesions a few millimeters across coalescing to produce large erosions. A rapid immunofluorescence test on material from the blister base enables a diagnosis within a few hours. Culture of the virus takes several days. A rising titer of complement-fixing antibodies can be demonstrated comparing acute and convalescent sera.

The child with cutaneous neonatal herpes should be assessed urgently for the presence and extent of other organ involvement. Immediate treatment with intravenous aciclovir is indicated.

### **Primary herpetic gingivostomatitis**

This is a common presentation of HSV infection in children (Fig. 30.25). The child is systemically unwell with a high fever and there is severe swelling, erosion and bleeding of the gums and the anterior part of the buccal mucosa. Posterior spread is rare but anterior spread to the lips and the facial skin often occurs. There may be considerable soft tissue swelling and prominent lymphadenopathy. The condition is extremely painful and the child often refuses to eat or drink, necessitating parenteral fluids as the condition may take up to 2 weeks to resolve. Oral antibiotics may be required for secondary bacterial infection. Unless the condition is very severe systemic antiviral therapy is not usually required.

### **Recurrent herpes simplex (herpes labialis)**

Recurrent herpes simplex of the face, particularly around the lips (herpes labialis), is common in childhood. As in adults various factors, including fever and sun exposure, may reactivate the virus. Saline bathing of the lesions speeds resolution and prevents secondary infection. Topical antiviral agents are of limited value.

### **Disseminated herpes simplex (eczema herpeticum)**

This occurs as a complication of atopic eczema and in immunosuppressed patients (Fig. 30.26). It may originate from a primary or recurrent infection, or from external reinfection. Spread is both on the surface of the skin and also by hematogenous dissemination. The lesions are vesicles or pustules 2–4 mm across which may spread with alarming rapidity and have a tendency to coalesce to produce extensive punched-out lesions. Topical steroids should be avoided as their application may spread the virus. Secondary bacterial infection should be treated with oral antibiotics. In most cases systemic aciclovir is indicated. Minor recurrences of HSV infection are seen in up to 20% of cases.

### **Varicella (chickenpox)**

Chickenpox (Ch. 28) is caused by the same herpes virus which produces herpes zoster/shingles (the varicella zoster virus). The incubation period is from 9 to 23 days (mean 14–17 days). After a prodrome of 2–3 days a vesicular eruption develops at the sites of erythematous papules. They appear in crops over 2–4 days, initially on the trunk then face and limbs. Vesicles are often seen in the mouth and occasionally affect other

Fig. 30.25 Perioral herpes simplex.

Fig. 30.26 Disseminated herpes simplex (eczema herpeticum).

mucous membranes. Pruritus and pyrexia are variable and resolution takes a little over 2 weeks. Complications (encephalitis, pneumonitis and hepatitis) are rare in otherwise healthy children and routine use of aciclovir is not recommended. A live attenuated vaccine is licensed for prophylactic use in North America.

### **Herpes zoster**

This usually occurs when the virus, which has remained dormant in the cells of dorsal root or cranial nerve ganglia following an attack of chickenpox, reactivates, replicates and spreads along the nerves from these ganglia to infect areas of skin supplied by them (Fig. 30.27). Herpes zoster is much less common in children than in adults but it may occur as early as the first year of life. In children who develop zoster in the first 2 years of life there is rarely a history of previous chickenpox in the child but often a history of maternal chickenpox during pregnancy.

Herpes zoster presents as a segmental blistering eruption on an erythematous base. Usually a single dermatome is affected but spread to

Fig. 30.27 Herpes zoster.

one or two adjoining dermatomes may occur. The eruption is essentially unilateral though there may be minor spread to the opposite side on the trunk or brow. Up to 20 or 30 scattered lesions identical to chickenpox commonly occur. Infection involving the ophthalmic division of the 5th cranial (trigeminal) nerve may produce keratitis and uveitis, threatening vision. An important cutaneous sign of potentially dangerous herpes zoster ophthalmicus is blisters on the nose indicating involvement of the nasociliary branch. Blisters in the oral cavity occur with involvement of maxillary and mandibular divisions of the trigeminal nerve. Anogenital blistering and sometimes disorders of urination and defecation occur with involvement of sacral nerves. Scarring and postherpetic neuralgia are rare complications in children.

### Management

This is directed at providing symptomatic treatment with wet compresses and appropriate analgesia, and dealing with any secondary bacterial infection. Early ophthalmological consultation is essential for ophthalmic zoster patients. Intravenous aciclovir is indicated in very severe cases, particularly of ophthalmic zoster and for all immunosuppressed patients.

### Molluscum contagiosum

This is a poxvirus infection which is rare under 1 year of age and occurs particularly in the 2–5-year age group (Fig. 30.28). Outbreaks may occur among children who bathe or swim together and in the adolescent age group sexual transmission becomes important. The typical lesion is spherical and pearly white with a central umbilication, but they may vary from tiny 1 mm papules to large nodules over 1 cm in diameter. They occur on any part of the skin surface with common sites being the axillae and sides of the trunk, the lower abdomen and anogenital area. Rarely they occur on the eyelids where they may cause conjunctivitis and punctate keratitis. A secondary eczema often occurs around lesions, particularly in atopics, and scratching of this spreads the mollusca. Hundreds of lesions may be present in an individual patient. Secondary bacterial infection may occur producing crusting, erythema and sup-puration. However, these same changes may be seen during spontaneous resolution which occurs in most within 6–9 months leaving normal skin or small varicelliform scars.

### Management

With multiple small lesions in a young child spontaneous resolution should be awaited. No controlled trials exist for treatment of mollusca in childhood. However cryotherapy after application of anesthetic cream, topical therapy with salicylic acid, podophyllotoxin, cantharidin and more recently imiquimod or cidofovir have all been reported with variable success. Physical extrusion of the contents of larger lesions can also be undertaken and is usually best after anesthetic cream application. Up

Fig. 30.28 Molluscum contagiosum.

to 10% of cases develop eczema around the lesions which resolves when the mollusca clear. Spontaneous regression may be associated with secondary bacterial infection requiring a topical antibiotic.

### Warts

Warts are benign tumors caused by infection with a variety of human papilloma viruses. The common wart (*verruca vulgaris*) occurs particularly at sites of trauma such as hands, feet, knees and elbows. Plane or flat warts, 1–3 mm pink or brown barely raised papules, occur on the face and often spread along scratch marks or cuts. Plantar warts occur particularly over pressure points on the soles and can be differentiated from calluses by a loss of skin markings over the skin surface. Unlike corns or callosities they tend to be painful on lateral pressure. Warts at mucocutaneous junctions often have a filiform or fronded appearance. Anogenital warts may be acquired from maternal infection during delivery, but their presence should always raise the suspicion of sexual abuse (Fig. 30.29).

### Management

Various forms of treatment are available: they depend on the area, the type of wart and the age of the patient. Because spontaneous disappearance is common, aggressive treatment is usually inappropriate. A Cochrane review<sup>32</sup> of local treatments for cutaneous warts shows that there is very little good evidence on which to determine best practice. The best available evidence was for the use of topical salicylic acid preparations. Perhaps surprisingly cryotherapy was not found to be superior. Other currently used topical agents include glutaraldehyde and formaldehyde preparations. Podophyllotoxin is less irritant than podophyllin but both can be used for isolated anogenital warts. Facial plane warts may respond to retinoic acid preparations. Caution or diathermy is useful for lesions on the lips or anogenital area but elsewhere recurrence is fairly frequent following their use and there is also a risk of producing a painful scar. The initial favorable response to oral cimetidine has not been replicated in double-blind placebo-controlled trials.<sup>33</sup>

### Papular acrodermatitis of childhood (Gianotti–Crosti syndrome)

Papular acrodermatitis of childhood was first described by Gianotti as an acraly distributed papular eruption occurring in young children due to the hepatitis B virus (Fig. 30.30). However, a similar eruption may occur with over a dozen different viruses and the condition is best regarded as a reaction pattern with multiple etiologies.<sup>34</sup>

This pattern of exanthem occurs particularly in children between 1 and 4 years of age. The rash comprises discrete firm red papules 1–5 mm in diameter, sometimes surmounted by vesicles. Pruritus is variable but not usually a significant feature. The lesions involve the limbs, particularly distally, and the face, with the trunk being essentially spared. The

Fig. 30.29 Perianal warts.

Fig. 30.30 Papular acrodermatitis of childhood.

rash fades within 3–4 weeks. Lymphadenopathy is usually present but the child is often otherwise remarkably well, leading to such misdiagnoses as insect bites and papular eczema.

Investigation should be aimed at excluding the more serious viral etiologies.

### Pityriasis rosea

Epidemiological studies suggest a viral origin, now thought to be human herpes virus 7. It occurs in children and young adults and has no sexual or racial predilection (Fig. 30.31).

The eruption commences with the appearance of the so-called herald patch, typically a single round or oval scaly lesion 1–5 cm in diameter, flat or slightly raised with a tendency to clear in the center. It usually occurs on the trunk, neck or proximal limbs. Some 5–15 days later the secondary eruption appears comprising multiple, variably pruritic, dull pink, oval macules with a peripheral collarette of scale. The typical distribution is on trunk and proximal limbs but may be very extensive. The long axis of the lesions on the trunk runs parallel with the ribs giving

Fig. 30.31 Pityriasis rosea (herald patch).

a 'Christmas-tree' pattern. Rarer variants have lesions which are papular, urticarial, vesicular, purpuric or pustular but some of the typical lesions are usually intermingled. Lesions crop at 2–3 day intervals for 7–10 days and then spontaneous resolution occurs over several weeks. Sun exposure may speed this resolution and meanwhile symptomatic therapy can be used for the pruritus if this is troublesome.

### BACTERIAL INFECTIONS

Staphylococcal and streptococcal infections of the skin are common in childhood. They take the following clinical forms:

#### Impetigo

This is a bacterial infection caused by *Staphylococcus aureus*, group A beta-hemolytic streptococcus (GABHS) or a combination of these organisms (Fig. 30.32). Recently there has been a worldwide increase in the predominance of staphylococci in the causation of impetigo.<sup>35,36</sup> An increasing proportion of *S. aureus* isolates are resistant to meticillin (MRSA).

Impetigo occurs in two forms, bullous and more commonly non-bullous (or crusted). Bullous impetigo (Fig. 30.33) is always due to staphylococci. Blisters arise on previously normal skin and increase rapidly in size and number, soon rupturing to produce superficial erosions with a peripheral brown crust. The erosions continue to expand, sometimes clearing centrally to produce annular lesions. The condition is usually neither itchy nor painful. Non-bullous impetigo may be due to either organism or to a combination. The lesions begin with a small transient vesicle on an erythematous base. The serum exuding from the ruptured

Fig. 30.32 Impetigo.

Fig. 30.33 Bullous impetigo.

vesicle produces a thick soft yellow crust, below which there is a moist superficial erosion. The lesions extend slowly and remain much smaller than those of bullous impetigo. Impetigo is often superimposed on other skin diseases such as insect bites, scabies, pediculosis and atopic eczema. As impetigo is an intraepidermal infection, the condition does not scar although postinflammatory pigmentation can occur, particularly in dark-skinned patients.

### Management

Impetigo is very contagious and the patient should, if possible, be isolated. A swab for culture and sensitivity testing should always be taken. Topical mupirocin is as successful as oral erythromycin in eradicating both *S. aureus* and GABHS<sup>37</sup> and a double-blind study has shown hydrogen peroxide cream to be as effective as topical fusidic acid.<sup>38</sup> However, topical therapies will not eradicate bacteria on clinically uninvolved skin and therefore in general oral antibiotics should be used. Because of the rarity in most areas of pure streptococcal impetigo, a penicillinase-resistant penicillin or erythromycin is the treatment of choice while awaiting culture results. In many areas of the world there is an emergence of erythromycin-resistant staphylococci<sup>35,39</sup> and knowledge of the local situation is important in selecting the antibiotic of first choice while awaiting sensitivity testing. Underlying diseases should be sought and treated appropriately if the pattern of impetigo suggests them. If a group A streptococcus is isolated the patient should be watched for 8 weeks for signs of glomerulonephritis.

### Folliculitis

Superficial bacterial folliculitis is common in children. It is characterized by inflammation confined to the opening of the hair follicle whereas furuncles or boils are cutaneous abscesses, centered around usually ruptured hair follicles. Both are caused by a wide variety of types and strains of *S. aureus* and predisposing factors are occlusion (e.g. overuse of very greasy emollients), friction, maceration and sweating. Patients with recurrent attacks are often found to carry the strains of *S. aureus* in their nose, axillae or perineum, or to be in close contact with another person who is a carrier. Folliculitis commences with perifollicular erythema with pustule formation that often ruptures to form a crust. Pruritus is common. Boils are larger, firm erythematous papules that evolve into fluctuant pus-filled nodules with central necrosis (pointing) and discharge.

Mild folliculitis is often self-limiting but can be treated with topical antiseptics. If the infection is persistent or recurrent, topical or oral anti-staphylococcal antibiotics should be given. Swabs should first be taken for culture from affected as well as *S. aureus* carriage sites. If necessary, other carriers who are in close contact should be identified and treated.

### Cellulitis

This is an acute bacterial infection involving the subcutis as well as the dermis. The lesion is erythematous sometimes with a purple or blue hue. It is warm and tender and has a less well-defined edge than erysipelas. Fever and malaise, leukocytosis and lymphadenopathy are usually present. When cellulitis follows a wound or other break in the skin, group A beta-hemolytic streptococcus is the commonest cause. Other organisms involved in cellulitis include *Haemophilus influenzae*, *Streptococcus pneumoniae*, *S. aureus* and *Pseudomonas aeruginosa*. Two special forms are discussed below.

#### Perianal streptococcal disease

This occurs in children between 1 and 10 years of age (Fig. 30.34). The child may complain of painful defecation or pruritus. Fresh blood is often found on the stool. There is a well-demarcated, very bright red erythema extending out several centimeters from the anus. The anal rim is often macerated and fissured. GABHS is grown from the skin and often also from the patient's throat. The condition may be surprisingly resistant to therapy, recurring after 5–10 days of oral penicillin therapy: an initial course of at least 14 days is advisable. The addition of topical mupirocin may further reduce the risk of recurrence.<sup>40</sup>

Fig. 30.34 Perianal streptococcal disease.

#### Facial cellulitis

Facial cellulitis in young children often occurs in the absence of any break in the skin and is due to *H. influenzae* or *S. pneumoniae* accompanying an upper respiratory tract infection or otitis media. Cellulitis due to these bacteria often has a lilac-blue color. The condition may be complicated by bacteremia, septicemia and meningitis. In all cases of facial cellulitis cultures should be taken from nasopharynx, ears, blood and, if indicated, cerebrospinal fluid. Needle aspiration from the lesion after saline injection may provide material from which the organism can be cultured.

Intravenous cefotaxime, a third generation cephalosporin, is the initial treatment of choice until an organism is identified and sensitivity tests performed.

#### Erysipelas

This is an acute bacterial infection of the dermal connective tissue and superficial lymphatics caused most often by GABHS but occasionally due to other streptococci, *H. influenzae* and *S. aureus*. A brightly erythematous, hot, tender area with a rapidly spreading distinct edge develops. Superimposed bullae may occur. There is accompanying fever and malaise and a leukocytosis. Predisposing factors include lymphatic obstruction and a break in the skin due, for example, to a wound, bite or tinea infection. The episode produces a lymphangitis which further damages the lymphatics, and chronic lymphedema may result from and further predispose to recurrent erysipelas. Treatment involves rest and high doses of the appropriate antibiotic, usually phenoxymethylpenicillin (penicillin V), orally or intravenously depending on the severity.

#### Staphylococcal scalded skin syndrome

##### Pathogenesis

The staphylococcal scalded skin syndrome (SSSS) is a widespread blistering disease caused by an epidermolytic toxin produced by certain strains of *S. aureus*, most often of phage group II, but occasionally phage group I or III (Figs 30.35 and 30.36). This toxin produces a superficial splitting of the skin with the level of split being high in the epidermis. Clinical disease occurs when there is sufficient toxin load produced from an infection with these organisms. The commonest sites of infection are the umbilicus (in neonates), the nose, nasopharynx or throat, the conjunctiva and deep wounds.

The condition commences with a macular erythema initially on the face and in the major flexures and then becoming generalized. The skin is exquisitely tender and the child draws back from contact. After 2 days flaccid bullae develop and the skin wrinkles and shears off. The exfoliation is most marked in the groin, neck fold and around the mouth and may involve the entire body surface but mucosae remain uninvolved. The child is usually febrile but because of the superficial level of the split fluid loss is rarely significant. The erosions crust and dry and heal with desquamation over the next 4–8 days leaving no sequelae.

Fig. 30.35 Staphylococcal scalded skin syndrome.

Fig. 30.37 Tinea.

Fig. 30.36 Staphylococcal scalded skin syndrome.

### Diagnosis

Cultures from skin and blister fluid are usually negative. Cultures should be obtained from any area of obvious infection but, if none is apparent, from nasopharynx and throat. The most important differential diagnosis is toxic epidermal necrolysis (TEN). In TEN the split is subepidermal and the blisters and erosions are usually hemorrhagic and mucosae are commonly involved. Microscopy of frozen or Giemsa-stained sections of the blister roof can detect the level of the split in the two conditions. Other conditions from which SSSS must be differentiated are scarlet fever, Kawasaki syndrome and toxic shock syndrome, all of which show mucosal involvement and rarely demonstrate frank blistering.

### Management

The child should be nursed with as little handling as possible. No topical agents should be applied. A penicillinase-resistant penicillin is the treatment of choice and should be given orally if possible. Insertion and securing of an intravenous line is very painful in these patients and should be performed only if oral antibiotics are refused or if rehydration is required in a child refusing oral fluids. Analgesia is often necessary in the early stages. Emollients are useful once the skin dries and desquamation commences.

## FUNGAL INFECTIONS

### Tinea

This is an infection due to dermatophyte fungi: the source of the fungus is an animal (e.g. dog, cat, guinea pig, cattle), the soil or another human (Fig. 30.37). Tinea occurs on any part of the skin surface and can involve hair and nails.

The classical features of tinea on the skin are itch, erythema studded with papules or pustules, annular or geographical lesions ('ringworm') with a tendency to central clearing and a superficial scale. Family members or pets are the usual source of infection. On the palms and soles erythema and increased skin markings may be the only signs. Between the toes maceration with a thick white scale is the main finding and an annular lesion may extend onto the dorsum of the foot. On the soles there are deep seated blisters or pustules which dry to produce brown crusts. Tinea is often unilateral and always asymmetrical, whereas eczema and psoriasis, which it may resemble, are often symmetrical in distribution. Nail tinea (onychomycosis) is uncommon in children but increases with age.

In the UK the principal dermatophytes causing tinea capitis are *Microsporum canis* and *Trichophyton tonsurans*. Both cause a combination of alopecia and inflammation with the hair loss being due to breakage of hair shafts. The inflammation varies from mild erythema and a fine dandruff-like scale to a pustular carbuncle-like lesion (kerion), which occurs most commonly with *Trichophyton* species. Other causes of alopecia to be differentiated from tinea are trichotillomania (q.v.) and alopecia areata (q.v.). Bright green fluorescence is seen under Wood's (ultraviolet) light in *Microsporum* infection of the scalp. Other varieties of scalp tinea produce no typical fluorescence and the Wood's light has no place in the diagnosis of tinea on the skin surface. The diagnosis of tinea is confirmed by plucking hairs or scraping scales. The fungus can be cultured on appropriate media.

Topical antifungals may be satisfactory for small localized patches of tinea on the skin. Griseofulvin is the only antifungal licensed for oral treatment in children. It is effective against dermatophytes but in general a 3 month course is used with longer courses for nail tinea. Terbinafine is not yet licensed for children but a number of published studies have shown it to be safe and effective for tinea capitis.<sup>41</sup>

### Candidiasis (moniliasis)

This is due to a yeast, *Candida albicans*. It occurs on both skin and mucosal surfaces and certain factors predispose to its establishment (Fig. 30.38). General predisposing factors in children include drug therapy with broad spectrum antibiotics, corticosteroids and immunosuppressives, diabetes and any disease which interferes with immunological competence. Local predisposing factors are particularly those which create a warm moist environment. Flexural areas are susceptible, especially in the presence of sweating, obesity and other skin disease. The oral mucosa in infancy also has a particular susceptibility to this infection which is usually acquired during passage through an infected birth canal.

On the general body skin, where candidiasis rarely occurs except in the presence of immunodeficiency, the infection is manifested by small round erythematous lesions with a peripheral overhanging scale.

Fig. 30.38 Candidiasis.

Occasionally small papules or superficial pustules occur, especially in the neonate. In flexural areas the typical picture is of a cheesy white material deep in the folds and satellite lesions with the typical peripheral scale. On mucosae a curd-like white material is superimposed on a red base. Acute or chronic paronychia may be seen, particularly in children that suck their fingers.

Chronic mucocutaneous candidiasis is a progressive candidal infection occurring in patients who have an inability to destroy candida due to a severe general immunodeficiency or due to a specific immunological defect. A variety of endocrinopathies may be associated with this syndrome.

The diagnosis of candidiasis is usually a clinical one which may be confirmed by microscopy and culture. *Candida* is frequently a secondary invader rather than a primary cause of skin disease and local and general predisposing factors should be eliminated. Once predisposing factors have been eliminated most localized infections respond well to topical agents including polyene antibiotics, nystatin and imidazole derivatives. Reduction of intestinal carriage with oral preparations is rarely necessary. Oral ketoconazole is useful in chronic mucocutaneous candidiasis and other candidal infections in the immunosuppressed.

### Pityriasis versicolor

This is an infection with *Malassezia* yeasts (*Pityrosporum* species) which are part of the normal skin flora. It occurs mainly in tropical and temperate zones and usually affects adolescents and young adults. It presents as well-demarcated, asymptomatic or slightly itchy macules with a fine branny scale which is often only obvious on light scratching of the lesions. Primary macules 1–10 mm in diameter coalesce into larger patches. They occur in two colors, red–brown especially in the fair skinned and hypopigmented in darker skinned. In a partially tanned individual, lesions of both colors may be found. In young children, unlike adults, approximately 30% present with only facial lesions.<sup>42</sup>

Diagnosis is confirmed by microscopic examination of skin scrapings to which 20% potassium hydroxide has been added. Grape-like clusters of spores and short fragments of thick mycelia are seen. In its hypopigmented forms the condition must be distinguished from: (a) vitiligo, where the depigmentation is total and scale absent; (b) pityriasis alba, where lesions are less well demarcated and some erythema may be seen; and (c) tuberculoid leprosy which is accompanied by anesthesia in the hypopigmented areas. The red-brown form has to be differentiated from seborrheic dermatitis, tinea and psoriasis, all of which lack the very fine branny type of scale.

Untreated the condition is persistent though some improvement may occur in winter. Various treatments are available. The treatment of choice is with topical imidazole creams. Alternatively two overnight applications of 2.5% selenium sulfide may be effective in the short term

but relapse is frequent. With the depigmented form, whatever therapy is used, sun exposure is required for full repigmentation.

## ECTOPARASITIC INFESTATIONS

### Scabies

This is due to *Sarcoptes scabiei*, an eight-legged, oval-shaped mite less than 0.5 mm in length. The disease is transmitted by close physical contact.

A small number of mites burrow into the skin in certain sites, particularly between the fingers, the ulnar border of the hand, around the wrists and elbows, the anterior axillary fold, nipples and penis and, in infants, the palms and soles. The pathognomonic primary lesion, a typical burrow, is a 2–3 mm long curved gray line with a vesicle at the anterior end. Other lesions which mark the sites of burrows are small blisters or papules, larger blisters on the palms and soles of infants, scratch marks, secondary eczema and secondary bacterial infection. Eczema or impetigo in the target areas for scabies should always raise suspicion of this disease as should blisters on the palms and soles of infants.

Often more prominent than the evidence of burrows is the so-called secondary eruption of scabies. This presents as multiple, very pruritic, urticarial papules which are soon excoriated (Fig. 30.39). They occur particularly on the abdomen, thighs and buttocks. Young children may show a striking dermatographism in the areas of scratch marks. When dermatographism occurs in the first year of life scabies should always be suspected. Large inflammatory nodules may form part of the secondary eruption, occurring particularly on covered areas especially axillae, scrotum, penis and buttocks. They may, however, be very widespread producing diagnostic difficulties. They may persist for months after effective scabies treatment.

The diagnosis of scabies is usually a clinical one but can be confirmed by demonstration of the mite. A burrow is scraped and the material smeared on a slide with potassium hydroxide for microscopic examination. Burrows may be more easily identified by rubbing a thick black marking pen over suspicious areas and wiping with an alcohol swab leaving a burrow outlined with ink.

### Management

The patient and all close contacts should be treated simultaneously. The treatment of choice is 5% permethrin cream<sup>43,44</sup>; it should be applied to

Fig. 30.39 Scabies.

all body surfaces from the neck down and left on overnight. A repeat application should be administered after 1 week. Bedclothes and clothing should be washed in the normal way. An irritant dermatitis may follow scabies treatment, particularly in atopics, and may require emollients and topical steroids once the miticide therapy is fully completed. Persistent nodules may respond to topical corticosteroids and families should be warned that it can take up to 3–4 weeks before the pruritus subsides.

### Pediculosis (lice)

Human lice are ectoparasites dependent on man for survival. They are wingless six-legged insects, gray – white in color or red – brown when engorged with blood. The head louse (*Pediculus humanus capitis*) and the body louse (*Pediculus humanus humanus*) have a 24 mm long slim body and three similar pairs of legs. The pubic louse (*Phthirus pubis*, crab louse) has a wider, shorter body 12 mm long and the second and third pairs of legs are larger than the first, producing a crab-like appearance. The nits or ova are seen as oval gray – white 0.5 mm specks firmly attached by a chitinous ring to hairs or clothing.

#### *Pediculosis capitis*

This is a very common infection, occurring in epidemics amongst schoolchildren. The infestation is most severe in and may be confined to the occipital area. It is very itchy and excoriations are seen but secondary eczematization and bacterial infection may mask the condition. Nits may be differentiated from epidermal scales and hair casts by their firm attachment and by fluorescence with a Wood's light. Occasionally the head louse infects the eyelashes in children (Fig. 30.40).

#### *Pediculosis corporis*

This is rare in children except in conditions of overcrowding and poor hygiene. The louse infects bedding and seams of clothing and nits are not found on the human. With body warmth the pediculi hatch and puncture the skin to produce small urticarial papules with hemorrhagic puncta. Pruritus is extreme and scratch marks are the main clinical sign.

#### *Pediculosis pubis*

The pubic hairs are the normal habitat of *Phthirus pubis* but it may also infect facial hair, eyelashes, general body hair and rarely the frontal margin of the scalp. Pubic infestation is usually sexually transmitted but bedding and towels may be responsible. Clinical signs may be minimal, even with severe itching, but excoriated papules and flat blue macules containing altered blood pigment may be seen as may evidence of secondary infection or eczematization. Eyelash infestation in children may occur from innocent close contact with an infected adult but the possibility of sexual abuse must always be considered.

Fig. 30.40 Pediculosis of eyelid.

### Management of pediculosis

The management of pediculosis corporis involves removing the infestation from clothing with hot water laundering, hot electric drying, hot ironing or dry cleaning.

Permethrin shampoo is an effective pediculocide for scalp infestations but the efficacy as an ovicide is less certain and repeat application after a few days is recommended. Removal of nits with a fine comb can be facilitated by prior wrapping of the scalp for 1–2 h in a towel soaked in vinegar which softens the chitin.

Pediculosis pubis is treated with 5% permethrin cream applied for 12 h to all hairy areas in the anogenital region, repeated after 1 week. Sexual contacts should be treated simultaneously and all underclothing appropriately laundered.

Pediculosis of eyelashes is best treated with petroleum jelly applied thickly twice a day for a week.

## URTICARIA AND ERYTHEMAS

### URTICARIA

The most characteristic feature of urticaria (nettle rash or hives) is its transience. Erythematous swellings develop in the skin and last for a few hours before disappearing. The urticarial wheals may be of variable size and may have an obvious annular configuration. Angioedema (giant urticaria) is a variant of urticaria which affects the face and genital region and mainly involves the subcutaneous tissues with resultant gross swelling of the tissues.

Urticaria is common in all age groups, and is particularly so in children. In children, widespread urticaria is often the presenting feature of a number of viral infections, when it is accompanied by fever and malaise. It is due to increased permeability of capillaries or other small vessels, with resultant transudation of fluid. Several chemical mediators are involved, which are mainly released from mast cells: these include histamine, prostaglandins and leukotrienes. Mast cell degranulation results from both immune (IgE, complement) and non-immune mechanisms.

#### IgE-mediated urticaria and angioedema

Urticaria and angioedema following ingestion of food allergens is quite common in children with atopic eczema and is often IgE mediated (confirmed by positive skin prick tests or radioallergosorbent tests). Swelling of the lips and tongue develops immediately after ingestion of the food, and contact urticaria may be seen if the food is in contact with the skin. If enough food allergen is ingested vomiting and diarrhea may occur, and the child may develop an asthmatic attack: generalized anaphylaxis may occur in a few children, especially with nuts. Widespread urticaria is common, usually occurring within 1 h of ingestion of the food, which may last for a few hours. Common foods involved in such reactions include hens' eggs, cows' milk, fish, nuts and soya. Food allergy is commonly outgrown by the age of 5 years although this is less likely for peanut and nut allergy.<sup>45</sup> IgE-mediated urticaria may also follow drug administration, particularly penicillin, and also insect stings, for example by bees or wasps.

#### Urticaria due to foods and drugs which is not apparently immunologically mediated

Certain foods such as strawberries, tomatoes and chocolate cause urticaria where no IgE-mediated mechanisms can be demonstrated. It seems likely that this is a direct effect on mast cells and is similar to that caused by tartrazine (a common coloring in foods), benzoates and salicylates. Aspirin and morphine also commonly cause urticaria by a non-immunological mechanism.

#### Chronic idiopathic urticaria

This type of urticaria is not very common in children. The urticaria may recur repeatedly for a period of years, with often daily exacerbations. It is now recognized that approximately one third of patients with chronic idiopathic urticaria have circulating histamine-releasing autoantibodies

directed against the high affinity IgE receptor or less commonly against IgE.<sup>46</sup> The detection of these antibodies, however, is available in only a small number of research laboratories.

### Papular urticaria

This is very common in children and results from insect, flea or mite bites. In Britain dog, cat and bird fleas are the usual cause, but human fleas, bed bugs, mosquitoes and dog lice may be implicated. The child presents with papules and blisters on exposed skin such as the legs and arms. Each lasts for about 7–10 days before resolving.

It often takes the parents quite a lot of convincing of the cause of the condition. The family pet should be inspected and treated if necessary.

### Treatment of urticaria

The management of a child with urticaria depends on the cause. If a food is implicated, this is usually fairly obvious, except perhaps in infants where skin prick testing may be helpful. Any food implicated should be withdrawn from the diet, though it may be possible to reintroduce it when the child is older. In chronic idiopathic urticaria, by definition no cause is found but certain ingested chemicals in foods (e.g. salicylates, benzoates, food colorings) may make it worse. A non-sedating H1 antihistamine can be given.

## MASTOCYTOSIS

This refers to a group of conditions whose signs and symptoms are due to the infiltration of tissues by mast cells and to the release of the chemical mediators contained in these cells. Local effects include erythema and swelling of lesions on rubbing (Darier's sign), dermatographism, pruritus, hemorrhage and blistering. General effects include generalized pruritus, fever and flushing; tachycardia and hypotension; headache and irritability; vomiting, diarrhea, increased salivation and peptic ulceration; rhinorrhea and bronchospasm; increased lacrimation; and a generalized hemorrhagic diathesis.

Approximately 65% of patients with mastocytosis present in childhood. A retrospective review of 173 pediatric cases confirms that mastocytomas and urticaria pigmentosa are the commonest presentations in this age group.<sup>47</sup>

### Mastocytoma

A round to oval flesh-colored to yellowish nodule or plaque usually presents at birth or appears in the first months of life (Fig. 30.41). Although it is usually solitary, some children develop a number of mastocytomas, particularly on arms or trunk. They usually regress spontaneously over a few years but while present they urticate on rubbing, and blisters, which may be hemorrhagic, often occur in infancy. These children commonly have attacks of generalized flushing but other symptoms and signs of mediator release are rare.

Fig. 30.41 Mastocytoma.

### Urticaria pigmentosa

Pigmented multiple macules, with occasional papules, nodules or plaques, occur in a widespread distribution, particularly involving the trunk (Fig. 30.42). Urticaria pigmentosa is the most common form of mastocytosis with an onset usually between 1 and 9 months of age. The lesions erupt over 1–2 months, then become static and finally in most cases resolve by adolescence. They may be pruritic and individual lesions can urticate (Darier's sign) and occasionally blister. There may be dermatographism in nearby clinically normal skin. Generalized pruritus and flushing may occur, and less frequently other signs of mediator release.

### Diffuse cutaneous mastocytosis

This is a rare form of mastocytosis with the onset usually at birth. Massive mast cell infiltration into the skin produces a diffuse thickening with associated edema, erythema and blistering. The skin may have a leathergrain or peau d'orange appearance or be nodular or verrucous. The color is yellowish or red. Blistering is prominent and may be so severe that the presentation is that of a generalized bullous disease. The full spectrum of local and systemic symptoms and signs of mediator release may be seen. These are usually severe and disabling and may be life threatening. The cutaneous lesions tend to improve with time but some degree of infiltration usually remains.

### Systemic mastocytosis

This is defined by infiltration of mast cells into organs other than the skin, and not simply systemic features due to the release of mediators from cutaneous mast cell infiltrates. It is extremely rare in childhood and is almost always associated with diffuse cutaneous involvement in this age group. Hepatosplenomegaly and lymphadenopathy may occur; the cells may infiltrate renal parenchyma and gastrointestinal mucosa; skeletal involvement produces both osteoporotic and osteosclerotic lesions. Mast cell leukemia is a very rare complication.

### Management

In general, mastocytosis is a self-limiting disease. If an isolated lesion is producing generalized flushing, excision can be considered. The patient should carry a list of agents (i.e. aspirin, morphine, codeine, d-tubocurarine, scopolamine, quinine, thiamin, procaine, polymyxin B, amphotericin B,

Fig. 30.42 Urticaria pigmentosa.

nonsteroidal anti-inflammatory drugs, and radiographic contrast media) which stimulate mast cell degranulation and avoid these where possible. Physical trauma to the lesions should be avoided.

H1 antihistamines are rarely effective in controlling symptoms and signs of mediator release but combined with H2 blockers they may be more effective. In more severe cases oral disodium cromoglicate, ketotifen and nifedipine may be tried.

A greater understanding of the underlying molecular abnormalities in the systemic mastocytoses is allowing patients to benefit from more specific therapy, for example 'kit-targeting' tyrosine kinase inhibitors.

## ERYTHEMA MULTIFORME

This is an uncommon condition in children which tends to follow herpes simplex infection, mycoplasma pneumonia and sulfonamide ingestion (Figs 30.43 and 30.44). Clinically, it is characterized by the formation of circular target lesions on the limbs, with a red periphery and blue (often bullous) center. Stomatitis and genital involvement are common. The rash of erythema multiforme, unlike urticaria, for which it is often mistaken, is fixed with lesions lasting days as compared to hours in urticaria. The lesions may be widespread, and if extensive erosions are present at two or more mucosal sites the diagnosis of Stevens–Johnson syndrome (SJS) can be made. SJS in turn overlaps both clinically and histologically with toxic epidermal necrolysis. The rash of erythema multiforme usually fades within 10 days but may recur, particularly in the case of erythema multiforme following recurrent herpes simplex infections. No randomized controlled trials have been performed for treatment of childhood erythema multiforme and there is therefore no evidence to

Fig. 30.43 Erythema multiforme, Stevens–Johnson: perineal.

Fig. 30.44 Erythema multiforme, Stevens–Johnson: oral.

recommend oral steroids. However, one double-blind placebo-controlled study in adults found benefit with continuous aciclovir in recurrent erythema multiforme.<sup>48</sup>

## VESICOBULLOUS DISORDERS

### DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is associated with gluten-sensitive enteropathy (celiac disease), and in a study of 57 children only 3 (5%) had normal jejunal biopsies.<sup>49</sup> Deposition of IgA in the dermal papillae of skin is the hallmark of the disorder.

It is rare before the age of 2 years, and presents with small intensely itchy blisters symmetrically on the elbows, knees, shoulders and buttocks. The correct treatment is a gluten-free diet, when the blisters, and small bowel mucosa, should resolve (permanently) within 2 years: concomitant treatment with dapsone or sulfapyridine is usually required.

### BULLOUS PEMPHIGOID

This rare blistering disease results from the formation of IgG antibodies to the basement membrane zone of the epidermis. The child presents with large and widespread blisters, which may (as in chronic bullous disease of childhood) be most marked on the face and around the genitalia. The hands and feet are more frequently involved in children 1 year or younger compared to older age groups. The diagnosis is confirmed by immunofluorescence of skin biopsy or serum (with appropriate substrate) to demonstrate anti basement membrane zone antibodies. Treatment is with oral steroids, which should be tapered off as the condition allows. In most the disease is self-limiting.

### PEMPHIGUS

Pemphigus is also rare in children, the most common types being pemphigus vulgaris and foliaceus. The blistering is less evident than in pemphigoid, though there may be widespread plaques and erosions. Over 50% of children with pemphigus vulgaris present with erosive stomatitis. The diagnosis is confirmed by immunofluorescence studies of skin and serum, which demonstrate IgG antibodies to the intercellular substance of the keratinocytes in the epidermis. Treatment is with oral steroids, as in pemphigoid.

### CHRONIC BULLOUS DISEASE OF CHILDHOOD

It is most commonly seen in young children, with blistering around the mouth, neck and genital regions (Fig. 30.45). Genital blistering may be mistaken for herpes simplex infection. Immunofluorescence studies of skin show linear IgA deposition along the basement membrane zone of the epidermis with evidence of circulating IgA antibodies in up to 80%.

Treatment with dapsone or sulfonamides usually clears the blisters very effectively. The disease is self-limiting, after months or years.

## VASCULITIS

Vasculitis can be classified according to the size and nature of the vessel and the infiltrate.<sup>50</sup>

### HENOCH–SCHÖNLEIN PURPURA

This is a distinct subset within the spectrum of leukocytoclastic (allergic) vasculitis that is relatively common in children (Fig. 30.46). The damage occurs to small blood vessels in the dermis, resulting in the development of purpura (often palpable) over the lower limbs, buttocks and forearms. Other organs involved in the vasculitis are the kidneys and intestinal vessels, resulting in proteinuria and hematuria, abdominal pain and gastrointestinal hemorrhage. In some arthralgia is also

Fig. 30.45 Chronic bullous disease of childhood.

Fig. 30.46 Henoch-Schönlein purpura.

prominent. It usually follows a virus or respiratory infection, the vasculitis resulting from deposition of immune complexes in the vessels of the skin, kidneys and intestines, with complement activation and resultant polymorph infiltration. In Henoch-Schönlein purpura the immunoglobulin deposited is IgA, whereas in other types of vasculitis it is IgG.

The prognosis is very variable. In most children the condition is self-limiting; others may develop renal failure (usually treatable with dialysis or renal transplant) or may die of gastrointestinal hemorrhage.

### URTICARIAL VASCULITIS

This is another variant of allergic vasculitis. The urticarial wheals last for several days, unlike those in 'classical' urticaria, where they last for a few hours. Urticarial vasculitis is often accompanied by arthralgia, and skin lesions may resolve with purpura. A skin biopsy shows leukocytoclastic vasculitis, and complement studies may reveal low CH50 and C3 levels. It may result from drug ingestion or viral infection, or may be a feature of lupus erythematosus.

### ERYTHEMA NODOSUM

This is rare in young children. It is a type of vasculitis affecting initially deep, dermal venules with subsequent development of a septal panniculitis.

Clinically, erythematous nodules develop, usually on the shins though sometimes on the thighs and forearms. They last for about 2–3 weeks and are characteristically tender. They resolve leaving bruising, but then tend to recur in crops. Causes include streptococcal infections, sarcoidosis, tuberculosis and sulfonamide ingestion: often it occurs without obvious reason. Treatment is of the underlying cause. Usually it resolves spontaneously, but occasionally treatment with oral steroids is indicated.

## ECZEMA, DERMATITIS AND PSORIASIS

Eczema and dermatitis are synonymous and are often used interchangeably. Eczema/dermatitis can be subdivided into atopic and non-atopic eczema, contact dermatitis (allergic and irritant) and other types (e.g. discoid, seborrheic, photosensitive).<sup>51</sup>

### ATOPIC ECZEMA

Atopy is a genetically determined disorder with an increased tendency to form IgE antibody to inhalants and foods (see Ch. 33). There is increased susceptibility to asthma, allergic rhinitis and atopic eczema (Figs 30.47 and 30.48). Although eczema may begin at any age, in 75% of patients first signs are present by 6 months. Recent evidence has demonstrated that abnormality of the epidermal barrier is a major predisposing factor in atopic disease through loss of function of the epidermal barrier protein filaggrin.<sup>52</sup>

### Clinical features

Diagnostic criteria have been defined for atopic eczema but the characteristic clinical features are erythema, generalized dryness and itching

Fig. 30.47 Atopic eczema: facial in young infant.

Fig. 30.48 Atopic eczema: flexural in older child.

which leads to excoriations and ultimately lichenification or thickening of the skin, particularly in children older than 2 years.<sup>51</sup> Involvement of the whole cutaneous surface may occur but the predominant areas are the face in infants, extensor aspects of the limbs as the child begins to crawl, and the limb flexures in older children. In severe cases the whole skin may be erythematous and in these patients white dermographism is often a prominent feature: this indicates that the condition is likely to be unstable and difficult.

### Complications

Patients with atopic eczema may develop secondary bacterial infection which presents either as impetigo or folliculitis, or simply as worsening eczema. Mollusca contagiosa appear more common, although there are no prevalence studies to confirm this. Atopic patients are at risk of developing severe widespread herpes simplex infections. The usual childhood immunizations are quite safe.

### Management

A comprehensive systematic review of all treatments for atopic eczema has been published.<sup>53</sup> This review summarizes the available data from all the randomized controlled trials. It is clear that although emollients and topical steroids are the mainstays of treatment there are very few objective data to recommend their use. Despite this, clinical practice suggests that they are very helpful in the management of atopic eczema.

Time should be taken in discussing factors that act as external irritants. Wool is a major irritant and should never be worn in direct contact with the skin. It is important to warn that wool contact may also occur with the parents' clothing, carpets, car seat and stroller covers, blankets and toys. Cotton material is always safe and cotton polyester combinations rarely irritate, but acrylic may be as troublesome as wool. Perfumed and medicated products, disinfectants and strong cleansers should be avoided. Soap in excess and bubble baths overdry the skin, so soap substitutes should be used.

It should be emphasized to parents that topical steroids are safe as long as these are used only where and when there is active eczema. In general, ointment bases, which are more emollient, are preferred. Only 1% hydrocortisone should be used on the face and in the groin but fluorinated steroids may be used elsewhere for short periods. Patients and parents should be educated regarding the quantities of creams necessary to apply and guidance has been published regarding amount and frequency of application.<sup>1,54</sup>

Second line therapy for severe cases or those not responding to routine treatment includes paste bandages or wet wraps. The latter involves applying two layers of tubular cotton bandages over topical steroids and emollients on the skin. The inner bandage is soaked in warm water prior to application. These dressings increase the hydration of the skin, physically prevent scratching, immediately reduce itching and enhance the penetration of topical steroids. In infants only weak steroids should be used because of the risk of absorption. The use of dressings should be adequately supervised and used for no more than a few days at a time with topical steroids.

Obvious secondary bacterial infection should be treated with oral antibiotics. However, these are indicated in most patients with severe weeping eczema even in the absence of clinically obvious infection. Although current randomized controlled trial evidence does not support the routine use of antihistamines in atopic eczema many parents say that their child appears to be more comfortable at night with less scratching after a nocturnal dose of a sedative antihistamine. Oral steroids should be avoided because a severe rebound can occur on withdrawal and after several courses the eczema is rendered very unstable.

Recently topical tacrolimus and topical pimecrolimus have received approval by the UK National Institute for Clinical Excellence (NICE) as second line treatments for patients greater than 2 years where topical corticosteroids have not worked or there is a serious risk of adverse effects with topical corticosteroids.<sup>55</sup> Concern has been raised about possible cancer risks based on information from animal studies, small

numbers of post-marketing reports and how the drugs work. These drugs should therefore be prescribed only by doctors with experience in skin disease.

Third line treatments include phototherapy (narrow band UVB or psoralen plus UVA), ciclosporin (although not yet licensed in the UK for pediatric eczema)<sup>56</sup> and azathioprine. Small studies in children suggest montelukast might be beneficial<sup>57</sup> although a larger study in adults concluded that montelukast is not an effective treatment.<sup>58</sup> Further studies are required in children.

Chinese herbal medicine (CHM) has been evaluated and 1 year follow-up of children treated with CHM showed good, sustained improvement in nearly 50% although 1 out of 37 developed abnormal liver function tests and 14 withdrew due to lack of efficacy or unpalatability.<sup>59</sup>

In the absence of a clear history of worsening of eczema relating to food, no alteration to the child's diet should be considered unless the eczema has failed to respond to conventional topical therapy. Dietary manipulation in the management of refractory eczema is covered in Chapter 33. The role of the dust mite in these severe cases is covered in the same section.

There is increasing interest in the primary prevention of atopic disease. Probiotics are cultures of potentially beneficial bacteria and a randomized controlled trial of *Lactobacillus* GG was effective in reducing the frequency, but not severity, of atopic eczema.<sup>60</sup> At present, evidence is lacking to show the benefit of probiotics in established eczema.

As a child becomes older discussion about future careers is important as certain occupations are likely to aggravate the skin, such as hairdressing or car mechanics. It is important to develop a trusting and cooperative relationship with the patient and his parents as they will require much encouragement to help them cope with this distressing condition.

### DISCOID ECZEMA (NUMMULAR ECZEMA)

In children this is often a manifestation of the atopic state. Well-defined patches of acute eczema occur in a strikingly symmetrical distribution (Fig. 30.49). In infants the commonest sites are the upper back and the tops of the shoulders; in older patients the extensor aspects of the limbs are particularly involved. The lesions may be very thick and exudative and they are very itchy. They have to be distinguished from tinea and impetigo which are less symmetrical and psoriasis which is rarely moist. The management involves emollients and topical steroids as for atopic dermatitis, with the continued use of emollient helping to prevent recurrences.

### PITYRIASIS ALBA

This condition appears as poorly defined, slightly scaly, hypopigmented patches occurring particularly on the face and the upper

Fig. 30.49 Discoid eczema.

arms. It probably represents a very mild eczema which, however, produces a striking postinflammatory hypopigmentation. Occasionally some areas will show erythema and more definite eczematous changes. The condition is more common in atopics. The mild irritation and signs of mild eczema respond to emollients and weak topical corticosteroids but the hypopigmentation may be very persistent and require sun exposure over a prolonged period before repigmentation is complete. Most lesions clear by puberty. The condition should be differentiated from vitiligo where there is total depigmentation and no scale and from tinea versicolor which has very well demarcated lesions with very fine branny scaling.

### SEBORRHEIC DERMATITIS

This condition usually presents between weeks 2 and 6 of infancy with a second peak in adult life; whilst in adults the dermatitis relates to sites of greatest sebum production, this relationship is less clear in infants.

The rash has an erythematous background and a greasy yellow scale. In the proximal flexures the scale may be absent and a glazed erythema the only sign. Scaling is particularly prominent on the scalp, producing the so-called 'cradle cap'. The main areas of involvement are scalp, glabella, behind and inside the ears, nasolabial folds, axillae and groin and in infants the neck and limb flexures. In the flexural areas candidiasis is commonly superimposed. The rash is usually asymptomatic.

Various conditions mimic seborrheic dermatitis including drug reactions (in children particularly due to phenytoin sodium), early psoriasis and Langerhans' cell histiocytosis. These should be considered when what appears to be a seborrheic dermatitis occurs at an unexpected age or fails to respond to therapy.

Seborrheic dermatitis usually responds quickly to weak topical corticosteroid preparations with the addition of an anticandidal agent for the flexural areas. On the scalp, sulfur and salicylic acid preparations left on overnight are usually more effective than corticosteroids. If the scale is very thick, warmed olive or paraffin oil can be used to soften it before the cream is applied. It should be emphasized that the disorder will tend to recur through infancy.

### NAPKIN DERMATITIS

Napkin dermatitis encompasses various skin diseases of different etiologies. Irritant contact dermatitis is the most common due to damage to skin integrity through friction, occlusion, excessive moisture and irritants under the nappy. Secondary infection (bacterial and candidal) usually occurs. Seborrheic dermatitis and psoriasis may also affect the napkin area.

The newer superabsorbent disposable napkins are often preferable to cloth napkins. A combination cream of 1% hydrocortisone and anti-candidal agent is usually effective and a silicone or zinc barrier cream may be added to protect the skin against moisture. There will usually be a quick response to therapy but recurrences are to be expected.

### ALLERGIC CONTACT ECZEMA

Allergic contact eczema is one of the main examples of delayed type hypersensitivity in the skin. It is much less common in children than in adults, probably due to lack of contact with sensitizing chemicals. The commonest allergen in children is nickel, which is contained in metal clips and studs (e.g. jeans studs) and in non-gold earrings. It seems likely that a number of children are sensitized following piercing of the ears and by wearing costume jewelry earrings. Other contact allergens in children include plants such as *Rhus* (particularly in the USA and Australia) (Fig. 30.50), chemicals used in rubber production and topical medications such as neomycin and gentamicin.

Identification of the allergen is essential, and this is carried out by patch testing the child. Interpretation requires expertise, as not all reactions are necessarily specific delayed type hypersensitivity reactions.

Fig. 30.50 Plant (*Rhus*) dermatitis.

### PHYTOPHOTODERMATITIS

This is a cutaneous phototoxic inflammatory response resulting from direct contact to naturally occurring plant psoralen followed by ultraviolet (UVA) sensitization. It typically manifests in spring or summer months as painful streaky/linear erythema on exposed sites that may blister and subsequently heal with postinflammatory hyperpigmentation. The most common plants to cause this reaction are in the Umbelliferae family.

### JUVENILE PLANTAR DERMATOSIS

This condition affects mainly children aged 3–14 years and is characterized by a shiny, smooth erythema affecting the plantar aspect of the weightbearing area on the foot. The forefoot and toes are typically commonly involved and the heels in about a quarter of patients. The feet are affected symmetrically and the toe webs are spared helping differentiate juvenile plantar dermatosis from tinea pedis. Pain from cracks and fissures is a major symptom. Rarely a similar pattern can be seen on the fingertips.

The exact cause is unknown but hot humid conditions caused by less porous, synthetic materials in socks and shoes are thought to contribute to the maceration process. Most cases will clear by adolescence but some are helped by changing footwear and use of emollients.

### PSORIASIS

A combination of epidemiological, family and human leukocyte antigen (HLA) studies indicate that psoriasis is a genetic condition. Its mode of inheritance is probably autosomal dominant with variable penetrance. Psoriasis appears by the age of 15 years in 30% of patients. Children may present with typical adult large erythematous plaques, with a thick silvery white scale, predominantly on the knees, elbows, buttocks and scalp, but usually the plaques are smaller and with a finer scale. A common presentation is acute guttate psoriasis with the eruption of small papules in a widespread distribution, often following an intercurrent illness, particularly a streptococcal throat infection. A micropapular form of psoriasis occurs particularly in dark-skinned children with 1–2 mm papules most marked on the extensor aspects of the limbs. These lesions are usually skin colored until scratching demonstrates the white scale.

The face and intertriginous sites, such as retroauricular areas, axillae, groin, genital and perianal area, are commonly affected in children. Children presenting with vulvitis, balanitis and perianal itching may be found to have psoriasis. In these areas the typical scale is absent and the condition presents as a glazed erythema often with fissuring. Generalized pustular psoriasis is rare in children and has an explosive onset with sheets of pustules on a background of bright erythema accompanied by severe systemic toxicity. It may be the first presentation of psoriasis and settle spontaneously in a few weeks leaving

Fig. 30.51 Napkin psoriasis.

normal skin. It often recurs and usually more typical psoriasis eventually supervenes. Pustular psoriasis of the palms and soles is also very rare in children. Acropustulosis, a glazed erythema studded with pustules followed by thick scaling and fissuring, involving one or more digits, is an occasional childhood presentation. Nail involvement is usually absent or minimal with minor pitting, and psoriatic arthropathy is extremely uncommon in children.

Controversy exists over whether or not the condition called 'napkin psoriasis' or 'sebopsoriasis' (Fig. 30.51) is in fact a form of psoriasis. It occurs in the first 3 months of life with a nonspecific napkin dermatitis suddenly becoming more severe and extensive with bright, well-demarcated erythema involving most of the napkin area including the folds. Lesions resembling typical psoriasis then erupt elsewhere, usually first on face and scalp, then neck fold and axillae and finally trunk and limbs. In the scalp the lesions may appear similar to seborrhea. Evidence for this representing a form of psoriasis rather than dermatitis comes from the work of Andersen & Thomsen<sup>61</sup> who found a family history of psoriasis in 26% of patients compared with 4.9% of controls, and of Neville & Finn<sup>62</sup> who, on review of these patients at 5–13 years, found psoriasis in 17% with the expected rate being 0.4%.

In any child with a difficult napkin dermatitis responding poorly to conventional measures psoriasis should be considered, particularly if the lesions have well-defined margins and remain fairly fixed in position.

### Management

Many systemic therapies (e.g. retinoids, methotrexate and ciclosporin) used in adults are inappropriate in children. As a general rule, psoriasis in children is better treated with tars than topical corticosteroids. They are often more effective, are safer for long term use, and rebound on their cessation is less of a problem. Tars may be irritant in infants, as they may be at any age when applied to the face or intertriginous areas. Useful preparations for guttate or small plaque psoriasis are coal tar and salicylic acid mixtures (equal parts 2–4%) in an aqueous cream base applied twice a day. A prospective, multicenter, double-blind study in children showed that the topical vitamin D analogue calcipotriol is effective and safe when applied to less than 30% of the body surface area.<sup>63</sup> Whilst oral antibiotics and tonsillectomy have been advocated for patients with recurrent guttate psoriasis following recent streptococcal infection, there are no data to show they are beneficial.<sup>64</sup> For large plaque psoriasis in older children the adult regimens of topical dithranol with or without ultraviolet B (UVB) (preferably narrow band) are usually tolerated.

Patients with generalized pustular psoriasis require urgent hospitalization and close monitoring of fluid and electrolyte balance and evidence of infection. Wet compresses give symptomatic relief while awaiting spontaneous recovery. Tars are contraindicated and topical steroids must be used very cautiously due to the risk of considerable absorption.

Palmoplantar pustulosis and acropustulosis usually respond slowly to tar preparations. Napkin psoriasis often clears quickly with hydrocortisone and anticandidal agents for the flexural areas and a weak corticosteroid elsewhere.

It is essential for the parents, and the child if old enough, to appreciate that psoriasis is a capricious, recurrent disease which will require varying treatments depending on the site, nature and severity of the condition at different stages. Long term follow-up, preferably with the same practitioner, is important.

## CONNECTIVE TISSUE DISEASES (Ch. 29)

### LUPUS ERYTHEMATOSUS (LE)

This is rare in children but neonatal lupus erythematosus is of considerable importance.

#### Neonatal lupus erythematosus

This occurs due to the passage of maternal antibodies through the placenta (Fig. 30.52), where the mother suffers from systemic LE, subacute cutaneous LE or the sicca syndrome. In 50% of cases the mother is asymptomatic but the vast majority have SS-A (anti-Ro) antibodies. The most important feature of neonatal LE is heart block of varying degrees. This is usually permanent, and without pacing there is a significant mortality (Ch. 21). Other features include autoimmune hemolytic anemia, thrombocytopenia, hepatitis, pneumonitis and splenomegaly.

The skin lesions resemble those of subacute cutaneous LE in the adult, occurring on the face, neck and scalp, with erythematous macules or plaques with scaling. They are often present at birth and disappear within the first year of life. There may also be photosensitivity. Treatment of the skin is with 1% hydrocortisone cream and protection from the sun.

#### Lupus erythematosus in the older child

This takes two main forms: systemic LE and discoid LE. It is thought that this is a spectrum of disease, as sometimes patients with discoid LE will progress to systemic LE and a proportion of those with discoid LE have circulating antinuclear antibodies, anemia, leukopenia and thrombocytopenia and other features such as Raynaud's phenomenon and arthralgia.

#### Discoid lupus erythematosus

This usually affects girls, who develop erythematous plaques on the face, the arms and dorsum of the hands. The most commonly affected parts of the face are the nose and the cheeks. Involvement of the scalp usually leads to scarring alopecia.

There may be mild anemia, leukopenia or thrombocytopenia and some children will have circulating antinuclear antibodies.

Fig. 30.52 Neonatal lupus erythematosus.

The prognosis is variable, as in some the plaques will resolve spontaneously whereas in others they tend to be persistent. Avoidance of sun exposure by the use of sunscreens and a hat is important.

### **Systemic lupus erythematosus**

As in discoid LE, the systemic form is more common in girls. It is a multisystem connective tissue disease which often carries a poor prognosis, due to renal involvement. This is discussed fully in Chapter 29 (see p. 1427). The skin manifestations include a butterfly rash on the face, which characteristically spares the nasolabial folds, discoid plaques usually on the face, reticulate livedo most marked on the legs, panniculitis, vasculitic ulcers, cuticular hemorrhages at the fingernail folds, and alopecia. Almost half of patients will have mouth ulcers.

## **DERMATOMYOSITIS**

This is a rare connective tissue disease affecting the skin, muscle and blood vessels. Its etiology is unknown, though in some adults there is an association with carcinomas of internal viscera and lymphomas. The histological changes in the skin may resemble those of LE, though the dermal edema is more marked. In the later stages the dermis becomes sclerotic, and the picture may be similar to the changes in scleroderma.

The clinical manifestations are extremely variable. In some children the skin signs may be very prominent with minimal myositis, whereas in others there is polymyositis with little evidence of skin involvement. Myositis is manifested by a proximal muscular weakness with difficulty in flexing the neck, climbing stairs and raising the arms above the shoulder girdle, and by a raised serum creatine phosphokinase. There may be concomitant fever and malaise.

The rash when present is very characteristic. A heliotrope (purplish-red) rash occurs on the face involving the eyelids, the forehead and upper cheeks. There may be marked edema of the hands and arms with an erythematous linear rash over the dorsum of the hands with nail fold telangiectasia. Erythema of the scalp may develop and there may be marked alopecia. Reticulate livedo is seen in some, and may lead to ulceration of the skin.

Calcification is common in children, affecting more than 50% of cases. It primarily involves the muscles, particularly around the pelvic and shoulder girdles, and may cause marked functional disability. It also occurs in the subcutaneous tissues, and there may be extrusion through the skin with ulceration.

The course of the disease is variable, but there is generally a good prognosis in children. Death may occur due to respiratory failure, difficulty in swallowing, or the side-effects of steroid therapy.

Treatment with methotrexate is now considered first line therapy in an attempt to reduce the cumulative dose of oral corticosteroids.<sup>65</sup> Therapy is usually necessary for months or years until the serum creatine phosphokinase returns to normal and the signs of the disease have disappeared. Physiotherapy may be useful to prevent contractures.

## **SCLERODERMA**

In children this may take two forms: morphea (localized scleroderma), which is relatively common, and systemic sclerosis which is very rare.

### **Morphea**

This is a localized and benign form of scleroderma, though it can cause quite marked disfigurement. On histological examination, the dermis is at first edematous with swelling and degeneration of the collagen fibrils, with later thickening of the dermis and loss of appendages. The etiology of the condition is unknown.

The areas of morphea occur usually as either plaques or linear lesions of sclerosis in the skin. These are at first purplish in color, and later become white and waxy. Hairs are lost within the area, with loss of sweating. They occur on the trunk and limbs. When they involve a limb (usually linear lesions), they may involve muscles and bone leading to shortening of the limb.

A particular disfigurement which results from morphea is the so-called 'coup de sabre', which occurs in the frontoparietal area. This starts with contraction of the skin over the affected area with development of an ivory plaque with hyperpigmentation at the edge and telangiectatic vessels coursing over it. The resulting groove may extend downwards, affecting the mouth and mandible. The tongue may be atrophic on the affected side, and there may be marked alopecia. There is marked facial asymmetry with consequent disfigurement.

A prospective, nonrandomized, open pilot study suggests that combined low dose methotrexate and high dose pulsed corticosteroids is an effective treatment (see Kreuter et al. Arch Dermatol 2005 – reference 66).<sup>66</sup>

### **Systemic sclerosis**

This is very rare in children. The etiology is unknown, but as similar changes may be seen in graft versus host reactions, it may be some sort of rejection phenomenon.

In the majority of patients the condition starts with Raynaud's phenomenon which may continue for several years before other manifestations occur. These include: swelling of the hands; sclerodactyly with atrophy of the pulps of the fingers; calcinosis of the finger pulps which may be prominent; ulceration; and gangrene. In some, terminal phalangeal absorption also occurs.

Later, other features occur with beaking of the nose, radial furrowing around the mouth which becomes smaller, macroglossia, esophageal dilatation and stricture, and abnormal colonic peristalsis.

The prognosis is variable and depends on internal organ involvement, though most patients continue with the condition for many years with increasing deformity. No formal trials have evaluated the wide range of potential immunosuppressive therapies.

## **LICHEN SCLEROSUS**

Although the precise etiology of lichen sclerosis is unknown, evidence for an autoimmune basis to the disorder is emerging. Circulating IgG autoantibodies to the glycoprotein extracellular matrix protein 1 (ECM1) have been demonstrated in the sera of about 75% of affected individuals.<sup>67</sup> Lichen sclerosis has a predilection for genital and perianal skin. It is more common in females and usually presents with itch although in children it may be asymptomatic. Erythema and excoriations appear in the early stages with subsequent development of well-defined pale atrophic areas. The lesions often occur in a figure of eight pattern around the vulva and anal region. Lichen sclerosis may be misdiagnosed as sexual abuse. In approximately 10% extragenital lesions are also present. In boys, the usual history is of balanitis and tightening of the foreskin which can progress to phimosis (balanitis xerotica obliterans). Potent topical steroids are the treatment of choice.<sup>68</sup> A Cochrane review of topical therapies is currently underway. The overall prognosis is good but for cases that persist long term follow-up is recommended because of the risk of malignant change in adults.

## **IDIOPATHIC PHOTOSENSITIVITY ERUPTIONS**

Before considering a child to have an idiopathic photosensitivity eruption, it is important to exclude one of the hereditary diseases (q.v.), and photosensitive drug eruptions which are common and may be caused by a number of drugs (notably sulfonamides, tetracyclines and phenothiazines).

### **POLYMORPHIC LIGHT ERUPTION (PLE)**

About 20% of patients with PLE present before the age of 10 years. A delayed reaction occurring several hours or the next day after exposure to the sun results in erythema, burning and itching, followed by papule and plaque formation. With avoidance of sun exposure this reaction will settle but will usually relapse when the child is exposed to the sun again. It usually presents during the summer, but in some children it is most marked in the spring and early summer, with remission of the

symptoms in midsummer with 'hardening' of the skin. Juvenile spring eruption is probably a localized variant of PLE with papules and vesicles confined to the helices of the ears.

Most children with PLE continue into adulthood with it. Action spectrum studies are usually normal, and are therefore unhelpful. Prevention of PLE depends on adequate topical photoprotection with sunscreens. In those children with severe PLE, photochemotherapy with oral psoralen and UVA light (PUVA) may be helpful.

## ACTINIC PRURIGO

This condition is clinically similar to PLE but is now recognized to be a separate entity. It is significantly associated with the haplotype HLA-DR4/DRB1\*0407.<sup>69</sup> Actinic prurigo nearly always develops in early childhood and 80% of patients are female. There is usually progressive improvement in adolescence.

Clinically all exposed sites are affected, including face, lips, neck, ears, arms, dorsum of hands and lower legs. In the majority there is also involvement of covered skin, though to a lesser extent. It is worse during summer months but very often persists even in winter. In most cases there is a family history and there is also a strong association with atopy.

Action spectrum studies are abnormal in the majority with sensitivity to both UVA and UVB; however, in some children these studies are normal. Treatment is similar to that of PLE, but thalidomide has also been found to be particularly effective in this condition.

## HYDROA VACCINIFORME

This is a very rare condition which invariably starts in childhood. On exposure to sunlight the child develops tingling and erythema followed by blistering and umbilicated papules on the face, ears, arms and dorsum of hands. These lead to crusting and varioliform scars.

Action spectrum studies are abnormal with sensitivity mainly involving UVA. Treatment is generally unsatisfactory, though broad spectrum topical sunscreens may be helpful.

## DISORDERS OF HYPOPIGMENTATION

### HEREDITARY DISORDERS OF HYPOPIGMENTATION

Pigmentary disorders may indicate a more serious systemic disease and the hereditary disorders of hypopigmentation are summarized in [Table 30.6](#).

### VITILIGO

This is possibly an autoimmune disease. Though specific antimelanocyte antibodies cannot be demonstrated by immunofluorescence, complement-fixing antibody to melanocytes has been shown in some patients. It is well recognized that patients with vitiligo frequently have thyroid, gastric and adrenal autoantibodies ([Fig. 30.53](#)). Vitiligo causes complete depigmentation of the skin (unlike tinea versicolor and pityriasis alba) due to absence of melanocytes and melanin in the epidermis. Vitiligo is common in adults, and is not rare in children. The depigmentation is usually symmetrical but localized, although in some patients the condition progresses to involve almost the whole body. Spontaneous repigmentation occurs more in children than in adults. In those that do not repigment topical corticosteroids can be tried although fluorinated steroids should not be used for prolonged periods. Photochemotherapy with topical or oral psoralen may be helpful in the older child although complete repigmentation rates are disappointing. The efficacy of PUVA (oral administration of psoralen and subsequent exposure to UVA) has been shown in adults to be enhanced by concurrent topical calcipotriol.<sup>70</sup> Several small studies and case reports have shown variable responses to topical immunomodulators (tacrolimus). Otherwise cosmetic camouflage may be applied to the depigmented skin to minimize disfiguration.

### NEVUS DEPIGMENTOSUS

Usually solitary, nevoid patches of hypopigmentation are present at birth and can involve any body site. A decrease but not absence of pigment helps differentiate nevus depigmentosus (achromic nevus) from vitiligo. Furthermore, unlike vitiligo, slight darkening may be seen in the affected site following ultraviolet light exposure. The differential diagnosis also includes ash leaf macules seen in tuberous sclerosis but these are often multiple and smaller. Systemic abnormalities have only been rarely reported.<sup>71</sup>

### HYPOMELANOSIS OF ITO

There is convincing evidence that hypomelanosis of Ito does not represent a distinct entity but is rather a symptom of many different states of mosaicism.<sup>72</sup> Incontinentia pigmenti type 1, which was subsequently shown to be hypomelanosis of Ito, is a sporadic condition associated with an X/autosome translocation involving Xp11.

Unilateral or bilateral macular hypopigmented whorls, streaks, and patches of hypopigmentation present at birth along the lines of Blaschko. Although some features are similar to those of classic incontinentia pigmenti the preceding inflammatory stage is absent. Abnormalities of the eyes and the musculoskeletal and central nervous systems occur in some.

## DISORDERS OF HAIR LOSS

The normal transition from vellus to terminal hair in the newborn may be delayed up to 1 year giving the false impression of diffuse congenital alopecia. Genuine inability to grow normal hair can be seen in a number of genetic conditions including the ectodermal dysplasias and hair shaft abnormalities. The latter group may be detected by light microscopy of the affected hair and includes trichorrhexis nodosa which occurs as an isolated problem or in Menkes syndrome; trichothiodystrophy, characterized by sulfur-deficient, brittle hair; trichorrhexis invaginata (bamboo hair) usually associated with Netherton syndrome; monilethrix (beaded hairs due to keratin mutations); and pili torti which describes flattened and twisted hairs.

### LOOSE ANAGEN SYNDROME

Diffuse or occasionally patchy hair loss is seen typically in fair-haired girls aged 2–9 years. The hair is a little unruly. Loose anagen syndrome is often familial and is diagnosed by an increased number of anagen hairs present when plucked from the scalp. The features become less prominent into adult life.

### TELOGEN EFFLUVIUM

This refers to hair loss following the abrupt transformation of anagen hairs to the telogen phase during which they are shed. Normally 80–90% of hairs are in anagen but up to half may change in synchronization to telogen. This results in hair loss 3–4 months after the initiating event which may be 'stress', severe illness or certain drugs, e.g. anti-coagulants, retinoids, etc.

### ALOPECIA AREATA

It seems likely that at least in some patients with this condition the process is due to autoimmunity, though conclusive proof is lacking ([Fig. 30.54](#)). There is an increased incidence of autoantibodies and autoimmune diseases. There is also an increased incidence of atopy, and atopic children are more likely to develop total alopecia. A family history of alopecia areata is present in 5–25% of cases.

Most children develop discoid areas of alopecia in the scalp with peripheral exclamation hairs, and these areas regrow hair normally in due course. In some children, however, particularly those with an ophioid distribution of hair loss (involving the temples and occipital region), the condition is progressive to become total, and regrowth is much less likely. There are also nail changes with fine pitting and horizontal depressions known as Beau's lines. Although alopecia areata is not a life threatening condition it is obviously distressing for children and parents.

Table 30.6 Hereditary syndromes associated with hypopigmentation

	Oculocutaneous albinism (OCA types I and II)	Chediak–Higashi syndrome	Hermansky–Pudlak syndrome	Piebald trait	Waardenburg syndrome (types I–III)	Cross syndrome
Inheritance	AR	AR	AR	AD	AD	AR
Pigment loss	Type I: total, hair white. Type II: freckles in sun-exposed sites, hair yellow	Variable (patchy) oculocutaneous albinism. Silvery hair which may be sparse	Tyrosinase-positive oculocutaneous albinism	White forelock, absent pigmentation (leukoderma) ventral chest, abdomen and midportion of limbs. Pigmented macules often within affected areas	Piebaldism	Reduction in skin pigment. Variable loss of hair color
Ocular features	Nystagmus, visual loss. Type I: photophobia	Nystagmus, visual loss, photophobia pale retinae, and translucent irides	Blindness, nystagmus, strabismus, iris transillumination, foveal hypoplasia, and albinotic retinal midperiphery	Heterochromia iridis	Type I: dystopia canthorum Type II: more frequently heterochromia iridis	Nystagmus, reduced eye color
Other features		Frequent and severe pyogenic infections. Progressive neuropathy and neurodegeneration Lymphadenopathy	Bleeding tendency due to poor platelet aggregation. Cellular storage problems lead to pulmonary fibrosis, granulomatous enteropathic disease, and renal failure		Sensorineural deafness more common in type II Type III: additional severe musculoskeletal abnormalities	Mental and growth retardation, spasticity, athetoid movements
Molecular defect	Type I: tyrosinase (TYR) gene Type II: transmembrane protein (P gene)	Lysosomal trafficking regulator gene (CHS1)	Seven gene defects are associated with the four known subtypes	KIT protooncogene and occasionally zinc finger transcription factor SNA12	Types I and III: paired box homeotic gene-3 (PAX-3). Type IIA: microphthalmia-associated transcription factor gene (MITF)	Unknown
Other	Type II most common type of OCA (types I–VI) OCAIII due to TRP-1 mutations. Individuals have reddish hair and reddish-brown skin		HPS type 2 patients also have immunodeficiency	Hirschsprung disease occasionally associated	Hirschsprung disease occasionally associated	Very rare. Also referred to as oculocerebral syndrome with hypopigmentation

AR; autosomal recessive. AD; autosomal dominant.

There is no effective treatment for alopecia areata at present. Intralesional steroids may cause some local hair growth but this has no permanent effect on the course of the alopecia. In older children, short contact dithranol treatment may induce hair growth but the result is rarely cosmetically acceptable. There is no evidence as yet that topical minoxidil is helpful.

### TRICHOTILLOMANIA (HAIR PULLING)

Trichotillomania is more common in girls. The alopecia is patchy with variable hair lengths in the affected region usually located on the contralateral

side to the child's handedness. Hair ingestion may lead to bowel symptoms. Trichotillomania is most often an isolated symptom with a good prognosis following appropriate psychological support. However, follow-up until resolution is important to avoid missing more severe psychological disease.

### THE HISTIOCYTOSES

Histiocytes include circulating monocytes and tissue macrophages as well as the dendritic cell system (antigen presenting cells). The histiocytoses

Fig. 30.53 Vitiligo.

have been classified into class I (Langerhans' cell histiocytosis), class II (proliferative histiocytoses of mononuclear phagocytes other than Langerhans' cell) and class III (malignant histiocyte disorders).<sup>73</sup>

#### CLASS I LANGERHANS' CELL HISTIOCYTOSIS (HISTIOCYTOSIS X)

This condition is rare (Ch. 24, pp. 1030) and the cells involved are Langerhans' cells which contain Birbeck granules and express the common thymocyte antigen CD1 markers. Although historically four types are recognized on the basis of clinical organ involvement, the presentations may overlap and the disease may progress from one subtype to another.<sup>74</sup>

#### Letterer–Siwe disease

This usually presents in the first year of life (Fig. 30.55). Discrete yellow–brown papules develop on the scalp, face, upper trunk and flexures, with a distribution mimicking seborrheic eczema. Purpura and crusting of the lesion may become evident. In some children mucous membranes are also involved, with gingivitis and oral and genital ulceration.

Signs of systemic involvement become manifest, with hepatosplenomegaly, lymphadenopathy and anemia. Chest X-ray shows miliary shadowing and bone scans may show osteolytic areas. Treatment with steroids and cytotoxic drugs has reduced the mortality and slowed the progression.

Fig. 30.54 Alopecia areata.

Fig. 30.55 Letterer–Siwe disease.

#### Hand–Schüller–Christian disease

This is a more benign form of histiocytosis X, which usually presents within the first 5 years of life and follows a chronic non-fatal course. The usual manifestations are radiological bone defects, exophthalmos and diabetes insipidus. Skin lesions similar to those in Letterer–Siwe disease are present in 30%.

#### Eosinophilic granuloma

This is the most benign form of histiocytosis X. It commonly presents within the first 5 years of life, and skin involvement is rare. When it does occur, yellowish or brownish papules are found on the scalp and trunk in a distribution similar to the other forms of histiocytosis X. Spontaneous resolution usually occurs.

#### Congenital self-healing histiocytosis

This usually affects skin only with lesions that are nodular or may mimic chickenpox. If this is the case spontaneous resolution occurs within months.

#### JUVENILE XANTHOGRANULOMA (JXG)

JXG is an example of a benign self-limiting non-Langerhans' cell histiocytosis (class II) (Fig. 30.56). Histologically lesions are characterized by histiocytes with foamy macrophages and multinucleated giant cells. Despite its name and appearance JXG is not associated with lipid disorders. Lesions are occasionally present at birth but typically before 1 year. They are dome-shaped nodules with a red and then orange color often located on the head and neck. Single lesions are more common but if multiple lesions are present up to 10% have ocular involvement which may lead to glaucoma.

Fig. 30.56 Juvenile xanthogranuloma (XJG).

## NORMAL VISUAL DEVELOPMENT

At around 6 weeks an infant will smile in response to visual stimuli; delay of this developmental stage is significant. Visually directed reaching commences at age 2–3 months.

Preferential looking grating measurements of vision reach 6/6 level at 3 years<sup>1</sup> however this test is dependent on complex sensory and motor responses. Cortical VEP estimates of visual acuity give a 6/6 response by age 6–8 months.<sup>2</sup> Stereopsis develops between the ages of 2 and 6 months.<sup>3</sup>

## CRITICAL PERIOD OF VISUAL DEVELOPMENT

Early visual experience is critical to the development of synaptic connections in the primary visual cortex.<sup>4</sup> Input from each eye 'competes' for cortical connections.<sup>5</sup> The visual outcome of congenital cataract surgery is poor if visual rehabilitation is delayed beyond 3 months of age. The visual outcome of surgery for unocular cataract is less satisfactory than that for binocular cataract<sup>6</sup> as the normal eye dominates synaptic development.

## PLASTIC PERIOD OF VISUAL DEVELOPMENT

While the critical period of visual development is at age 0–3 months, the visual system remains plastic until at least the age of 8–12 years, and probably longer.<sup>7</sup> Interrupted visual development below the age of about 6 years<sup>8</sup> may lead to permanent reduction of visual acuity even after the causative abnormality has been removed. This is termed 'amblyopia'. The younger the age at which developmental interruption happens, the greater the degree of amblyopia that may occur. Once again unocular defects produce a greater effect than binocular defects, because of competition effects at the occipital cortex. Amblyopia may be treated during the critical and plastic period of visual development – up to approximately age 8–12 years.<sup>7</sup>

## CLINICAL ASSESSMENT

### CLINICAL HISTORY

Symptoms related to visual functions cover a wide spectrum of difficulties. Progressive bilateral visual loss in young children may go unnoticed until a relatively late stage, and may present with impairment of a wide spectrum of visually dependent behaviors. Symptoms related to consistently bumping into doorways may indicate visual field reduction on one side. Symptoms related to difficulties coming down stairs or frequent tripping may indicate inferior visual field restriction. Increased sensitivity to light (photophobia) may indicate ocular inflammation or retinal cone dysfunction. Difficulties in dim light (night blindness) may indicate poor retinal rod function. The prenatal history, birth history, developmental history, drug history, family history and educational history should always be taken.

In older children perceptual visual difficulties related to central nervous system (CNS) disease may go undetected unless a careful history is taken. Useful screening questions include:

- Does the child have difficulty identifying objects within a 'busy' or 'fast-moving' environment?
- Does the child have difficulty with coordination and movement in three-dimensional space?
- Does the child have difficulty recognizing familiar faces?
- Does the child have difficulty with orientation in familiar environments?

### VISION ASSESSMENT

In infants and very young children, observed visual behavior will give useful qualitative information about visual function. A visually alert infant will fixate on and follow the movement of small objects of interest held by an examiner. Each eye is tested separately by covering one eye with a hand or eye patch. If a child will not tolerate unocular testing then some useful information may be obtained from binocular testing. However, poor vision in one eye will not be detected by binocular testing.

### QUANTITATIVE MEASUREMENTS OF VISUAL ACUITY

'Visibility' refers to the ability to identify a single object such as a sweet, thread on a carpet, or airplane in the sky. 'Resolution' refers to the ability to distinguish between two points or lines. Visual acuity tests measure resolution. Clinical tests of visibility such as Stycar balls, Catford drum, etc. may significantly overestimate results obtained with resolution tests and should be interpreted with caution.

Fig. 31.1 Forced choice preferential looking test (Keeler cards). The tester looks through a hole in the card and chooses which target area the child looks at.

### PREFERENTIAL LOOKING ACUITY CARDS

An infant will 'prefer' to look at an object of interest rather than at a blank background. Black and white stripes (gratings) of varying widths ('spatial frequency') are used as the stimulus (Fig. 31.1). The tester uses a series of test cards, each of which has two test areas – one blank and one a test grating. The tester observes the area the infant looks at. The test is repeated a number of times, using various stripe widths. The narrowest stripe width (lowest spatial frequency) consistently looked at by the infant is a measure of the infant's visual resolution. Preferential looking tests may be successfully used in most infants, but are of less interest to 18–24-month-old children.

*Cardiff cards* use black and white lines shaped into interesting pictures (Fig. 31.2). These are useful in children aged 1–3 years. The child will look at the picture if the black and white stripes are sufficiently wide to be observed (resolved).

Fig. 31.2 The tester observes whether the child looks at the top or bottom half of the test card. The images are randomly distributed to the top halves and bottom halves of the test cards. The test is normally performed at 50 cm or 100 cm.

Fig. 31.3 Kay picture optotypes. The test is normally performed at 3 m or 6 m.

### OPTOTYPE TESTS

From the age of 3 years upward more traditional 'optotype' visual acuity symbols may be used. Kay pictures use simple line drawings (Fig. 31.3). The Sheridan Gardiner test uses letters. A limited range of letters is used so that the child may match the shape of the letter rather than name it (Fig. 31.4). A letter placed among a line of other letters is less easily observed than a single letter. Charts that use lines of letters arranged in log unit size are preferred in children aged 4–5 years and upwards – LogMAR charts (Fig. 31.5).

Fig. 31.4 Sheridan Gardiner optotypes. The test is usually performed at 6 m and the child matches the test letter to the key card.

Fig. 31.5 LogMAR optotypes (Glasgow cards). The test is usually performed at 6 m and the child matches the test letter to the key card. Reduced vision due to 'crowding' is detected as the test letter is placed within a row of letters.

### VISUAL FIELDS

Visual field testing may be undertaken in infants and young children by introducing an object of interest from either side and observing the response. Two observers are required (Fig. 31.6). The child sits on the lap of a carer. An observer sits approximately 1–2 m in front of the child. A second observer stands behind the parent and child. The second observer slowly brings an object of interest into the field of vision of the child. The child will turn to look at the object when it comes into the observable visual field. Binocular testing is more easily performed than uniocular testing, and will adequately detect a significant binocular visual field defect such as homonymous hemianopia or inferior visual field restriction.

In children aged 6 years upwards, Goldman visual field testing may be possible. This type of detailed visual field testing requires considerable

Fig. 31.6 Binocular visual field testing. Observer 1 maintains interest while observer 2 brings the test object (panda) into the child's visual field from behind. The child turns to look at the test object when it becomes visible.

Fig. 31.7 Goldman visual field testing. The tester observes the eye fixing behavior of the child. The child fixes on the center target within the bowl and presses a buzzer when the test spot of light becomes visible in the peripheral visual field.

cooperation from the child. The child must fix on a central point in the testing bowl and a spot of light is brought in from the peripheral field of vision (Fig. 31.7). The child presses a buzzer when the spot of light comes into view. The test is very operator dependent. Testing is normally performed unilaterally, and accurate and reproducible charting of visual field defects related to optic nerve and CNS disease may be obtained.

### CLINICAL EYE MOVEMENT TESTING

The cover test may be performed in order to detect a strabismus. When the straight eye is covered the strabismic eye quickly moves in order to take up fixation (Figs 31.8 and 31.9).

The range of eye movements may then be observed. The child is asked to observe an interesting target moved by the examiner. The examiner may use his or her face as the target and move from side to side and up

Fig. 31.8 Cover test. The child fixes on a test target at 6 m or 50 cm. The normal eye is covered. The strabismic eye then moves in order to take up fixation. Small flicks of movement may be easily detected, allowing diagnosis of small angled deviations.

and down in front of the child. Limitations of movements and changes in palpebral fissure width are observed.

Nystagmus may be described using the mnemonic 'DWARF':

- Direction (horizontal or vertical)
- Wave form (jerk or pendular)
- Amplitude (large amplitude or small amplitude oscillations)
- Rest (primary position (at rest/gaze evoked))
- Frequency (rapid movements or slow movements).

The direction of nystagmus movements is recorded as the direction of the fast phase (jerk) of the oscillation.

While some information on nystagmus movements may be obtained by clinical observation, more detailed information may be obtained by analysis in an eye movement laboratory.

### EXTERNAL EYE EXAMINATION

The eyelids, conjunctiva, cornea and iris may be observed using a torch. Ophthalmologists use magnification in the form of a slit lamp microscope to allow detailed examination of these structures (Fig. 31.10). Where there is a suspicion of a corneal epithelial abrasion or other corneal epithelial disease a drop of fluorescein dye may be instilled and the corneal epithelium may be observed using a blue light (Fig. 31.11). Any defects in the corneal epithelium will absorb fluorescein and these areas will fluoresce yellow.

Corneal signs such as posterior embryotoxon may be visualized with a slit lamp (Fig. 31.12).

### PUPIL RED REFLEX

The transparency of the 'media' of the eye may be observed by observing the red reflex. When the media are transparent a beam of light directed from a direct ophthalmoscope will be observed to produce an orange-red reflection of the fundus, observable in the pupil area (Fig. 31.13). When cataract or vitreous opacity is present the red reflex will be dark or absent. A white reflex in the pupil area (leukocoria) is an important sign of possible underlying retinoblastoma or other significant ocular pathology. The normal red reflex is more difficult to detect in dark brown eyes.

### PUPIL REACTIONS

The relative size of the pupils should be observed. Slight asymmetry of pupil size (anisocoria) may be physiological and the difference in pupil size is constant in light or dark. A torchlight may then be shone in each eye and the direct response to light observed. The light is then alternately shone in each eye, with the torch swinging backwards and forwards from eye to eye; this tests for relative afferent pupil defect. When the torch is shone in the healthy eye, the pupil constricts. However when the torch is then swung across to the eye with a sensory defect the pupil of this eye paradoxically dilates. This is because limited neural stimulation is produced by light shining in the defective eye and the dominant effect is the withdrawal of light from the healthy eye. Pupil dilatation in both eyes results and is observed in the defective eye. Motor pupil defects such as those seen following anticholinergic eye drop instillation or a III nerve palsy result in an absent pupil reaction to any stimulus.

### RETINOSCOPY

The focusing of the eyes may be measured at any age using a streak retinoscope. Anticholinergic eye drops are instilled to dilate the pupil and relax the ciliary muscle so that there is no accommodation. In Caucasians cyclopentolate 1% eyedrops may be used, with measurements performed 30 min after instillation. In children with dark brown eyes it may be necessary to use atropine 1% eyedrops or ointment, instilled on two or more occasions a number of hours before the examination. A streak of light is directed into the pupil area and movement of the pupil light reflex is observed when the streak of light is moved from

**Fig. 31.9** The cover test for squint. Where there is no squint and there is normal binocular vision, both eyes maintain steady fixation on a distant object. There will be no deviation when one or other eye is covered and this is the basis of a cover test. When there is a latent or manifest squint some deviation will be observed on occluding one or other eye. (a) In manifest convergent squint the squinting eye is turned in and the nonsquinting eye maintains fixation. If the squinting eye is occluded in the cover test there will be no variation in the angle of squint, but when the nonsquinting eye ('fixing eye') is occluded it converges and the squinting eye takes up fixation. When the occluder is removed the original position of the eyes is resumed. (b) In alternating convergent squint either eye can maintain fixation while the other eye is turned in. If the squinting eye is occluded there is no alteration in the angle of deviation, but when the 'fixing eye' is occluded the opposite eye fixes the distant object and the previously straight eye converges. The former position is not resumed when the occluder is removed and the previously squinting eye maintains fixation (and the previously straight eye converges) until the occluder covers the originally squinting eye, when the originally fixing eye takes up position. (c) In latent squint both eyes will fix on a distant object but when one eye is covered it deviates. When the cover is removed the eye with the latent squint resumes fixation. The other eye does not shift or lose fixation while the opposite eye is being covered or uncovered. (d) The cover test is used to diagnose vertical squint as in horizontal squint, e.g. in left hypertropia the left eye is elevated (or the right eye depressed) and when the fixing eye is covered the opposite eye moves vertically to take up fixation.

**Fig. 31.10** The slit lamp is a binocular microscope with an illuminating light in the form of a slit. This enhances stereoscopic viewing of tissues.

Fig. 31.11 Yellow/green fluorescein staining of an area of cornea abrasion visualized using blue light.

Fig. 31.12 Posterior embryotoxon. The edge of the basement membrane of the corneal endothelium is visible as a fine white line just inside the edge of the cornea. This is termed 'posterior embryotoxon'. This line is normally more peripheral, and therefore not visible.

Fig. 31.13 Pupil red reflex testing using a direct ophthalmoscope. This is normally performed in a dimly lit room.

Fig. 31.14 Retinoscopy measurement of eye focusing.

side to side. A test spectacle lens is then held in front of the eye and the process is repeated (Fig. 31.14). The power of the lens that neutralizes movements of the pupil light reflex gives a measure of the focusing of the eye.

## OPHTHALMOSCOPY

The fundi may be examined with the pupils dilated. Fundus examination of infants and young children is difficult with a direct ophthalmoscope. Ophthalmologists prefer to use an indirect ophthalmoscope. The light source is worn on the head and a convex lens is held in front of the eye in order to produce a focused image of the fundus (Fig. 31.15). The optic disc, macula, retinal vessels and retinal periphery may be examined. In older children, more detailed examination of the optic disc may be performed using a slit lamp microscope, in conjunction with a high powered convex lens. This allows detailed stereoscopic examination of the optic disc.

Fig. 31.15 Binocular indirect ophthalmoscope examination of the fundus.

## SPECIALIZED METHODS OF EXAMINATION

### ULTRASOUND

Ultrasound imaging may be used to examine the retina when the media are opaque due to cataract or other pathology (Fig. 31.16). The diameter of tumors such as retinoblastoma may be measured. High-definition ultrasound scans may be used to image the optic nerve head and optic nerve. Optic nerve head drusen may be detected. Widening of the cerebrospinal fluid (CSF) space around the optic nerve may be helpful in the diagnosis of raised intracranial pressure with papilledema.<sup>9</sup>

### FUNDUS FLUORESCEIN ANGIOGRAPHY

Angiogram photographs of the retinal blood vessels may be obtained using i.v. or oral fluorescein dye (Fig. 31.17). This technique may be of value in assessing retinal vascular disease, retinal inflammatory disease and optic disc abnormalities. In the presence of optic disc edema, capillaries on the surface of the optic disc are dilated and leaky (Fig. 31.18). Optic nerve head drusen 'autofluoresce'—angiogram fluorescence is seen in the absence of fluorescein dye.

### ELECTROPHYSIOLOGY STUDIES

Studies of the visual system using visually evoked potentials (VEPs) and of the retina using the electroretinogram may be of great diagnostic value in infants and young children with reduced vision. The stimulus for a VEP is a flash of light or a reversing pattern of black and white squares (Fig. 31.19). Pattern onset stimulation may be used as an

Fig. 31.16 Ocular ultrasound examination.

Fig. 31.17 A digital fundus camera images the retina following i.v. injection of fluorescein dye.

Fig. 31.18 Fluorescein dye is seen in the retinal arteries and capillaries 12s after i.v. injection. Dye is starting to return to the veins.

Fig. 31.19 Visually evoked potential examination using a reversing checker pattern stimulus.

alternative to pattern reversal. Uniocular testing and hemifield testing may be performed. The occipital cortex response is detected using electroencephalogram (EEG) electrodes. Delayed VEP response following stimulation of one eye may indicate optic nerve demyelination on that side, while reduced amplitude may indicate reduced axonal function as in optic nerve hypoplasia (Fig. 31.20). In albinism there is increased chiasmal nerve crossing, which produces asymmetrical occipital cortex responses to uniocular stimuli.

VEPs may be used to measure visual acuity in infants. Statistical analysis of a rapid sequence ('sweep') of checker pattern sizes is used to produce an estimate of visual acuity.

The electroretinogram (ERG) gives information about retinal function. The stimulus is a flash of light. The response is detected by skin electrodes on the eyelids or by ocular contact electrodes.<sup>10</sup> The electrical response is generated in the retina—the 'a' wave by the photoreceptors and the 'b' wave by the inner retina. Cone function and rod function may be analyzed separately by using a range of test strategies in which the background illumination is varied and the light flash stimulation is varied. Rod responses are measured using dim flash stimuli after dark adaptation (scotopic responses). Cone responses are measured in normal lighting conditions (photopic responses) (Fig. 31.21). 30 Hz flicker stimuli are used to isolate cone responses. The individual components of

Fig. 31.20 Pattern reversal visual evoked response. The VER of two eyes where the left eye (upper trace) shows a normal pattern and there is a slight delay in the right eye (lower trace).

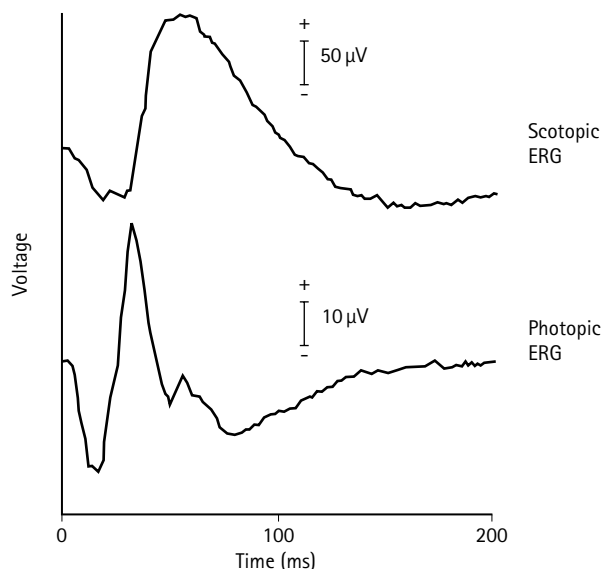

Fig. 31.21 A normal electroretinogram (ERG) showing the typical wave pattern and amplitude. The electroretinogram is taken under photopic (light adapted) conditions and scotopic (dark adapted) conditions. The wave pattern is reduced or abolished in various pathological conditions of the retina.

the ERG are best seen in the bright flash response following dark adaptation. Diseases that predominantly affect rod function produce abnormal scotopic ERG responses. Diseases that predominantly affect cone function produce abnormal photopic and 30Hz flicker ERG responses. Diseases that predominantly affect the inner retina produce abnormal ERG b-wave responses.

## REFRACTIVE ERRORS AND AMBLYOPIA

### REFRACTIVE ERRORS

Refractive errors may be treated with spectacles. However the presence of a refractive error may also be of diagnostic importance. Leber's congenital amaurosis is often associated with hypermetropia,<sup>11</sup> and Marfan syndrome<sup>12</sup> with myopia.

In hypermetropia, additional accommodation is used to maintain clear focus. This may lead to excessive convergence of the eyes and is a common cause of convergent squint. In myopia, distance vision is blurred but near vision is in focus. Astigmatism causes irregular focusing due to the toric (oval) curvature of the corneal surface.

Most infants are slightly hypermetropic, which normally resolves by age 2 years – 'emmetropization'.<sup>13</sup> Hypermetropia present after the age of 2 years normally persists into adult life. Myopia is rare in young children. When high degrees of myopia do occur an underlying disease such as homocystinuria,<sup>14</sup> Marfan syndrome<sup>12</sup> or Stickler syndrome<sup>15</sup> should be considered. While refractive errors are relatively uncommon among schoolchildren in resource limited countries,<sup>16</sup> the incidence of myopia among schoolchildren is rapidly increasing in resource rich countries.<sup>17,18</sup>

### AMBLYOPIA

When one eye is more hypermetropic than the other, accommodation produces a clear image in the more normal eye. However the retinal image in the more hypermetropic eye remains blurred, as accommodation amplitude is under bilateral neural drive. Untreated, occipital cortex synaptic connections related to the hypermetropic eye will remain underdeveloped.<sup>19</sup> This is termed 'anisometropic amblyopia'.

When a squint develops, the brain suppresses vision from the squinting eye in order to avoid diplopia. However continued suppression leads to failure of development of synaptic connections in the occipital cortex and once again the affected eye becomes amblyopic – strabismic amblyopia.<sup>19</sup> Anisometropic and strabismic amblyopia may coexist.<sup>20</sup>

The treatment of amblyopia is to first treat the underlying cause with glasses.<sup>21</sup> Occlusion of the normal eye is then used to drive development of synaptic connections relating to the amblyopic eye (Fig. 31.22). Atropine eyedrops may be used to blur vision in the normal eye, as an alternative to occlusion (atropine penalization).<sup>21</sup>

Fig. 31.22 Occlusion treatment.

Community visual screening programs are used to detect amblyopia. These are particularly necessary for the detection of anisometropic amblyopia, which is generally asymptomatic. Visual acuity measurements in each eye detect reduced vision in the amblyopic eye and lead to referral for assessment and treatment.<sup>22</sup> Screening may also detect small angled strabismus with amblyopia. Photographic techniques, which use pupil light reflex patterns to measure refractive errors, are an alternative approach to community screening.<sup>23</sup>

## CEREBRAL VISUAL IMPAIRMENT

CNS disease is the most common cause of visual impairment in children.<sup>24,25</sup> Causes of cerebral visual impairment (CVI) in children are given in Table 31.1. A wide spectrum of severity and type of impairment may occur. Damage to the anterior visual pathways, optic radiations and occipital cortex lead to reduced visual acuity and limited visual fields. Damage to visual association areas also causes significant impairment in children, which is often under-recognized. Two key pathways associated with visual processing are the 'ventral stream' and the 'dorsal stream'.<sup>26</sup>

The ventral stream connects the primary visual cortex with the fusiform gyri of the inferior temporal lobes. An 'archive' of learned images is held in this area. Children with ventral stream dysfunction may have difficulty recognizing faces, shapes and objects. They may also have difficulty with orientation in familiar environments.

The dorsal stream connects the primary visual pathway with the posterior parietal lobes, and associated pathways. Dorsal stream structures subserve visual attention and visually guided motor functions. Visual attention refers to the ability to analyze complex visual scenes, concentrate on specific elements of these scenes, and suppress other elements in order to avoid distraction. Ability to suppress auditory and tactile input is an additional requirement of visual attention.

Dorsal stream structures also provide information about orientation in three-dimensional space. Connections to the motor cortex guide limb movements and connections to the frontal eye fields guide saccadic eye movements.

### Timing of insult

The pattern of CVI impairment in an individual child is largely determined by the timing of the insult. Preterm infants typically sustain ischemic injury to the periventricular white matter and associated pathways (periventricular leukomalacia – PVL) following neonatal periventricular haemorrhage.<sup>27</sup> Symptoms emerge at about the age of 2–5 years. Reduced visual acuity, inferior visual field defects, nystagmus, and diplegia may be present. Dorsal and ventral stream impairments frequently occur. The optic discs show an enlarged physiological cup, which may be due to transsynaptic degeneration of fibers synapsing in the lateral geniculate bodies.

Damage to the visual pathways and to the dorsal and ventral streams occurs in relation to perinatal or antenatal insult in term infants. A variable combination of visual acuity, visual field and dorsal and ventral

Table 31.1 Causes of cerebral visual impairment

Prenatal	Brain malformations Intrauterine infections Placental dysfunction
Preterm neonatal	Preterm neonatal periventricular haemorrhage
Perinatal	Neonatal asphyxia Intracerebral hemorrhage Meningitis Encephalitis
Postnatal	Trauma (accidental and non-accidental) Cardiac arrest Meningitis Encephalitis Neurodegenerative disorders

stream impairments occur. Optic atrophy may occur as a result of the primary insult or secondary to posterior visual pathway damage. Many of these infants also develop cerebral palsy.

Ischemic injury in children after infancy typically results in watershed infarcts of the cerebral cortex, especially the occipital cortex. The pupil responses are preserved. Variable degrees of optic atrophy may be present. Nystagmus is usually not present.<sup>28</sup> The VEP may be normal or abnormal. The visual defect may be total initially, but there is variable improvement with time, dependent on etiology and severity. Most children achieve some navigational vision. Recovery when it does occur may take from a few hours to 2 years. Full recovery has been reported after head injury and cardiac arrest, but is less likely after bacterial meningitis and does not occur in children with neurodegenerative disorders.

### Ocular motor defects and CVI

Impaired eye movement control causes further visual difficulties for children with CVI. Strabismus, nystagmus, dystonic movements, impaired pursuit movements and impaired saccadic movement control may occur. In addition poor control of accommodation may lead to significant blurring of vision, especially for near tasks. Spectacles to correct hypermetropia and accommodation deficits are often helpful.<sup>29</sup>

### Coping strategies for children with CVI

Educational approaches to help children with visual impairment are given in the section entitled 'Education of visually impaired children'. Symptoms due to inferior visual field loss may be aided by using a tilted work board so that the child may look directly at written material rather than looking down. An awareness of reduced visual field to one side will ensure that parents and teachers introduce objects of interest (including themselves) in seeing areas.

Dutton has developed behavioral strategies to reduce the impact of dorsal and ventral stream impairments, and these are given in Table 31.2.<sup>26</sup>

Table 31.2 Cerebral visual impairment – ventral stream and dorsal stream defects and suggested coping strategies (modified from Dutton et al.<sup>26</sup>)

Defects	Suggested coping strategies
<b>Ventral stream</b>	
Impaired recognition of familiar faces	Verbal introduction; wear color/shape identifiers
Impaired orientation in familiar environment	Orientation training using cues and pathway markers
<b>Dorsal stream</b>	
Confused by complex ('busy') visual scenes	Store toys separately Store clothes separately (in transparent containers) Use plain carpets, bed covers and wall decoration
Difficulty identifying an individual in a group	Wave and speak
Disorientation in crowded environment	Train to use landmarks Visit shops when they are quiet
Reading	Mask surrounding text
Visually guide movements – upper limbs	Occupational therapy training strategies for reaching
Visually guide movements – lower limbs	Use tactile guide to height of ground – push a toy pram or bicycle, hold elbow or clothing of accompanying person
Distraction, leading to frustration at school and home	Limit visual and auditory 'clutter' in order to enhance concentration
Lose visual attention and bump or trip when talking or listening while walking	Keep quiet while walking

## STRABISMUS

### TERMINOLOGY

The term 'strabismus' and 'squint' are used interchangeably. 'Strabismus' is preferred. The prefix 'eso' is used for convergent deviations, and 'exo' for divergent deviations. 'Hyper' refers to upward deviation of an eye and 'hypo' to downward deviation. A 'tropia' is a manifest strabismus, which is present in binocular viewing conditions and is detected using the cover test. A 'phoria' is a latent strabismus, which is only apparent when binocular viewing is disrupted. The word 'deviation' is used to include both tropias and phorias. In 'concomitant' strabismus the deviation angle is the same in all directions of gaze. In 'incomitant' strabismus the deviation angle may be greater in one direction of gaze – for example in the direction of action of a paretic muscle. Adduction refers to medial movement of one eye, towards the nose, and abduction to lateral movement of one eye. 'Primary position' refers to the straight-ahead viewing position.

'Pseudosquint' refers to the appearance of apparent esotropia due to wide epicanthic skin folds. No true ocular deviation is present when a cover test is performed.

There are three common types of concomitant strabismus in childhood.

### INFANTILE ESOTROPIA

This type of convergent strabismus becomes apparent at age 3–4 months (Fig. 31.23). Infants who have developmental neurological problems are at increased risk of developing infantile esotropia. The typical characteristics of infantile esotropia are a large angled convergent strabismus, which alternates between the eyes. There is no amblyopia as each eye is alternately used. There is no significant refractive error in most cases. Hypermetropia is present in some cases. The lateral recti may appear to be weak, as the infant habitually tends to use the right eye to look to the left side and vice versa ('cross fixation'). This may lead to the suspicion of bilateral VI cranial nerve weakness. Occlusion of one or other eye for 20–30 min will usually reveal normal abduction of the uncovered eye rather than VI palsy.

A characteristic type of nystagmus may be present, termed 'manifest latent nystagmus'. In this form of nystagmus, the nystagmus is exaggerated by covering one eye. The uncovered eye develops a jerking nystagmus with the jerk towards the side of the fixing eye.

When present, hypermetropia should be treated with spectacles.<sup>30</sup> Very early surgery, performed during infancy, improves binocular function outcome.<sup>31</sup>

### ACQUIRED ESOTROPIA

Children who are hypermetropic habitually use extra accommodation in order to maintain clear focus. As accommodation and convergence

Fig. 31.23 Infantile esotropia. The right eye was converging when the photograph was taken.

reflexes are linked, this may lead to excessive convergence. Loss of control of convergence will lead to a convergent strabismus. The treatment is to promptly provide full spectacle correction.<sup>32</sup> This may reverse the condition. However if the strabismus does not fully reverse, occlusion treatment for amblyopia and surgical treatment may be needed. The use of preoperative prism spectacles improves the accuracy of surgical outcome.<sup>33</sup>

A late onset acquired esotropia may be mistakenly diagnosed as an acute VI nerve palsy. Patients with acute onset of esotropia should be assessed by an ophthalmologist as this may lead to prompt curative spectacle treatment rather than to a series of neurological investigations. Conversely concomitant convergent strabismus may be a presenting feature of VI nerve weakness due to a brainstem glioma, raised intracranial pressure or other pathology. A high index of suspicion for underlying neurological disease must therefore be maintained.

### INTERMITTENT EXOTROPIA

The third common cause of strabismus in children is intermittent exotropia. In this condition binocular control is maintained at times but at other times one eye deviates laterally. The child may close the deviating eye in order to concentrate when using the straight eye. Vision is normal in each eye. Usually there is no significant refractive error and no treatment is needed unless the child is significantly symptomatic, in which case surgical correction may be undertaken.<sup>34</sup>

### CONVERGENCE WEAKNESS

Weakness of convergence is usually an isolated abnormality, and can be treated with orthoptic convergence exercises.

### STRABISMUS AS A SIGN OF UNDERLYING ORGANIC DISEASE

All cases of strabismus should be promptly assessed, as both convergent and divergent strabismus may be a presenting feature of underlying neurological disease (Table 31.3). Mild VI cranial nerve weakness can cause apparently concomitant strabismus.

### INCOMITANT STRABISMUS

Weak lateral rectus function is the most common cause of incomitant strabismus. VI cranial nerve weakness should be considered in all cases (Table 31.4).

Table 31.3 Conditions that may present with (apparent) concomitant strabismus

VI cranial nerve paresis:
Raised intracranial pressure
Brainstem glioma
Moebius syndrome
Duane's syndrome
Esotropia (abduction is usually normal)

## Incomitant strabismus syndromes

### *Duane syndrome*

In Duane syndrome VI cranial nerve innervation of the lateral rectus muscle is variably defective, and an anomalous branch of the III cranial nerve supplies the lateral rectus muscle. On attempted abduction there is variable lateral rectus weakness, which may be mistaken for VI cranial nerve palsy caused by acquired neurological disease. On attempted adduction of the eye the medial rectus and lateral rectus muscle co-contract and the eye retracts into the orbit, with narrowing of the palpebral aperture. A number of associated neurological deficits, including partial sensorineural deafness, are associated with Duane syndrome.

Surgical treatment is reserved for those children who develop a significant compensatory head turn (towards the side of the affected eye), or strabismus in primary position.<sup>35</sup>

### *Moebius syndrome*

Moebius syndrome consists of congenital absence of cranial nerve nuclei, including the VI and VII nerve nuclei. Abduction is absent in each eye, and there is bilateral facial palsy.

### *Brown syndrome*

In Brown syndrome there is a congenital anomaly of superior oblique tendon and trochlea function. When the affected eye is adducted it shoots downwards. The condition is usually treated conservatively as some spontaneous recovery may occur. In severe cases superior oblique tendon surgery may be performed.

### *Congenital superior oblique tendon laxity*

Weakness of superior oblique function in children (and adults) is more commonly caused by congenital laxity of the superior oblique tendon than by IV cranial nerve paresis. Typically there is a compensatory head tilt to the opposite side. This may be mistaken for sternomastoid muscle induced torticollis. Eye movement examination reveals weakness of the affected superior oblique, with secondary overaction of inferior oblique function. Surgery may be performed if there is a significant compensatory head posture, or strabismus in primary position. The lax tendon may be tucked, or the overactive inferior oblique muscle may be weakened by recession surgery.

## PUPIL ABNORMALITIES

Children presenting with unequal pupil size (anisocoria) tend to cause great concern to both the parents/carers and clinicians. In practice, intracranial pathology is uncommon. The most common cause is physiological anisocoria; other causes include III nerve palsy, Horner syndrome, previous blunt trauma or dilating eye drops.

The examination should be directed at determining the presence or absence of ptosis, eye movement abnormalities such as III palsy and other cranial and peripheral nerve palsies. In physiological anisocoria, the difference in pupil size is proportionately the same in bright or dim lighting.

### III (OCULOMOTOR) PALSY

There is usually a marked or complete ptosis and restriction of eye movements. The eye is typically turned down and outwards. The pupil on the affected side may be enlarged. Causes include congenital (usually idiopathic), head injury, and tumors. Prompt neuroimaging is indicated in acquired cases.

### HORNER SYNDROME

Horner syndrome is caused by reduced sympathetic nerve supply to the eye and comprises a partial ptosis with a small (miosed) pupil. Most cases in children are congenital. Acquired cases require prompt investigation for possible abdominal neuroblastoma. In Horner syndrome, the anisocoria is more pronounced in dim light due to failure of the affected pupil to dilate.

## NYSTAGMUS

### CONGENITAL IDIOPATHIC NYSTAGMUS

In congenital idiopathic nystagmus the onset of nystagmus occurs between the ages of 2 and 3 months. Some cases are familial – dominant, recessive and X-linked inheritance has been described. An underlying vision defect should be excluded. Typically the nystagmus is horizontal and the amplitude is greater on looking to one side and less on looking to the other side (null zone). Head nodding may be present. Ocular examination is otherwise normal and there are no neurological abnormalities. The ERG and VEPs are normal. On follow up, near vision develops to a relatively normal level. There is moderate reduction of distance vision and some modification of the classroom environment is often helpful. Treatment consists of spectacle correction of refractive errors. Surgical treatment may produce some benefit in selected cases,<sup>36</sup> and medical treatment with gabapentin is currently under investigation.<sup>37</sup>

### SENSORY DEFECT NYSTAGMUS

Infants with congenital nystagmus may have an underlying vision defect. In most cases an ocular abnormality is present and a systematic approach to ocular and electrophysiological examination is required. A differential diagnosis is given in Table 31.5. In general, posterior visual pathway defects do not result in nystagmus.<sup>28</sup> Periventricular leukomalacia is an exception to this rule.<sup>27</sup>

### ALBINISM

Albinism refers to a group of conditions that may be divided into oculocutaneous albinism (OCA) and ocular albinism (OA). The ocular abnormalities found are common to all forms of albinism. In addition to defective iris and fundus pigmentation, abnormalities include: reduced vision and photophobia; nystagmus; strabismus; delayed visual maturation; foveal hypoplasia and abnormal chiasmal crossing. More than 90% of fibers cross at the chiasm, resulting in cortical asymmetry of VEP responses. Iris translucency varies in severity and relatively minor defects of iris pigmentation may only be detected by slit lamp transillumination performed in a dark room. Most forms of OCA are autosomal recessive. Two rare forms of OCA are associated with systemic disease – increased susceptibility to infection in Chediak–Higashi disease<sup>38</sup> and frequent bruising due to platelet dysfunction in Hermansky–Pudlak syndrome.<sup>39</sup>

In ocular albinism typical ocular abnormalities are present, but skin and hair color are normal.

Refractive errors should be corrected with spectacles, and photophobia reduced with tinted spectacles and peaked hats. Mainstream education, with some attention to the classroom environment, and normal educational attainment may be anticipated in almost all cases.

### ANIRIDIA

Aniridia is an autosomal dominant condition caused by mutations in the PAX 6 homeobox gene. About 30% of cases are sporadic, with deletions at 11p13. Sporadic cases have a high incidence of associated abnormalities, including Wilms tumor,<sup>40</sup> genitourinary abnormalities and mental retardation. Abdominal palpation and/or abdominal ultrasound examination should be performed in all new cases and as part of follow up.

Table 31.5 Causes of sensory congenital nystagmus

Albinism
Leber's amaurosis
Aniridia
Optic nerve hypoplasia
Retinal cone dystrophy

Fig. 31.24 Aniridia. No iris tissue is seen. There is fibrovascular pannus covering the peripheral cornea in this case.

Aniridia represents a defect of neural crest cell development. In addition to the striking absence of iris tissue, with only very rudimentary stubs of iris tissue present, the following ocular abnormalities are frequently seen: nystagmus, fibrovascular corneal pannus, refractive errors, glaucoma, cataract, foveal hypoplasia and optic nerve hypoplasia (Fig. 31.24). Foveal hypoplasia refers to poorly differentiated foveal structures; in extreme cases major retinal blood vessels may cross the normally avascular fovea. Corneal disease is due to defective limbal stem cell function, and responds to stem cell transplant surgery. Glaucoma surgery outcomes are limited by conjunctival scarring. Cataract surgery is also complicated, because of absent iris tissue and weak lens zonules. Progressive loss of vision over decades is usual in aniridia patients.

### ACQUIRED NYSTAGMUS

Acquired nystagmus in childhood always requires prompt ophthalmic and neurological assessment. A differential diagnosis is given in Table 31.6. Vertical nystagmus may consist of downbeat nystagmus, associated with craniocervical junction abnormalities, or more rarely upbeat nystagmus, associated with brainstem and cerebellar lesions. Urgent neurological investigation, including brain imaging, is required in all cases of acquired nystagmus.

### SPASMUS NUTANS

Spasmus nutans is a syndrome of infancy with nystagmus, head nodding and torticollis. Investigation to exclude an intracranial tumor is required. The syndrome resolves after 12–18 months and the diagnosis is one of exclusion, made retrospectively.

### THE APPARENTLY BLIND INFANT

A carer's concern for an infant's vision is usually reliable. Infants with poor visual behavior require urgent assessment by an ophthalmologist. Treatable disease such as cataract must be dealt with promptly in order to avoid the development of irreversible amblyopia. In most cases the

cause is apparent following ophthalmic examination. Ocular defects that may cause bilateral congenital blindness are given in Table 31.7.

In some cases there may be no ocular abnormality evident, or only very subtle defects are found (Table 31.8). In these cases electrophysiological and neurological investigations may be required.

### DELAYED VISUAL MATURATION

Delayed visual maturation (DVM) refers to visual unresponsiveness from birth that subsequently improves.<sup>41</sup> The diagnosis is one of exclusion and is always retrospective. The onset of visually stimulated smiling is delayed; clinical pupil responses are normal and there is no nystagmus.

### LEBER'S CONGENITAL AMAUROSIS

Leber's congenital amaurosis (LCA, isolated infantile rod–cone dystrophy) is an autosomal recessive congenital retinal dystrophy.<sup>42</sup> Vision is absent or severely reduced from birth and the ERG is markedly reduced or absent. The pupils may show a sluggish afferent response. Refraction usually shows significant hypermetropia. The fundus appearances are normal or near normal. The term 'Leber's congenital amaurosis' should be reserved for cases of isolated infantile rod–cone dystrophy, and the diagnosis of Leber's congenital amaurosis should only be made after

**Table 31.9** Syndromes associated with infantile rod–cone dystrophy

Cerebellar vermis hypoplasia, e.g. Joubert's syndrome
Deafness, e.g. Usher's syndrome type 1
Renal disease, e.g. nephronophthisis

Mitochondrial cytopathies, e.g. hydroxyacyl-CoA dehydrogenase deficiency
Amino acid disorders, e.g. methylmalonic aciduria

exclusion of other recognized syndromes (Table 31.9). Hearing, neurological, renal and metabolic abnormalities should be sought.

While no active treatment for LCA is possible at present, gene therapy trials are under development.<sup>43</sup> Genetic counseling and molecular diagnosis are therefore required.

### OPTIC NERVE HYPOPLASIA

Optic nerve hypoplasia (ONH) is not inherited, and most cases are idiopathic. Insults in early embryonic development have been associated with ONH – maternal diabetes, maternal alcohol and other substance abuse. ONH may occur in isolation or in association with failure of development of the anterior midline structures of the brain (septo-optic dysplasia [SOD]), hydranencephaly, porencephaly, cerebral atrophy or leukomalacia. ONH also occurs in aniridia. A genetic basis has been identified in a small number of cases of SOD.<sup>44</sup> Severe bilateral cases are associated with neuroendocrine dysfunction. Hypoglycemia may occur in the neonatal period. Sudden infant death may occur as a result of an abnormal stress response to febrile illness. All cases should be referred for endocrine investigation. In addition to abnormal cortisol response, growth, thyroid and gonadotrophic hormones may be defective. Magnetic resonance imaging (MRI) is useful as a predictor of neuroendocrine dysfunction and allows assessment of optic nerve size.

There is a spectrum of severity ranging from complete blindness with very tiny optic nerve structures to virtually normal vision with very minor degrees of ONH. Cases may be unilateral, bilateral or asymmetric.

Mild cases present later in childhood. The optic disc appearances vary (Fig. 31.25) and include:

- variably small optic disc;
- peripapillary pigmented ring (double ring sign);
- slightly tortuous retinal vessels;
- associated optic atrophy;
- segmental disc hypoplasia.

**Fig. 31.25** Hypoplastic disc. Optic nerve hypoplasia. The optic disc is anatomically very small in this case, with severely reduced vision.

Mild cases present with reduced vision in one or both eyes, or with strabismus. Mild degrees of optic nerve hypoplasia may be misdiagnosed as amblyopia, and cases of amblyopia that do not respond well to occlusion treatment should always be carefully examined for the presence of subtle optic nerve hypoplasia.

### OCULOMOTOR APRAXIA

Absent saccadic eye movements may be mistakenly interpreted as defective visual function. The ERG is reduced in some cases,<sup>45</sup> further increasing the possibility of misdiagnosing Leber's congenital amaurosis. Once the child is able to support and move their head, characteristic side-to-side head thrusting movements develop. These head movements are used as a substitute for voluntary saccadic eye movements.

### ACQUIRED VISUAL LOSS IN CHILDREN

Acquired visual loss at any age requires urgent investigation. Unilateral visual loss may result in the development of strabismus. Binocular visual loss will lead to impaired visual behavior and, in older children, a complaint of reduced vision. In most cases, acquired visual loss is due to retinal, optic nerve or neurological disease (Table 31.10). When the cause is not evident on ophthalmic examination, neurological, electrophysiological, and neuro-imaging assessment will be needed.

### CATARACT

Bilateral cataract developing in later childhood is rare. Metabolic disorders such as diabetes mellitus and disorders of galactose metabolism should be excluded.<sup>46</sup>

### RETINAL DYSTROPHIES

This term refers to genetic abnormalities of the retina or retinal pigment epithelium that lead to reduced retinal function. Rod dysfunction presents with reduced vision, especially in dim lighting conditions. Cone dysfunction presents with reduced vision, photophobia, and reduced color vision. Fundus examination may show pigmentary disturbance. When the rods are predominantly affected, black spiky

Fig. 31.27 Retinal cone dystrophy with typical 'bull's eye' pigmentation at the center of the macula.

blotches of pigment are seen in the retinal periphery (bone spicule pigmentation) (Fig. 31.26). This appearance leads to the historical term 'retinitis pigmentosa'. When the cones are affected pigmentation may be present at the macula, often in a ring shape (bull's eye) (Fig. 31.27). The diagnosis is made on clinical grounds, supported by electroretinogram abnormalities of rod and cone functions.

Most types of retinal dystrophy are currently not treatable. Two rare forms of rod-cone dystrophy of childhood are amenable to treatment. In Refsum disease serum phytanic acid levels are raised. Dietary intervention will improve the prognosis for vision and also reduce morbidity due to other systemic features of the disease. In abetalipoproteinemia, vitamin and dietary treatment improve the prognosis.

### STARGARDT DISEASE

Stargardt disease is an autosomal recessive disease with onset in late childhood. Symptoms are limited to reduced visual acuity, with no symptoms of night blindness or of photophobia. Typically there are creamy fish-tail-shaped flecks in the retina (fundus flavimaculatus) with additional retinal pigment epithelium atrophy at the macula (Fig. 31.28). The disease progresses until visual acuity is reduced to about 6/60.<sup>47</sup>

### AUTOSOMAL DOMINANT OPTIC ATROPHY

The finding of reduced vision and optic atrophy should lead to prompt neurological and neuroimaging investigations. In autosomal dominant optic atrophy neurological investigations are normal. The condition is associated with defects in the OPA1 gene.<sup>48</sup> There is reduced visual acuity, some reduction of color vision, reduced visual field sensitivity between fixation and the blind spot ('centrocaecal scotoma'), reduced amplitude pattern VEP and variable pallor of the temporal part of the optic disc. Visual loss is not severe, and progression is very slow.

### CHILDHOOD VISUAL LOSS WITH NO ABNORMALITY ON OPHTHALMIC EXAMINATION

#### BATTEN DISEASE (JUVENILE NEURONAL CEROID LIPOFUSCINOSIS)

The neuronal ceroid lipofuscinoses (NCLs) are a group of autosomal recessive neurodegenerative lysosomal storage diseases. While classification by age of disease onset has been helpful in the past, more precise molecular genetic diagnosis is now possible.<sup>49</sup> The majority of cases of juvenile NCL have a mutation in the CLN3 gene. These cases may present with visual loss.<sup>50</sup> Neurological degenerative symptoms may not develop for up to 3 years later. The diagnosis must therefore be considered in any child aged 4–10 years with visual loss that cannot be explained on ophthalmic examination. The fundi may initially appear normal. The ERG is reduced, and typically shows an electronegative waveform. Later a pigmentary disturbance develops at the macula. The disease is progressive, with epileptic seizures and dementia. No treatment is currently available.

### FUNCTIONAL VISUAL LOSS

A relatively common cause of apparent reduction of vision in young teenagers is 'functional' visual loss. Symptoms are precipitated by stress. Typically the child complains of blurred vision. On examination there are no objective abnormalities. The diagnosis can be made if the child is 'tricked' into giving normal visual acuity test results by using neutralizing combinations of spectacle lenses or other means. Having made the diagnosis, psychological counseling may be helpful. Underlying problems at school or in the home may be detected. The prognosis is usually good, as the underlying psychological disturbance tends to be relatively minor. When a positive diagnosis cannot be made, follow up and investigations to exclude other causes of visual loss are necessary.

## DISEASES OF ORBITAL AND OCULAR TISSUES

### ORBITAL DISEASE

#### Congenital abnormalities of skull development

A number of craniosynostoses have ocular features. Crouzon, Apert and Pfeiffer syndromes result in shallow orbits, which can lead to corneal exposure. Hydrocephalus is common in these conditions and regular optic disc examination is required. Visual loss may also occur because of amblyopia secondary to refractive errors and strabismus.<sup>51</sup> Complex horizontal and vertical strabismus patterns are frequently present. Strabismus surgery may be considered after corrective skull surgery has been performed.

#### Symptoms and signs of orbital disease

Symptoms of orbital disease include reduced vision, diplopia and altered appearance. Signs include proptosis, which may be axial (forward protrusion of the eye in the axis of the orbit) or non-axial. The pattern of non-axial proptosis gives useful clues to the site of orbital disease. For instance, if the eye is deviated laterally, it is likely that the site of orbital disease will be medial. Eye movements may be reduced. Visual acuity may be reduced and there may be sensory abnormalities of pupil reactions.

#### Preseptal cellulites

Preseptal cellulitis refers to eyelid cellulitis that does not extend beyond the orbital septum into the orbit. The eye appears normal and vision remains normal. While the infection may be related to local skin infection or local skin trauma, this form of cellulitis is commonly secondary to sinus infection with *Haemophilus influenzae* or *Streptococcus aureus* and is part of the spectrum of orbital cellulitis.<sup>52</sup> An orbital computerized tomography (CT) scan may be indicated when severe eyelid swelling prevents adequate eye examination. Treatment is with i.v. antibiotics.

#### Orbital cellulitis

True orbital cellulitis is much less common than preseptal cellulitis. The orbit becomes inflamed with proptosis of the eye, reduced eye movement and reduced vision. Prompt and effective treatment must be instituted as orbital cellulitis may lead to orbital or even brain abscess. Most cases are secondary to ethmoidal sinusitis. Since the advent of *H. influenzae* vaccination, streptococci sp. have become the most common organisms responsible.<sup>53</sup> Blood cultures should be performed and an orbital CT scan should be performed. Treatment is with broad-spectrum i.v. antibiotics covering Gram positive, Gram negative and anaerobic organisms. Visual acuity should be monitored regularly. An otolaryngologist should be involved in all cases as urgent sinus drainage may be needed in order to protect vision.<sup>54</sup>

#### Orbital tumors

Capillary hemangioma, venous-lymphatic malformations and dermoid cysts are the most common orbital masses in infants and children under the age of 2 years.

*Capillary hemangiomas* grow rapidly during the first 6 months of life, stabilize, and then regress at age 3–8 years. Superficial lesions are a typical 'strawberry' color (Fig. 31.29); deeper lesions have a bluish appearance. The diagnosis may be made clinically, and CT or MRI scans may be used to delineate the extent of the lesion. Visual loss is usually related to amblyopia,<sup>55</sup> but can be due to optic nerve compression or corneal exposure. Amblyopia may be due to occlusion of the pupil, or astigmatism in the axis of the lesion. Treatment is conservative when there is no threat of amblyopia. However lesions that occlude the pupil or cause significant astigmatism may require early intervention to prevent amblyopia. Intralesional depot steroids or even systemic steroids may be used.<sup>55</sup> Surgery is normally deferred until maximal spontaneous regression has occurred at about age 8 years.

*Venous-lymphatic malformations* present with proptosis in childhood, which may be abrupt if bleeding occurs into a cystic space. While the

Fig. 31.29 Capillary hemangioma of the lower eyelid.

lesions consist of venous-like vascular channels they are not directly connected to the venous system.<sup>56</sup> They may be delineated by CT or MRI scan. Unlike capillary hemangiomas they do not regress with age. Surgical intervention is unsatisfactory and most lesions are best treated conservatively.

*Dermoid cysts* may be superficial or deep. Superficial lesions are most often found at the upper outer angle of the orbit. Having excluded a deeper component of the lesion by clinical examination, ultrasound examination, MRI or CT scan, excision may be performed. Deeper lesions tend to present with proptosis, at a later age. Conservative treatment is often appropriate.<sup>57</sup>

*Rhabdomyosarcoma* is the commonest malignant orbital tumor of childhood and usually develops between the ages of 4 and 12 years. The tumor enlarges rapidly with increasing proptosis, mild redness and edema of the eyelids and reduced eye movements.<sup>58</sup> The diagnosis is made by biopsy, and as much tissue as possible should be removed for examination. A direct approach to the lesion should be performed, as tumor seeding may occur in the biopsy track. Depending on clinical stage, chemotherapy with or without radiotherapy is the initial treatment. Orbital exenteration may be needed if primary treatment fails.

## EYELID ABNORMALITIES

*Epiblepharon* refers to the presence of a fold of skin near the lower eyelid margin, which may cause inturning eyelashes (Fig. 31.30), most commonly affecting oriental infants. The natural history is spontaneous resolution during the first 1–2 years of life and surgery is reserved for severe cases.

Fig. 31.30 Epiblepharon.

*Blepharitis* refers to inflammation of the eyelid margins. This is a relatively common condition in older children and in adults. Hot bathing and eyelid margin toilet using cotton tipped buds may be effective. When secondary staphylococcal infection is present, treatment with topical fucidic acid cream is indicated. In a small number of cases corneal inflammation with vascularization and scarring may develop, and topical steroid therapy may be needed to control this process.

A *tarsal cyst* is a retention cyst of an oil-producing meibomian gland of an eyelid. These cysts resolve spontaneously over a period of months. Surgical drainage is indicated in the minority of cases in which significant eye discomfort is present.

### CONGENITAL PTOSIS

Dystrophic changes of the levator muscle of one or both upper eyelids will result in drooping of the upper eyelid, termed 'ptosis' (Fig. 31.31). Congenital III nerve palsy and Horner syndrome should be excluded. Congenital Horner syndrome is associated with neuroblastoma.<sup>59</sup> The jaw winking (Marcus Gunn) phenomenon should be sought – lateral movements of the jaw produce synkinetic movements of the ipsilateral upper eyelid.

If the pupil is occluded by ptosis, prompt surgery is indicated in order to prevent amblyopia. However in milder cases corrective surgery is best deferred until teenage years, when cooperation with surgery under local anesthetic may be obtained, leading to a better cosmetic result. Surgery generally involves advancement or resection of the levator aponeurosis.

## LACRIMAL SYSTEM

### CONGENITAL NASOLACRIMAL DUCT OBSTRUCTION

The nasolacrimal duct commonly has a persistent membranous occlusion at the distal end of the duct. This leads to watering (epiphora) of the affected eye or eyes. Epiphora is almost always first noticed during the first month of life. The fluorescein dye disappearance test is useful in diagnosis. A drop of fluorescein dye is placed in the conjunctival sac and the time taken for dye to clear is observed. Delayed drainage implies that the nasolacrimal duct is not patent. The natural history is spontaneous resolution of watering during the first 1–2 years of life. If watering persists beyond the age of 2 years, probing of the nasolacrimal duct may be undertaken.<sup>60</sup> While waiting for spontaneous resolution, the eyes should be bathed if they become sticky. Topical antibiotics need only be used if signs of active tissue inflammation are present.

### LACRIMAL OBSTRUCTION IN OLDER CHILDREN

In some children, epiphora persists despite probing. In these cases intranasal anatomical abnormalities may be found.<sup>61</sup> Endoscopic

Fig. 31.31 Congenital ptosis of the left upper eyelid due to levator muscle dystrophy.

exploration, with silicone intubation of the lacrimal system, is effective in 80% of cases.<sup>62</sup> Where severe anatomical occlusion of the nasolacrimal duct is present, dacryocystorhinostomy surgery may be required. However epiphora in older children is more often due to allergy or upper respiratory tract infection than to nasolacrimal duct occlusion.<sup>63</sup>

## CONGENITAL ABNORMALITIES OF EYE DEVELOPMENT

The whole eye may be absent at birth (anophthalmos) (Fig. 31.32) or may be small (microphthalmos).

Orbital growth is partly stimulated by the volume effect of the eye. Orbital growth is reduced if an eye is removed during early childhood. Hydrophilic tissue expanders are therefore used to enhance orbital growth in cases of anophthalmos or severe microphthalmos.

Microphthalmos is commonly associated with coloboma due to embryonic optic fissure closure defects. Typically the inferior part of the iris is absent along with the inferior choroid and retina (Fig. 31.33). The optic disc may or may not be involved. Microphthalmos and coloboma may be isolated abnormalities, associated with chromosomal syndromes such as trisomy 13, or associated with a single gene defect such as choanal atresia with ear, eye, heart and genital defects (CHARGE) syndrome.<sup>64</sup>

## CONJUNCTIVITIS

Neonatal conjunctivitis has been discussed in Chapter 12. Bacterial infection, viral infection, chlamydial infection and allergy may cause conjunctivitis in older infants and in children.

Fig. 31.32 Anophthalmos. No identifiable ocular structures are apparent.

Fig. 31.33 Coloboma of the inferior iris.

Bacterial conjunctivitis produces a purulent discharge and is generally self-limiting – topical antibiotics are generally not indicated.<sup>65</sup> Viral conjunctivitis produces a watery discharge with a mucous component and is generally self-limiting. Chlamydial neonatal infection has been discussed in Chapter 12. In hot, dry countries with limited water supplies flies cause endemic chlamydial conjunctivitis – trachoma. Conjunctival scarring leads to dry eyes and eyelid scarring. Secondary corneal scarring follows, and remains a common avoidable cause of blindness worldwide. Prevention is by improved water supply and hygiene, and treatment of acute infection by community use of oral azithromycin.<sup>66</sup>

Chronic allergy in the form of vernal keratoconjunctivitis results in morbidity due to ocular discomfort and visual loss. Corneal scarring may be present along with papillary inflammation of the tarsal conjunctiva. Treatment is with mast cell stabilizers such as sodium cromoglycate, steroid eye drops, and topical cyclosporin eye drops. Topical steroid eye drops may cause glaucoma and cataract. Close supervision by an ophthalmologist is required.

Conjunctival dryness (xerosis) and corneal melting are features of vitamin A deficiency. Acute deficiency signs may be precipitated by intercurrent respiratory or gastrointestinal infection and urgent treatment with high doses of vitamin A is then needed.

## CORNEAL DISEASE

Corneal scarring due to trachoma and vitamin A deficiency remains a leading cause of childhood blindness in resource poor countries.

In wealthy countries herpes simplex corneal infection is a relatively frequent cause of morbidity. Prompt treatment with topical antiviral drops or ointment (e.g. aciclovir) is usually sufficient to clear the infection, but in some cases areas of chronic inflammation and scarring of the cornea develop. Epidemics of adenovirus keratoconjunctivitis occur from time to time. While the condition is limited to viral conjunctivitis in most cases, some individuals develop inflammatory infiltrates deep to the corneal epithelium. Cautious use of topical steroids reduces symptoms, and reduces scarring.

Congenital corneal opacities due to dystrophies or as part of Peter's anomaly or sclerocornea are relatively rare. In bilateral cases corneal transplant surgery may be indicated. As with congenital cataracts, surgical treatment must be undertaken early if visual loss due to amblyopia is to be avoided. Corneal transplant surgery in infants, and the necessary intensive aftercare, are very demanding of the surgeon and the family and treatment is best undertaken in specialized referral departments.

Congenital limbal dermoids (Fig. 31.34) may occur in isolation or as part of a number of syndromes. They may be excised later in childhood. Surgery in infancy is generally not required.

Fig. 31.34 Limbal dermoid.

## UVEITIS

Uveitis screening is necessary in children with juvenile idiopathic arthritis (JIA) (Fig. 31.35). This is because the intraocular inflammation may be asymptomatic in its early stages, but untreated, may lead to glaucoma and cataract development. Slit lamp screening examination should be performed urgently when a diagnosis of JIA has been made. The groups at highest risk are those with oligoarticular disease and those who are antinuclear factor positive.<sup>67</sup> These children should be screened every 2–3 months initially. The children at lowest risk are children with systemic onset JIA, juvenile spondyloarthritis and juvenile-onset rheumatoid factor positive arthritis. In these cases, screening is only required once, at disease onset. Children with other categories of JIA are at intermediate risk and should be examined every 3–4 months. Screening may generally be discontinued at age 12 years. Detailed guidelines for screening have been published by the American Academy of Pediatrics, and these are summarized in Table 31.11.<sup>68</sup> When iritis is detected, topical steroids and mydriatics may be used. Supervision of treatment by an ophthalmologist is needed because of the risks of glaucoma and cataract development due to steroid treatment. In more severe cases, or when there is a persisting topical steroid requirement, treatment with low-dose methotrexate, with mycophenolate or with the anti-TNF alpha agent infliximab may be required in order to reduce exposure to glucocorticoids and their side-effects.<sup>69</sup>

Fig. 31.35 Iritis. The pupil has been dilated and adhesions between the iris and lens (posterior synechiae) are seen.

Table 31.11 Guidelines for screening for uveitis in juvenile arthritis (taken from American Academy of Pediatrics guidelines.<sup>68</sup>)

Juvenile arthritis subtype at onset	Age onset < 7 years	Age onset $\geq$ 7 years
Oligoarticular, ANA positive	High	Medium
Oligoarticular, ANA negative	Medium	Medium
Polyarticular, ANA positive	High	Medium
Polyarticular, ANA negative	Medium	Medium
Systemic	Low	Low

Rules:  
 High risk = examinations 3–4 monthly  
 Medium risk = examinations 6 monthly  
 Low risk = examinations 12 monthly  
 Onset age < 7 years – risk becomes low 7 years after disease onset  
 Onset age  $\geq$  7 years – risk becomes low 4 years after disease onset  
 All 'high risk' becomes 'Medium risk' 4 years after disease onset

## CATARACT

Congenital cataract remains a major cause of childhood blindness worldwide (Fig. 31.36). In resource rich countries severe visual handicap due to congenital cataract is now rare because of improvements in surgical management.<sup>24</sup> The key to a satisfactory outcome is early detection and early surgery in order to avoid amblyopia.<sup>70-72</sup>

Two thirds of cases of congenital cataract are bilateral and one third unilateral.<sup>73</sup> Underlying causes or associated risk factors were present in 62% of bilateral and 8% of unilateral cases in a national UK study.<sup>74</sup> The causes of congenital cataract are given in Table 31.12. Every infant with congenital cataract should be examined for dysmorphic features or

Fig. 31.36 Congenital cataract. This is a partial, lamellar cataract with relatively good vision. Surgery in infancy was not needed in this case.

Table 31.12 Causes of congenital cataracts

Idiopathic		
Isolated inherited	Dominant, recessive, X-linked

Ocular associations	Microphthalmos Aniridia Persistent fetal vasculature Peter's anomaly Endophthalmitis	

evidence of metabolic disease. The parents should be examined for evidence of cataract as autosomal dominant cataracts may vary in disease expression.

Surgery should be performed within the first 6 weeks of life in order to ensure that optical rehabilitation has been completed by the age of 8–10 weeks.<sup>73</sup> Delayed detection and treatment will lead to irreversible visual loss due to amblyopia.<sup>74</sup> In bilateral cases the surgery is performed on one eye initially, with surgery to the second eye a few days later. There is uncertainty as to whether intraocular lens implants should be used at primary surgery.<sup>76</sup> An alternative to primary intraocular lens implantation is the use of contact lenses for primary optical correction, followed by secondary lens implantation at approximately age 2 years.

## LENS SUBLUXATION

The most common cause of lens subluxation (Fig. 31.37) in children is Marfan syndrome.<sup>75</sup> The lenses tend to be subluxed from an early age and there is rarely any significant progression with time.<sup>75</sup> For this reason a single screening examination in early childhood is sufficient to detect lens subluxation and regular follow up is generally not required. The differential diagnosis includes homocystinuria.<sup>76</sup>

When lens subluxation occurs, treatment may be either optical or surgical. Surgical treatment generally involves removing the whole lens and using contact lenses or sutured intraocular lens implants for optical correction.<sup>78</sup>

## GLAUCOMA

### PRIMARY CONGENITAL GLAUCOMA

Primary congenital glaucoma typically occurs in boys between the age of birth and 2 years. Some cases are autosomal recessive and there is a one in 20 empirical recurrence risk in siblings. The presenting signs may be present in one or both eyes. Watery, photophobia and enlargement of the corneas occur (Fig. 31.38). The diagnosis is made by performing an examination under anesthetic and measuring the intraocular pressure; i.v. or i.m. ketamine sedation is preferred for these examinations as ketamine produces a small, predictable rise in intraocular pressure. In contrast inhalational anesthetics produce a variable lowering of intraocular pressure. Treatment is surgical and demanding. Multiple operations may be required and surgical treatment is better undertaken in a pediatric glaucoma referral center.

### SECONDARY GLAUCOMAS

Glaucoma may be secondary to other congenital ocular abnormalities. These include Reiger syndrome (Fig. 31.39) and aniridia. Glaucoma may develop secondary to iritis and steroid therapy in patients with JIA.

Fig. 31.37 Subluxed lens.

Fig. 31.38 Congenital glaucoma. Note enlarged corneas. This child had goniotomy surgery performed in infancy, which satisfactorily controlled the intraocular pressures.

Fig. 31.40 Sturge-Weber syndrome. Note eyelid port wine stain, and abnormal scleral blood vessels.

Fig. 31.39 Reiger syndrome. Note posterior embryotoxon and abnormal pupil shape and position (corectopia).

A particularly difficult form of childhood glaucoma is aphakic glaucoma in children who have had congenital cataract surgery.<sup>79</sup> Complex surgical treatment may be required.

Glaucoma may develop in Sturge-Weber syndrome, especially if the upper eyelid has a port wine stain lesion (Fig. 31.40).

## RETINAL DISEASES

Retinal disorders, which cause bilateral visual loss in children, have been described earlier. Causes of unilateral retinal disease include those following.

### COATS DISEASE

Coats disease is a primary retinal telangiectatic disease in which leaky vessels cause progressive accumulation of fatty deposits in the subretinal space (Fig. 31.41). Mutations in the gene for Norrie disease have been identified as the underlying cause.<sup>81</sup> The condition is diagnosed at a median age of 5 years, is more common in males and is almost always unilateral.<sup>81</sup> There are no systemic associations. Treatment with laser therapy or cryotherapy can reduce serous leakage and improve visual prognosis.<sup>82</sup>

### RETINOBLASTOMA

Retinoblastoma (RB) is a malignant neuroblastic tumor of the retina, which normally develops during the first 2 years of life. Presenting signs include leukocoria (white pupil) and strabismus. Approximately 50% of cases are heritable, with a mutation of the RB1 tumor suppressor gene. In these cases, additional somatic mutations of allelic RB1 genes in retinal cells lead to loss of tumor suppressor function and neoplasia occurs. Tumors are usually multiple. Approximately 50% of heritable cases have a family history of retinoblastoma; the remainder represent new germline mutations.

In cases in which there is no germ-cell mutation, two mutations are needed to produce neoplasia in a retinal cell.<sup>83</sup> In these cases, the tumor is almost always solitary, with slightly later onset than heritable cases (median age 24 months compared to 12 months). However 15% of cases with solitary tumors have an underlying germ-cell mutation.

The diagnosis is made clinically. Typically the tumors have a creamy white appearance, are moderately vascular, and have areas of calcification (Fig. 31.42). The tumors tend to grow out from the retina into the vitreous ('endophytic') or grow underneath the retina ('exophytic'). Rarely the tumor diffusely infiltrates the retina. A relatively benign form of retinoblastoma – 'retinoma' – also exists. The age of onset is older, retinal pigment epithelium changes are seen surrounding the elevated gray retinal mass, and the tumor remains nonprogressive.

Fig. 31.41 Coats disease. Massive subretinal lipid exudation is seen at the macula, with severely reduced visual acuity.

Fig. 31.42 Retinoblastoma. Creamy white tumor. Image taken with 'Retcam' digital fundus camera.

The differential diagnosis includes Coats disease, tuberous sclerosis, retinal hamartomas, Norrie disease, *Toxocara* infection, and, in diffuse cases, endophthalmitis. When the optic nerve is clinically in contact with retinoblastoma tissue, assessment will include examination of the CSF and imaging of the brain and orbits. The scan will delineate the extent of the tumor, and exclude a coexisting pineal tumor ('trilateral retinoblastoma'). The most common route of spread is along the optic nerve. In advanced cases blood spread to bone marrow may occur.

An ocular oncology team in specialized referral centers should undertake management.

A range of treatment modalities may be used. Primary enucleation surgery is indicated for advanced disease (Fig. 31.43). A long length of optic nerve should be removed with the eye, and a primary orbital implant placed within the muscle cone.

Chemotherapy is now the first-line treatment for bilateral cases, though it is often necessary to enucleate one eye later. Unilateral cases that have been detected at an early stage may also be treated with chemotherapy. Six cycles of cisplatin, etoposide and vincristine are given.<sup>84</sup> Additional treatment modalities are required in some cases. These include retinal laser therapy, retinal cryotherapy, plaque brachytherapy and external beam radiotherapy.<sup>85</sup>

Frequent follow-up examinations are performed in order to detect tumor regression, and to look for new tumors, which develop in 10% of cases.<sup>86</sup> If there has been no evidence of local or metastatic disease for 3 years after local disease control, cure is very likely. Long-term survival is over 95%.

Heritable cases will transmit the defective RB1 gene to 50% of offspring, with 90% penetrance. The risk of disease is therefore 45%. All cases should have molecular genetic testing for an RB1 gene mutation.<sup>88</sup> This includes cases of solitary tumor, as 15% of these cases have an underlying germline mutation. The siblings of cases and the offspring of cases should also have molecular genetic testing.<sup>87</sup> If a defect is detected, or when there is uncertainty about the genetic status of an individual, regular retinal examinations must be performed. The initial examination may be performed without general anesthetic soon after birth. Examinations under anesthetic are then performed every 2–4 months until age 2 years. At each examination the peripheral retina must be fully visualized using scleral indentation. Further examinations without anesthetic are then performed 4–6 monthly until age 5 years.

All heritable cases require long-term oncology follow up. The product of the RB1 gene is the retinoblastoma protein pRB. RB1 mutations normally result in no detectable pRB production. pRB is a phosphoprotein that is involved in cell cycle control and inhibits cell proliferation. Its function is tissue specific – RB1 mutations increase the risk of retinoblastoma, pineal tumors (which presents with hydrocephalus), osteogenic sarcoma (especially in the orbit following ocular radiotherapy for retinoblastoma),<sup>88</sup> other sarcomas, and some carcinomas. However the RB1 gene does not predispose to other childhood neoplasias such as leukemia.

### TOXOCARA INFECTION

*Toxocara* infection of the retina may occur in early childhood either in subclinical infection or as part of a systemic illness. The nematode dies

Fig. 31.43 An enucleated eye showing a large retinoblastoma causing detachment of the retina and almost filling the vitreous cavity.

Fig. 31.44 Toxoplasmosis. Pigmented scar at macula. No active inflammation present.

within the eye and antigen release incites a profound inflammatory reaction. This leads to an isolated area of fibrosis with associated retinal traction. No active treatment is possible.

### TOXOPLASMA INFECTION

The congenital toxoplasmosis syndrome includes chorioretinitis, intracranial calcification, seizures, hydrocephalus, microcephaly, hepatosplenomegaly, jaundice, anemia and fever.

However *Toxoplasma* infection acquired in the late prenatal period, or postnatally may remain quiescent for many years and then reactivate. The individual may have no neurological or systemic features of *Toxoplasma* infection. At the time of infection recurrence, an area of scarring of the choroid and retina is seen, with an adjacent area of retinal and vitreous inflammation (Fig. 31.44). The symptoms are reduced vision and floaters. A number of antimicrobial treatments have been used. Controlled trial evidence of efficacy is lacking.<sup>89</sup> Azithromycin has been used as monotherapy. Triple therapy with sulfadiazine, pyrimethamine and folinic acid has also been used. When antimicrobial therapy is given, very close follow-up is needed as death of the organisms may lead to increased inflammation due to antigen release. For this reason oral steroid treatment is often given 24–48 h after commencement of antimicrobial treatment.

## DISEASES OF THE OPTIC NERVE

### OPTIC ATROPHY

The causes of optic atrophy have been discussed earlier. Significant optic atrophy leads to reduced visual acuity, reduced color vision, and constricted visual fields.

### OPTIC DISC EDEMA

#### Optic disc edema with severe visual loss

Optic disc edema due to inflammatory diseases (optic neuritis) results in profound visual loss. In children the most common pattern is bilateral optic neuritis. The discs are swollen, but hemorrhages and exudates are rare. Afferent pupil defects are present. Spontaneous, complete recovery over a period of days is usual. A neurological assessment should be carried out, including neuroimaging. There are usually no long-term neurological sequelae and the condition should be regarded as an entity separate from multiple sclerosis.

#### Optic disc edema without severe visual loss

The most significant cause of optic disc edema is raised intracranial pressure and the term 'papilledema' is normally used in these cases.

Fig. 31.45 Severe papilledema with hemorrhages and exudates.

Papilledema may cause no visual symptoms. However in more severe cases brief periods of visual disturbance (visual obscurations) occur, and urgent investigation and control of intracranial pressure is required. Visual field examination shows enlarged blind spots in almost all cases. Paracentral scotomas may also be found. Poor intracranial pressure control leads to progressive loss of axons, with progressive constriction of the visual fields and visual impairment.

In its mildest form, papilledema causes slight blurring of the optic disc margins superiorly and inferiorly. As severity increases a larger portion of the optic disc circumference becomes blurred and the optic disc develops a pink appearance. The normal 'physiological' optic disc cup is lost, and normal venous pulsation is lost. In severe cases hemorrhages and exudates (nerve fiber layer infarcts) are seen (Fig. 31.45).

In mild cases the diagnosis may be aided by fluorescein angiography. In mild optic disc edema the capillaries on the surface of the optic disc are dilated and leak fluorescein dye (Fig. 31.46). High definition ultrasound examination of the optic disc and orbital optic nerve may allow detection of enlargement of the CSF space within the optic nerve sheath.

The differential diagnosis of papilledema includes hypermetropia and optic disc drusen. Moderately severe hypermetropia leads to small 'crowded' optic discs, which may have blurred edges and may be elevated. Optic disc drusen are deposits of amyloid tissue deep within the optic discs, leading to apparent swelling of the optic discs (Fig. 31.47). Drusen may be diagnosed using fluorescence photography or ultrasound examination.

## THE EYE IN RELATION TO MEDICAL PEDIATRICS AND CLINICAL GENETICS

### DIABETES MELLITUS

Diabetic retinopathy is exceptionally rare before puberty. Retinal screening examinations should be carried out annually from puberty. Cataract may develop as an acute feature of diabetes mellitus.

### NEUROMETABOLIC STORAGE DISEASES – EYE SIGNS

#### Cherry red spot

In Tay–Sachs disease (GM2 type1) ganglioside accumulation in retinal ganglion cells leads to a 'cherry red spot' appearance (Fig. 31.48). The central fovea has no overlying ganglion cells and remains a red color due to the underlying choroidal circulation. The surrounding retina is a milky white color due to ganglioside storage in the ganglion cells. The ERG is normal, but the VEP is reduced. A cherry red spot is also seen in Niemann–Pick disease type A (sphingomyelinase deficiency) and neuraminidase deficiency (sialidosis types 1 and 2). With disease progression the cherry red spot fades as ganglion cells die and optic atrophy develops.

Fig. 31.46 (a-d) Fundus fluorescein angiogram showing dilated capillaries on the optic disc surface.

Fig. 31.47 Optic disc drusen.

Fig. 31.48 Cherry red spot due to Tay-Sachs disease.

## Corneal clouding

Corneal clouding develops in:

- mucopolysaccharidoses, all of which show corneal clouding, except MPSII and MPSIII;
- mucopolysaccharidoses;
- fucosidosis;
- mannosidosis.

## WILSON DISEASE

Copper deposition in the peripheral cornea may be detected on slit lamp examination.<sup>90</sup>

## OPHTHALMOLOGY CHANGES IN LEUKEMIA

Retinal hemorrhages may be found in severe anemia and leukemia (Fig. 31.49). The iris may act as a sanctuary site following chemotherapy for lymphoblastic leukemia. During remission periods, disease recurrence may occur in the iris, with clinical effects similar to those seen in iritis. Clinical suspicion and, if necessary, iris biopsy, will allow the correct diagnosis to be made. Treatment with further chemotherapy, and with radiotherapy to the irises, is indicated.

Opportunistic infections occur in immunosuppressed children. Infections commonly seen include herpes zoster and herpes simplex infections of the cornea or retina; and cytomegalovirus, *Toxoplasma* or *Candida* infections of the retina.

## OPHTHALMOLOGY AND THE CLINICAL GENETICIST

The ophthalmologist may be asked to look for diagnostic signs in a range of inherited syndromes.

### Marfan syndrome

Screening for lens subluxation may be requested. A single examination in early childhood is usually sufficient as lens subluxation develops early in life and there is rarely any significant progression with time.<sup>78</sup>

### Neurofibromatosis

The ophthalmologist may provide diagnostic information in cases of suspected neurofibromatosis types 1 and 2 (NF1, NF2). Lisch nodules of the iris will be present in over 90% of children aged 8 years or older who have NF1 (Fig. 31.50), but are less frequent in younger children.<sup>91</sup> Symptomatic optic nerve gliomas are normally diagnosed by age 3 years.<sup>91</sup> Vision may fluctuate, deteriorate or remain stable for many years. When there is consistent deterioration of visual function, active treatment may be considered, such as chemotherapy using etoposide and cisplatin. Children with confirmed NF1 should have regular

Fig. 31.49 Retinal hemorrhages related to leukemia.

Fig. 31.50 Lisch nodules of the iris. Multiple pigmented nodules are easily visualized against the background of a lightly pigmented iris in this case.

screening examinations for anterior optic pathway gliomas. Screening examinations include measurement of visual acuity, color vision, pupil reactions, visual field measurements and optic disc examination (Fig. 31.51). Neurofibromas of the upper eyelid are associated with glaucoma in the ipsilateral eye.

In NF2, posterior subcapsular cataract is present in more than 50% of cases and is a useful diagnostic sign.<sup>92</sup>

### Tuberous sclerosis

Fundus examination for retinal hamartomas should be performed in children with seizures and delayed cognitive development, as part of the diagnostic work-up for tuberous sclerosis. Hamartomas are found in the majority of patients with tuberous sclerosis.<sup>93</sup> These may appear as minimally elevated smooth translucent retinal lesions anywhere in the fundus, or as yellowish multinodular masses near the optic disc (Fig. 31.52). The lesions usually do not change significantly with time and do not cause significant visual defects, however occasional exceptions to this rule have been reported.<sup>94</sup>

### Von Hippel–Lindau disease

Retinal angiomas are the earliest and most common clinical features of von Hippel–Lindau disease. Careful annual fundus examination is required in order to detect early lesions, which are most often found in the mid periphery.<sup>95</sup> The lesions tend to grow, and larger lesions leak serous fluid, which may lead to visual impairment. Early lesions should therefore be treated with laser or cryotherapy.<sup>96</sup>

Screening retinal examinations are needed for patients with known von Hippel–Lindau disease, and for presymptomatic family members who are known to have a mutation of the von Hippel–Lindau gene (3p25–26).

## OCULAR TRAUMA

Significant ocular trauma remains a relatively common occurrence in children. Examination of an injured child requires patience, and examination under anesthetic is often preferred, especially when there is a suspicion of ocular perforation. Foreign bodies tend to lodge in the corneal epithelium, or become trapped underneath the upper eyelid. Corneal abrasions may be more easily detected by instilling a drop of fluorescein dye. A prophylactic topical broad-spectrum antibiotic should be prescribed when the corneal epithelium has been damaged. Eyelid lacerations should be carefully repaired, with particular attention to correct apposition of lacerations that involve the eyelid margins. Small ocular

Fig. 31.51 (a) Right optic disc showing pallor on the temporal side. MRI scan showed optic nerve glioma. (b) Normal left optic disc.

lacerations may result in a distorted pupil, with prolapse of iris tissue at the perforation site.

Nonpenetrating blunt injuries most frequently present with hyphema – blood within the anterior chamber (Fig. 31.53). The intraocular pressure should be measured, and treated if elevated. Topical steroid and mydriatic eyedrops are given to treat associated iritis. Follow-up examinations are required in order to detect fundus abnormalities and traumatic glaucoma. Permanent visual loss is most often due to choroidal rupture (Fig. 31.54) or retinal detachment.

### SHAKING INJURIES

Shaking injuries commonly produce extensive retinal hemorrhages and an ophthalmologist should be involved early in the diagnostic process.<sup>97,98</sup> Possible mechanisms include raised venous pressure and direct shearing forces within the retina and at the vitreoretinal interface. Typically hemorrhages are extensive, covering the whole retina from the optic disc to the ora serrata (Fig. 31.55). The hemorrhages are present deep within the retina (dot and blot hemorrhages), on the surface of the retina (flame-shaped hemorrhages within the nerve fiber layer) and on the surface of the retina (preretinal hemorrhages). Vitreous hemorrhage and traction retinal detachment may be present in more severe cases.

Fig. 31.53 Hyphema. Blood in the anterior chamber obscures the iris.

Fig. 31.52 Large multinodular retinal hamartoma adjacent to optic disc in a case of tuberous sclerosis.

Fig. 31.54 Choroidal rupture. Blunt force has caused a curved tear in Bruch's membrane deep to the retinal pigment epithelium. There is additional pigment scarring at the macula.

Fig. 31.55 Retinal hemorrhages following non-accidental shaking injury in an infant. Image taken with 'Retcam' digital fundus camera.

Flame-shaped surface retinal hemorrhages tend to clear within 1–2 weeks, although deep retinal hemorrhages and pre-retinal and vitreous hemorrhages may persist for a number of weeks. The differential diagnosis is given in Table 31.13 and includes birth hemorrhages and retinal hemorrhages secondary to blood clotting disorders. Retinal hemorrhages do not occur as a part of accidental head injury unless trauma is severe.<sup>99</sup> A few small retinal hemorrhages have been found in case series following seizures, and following cardiopulmonary resuscitation.<sup>100</sup>

No specific treatment is indicated for retinal hemorrhages secondary to shaking injury. On follow-up, long-term visual loss is more often due to associated brain and optic nerve injury than to retinal injury.<sup>101</sup>

## MANAGEMENT OF THE VISUALLY IMPAIRED CHILD AND THEIR FAMILY

The diagnosis of visual impairment in an infant or child may be devastating for a family. Parents are often in a state of shock when bad news is

Table 31.13 Differential diagnosis of retinal hemorrhages in an infant with suspected shaking injury (not exhaustive).

Copper deficiency

given and an early review consultation is helpful in order to further discuss the implications of the diagnosis. Visual impairment in infants has secondary effects on general development, and appropriate use of sound and tactile stimuli by the parents will improve developmental progress. Considerable social and educational support will be needed in addition to medical interventions. Local and national parent support groups are available and should be used. Useful information may be obtained at [www.viscotland.org.uk](http://www.viscotland.org.uk).

## EDUCATION OF VISUALLY IMPAIRED CHILDREN

Many children with visual impairment may be satisfactorily educated in a mainstream school, provided that adequate additional teaching resources are made available. Simple measures such as satisfactory positioning of the child within the room and satisfactory lighting should be considered. Impairment due to reduced visual acuity may be helped in a wide range of ways, which include: allowing the child to observe objects of interest and text very close to their face; the use of large text (produced by photocopying with enlargement if necessary); the use of optical magnification devices and the use of computer-based technology. Braille supplemented by audiotape and speech recognition computer software enables many severely visually impaired children to progress to tertiary education. Strategies related to cerebral visual impairments are given in Table 31.2.

## THE EAR

### CONGENITAL ABNORMALITIES

#### Microtia/anotia/meatal atresia

The auricle forms from the six tubercles of His. Malformations include microtia, a misshapen auricle, or anotia, the absence of the auricle. Both may be associated with accessory auricles, which are small residual tubercles that may lie sometimes over the cheek without function. Either of these congenital abnormalities of the auricle may be associated with meatal atresia, the absence of the bony meatus. They are commonly associated together in a variety of congenital conditions and syndromes. They may present as a unilateral problem, e.g. first arch syndrome, or as a bilateral problem, e.g. craniofacial dysostosis or Treacher Collins syndrome. If the deformity is a unilateral one it is extremely important to investigate the normal ear to ensure that the hearing is normal on the unaffected side. Assuming the contralateral ear has normal hearing, then surgical or other intervention on the affected side becomes purely cosmetic. If the condition is bilateral, then the degree of conductive hearing loss should be established and, in the first instance, a bone conduction hearing aid fixed by a head band should be fitted at an early age. With the advent of osseointegrated implants, this bone conduction hearing aid should be replaced by an osseointegrated, bone-anchored hearing aid (BAHA) when the skull is thick enough to sustain this (usually ages 3–4 years). Surgical attempts to construct a patent meatus have not been successful and have been largely abandoned but reconstruction of the pinna using sculpted rib graft is becoming increasingly popular. An alternative to this is an osseointegrated prosthesis.

#### Meatal stenosis

Meatal stenosis may occur either as a congenital abnormality or as a result of chronic otitis externa. Down syndrome children have very narrow external auditory meati and they often have middle ear problems. This sometimes makes the fitting of grommet tubes difficult and hence careful monitoring of their hearing is important.

#### Ossicular abnormalities

Congenital abnormalities of the ear ossicles are rarely seen in isolation and are usually associated with some other manifest congenital abnormality. Attempts at surgical repair of ossicles in children are not normally

advisable and any bilateral hearing deficit should be treated by a hearing aid.

### TRAUMA AND INJURIES

Direct trauma to the auricle may produce a hematoma and is commonly seen in sporting injuries. The hematoma should be aspirated and a pressure bandage applied to avoid the cosmetic abnormality known as 'cauliflower ear'.

#### Perforation of tympanic membrane

This can be caused either by an object inserted into the ear or alternatively by pressure, e.g. in non-accidental injury, where a slap across the ear can cause a perforation of the drum due to the pressure of the air column in the narrow meatus. This form of injury is also seen in explosions or in diving accidents. Head injuries may be associated with perforation of the eardrum and also leakage of cerebrospinal fluid.

Treatment of perforation of the eardrum is conservative; the ear is kept dry and in the great majority of traumatic perforations the eardrum will heal spontaneously. This healing may take several months but no attempt at surgical intervention should be considered for at least 6 months.

*Ninety-five percent of traumatic tympanic membrane perforations will close spontaneously and return to normal.*

#### Foreign bodies

Aural foreign bodies are quite common and can present at any age. They usually are found in those aged 4 years or older who have the manual dexterity to put objects into their ears. They are best removed; this often requires a general anesthesia. Syringing is not recommended as this can push the object, often a bead or plastic toy, further in, potentially damaging the tympanic membrane.

#### Wax

It is normal for wax to be present in ears and this causes no problems unless it has been pushed into the external auditory meatus usually by the use of cotton buds. The superficial squamous epithelial cells in the external meatus have a natural flow pattern outwards, so that wax will be naturally

extruded from the ear and hence, if the wax is kept soft by the use of simple olive or almond oil drops, syringing of the ears should not be required. As a general rule it is preferable not to syringe children's ears as they will find it uncomfortable and it will interfere with the natural extrusion process.

## INFECTIONS OF THE EARS

### Otitis externa

This condition does not occur commonly in children. The basis of treatment is aural toilet and the application of a topical antibiotic, with or without steroids, either on a small gauze dressing, which is preferable, or, alternatively, administered as eardrops. The skin of the meatus is often swollen and extremely tender and aural toilet may have to be carried out under a general anesthetic.

### Furunculosis

A furuncle, or boil, in the external meatus will produce an acutely painful ear that is tender to the touch. It is often associated with a tender lymph node over the mastoid and hence the combination is often mistaken as an acute mastoiditis. The swelling in the latter is more widespread and the child is systemically unwell. Treatment of furunculosis is with oral antibiotics, usually flucloxacillin, and local dressings.

### Acute otitis media

This occurs more commonly in those in the 6–36-month age range than in any other group. This is probably due to immaturity of the immune system, which can be slow in developing antibodies against bacteria with polysaccharides in their capsules, e.g. *Streptococcus pneumoniae* and *Haemophilus influenzae*. Infants also have short, wide horizontal Eustachian tubes that may allow easier passage of bacteria from the nasopharynx. Acute otitis media may occur as an accompaniment to an upper respiratory tract infection<sup>1</sup> but it can also occur on its own.

Clinically it will present with acute otalgia, sometimes bilateral, and the child will be fevered and may have a febrile convulsion. The eardrum, if inspected, will appear either acutely inflamed or bulging, with obvious pus behind it, the pain being due to the build-up of mucopurulent secretions in the middle ear. The first-line treatment is analgesics/antipyretics. Antibiotics provide only a small benefit for acute otitis media in children.<sup>2</sup> A Cochrane review<sup>3</sup> compared the outcome of antibiotics for 5 d with antibiotics for 8–10 d and concluded that 5 d of antibiotics (ceftriaxone or azithromycin) is effective. If the eardrum perforates, the pain will subside. In the vast majority of patients the drum will heal once the infection has settled. The treatment of infants and children with recurrent attacks of acute otitis media is either by repeated use of antibiotics or by surgical intervention. In young children, whose adenoids have not developed, the insertion of ventilation tubes (grommets) in the tympanic membranes will prevent recurrent attacks of acute otitis media. In older children who have significant adenoids, their removal may reduce further attacks of otitis media.

*Acute otitis media is the commonest cause of otalgia with fever in children.*

### Acute mastoiditis

Acute mastoiditis still occurs but not nearly as frequently as it used to. This may be due to the use of antibiotics for acute otitis media but is more likely to be a reflection of a healthier population. Clinically, the child with acute mastoiditis will present with an acutely tender swelling in the postauricular region with the area of maximum tenderness being over the surface marking of the mastoid antrum, which is at the level of the top of the tragus. If looked at from behind, the auricle will be seen to be projecting outwards from the skull due to the loss of the postauricular sulcus and this is most commonly due to the collection of subperiosteal pus. The ear may or may not be discharging. The child will usually be in considerable pain and will be febrile. Treatment is admission, administration of i.v. antibiotics and analgesics and careful monitoring of the pulse and temperature for 24–48 h. If the postauricular

swelling is increasing or if the temperature is not settling in that time, then surgical drainage of the subperiosteal pus and drilling away of the diseased cortical bone should be undertaken under general anesthesia. Acute mastoiditis rarely becomes a recurrent problem nor does it lead to chronic otitis media or cholesteatoma formation.

*Postaural subperiosteal swelling with a protruding pinna is pathognomonic of acute mastoiditis.*

### Chronic otitis media

Chronic otitis media is associated with a permanent perforation of the tympanic membrane. There are two quite distinct groups: tubotympanic disease and attic/antral disease.

#### *Tubotympanic disease*

Usually such children have had recurrent attacks of otitis media that have either been inappropriately treated or that have resulted in a permanent residual anterior central perforation of the tympanic membrane. The clinical presentation is of intermittent, quite profuse painless mucopurulent discharge from the ear. The profuse discharge occurs in association with an upper respiratory tract infection or following the child swimming or getting the ear wet. If treated with oral antibiotics, the discharge should cease. The hearing loss will be minimal. Effective antibiotic treatment of tubotympanic disease is required and the child should keep the ear dry. Closure of the perforation by myringoplasty using a temporalis fascia graft is not advisable until the child has gone at least 6 months without any discharge from the ear and this will rarely be before the age of 8 or 9 years.

#### *Attico/antral disease*

These children have a continuous painless moderate purulent or blood-stained discharge from the ear. There may be middle ear granulations. This discharge will often be foul-smelling as the commonest organism is *Pseudomonas pyocyaneus*. This form of chronic otitis media does not usually respond to antibiotics and is more serious as it is usually associated with cholesteatoma in the mastoid antrum or mastoid air cell system, which may erode the ossicles and cause a significant hearing loss. If cholesteatoma is identified in the ear by suction clearance, under general anesthesia, then mastoid surgery is indicated as facial nerve palsy or cerebral complications can occur if the cholesteatoma is not cleared completely from the mastoid system.

## REFERRED OTALGIA

Referred pain in the ear may be from the tonsils, nasopharynx or teeth, all of which must be considered in a child who has unexplained otalgia.

### Otitis media with effusion

This is a very common condition in childhood that can occur at any age but is found most commonly between the ages of 4 and 6 years. It is commoner in boys. It is alternatively called 'serous otitis media', secretory otitis media, or simply 'glue ear'. Children with otitis media with effusion (OME) commonly present with a hearing loss due to the collection of fluid in their middle ears. The fluid contains polymorphonuclear leukocytes, macrophages and cell debris but no ciliated columnar cells or eosinophils. The fluid is invariably sterile and various searches for viruses have proved negative. The fluid contains glycoproteins and nucleoproteins and this gives the fluid its thick, tenacious quality.

#### *Clinical presentation*

Classically, a child with secretory OME will present with painless insidious bilateral conductive deafness that should not be greater than 40 dB. Fluid will collect without prior middle ear infections and often the child does not remark on the loss of hearing. The problem may not be identified until routine audiometric testing is done at school. The fluid collects secondary to functional blockage of the Eustachian tube. If children are left for up to 12 weeks in 30–40% of them the fluid will disappear and their hearing will return to normal. Other children present as having recurrent

episodes of otalgia and hearing loss not responding completely to antibiotics or analgesics. Occasionally the ear drum may perforate. Some children can develop behavioral problems, becoming withdrawn or naughty presumably as they cannot hear properly. Others, especially toddlers, can become unsteady on their feet and start falling over, due it is thought to the vestibular system being affected by fluid in the middle ear.

### Prevalence

At any one time, one child in 100 will have OME and approximately 10% of children under 10 years will have had OME.

*Otitis media with effusion is the commonest cause of conductive deafness in childhood.*

### Diagnosis

Diagnosis is usually made by taking a careful history from the parents and/or the teachers, who are seeing the child on an everyday basis. Otoscopic examination will reveal an abnormal eardrum that may be retracted, bulging, dull, blue/yellow in color, or have an air–fluid level or bubbles visible behind it. Puretone audiometry will reveal a conductive hearing loss that is usually bilateral and worse in the lower frequencies than the higher frequencies but never greater than 40 dB. Impedance audiometry will give a flat tympanogram with a negative middle ear pressure and a greatly reduced tympanic membrane compliance.

### Etiology

The underlying cause is believed to be Eustachian tube dysfunction, and certainly children with cleft palate and hence impaired Eustachian tube opening have a greatly increased risk of having OME. Children with chronic OME do have persistent negative middle ear pressure and this results in the loss of the middle fibrous layer of the tympanic membrane with atelectasis or atrophy of the membrane. Adenoids blocking the Eustachian tube orifice in the nasopharynx have long been associated with this condition and so their removal is often undertaken as a form of treatment. However, children without adenoids still get OME and therefore there must be more complex factors involved. Attempts to associate nasal allergy with OME have never been substantiated and apart from the already mentioned age and sex factors, the only other recently proven etiologic factor is passive smoking within the home environment.<sup>4</sup> Because the Eustachian tube is situated so centrally, it is extremely difficult to investigate its function in these children, and hence the etiology remains obscure.

### Treatment

Management of OME remains controversial. The policy of 'watchful waiting' is the mainstay of treatment as over 50% of cases will spontaneously resolve in 12 weeks.<sup>5</sup> Medical treatment using antibiotics decongestants or nasal steroids have been shown to be ineffective.<sup>6</sup> Grommets offer a short-term hearing improvement only and therefore surgery is reserved for those with persisting hearing loss or those who are at increased risk of persistence at presentation.<sup>7-9</sup> These include those presenting in July to December and those whose hearing thresholds are worse than 30 dB in the better ear.

Surgery consists of myringotomy (drainage of the fluid) and insertion of ventilation tubes (grommets). This should be combined with adenoidectomy if a child presents with symptoms of enlarged adenoids (chronic mouth breathing, snoring, etc.) Adenoids are very small at birth but grow to a maximum size between the ages of 4 and 8 and it is in this group that adenoidectomy may be required. By ventilating the middle ear, grommet tubes reduce negative middle ear pressure and prevent the development of an effusion.

Children who have grommets can go swimming but are advised not to dive. It is sensible however to wear earplugs either customized or held in place by a headband. Grommets stay in place for 6–15 months and can cause minor scarring of the ear drums. Occasionally infections occur requiring antibiotic or removal of the grommet(s) and about 1% are associated with persisting perforations.

*Surgery for otitis media with effusion should only follow 3 months of watchful waiting.*

## DEAFNESS

OME will produce a conductive deafness of up to 40 dB, which can affect speech and language development. If a child has a hearing loss it is important to identify whether it is conductive, sensorineural or a combination of the two. In conductive deafness the disability is not so severe and often there may be a surgical or medical method of treating it.

Sensorineural deafness in children is not uncommon. In resource rich countries, the incidence of bilateral significant sensorineural deafness is one in 1000 live births. 'Significant loss' is a loss of between 25 and 35 dB in the better ear. It is the high-frequency component of the loss that is usually important. If the loss in the better ear is at a level of 30 dB when averaged over the four frequencies 500 Hz, 1 kHz, 2 kHz and 4 kHz, then the child will require some kind of amplification to attain normal speech and language.

*Significant bilateral sensorineural deafness has an incidence of one in 1000 live births.*

### Causes of sensorineural deafness

Only about 50% of children with significant bilateral sensorineural loss have an identifiable cause.

#### Hereditary prenatal causes

There are large numbers of syndromes in which deafness is a recognized factor:

*Wardenburg syndrome.* This autosomal dominant condition with variable expression consists of some or all of the following characteristics: unilateral or bilateral sensorineural deafness (20% of cases); hypertrichosis of the eyebrows that meet in the midline; heterochromia of the irises; or a white forelock.

*Klippel–Feil syndrome.* These children have short necks, which limits head movements. The hairline is low at the back, there may be paralysis of the external rectus muscle in one or both eyes and there is sensorineural hearing loss, which may be severe.

*Alport syndrome.* This is X-linked dominant and affects boys more severely than girls. There is severe progressive glomerulonephritis and a progressive sensorineural hearing loss, which does not show itself until the boy is about 10 years old.

*Pendred syndrome.* This is autosomal recessive and causes simple goiter at about the age of 4–5 years. There is an associated deafness that is often severe.

*Refsum syndrome.* This consists of ichthyosis, ataxia, retinitis pigmentosa, night blindness, mental retardation and sensorineural deafness.

*Usher syndrome.* This is autosomal recessive. There is retinitis pigmentosa with contraction of the visual fields and a severe sensorineural hearing loss that may be progressive.

*Jervell and Lange–Nielsen syndrome.* This is autosomal recessive with a cardiac arrhythmia secondary to a prolonged QT period, and a profound sensorineural deafness. These children may present with syncopal attacks and if untreated, these attacks can be fatal.

The inheritance of deafness is well recognized and in some children with recessive inheritance, the sensorineural hearing loss may be progressive. Nonhereditary prenatal deafness may be due to maternal illness, especially in the first trimester of pregnancy. Cytomegalovirus infections, toxoplasmosis, glandular fever and rubella are the most common, but parental syphilis and the taking of certain ototoxic drugs by the mother may also cause deafness in the baby.

Ototoxic drugs that should be specifically avoided during pregnancy are the aminoglycosides, quinine and to a lesser extent salicylates and alcohol.

Perinatal causes of deafness are usually related to prematurity or hypoxia. With the advances in neonatology, when extremely immature babies with complex neonatal problems are now surviving, the number of children with significant bilateral deafness sometimes associated with other abnormalities, and often related to hypoxia, is increasing. The cochlea is particularly sensitive to lack of oxygen. As neonatology

improves further, the numbers of children with perinatal deafness will hopefully reduce.

*Early diagnosis of sensorineural deafness is vital for acquisition of speech and language.*

### Postnatal causes

Middle ear problems cause conductive deafness and the causes of these have already been discussed. Sensorineural loss may result from head injury, from the use of ototoxic drugs and as a result of specific infections. Parents whose children get repeated attacks of acute otitis media are often concerned that significant sensorineural loss may result, but this is extremely rare.

**Measles and mumps.** Measles and mumps remain the specific infections that can cause significant sensorineural hearing loss. Mumps, although it will sometimes cause a profound sensorineural loss, is generally only a unilateral loss. The increasing use of the measles/mumps/rubella (MMR) vaccine will reduce the incidence of deafness from these infections.

**Meningitis.** Meningococcal or pneumococcal meningitis may give severe bilateral sensorineural hearing loss that will be permanent and may progress in severity following recovery from the meningitis. All children who have recovered from bacterial meningitis should have their hearing tested and monitored.

### Diagnosis of deafness

The first 2 years of life are vital for the acquisition of speech and language and hence the early detection of significant hearing loss in a baby is extremely important.

#### Neonatal hearing screening

Programs for this are now in place throughout the UK. They are based around maternity units, the aim being to test all newborns before they leave hospital. Techniques used are otoacoustic emissions then going on to automated brainstem audiometry, if necessary

*Only 50% of children with sensorineural deafness have an identifiable cause.*

### Subjective audiometry

#### Distraction audiometry

This is still a reliable, efficient method of testing that requires the minimum of equipment. The disadvantage is that it cannot be performed until the child is holding his head up unsupported. In the UK this is carried out by the health visitor as one of the routine screening tests at 7 or 8 months.

#### Conditioned audiometry

As the child gets older, he can be conditioned to perform a specific task in response to the input of sound.

#### Puretone audiometry

This is the main method of testing but cannot be done until the child will tolerate wearing headphones and can be relied upon to respond accurately to puretone sounds.

### Objective audiometry

#### Brainstem evoked response audiometry

This is the most reliable form of objective audiometry and can be performed at any age. It is not, however frequency specific and young children, apart from neonates, require sedation or anesthetic.

#### Otoacoustic emissions

This test is based on the cochlear echo, which is an acoustic response of the cochlea when it is exposed to sound. It is easily done very quickly and gives a qualitative result as to whether the child's cochlea is working normally or not. Its disadvantage is that it does not distinguish between conductive deafness and sensorineural deafness, and any children

who fail the otoacoustic emission test usually have to then progress to brainstem-evoked response audiometry.

### Impedance audiometry or tympanometry

This is a simple test that measures the compliance of the eardrum and the pressure of the air in the middle ear. It is ideally suited for identifying otitis media with effusion and is useful in screening those who have failed their routine school audiometric testing.

### Treatment of deafness

Treatment of conductive deafness has been discussed elsewhere in this chapter. There is no medical treatment for sensorineural deafness and management is based on prophylaxis. Genetic counseling and preventive measures such as immunization are important to avoid some causes of sensorineural hearing loss. As neonatology advances and hypoxia becomes less common, the incidence of deafness amongst ex-premature infants will be reduced. Sensorineural hearing loss is not normally progressive but in some congenital conditions it is, and so careful monitoring of the child's hearing is vital once the diagnosis has been made.

The mainstay of treatment remains amplification by some form of hearing aid. A large range of hearing aids is now available for children with sensorineural hearing loss and it is extremely important that the degree of handicap and the shape of the audiogram is known before the hearing aid is prescribed. Nowadays the hearing aid can be customized to the individual child's specific hearing loss.

### The phonic ear

Teaching the deaf has been revolutionized by the advent of the phonic ear. This is a radio-aid type of hearing device where the mother or the teacher wears a microphone and a transmitter and the child wears the radio receiver. This means the child can sit anywhere in the class and be in direct radio contact with the teacher and hence the degree of amplification can be greatly enhanced. Many children with quite severe hearing handicap can therefore now be educated in their own local school rather than having to go to specific schools for the hearing impaired.

### Cochlear implants

These have been used in children for nearly 20 years and are now established as the most effective way of enabling children to develop speech and language where hearing aids are not providing adequate amplification of sound. They are considered only after a thorough trial of hearing aids but experience is showing that the younger the child is implanted the better the outcome in terms of speech and language. The devices are expensive and are only available in specialized centers. Implantation is then followed by programming of the device and an intensive ongoing process of habilitation involving audiologists, teachers of the deaf, speech and language therapists, social and community workers as well as medical staff.

*Cochlear implants are only required for a very small number of profoundly deaf children.*

## THE NOSE, SINUSES AND THROAT

### THE NOSE

The nose functions as an air conditioner for the lower respiratory tract. It achieves this by cleaning, warming and humidifying the inspired air. The turbinates (Fig. 32.1) project from the lateral wall, increasing the surface area and causing turbulence. This allows heat and fluid exchange and causes any particles to be deposited on the lining of the nose in the sticky mucus, which then passes posteriorly and is swallowed. The function of the paranasal sinuses is unknown.

### Foreign bodies

These present as foul-smelling, sometimes bloodstained unilateral nasal discharge. They occur most often in children between the ages of 2 and 4 years, and are usually bits of foam rubber or toys that

Fig. 32.1 Normal coronal CT scan of an 11-year-old boy showing: (1) nasal septum; (2) inferior turbinates; (3) middle turbinates; (4) maxillary sinuses; (5) ethmoid sinuses.

they have inserted themselves. It is rare for them to cause lower respiratory tract infections and the treatment is removal of the foreign body.

This can be done in a treatment or outpatient area sometimes by a 'parental kiss', where the parent blows into the child's mouth, the aim being to blow the foreign body out of the nose. If this is unsuccessful, and a headlight and appropriate instruments are available, and the child is cooperative, they can be removed under direct vision. Often, however, it has to be done under a general anesthetic.

*Unilateral foul-smelling nasal discharge in a young child is pathognomic of a nasal foreign body.*

### Fracture of the nose

The nose is the commonest bone in the body to be broken. In children nasal fractures are less common than in adults as the nasal bones are smaller and the tissues more pliant.

Nasal fractures result from direct trauma. Initially, there is swelling over the bridge of the nose and around the eyes, which takes 5–7 d to subside. It is then possible to see whether the nasal bones are deviated, when manipulation under general anesthetic to straighten them is usually advised. Manipulation must be carried out within 21 d of the injury otherwise the bones become fixed.

Hematoma of the septum presents as severe blockage of the nose after an injury. This inevitably becomes infected, resulting in development of a septal abscess and destruction of cartilage and requires surgical drainage and a broad-spectrum antibiotic for 10 d.

### Epistaxis

This is common after infancy. The bleeding can be spontaneous or secondary to mild trauma and usually arises from Little's area, in the anterior part of the nasal septum. Epistaxis can occur in leukemia or patients with bleeding disorders (e.g. hemophilia or thrombocytopenia) but is rarely the presenting feature of these conditions. First-aid treatment consisting of pinching the anterior cartilaginous portion of the nose with the child upright is usually successful. If there are repeated episodes, nasal cauterization is indicated.

*Epistaxis in a child usually comes from Little's area at the front of the nose and can be controlled by local pressure.*

After identifying the source of bleeding, local anesthetic, 5% topical lidocaine (lignocaine) with 0.5% phenylephrine hydrochloride (co-phenylcaine) is applied using cotton wool or a spray. The area is then cauterized using a silver nitrate stick. In rare cases not responding to cautery, admission with nasal packing and i.v. fluid replacement may be required.

Epistaxis or oronasal hemorrhage in the first year of life is rare; coagulation disorder needs to be ruled out, and in the absence of this or obvious trauma, suffocatory child abuse should be considered.

### Rhinitis

This is extremely common and is characterized by swelling and inflammation of the lining of the nose, often accompanied by clear or purulent rhinorrhea.

#### *Viral rhinitis (the common cold or coryza)*

This occurs very commonly with a pyrexial illness, runny nose, throat discomfort, sneezing and occasional earache. Treatment is symptomatic – analgesics and antipyretics as required. There is no proven place for decongestants in this condition. Viruses that have been identified as causing the common cold include rhinovirus, reovirus and adenovirus.

Viral rhinitis may be the precursor of laryngotracheobronchitis or pneumonia. A simple cold will normally last for 7–10 d and the child will not be unwell.

#### *Bacterial rhinitis*

This usually presents as purulent discharge following acute rhinitis. Antibiotics are rarely required unless the nasal blockage becomes worse or systemic symptoms such as fever and headaches occur, when adenoiditis or sinusitis should be suspected. In some children there is a constant low-grade bacterial rhinitis variable in severity, where no definitive underlying cause can be found. This can be associated with poor diet, damp housing and parental smoking. The underlying problem is thought to be lowered local nasal immunity. Antibiotics can sometimes stop persistent runny noses in children but there is no evidence of long-term benefit.<sup>10</sup> Most children with this condition will improve spontaneously from about the age of 8 years onwards. Immotile cilia syndrome is a rare cause and will often be associated with lower respiratory tract disease.

#### *Allergic rhinitis*

This usually occurs in children older than 5 years old. It presents as sneezing, associated with clear rhinorrhea and nasal blockage, and can be accompanied by conjunctivitis and sore throat. Seasonal rhinitis usually occurs in the summer and is caused by allergy to pollens. Perennial rhinitis can occur at any time of the year and can be associated with exposure to extrinsic allergens such as animals (e.g. cats or dogs) or housedust mite.

The diagnosis is made from the history. On examination, the nasal lining will usually be slightly pale and swollen. Confirmation of the allergic basis can be made by carrying out skin testing or serum immunoglobulin E assay.

Treatment is, if possible, by removal of the allergen but if this is not possible (e.g. seasonal rhinitis), a non-sedating antihistamine such as loratadine, supplemented by occasional use of a nasal steroid spray such as beclometasone may be helpful. Allergy to the housedust mite and housedust is increasingly recognized as a cause of rhinitis and allergic asthma. Treatment consists of cutting down the allergen in the bedroom by use of sprays or antiallergic sheeting. Non-sedating antihistamines and sometimes a short course of steroid sprays are also useful in combating this condition.

#### *Non-allergic rhinitis (vasomotor rhinitis)*

This presents as nasal blockage and catarrh and is differentiated from allergic rhinitis by negative allergy testing. Treatment is by antihistamine and decongestant combinations, and occasionally by steroid sprays for 2 months. Where there is no response to medical treatment,

surgical diathermy or laser reduction of the inferior turbinate can be carried out.

### NASAL SEPTAL DEVIATION

This can be traumatic but is more commonly developmental. Slight deviation is common and causes no symptoms, but more severe deviation will cause nasal obstruction, sometimes on both sides, occasionally with external nasal deformity. There may be associated allergic or vasomotor rhinitis. Surgery is only indicated for significant nasal blockage and is usually performed only in older children as surgery in young children can cause deformity, which increases with age.

### DISEASES OF THE PARANASAL SINUSES

The paranasal sinuses (maxillary, ethmoid, frontal and sphenoid; Fig. 32.1) are all derived from the nasal cavity and are lined by respiratory epithelium. The maxillary sinuses are small at birth and do not attain significant size until 4 or 5 years of age. The ethmoid sinuses are well developed at birth, but the frontal sinuses do not develop until 9 or 10 years of age. The sphenoid sinuses rarely cause symptoms in childhood.

There is slight inflammation of the sinus mucosa in all forms of rhinitis and when the ostium to the sinus gets blocked, secretions are retained and purulent sinusitis develops. Treatment with antibiotics and local decongestants opens up the ostium and allows the sinuses to drain.

#### Maxillary sinusitis

This is rare under the age of 6 and it usually follows influenza or parainfluenza. The nose becomes very congested, there is copious purulent catarrh and there may be associated headache and fever. The commonest organisms found are *Pneumococcus* and *Haemophilus influenzae*. Diagnosis is on suspicion and the finding of purulent catarrh in the nose and throat. Treatment is by ephedrine nosedrops, combined with a broad-spectrum antibiotic such as amoxicillin or erythromycin for 1 week. X-rays are indicated only if there is no response to the appropriate antibiotics, at which time surgical drainage may occasionally be required.

#### Ethmoiditis

This is a potentially serious condition that occurs in children from 3 years upwards. It usually follows an upper respiratory tract infection. The symptoms are of frontal headache and pain around the eye with fever and nasal blockage. Examination shows periorbital swelling and tenderness with marked inflammation. If there is abscess formation it is usually subperiosteal and this causes lateral displacement of the globe. The clinical diagnosis is now confirmed by a computerized tomography (CT) scan. Urgent treatment with a parenteral broad-spectrum antibiotic and ephedrine nose drops is required with surgical drainage if there is abscess formation.<sup>11</sup> If the condition is not treated or inadequately treated, extension of the infection can result in the serious complication of cavernous sinus thrombosis or intracranial abscess.<sup>12</sup>

*Periorbital infection often arises from infection of the ethmoid or frontal sinuses and should be treated vigorously.*

#### Frontal sinusitis

This is less common than ethmoiditis and presents in children over 10. Like ethmoiditis, it is potentially serious with a risk of spread to involve the orbit or intracranial structures. It usually occurs after a cold or flu and causes severe frontal headache associated with inflammation and tenderness over the frontal sinus. Nasal symptoms are often minimal. Diagnosis and treatment are similar to that for ethmoiditis. Spread can occur inferiorly to involve the eye.

### NASAL POLYPS

These present as unilateral or bilateral nasal blockage. Examination of the nose will show a pale, fleshy, usually mobile structure. Most common

is a unilateral antrochoanal polyp arising from the maxillary antra. These grow into the nose and down into the nasopharynx, often causing total obstruction of one side with purulent catarrh. They are benign and treatment is removal.

Ethmoidal polyps are less common and cause nasal blockage and catarrh. Ethmoidal polyps occur in children with cystic fibrosis, when the histology is different from the usual 'allergic type'. Treatment is removal under general anesthetic.

### CHOANAL ATRESIA

This rare anomaly is due to failure of breakdown of the nasobuccal membrane, which normally occurs at 6 weeks' fetal development. The incidence bilaterally is one in 8000 but unilateral atresia is more common. Of these cases, 50% are associated with the choanal atresia with ear, eye, heart and genital defects (CHARGE) syndrome.

*Gasping respiration in a neonate is suggestive of choanal atresia.*

Bilateral choanal atresia is a neonatal emergency. The nose-breathing neonate may gasp and make significant respiratory efforts but soon becomes hypoxic and requires airway support. Some cases may mouth breathe, but then have difficulty when feeding. The diagnosis is by suspicion, by inability to pass a catheter along the nose and confirmation by endoscopic examination. The treatment consists of establishment of either an oral or orotracheal airway. A CT scan is carried out to determine the characteristics and extent of the atresia. Reviews using CT studies suggest that most atresias contain both bony and membranous components. Corrective endoscopic surgery is carried out as soon as is practicable.<sup>13</sup>

### DISEASES OF THE NASOPHARYNX

#### Adenoids (nasopharyngeal tonsil)

These are part of the Waldeyer's ring of lymphoid tissue, which protects the upper airway. Adenoids are normally small at birth but enlarge from 18 months and regress normally at 8–9 years.

#### Adenoid hypertrophy

Since all children have adenoids, obstruction is a result of either a relatively small nasopharynx or large adenoids. Persistent enlargement causes snoring and often results in children having upper respiratory tract infections that last for 3–4 weeks instead of for 7–10 d. Such children usually mouth breathe and have hyponasal speech. There is an association between enlarged or infected adenoids and middle ear disease.

Adenoid hypertrophy is suspected with the above history and on the finding of a patent anterior nasal airway. Confirmation of adenoid size can be carried out by a lateral soft tissue X-ray of the neck (Fig. 32.2). In mild or intermittent cases, treatment is reassurance that the adenoids will go away. Surgery should be reserved for more persistent problems.

#### Adenoiditis

Adenoiditis occurs with viral infections and exacerbates nasal blockage. It can be quite severe in a small child with fever and purulent nasal discharge. A broad-spectrum antibiotic for 5 d is indicated in severe cases.

#### Adenoidectomy

Removal of the adenoids is indicated for:

1. airway obstruction in a small child (see airway obstruction, tonsillitis);
2. severe persistent nasal obstruction;
3. recurrent acute otitis media;
4. otitis media with effusion.

Primary or secondary hemorrhage occurs in about one case in 200.

#### Angiofibroma

This is a benign tumor of the back of the nose and nasopharynx that presents in males in their early teens. Its symptoms are of nasal blockage

Fig. 32.2 Lateral soft tissue X-ray of a 4-year-old boy showing enlarged adenoids occluding the postnasal airway (arrowed).

with epistaxis. If expansion is rapid, cranial nerve compression can occur. The diagnosis is confirmed by endoscopy and a CT scan. Treatment is by surgery initially, radiotherapy being reserved for intracranial extension.

## DISEASES OF THE PHARYNX

### Pharyngitis

This is very common and usually of viral origin. It is a common presenting symptom of many upper respiratory tract infections, including the common cold, and may also precede the exanthemata of rubella or measles. There is generalized inflammation of the pharynx and often rhinitis. Treatment is supportive with antipyretics and analgesics as necessary.

### Tonsils

The palatine tonsils, like the adenoids, are part of the body's defensive mechanism and serve to protect the upper airway from infection. Their removal, however, causes no subsequent immunological problems, nor is it associated with any deleterious long-term effect.

### Acute tonsillitis

This is commonest between the ages of 3 and 8, but can occur at any age. Of these cases, 50% are viral and 50% are bacterial, with the beta-hemolytic streptococcus being commonest, although *Staphylococcus aureus*, *Pneumococcus* and *H. influenzae* are also implicated.

The onset is abrupt, with pain in the throat, associated shivering and a pyrexia up to 39°C. The pain may be severe and radiate to the ears. Swallowing is acutely sore and solid food is refused, although fluids may be accepted. The disease progresses over 48 h, even with antibiotic therapy, and the swelling of the throat and the tonsils results in dysphagia for fluids and even for saliva that may dribble from the mouth. Speech may become thick and muffled and there is often painful enlargement of cervical glands.

On examination, the mucosa of the pillars of the fauces and soft palate are congested and as the disease progresses the tongue becomes coated and the breath become offensive. The tonsils are swollen and inflamed, with a purulent exudate. In severe cases, edema of the palate and the uvula may make the voice muffled and thick. Sometimes in streptococcal infections a scarlatiniform rash appears over the body.

### Investigation

Throat cultures showing Group A beta-hemolytic *Streptococcus* may confirm the diagnosis but a negative culture does not rule it out. There is also a high asymptomatic carrier rate of this *Streptococcus*.<sup>14</sup> Throat swabs should not be carried out routinely in sore throats according to the Scottish Intercollegiate Guidelines Network (SIGN) guidelines.<sup>15</sup>

Rapid antigen testing, e.g. antistreptolysin O titer, although widely used and although showing a high specificity, shows a low sensitivity compared both with throat culture and clinical assessment.<sup>16,17</sup> Rapid antigen testing should therefore not be carried out routinely in the case of a sore throat.<sup>15</sup>

### Differential diagnosis

1. *Infectious mononucleosis*. This occurs in older children and is often accompanied by marked lymphadenopathy in the neck and other areas. The child is miserable with throat discomfort due to generalized congestion of the throat and swelling of the tonsils. Serological confirmation can resolve doubt and treatment is supportive with analgesia and fluids.
2. *Viral pharyngitis*. In this condition, the child is less ill and has other symptoms, e.g. a blocked-up nose.
3. *Herpangina*. This self-limiting condition due to Coxsackie virus has papular, vesicular and ulcerative lesions on the anterior pillars of the fauces, palate and tonsils.
4. *Herpes simplex stomatitis*. This may be quite severe although it is self-limiting in the toddler, with severe pain and drooling of saliva from the pain of swallowing.
5. *Moniliasis*. White patches are present on the tongue and on the tonsils and pharynx. This is usually associated with immunodeficiency but can occur after antibiotic therapy.

### Treatment

In mild tonsillitis, analgesia, usually paracetamol, and adequate fluid intake is all that is required. Antibiotics are of limited use in most people with sore throats<sup>18</sup> but it has been traditional in more severe cases to give penicillin V for 7–10 d. Erythromycin has been used where there is penicillin sensitivity. Amoxicillin or co-amoxiclav if given to a child with mononucleosis will result in an extensive skin rash. Parenteral penicillin may be required in persistent cases. The child should be encouraged to drink and eat a soft diet if possible. There is no clear evidence that the use of antibiotics in tonsillitis expedites symptomatic improvement, prevents rheumatic fever or glomerulonephritis or reduces the occurrence of suppurative complications, e.g. quinsy.<sup>15</sup>

*There is no good evidence that antibiotics for tonsillitis alter the course or severity of the acute episode.*

### Complications of tonsillitis

1. *Peritonsillitis*. Inflammation spreads outwith the tonsillar area and the child develops increasing pain and fever, often with significant swelling of the soft palate. Parenteral penicillin for 3–4 d can be changed to oral medication as the fever and pain subside.
2. *Peritonsillar abscess (quinsy)*. When peritonsillitis localizes, an abscess can form. Although this condition is less common in children, it still presents as a serious and potentially lethal complication. It occurs during or just after an acute attack of tonsillitis, presenting with increasing pain and swelling, usually on one side of the throat, with marked dysphagia and often otalgia. The child will have difficulty in opening his mouth. Examination can be difficult because of trismus but will show the affected tonsil to be very red, covered in pus and pushed medially. In addition,

there will be gross swelling and redness of the palate and marked cervical lymphadenopathy on the ipsilateral side. If untreated, the abscess can spread to give rise to a parapharyngeal abscess with the risk of spread to the base of the skull or even into the superior mediastinum. The treatment is drainage under general anesthetic and can be a hazardous procedure. If it is not certain that pus is present, i.v. penicillin or erythromycin is given with fluids and analgesics.

3. *Airway obstruction.* This usually occurs in children aged 2–3 as a result of chronic hypertrophy of the adenoids and tonsils. The child breathes noisily at night and often during the day. Occasionally the parents will volunteer that the child stops breathing for short periods during the night and this can cause them some understandable alarm. At other times more direct questioning is required to elicit this symptom. If untreated, this relatively common complication of tonsillitis can lead to chronic hypoxia, pulmonary hypertension and, in severe cases, cor pulmonale. Where there is any suggestion of airway obstruction, the child should undergo a sleep study with monitoring of the oxygen saturation. If there are episodes of desaturation, indicative of sleep apnea, and there is no other cause for the airway obstruction, adenotonsillectomy usually cures the condition.<sup>19</sup> Such children should be admitted to the high-dependency unit on the night of surgery and their breathing pattern should be monitored. In some more severe cases the respiratory drive is depressed. Oxygen may be needed until the respiratory drive returns to normal.
4. *Rheumatic fever and glomerulonephritis.* These are very rarely seen now as a complication of tonsillitis.

### Indications for tonsillectomy

The following are indications for tonsillectomy (enlargement of the tonsils on their own is not an indication for their removal):

1. Airway obstruction in small children with persistent noisy breathing and suspected or proven sleep apnea. The adenoids will also be removed.
2. Suspicion of other pathology, e.g. lymphoma, is also an absolute indication. There is usually a change in the architecture of the tonsil that would suggest lymphoma.
3. Two or more attacks of peritonsillar abscess.<sup>20</sup>
4. Recurrent acute tonsillitis. By this is meant five or six attacks of definite tonsillitis in 1 year.<sup>15</sup> This number has been arrived at arbitrarily.<sup>21</sup> Mild symptoms do not benefit from surgery.<sup>22</sup>

### Complications of tonsillectomy

A primary hemorrhage occurs within the first 24 h in 0.5–1.0% of children. Usually this is in the first 6 h after surgery and the child will start coughing up blood or, if unrecognized, may vomit a variable quantity of blood. After fluid replacement the child is returned to the operating room, where the bleeding vessels are identified and controlled by diathermy or ligation. A secondary hemorrhage occurs after 7–10 d. Often the child's throat will have started to become sore again and he then becomes aware of blood coming into his mouth. These children should be admitted, cross-matched and i.v. access obtained.

A broad-spectrum antibiotic such as amoxicillin is administered and local treatment consisting of hydrogen peroxide gargles and, occasionally, local adrenaline swabs can be carried out. If the bleeding persists, return to theater for ligation of the vessels or in rare cases packing of the tonsillar fossa.

## DISORDERS OF PHONATION

### Dysphonia

Dysphonia, or difficulty in producing sound, is usually associated with laryngeal disease (hoarseness). Some children have weakness or roughness of their voice in the course of an upper respiratory tract infection, this being a manifestation of laryngitis. Following recovery the voice usually returns to normal and no further investigation is required. Persistent hoarseness should be investigated and this can only be done by visualization of the larynx with a fiberoptic endoscope passed along the nose, into the nasopharynx. This can be done in the clinic where the child is cooperative but where this is not possible, examination under a general anesthetic is indicated to define the pathology.

The causes of hoarseness in children are as follows:

1. *Vocal nodules.* These occur at the junction between the anterior third and posterior two thirds of the vocal cords. They are usually secondary to voice abuse and in loud and noisy children are known as 'screamers' nodes. Small nodules can improve with speech therapy or if the nodules grow, surgery involving microscopic dissection is indicated. Histology shows hypertrophic squamous epithelium with underlying edema of Reinke's space.
2. *Polyps of the larynx.* These occur spontaneously or following intubation and cause variable hoarseness. They are removed under general anesthetic.
3. *Laryngeal papillomas.* These are a rare cause of hoarseness associated with maternal genital warts (papilloma virus). They present as persistent hoarseness, sometimes with aphonia and occasionally airway obstruction. Treatment is by removal and multiple operations may be required. They do not become malignant but can spread into the trachea and in rare cases, into the bronchus.
4. *Unilateral vocal cord paralysis.* This can follow surgical or nonsurgical trauma to the neck, or occur following viral infections including mononucleosis. The voice may be breathy if the cord is abducted or well maintained if the cord is medialized. The diagnosis is usually made on fiberoptic endoscopy, and treatment consists of speech therapy.

### Aphonia

Complete loss of voice can occasionally occur with laryngeal pathology, e.g. papillomas, and in most cases the larynx should be visualized. Complete aphonia in an otherwise healthy child should be viewed with suspicion. Functional or 'hysterical' aphonia occurs after emotional or physical trauma, e.g. tonsillectomy. It usually affects older children and in most cases is self-correcting. Occasionally a laryngoscopy may have to be carried out to establish the diagnosis, but usually explanation of the problem together with counseling will suffice.

## DEFINITIONS AND EXPLANATION OF TERMS

The widespread misuse of the word 'allergy' causes confusion. It is essential to have a definition or explanation of terms as follows.

### ALLERGY

Allergy is a reproducible adverse reaction to an extrinsic substance mediated by an immunological response, irrespective of the precise mechanism. The substance provoking the reaction may have been ingested, injected, inhaled or may merely have come into contact with the skin or mucous membranes. The terms 'allergy' and 'hypersensitivity' have the same meaning and are interchangeable.

### ATOPY

There is no good definition of atopy. The term was introduced to describe the 'asthma and hay fever group' of diseases. Subsequently, atopy has been redefined as a hereditary predisposition to the production of IgE antibody, an unsatisfactory oversimplification. The atopic diseases comprise atopic dermatitis, asthma, allergic rhinoconjunctivitis and some cases of urticaria. The association between food allergy and these atopic diseases is so strong that there is a case for considering food allergy as an atopic disease.<sup>1</sup>

### ANAPHYLAXIS

The term 'anaphylaxis' is usually reserved for an allergic reaction associated with severe, life-threatening circulatory and/or respiratory compromise.

### FOOD INTOLERANCE

Food intolerance is a reproducible adverse reaction to a specific food or food ingredient, and it is not psychologically based. Food intolerance occurs even when the subject cannot identify the type of food that has been given. This definition does not take into account dosage. Clearly any food in vast excess will cause a reproducible adverse reaction. Such events are not generally covered by the term 'food intolerance'.

### IMMUNE MECHANISMS AND TIMING OF THE ALLERGIC RESPONSE

When the skin, airways, or conjunctivae are challenged by a single dose of allergen, an allergic reaction can be classified as immediate, delayed or dual (that is both immediate and delayed). Two main immune mechanisms determine the timing of these allergic responses (see Table 33.1). Immediate (acute) reactions usually occur within

Table 33.1 Immune mechanisms leading to allergic reactions

Mechanism	Clinical characteristics
Direct, IgE- or IgG-mediated <b>mast cell degranulation</b> with release of proinflammatory mediators (e.g. histamine, bradykinin, leukotrienes, platelet-activating factor)	Immediate/acute hypersensitivity reactions
RAST and SPT only useful if IgE mediated	Rapid onset (usually minutes) Urticaria/angioedema, rhinoconjunctivitis/pharyngeal edema/bronchospasm, hypotension, vomiting/diarrhea, anaphylaxis Mainstay of pharmacological treatment: antihistamines, adrenaline for anaphylaxis
<b>T-lymphocyte-mediated</b> , release of cytokines and chemokines	Delayed hypersensitivity reactions
RAST and SPT not indicated	Slower onset over hours/days Contact dermatitis/atopic dermatitis, chronic asthma, allergic enterocolitis Mainstay of pharmacological treatment: topical/local corticosteroids

minutes of contact with the allergen and are caused by mast cell degranulation usually triggered by antigen cross-linking IgE on the mast cell surface. Delayed hypersensitivity reactions may occur hours after contact with the allergen and are mediated by T-lymphocytes and the inflammatory cytokines they release. Although IgE-based allergy (skin prick tests and serum-specific IgE [RAST]) tests may be useful in the diagnostic workup of some immediate-type allergic reactions, they are not useful in delayed reactions, which are typically not IgE mediated. A summary of the types of the clinical spectrum of diseases is given in Table 33.2. The pathogenesis and mechanisms of allergic disorders are reviewed in more detail elsewhere.<sup>23</sup> It should be noted that some allergic reactions, for example reversible airway obstruction (asthma) may be mediated by both humoral and cellular immune mechanisms.

Table 33.2 Clinical spectrum of allergic disease based and immune responses aimed at allergen avoidance and removal

Body interface		
Skin	Respiratory tract	Gastrointestinal tract
<b>A. Diseases</b>		
Urticaria (humoral)	Rhinoconjunctivitis (humoral)	Food intolerance (humoral/cellular)
Atopic eczema (cellular)	Asthma (humoral/cellular)	
<b>B. Protective responses against allergens</b>		
Pruritus (rubbing/scratching)	Copious secretions Sneezing and coughing	Vomiting and diarrhea
Hyperkeratosis (barrier)	Bronchospasm (prevent/reduce further exposure)	

## HYGIENE HYPOTHESIS

The hygiene hypothesis is derived from the notion that infections and unhygienic contact might confer protection against the development of allergic illness.<sup>4-6</sup> The hypothesis attempts to reconcile the following facts:

- **Increase in the prevalence of atopic diseases over the last few decades:** The prevalence of atopic diseases (atopic dermatitis, asthma and allergic rhinitis) has doubled over the last few generations.<sup>7</sup> These diseases are largely a problem of developed countries such as the UK, USA, Australasia and Canada. Within these countries, the affluent within these communities (social classes I and II) are most commonly affected. Because this increase in prevalence has occurred over only a few generations, it must be due to environmental rather than genetic causes.<sup>8</sup>
- **Increase in certain autoimmune conditions over the last few decades:** What is often less appreciated is that as well as a rise in allergic diseases, there has been a parallel increase in some autoimmune conditions, such as multiple sclerosis, Crohn's disease and insulin-dependent diabetes mellitus. Other autoimmune diseases have either shown little change in prevalence (ulcerative colitis) or a reduced prevalence (rheumatoid arthritis).
- **Reduction in exposure to certain environmental microbes, particularly those spread via the orofaecal route, over the same time period:** This evidence comes from two main sources. Firstly, a Japanese study of 867 children over the age of 12 years showed a clear negative relationship between delayed hypersensitivity responses to tuberculin and the presence of asthma.<sup>9</sup> Secondly, a number of studies performed in Switzerland, Austria and Germany have provided convincing evidence that growing up on a farm with regular contact with farm animals protects against allergic sensitization and the development of childhood allergic diseases.<sup>10-12</sup>

Based on these observations, the hygiene hypothesis proposes that certain environmental viruses and bacteria help to induce immune tolerance to normally innocuous environmental antigens (allergens) and self (autoantigens). The hypothesis is that reduced exposure to these environmental microbes, associated with modern western living has led to a lack of immune tolerance and thus an increase in immune hypersensitivity, atopy and autoimmunity.

## GENETICS OF ALLERGY AND ALLERGIC DISORDERS

As well as environmental factors, there is no doubt that genetic factors are also important in the development of atopic diseases. Evidence for this comes from a number of sources:

- **Epidemiology: family history and twin studies:** Strong family history of atopic disease in many affected individuals, as well as twin studies point to a strong genetic influence.<sup>13</sup> For instance, the risk of atopic disease in the general community is approximately 10%, but this increases to 50% if one parent is affected and up to 75% if both parents are affected. Twin studies suggest that the genetic component accounts for approximately 80% of the predisposition to atopic dermatitis, asthma, allergic rhinoconjunctivitis and peanut allergy.
- **Polygenic disease:** In most cases, predisposition to allergic diseases is thought to be due to not one but the additive or synergistic effect of a number of genes. Rarely single gene mutations may cause allergic symptoms such as the FoxP3 gene in IPEX and the WASP gene in Wiskott-Aldrich syndrome (see Chapter 27).
- **Specific genes largely unknown:** The specific genes causing allergic disease in most patients are still unknown. Although numerous candidate genes have been implicated in the development of atopy, definitive evidence linking any one of these genes as a major cause of clinical atopy is lacking.<sup>14</sup>
- **Candidate genes now thought to relate to molecules sensing foreign antigens and those involved in immune tolerance induction:** Current research is focusing on genes that regulate the

innate and acquired immune responses, particularly genes that code for receptors on dendritic cells and T-lymphocytes recognizing foreign microbes (e.g. CD14, TLR 2, 4, 6, 10, TIM3).<sup>15-17</sup> Genetic factors that are important in regulatory immune cell function (FoxP3, TGF- $\beta$ , IL-10) are also being studied.<sup>18</sup>

## CLINICAL SPECTRUM OF DISEASE

Clinical features of allergic disease occur mainly at the three major interfaces between the body and its environment: the skin, upper and lower respiratory tract and gastrointestinal system. This subdivision, although paralleling the types of pediatric specialists to whom such patients will be referred (namely dermatologists, respiratory physicians and gastroenterologists), is artificial. Moreover in some ways it may be unhelpful to characterize allergic diseases in this way. For instance, acute allergic reactions to ingested food may manifest not only as vomiting and diarrhea, but in some cases solely as cutaneous urticaria and in others as acute pharyngeal angioedema or bronchospasm, or in yet other cases with clinical features related to all three systems. Allergic disease is primarily a systemic illness with many overlapping features.

## SKIN

### URTICARIA

#### Acute urticaria

Acute urticaria is the result of a variety of causes (often not identified) and mechanisms. The proportion of cases in which a cause is found varies; in childhood the most common is viral infection. Urticaria may develop during an illness or within 1–2 weeks after the illness, and remain a problem for a few days or weeks. Immediate allergic reactions to foods are the other major cause of acute urticaria. A parent notices, for example, that whenever a child eats fish his lips swell and he develops an urticarial rash. Fish is avoided, and the problem disappears. Occasional lapses of avoidance either demonstrate continued intolerance or, with time, loss of symptoms. Cases that come to medical attention are mostly severe (e.g. associated with pharyngeal edema), atypical, or associated with other disorders, notably atopic eczema. The common foods incriminated (cows' milk, egg, nuts, fish, tomatoes and fruit) are similar to those that cause allergic contact urticaria (see later), the difference being that children are in general more likely to touch raw foods than to eat them, and raw foods are on the whole more likely to trigger urticaria than cooked foods.

#### Allergic contact urticaria

This is an immediate allergic reaction, and should not be confused with contact dermatitis, which represents a delayed reaction. Although certain foods, such as cows' milk, raw eggs, raw potatoes, raw fish, apples and nuts are particularly common causes, any food containing protein could in theory cause allergic contact urticaria. The tissues and secretions of pet mammals are also common causes of allergic contact urticaria in childhood. Other causes are grass pollen, chemicals, a number of drugs applied topically, and a few vehicles contained in topical medicaments.

#### Irritant contact urticaria

Common causes are plants such as stinging nettles or creatures such as jellyfish, moths and caterpillars. Chemicals are a major cause of irritant contact urticaria, and the relevant chemicals are widely used in food, medicines and cosmetics.

#### Chronic urticaria

Chronic urticaria is defined as urticaria that has persisted for more than 6 weeks and affects the patient for several days each week. The condition can be associated with serious adverse effects on quality of life, sleep and daily activities, but is rarely associated with systemic features or life-threatening anaphylaxis.<sup>19,20</sup> Of these patients, 40% also have angioedema. Very few cases are caused by allergy and therefore allergy testing

is rarely indicated. One half are associated with physical triggers such as cold, heat, sunlight, or stress (home or school). An autoimmune etiology should be considered, particularly in teenage girls and where there is a personal or family history of autoimmune disease, especially thyroid disease. In these cases IgG autoantibodies bind specifically to Fc $\epsilon$  receptors on mast cells triggering degranulation. Thyroid function should be monitored in this subgroup of children, as up to one third of patients are at risk of autoimmune thyroid disease. In younger children viral or bacterial infections may also trigger the condition. Salicylates in drugs and sometimes foods can also provoke urticaria.<sup>21</sup> Rarely chronic urticaria may be a manifestation of cutaneous mastocytosis and therefore a careful examination of the skin is required. The natural history varies with the cause. Urticaria caused by infection or drugs is most likely to resolve, while physical and autoimmune urticaria often persists for years. Most cases respond to avoidance of obvious triggers and oral antihistamines. For refractory or more urticarial vasculitis as detailed later, immunosuppressive drugs may be required and referral to a specialist is indicated.

If urticaria persists in one location for over 48 h, or leaves residue (e.g. hyperpigmentation), or is associated with purpura or systemic manifestations (arthritis, fever, etc.) an underlying vasculitis (urticarial vasculitis) should be considered.<sup>22,23</sup> Skin manifestations are typically recurrent episodes of urticaria-like weals, often associated with arthralgia (50%) and angioedema (40%). In addition to the skin, the respiratory (20%), renal (5–10%) and gastrointestinal (20%) systems are most frequently involved in the disease. Urticarial vasculitis is most commonly an acquired idiopathic phenomenon but may occur in association with other disorders, most often systemic lupus erythematosus (SLE), Sjögren syndrome and serum sickness. Of these patients, 60–80% is female. Investigations should include a skin biopsy with immunofluorescent staining for immunoglobulin deposits. The most common laboratory abnormalities reported are an elevated ESR, hypocomplementemia and circulating immune complexes. Measurement of serum complement is useful prognostically, as hypocomplementemia is associated with more serious systemic involvement. There is no universally effective therapy for urticarial vasculitis but commencing treatment with antihistamines and proceeding through nonsteroidal anti-inflammatory drugs (NSAIDs), to colchicine, dapsone or hydroxychloroquine. If these medications do not achieve control, systemic steroids and azathioprine can be tried. The causes of urticaria and angioedema (see later) are listed in Table 33.3.

Table 33.3 Classification of urticaria and angioedema

Urticaria	
1.	Local irritants: plants, jellyfish, chemicals
2.	Direct mast cell activation: opiates, antibiotics, curare, contrast media physical (cold: consider cryoglobulinemia, solar: consider SLE and porphyria, exercise, cholinergic, vibration)
3.	Agents altering arachidonic acid metabolism: aspirin/NSAIDs, benzoates
4.	IgE mediated: allergen mediated (pollens, dander, foods, worms, molds, <i>Hymenoptera</i> venom, drugs)
5.	IgG mediated: viral infections, autoimmune (associated with other autoimmune diseases, especially thyroid disease), urticarial vasculitis
6.	Idiopathic
Angioedema	
1.	Complement inhibitor deficiency: hereditary angioedema
2.	Complement activation: vasculitis, infections, serum sickness
3.	Angiotensin-converting enzyme (ACE) inhibitors

## ANGIOEDEMA

Unlike urticaria, where the inflammatory edema is in the superficial dermis, in angioedema the swelling is mainly in the deeper subcutaneous and submucosal layers. Angioedema may be painful rather than pruritic, and commonly affects the face and extremities. In the upper respiratory tract it is associated with swelling of the lips, tongue, and pharyngeal tissues, which may rarely lead to life-threatening upper airway obstruction. Angioedema of the gastrointestinal tract usually manifests as abdominal pain. The major mediators of angioedema are plasma kinins (e.g. bradykinin), the activation of which is inhibited by C1 inhibitor and other protease inhibitors. Angioedema is associated with urticaria in 80% of cases; in the remaining 20% of cases angioedema occurs without any urticaria.

### Hereditary angioedema

The most important differential diagnosis of allergy-induced angioedema is hereditary angioedema, because the prognosis and management of this condition is different.<sup>24</sup> In the past, the mortality rate for attacks involving the upper airways were around one third of patients. Subcutaneous, respiratory and gastrointestinal tract angioedema characteristic of hereditary angioedema is due to an autosomal dominantly inherited deficiency of C1 esterase inhibitor.<sup>25</sup> Swelling of the gastrointestinal mucosa results in nausea, vomiting, diarrhea and severe pain that can mimic a surgical emergency. The subcutaneous swellings are disfiguring but not erythematous, pruritic or painful. The angioedema is solely mediated by kinins and never associated with urticaria. That is why angioedema in combination with urticaria rules out a diagnosis of hereditary angioedema. Interestingly the pulmonary vascular tree is spared, probably because the cells lining the pulmonary vessels have surface enzymes that inactivate bradykinin and other kinins. Symptoms can last from 1–4 d. Symptom frequency may vary from very few, if any, particularly in prepubertal children, to frequent daily or weekly episodes.

The diagnosis of hereditary angioedema should be considered if: (1) angioedema occurs without urticaria; (2) there is an atypical pattern of angioedema (hands, feet, abdomen rather than face); (3) there is a family history (but 20% of cases are sporadic); (4) there are abdominal symptoms. There are two types of disease: type 1 (85% of cases) due to absent C1 inhibitor and type 2 (15% of cases) where there are normal or elevated levels of C1 inhibitor antigen, but the protein is dysfunctional.

Diagnosis in suspected cases is made by measuring C1 inhibitor levels and function as well as C4, which may be low only during acute attacks.

Unlike allergen-mediated urticaria and angioedema, antihistamines, adrenaline (epinephrine) and steroids are of little or no use in the treatment of hereditary angioedema. C1 esterase inhibitor concentrate, which should be available in all hospital emergency departments, is the treatment of choice for pharyngeal edema and severe abdominal attacks. If the concentrate is not available, fresh-frozen plasma may be used. Danazol can be used as prophylaxis in postpubertal children and non-pregnant adults. In younger children the plasmin inhibitor tranexamic acid is an alternative. Angiotensin-converting enzyme (ACE) inhibitors may precipitate attacks by blocking bradykinin degradation and should be avoided, as should estrogen-based contraceptives.

## ALLERGIC ASPECTS OF ATOPIC DERMATITIS

Approximately 10% of infants attending community clinics and up to 30% of infants and young children attending specialist allergy clinics may benefit from antigen avoidance regimens.<sup>26,27</sup> Older children are less likely to respond to dietary manipulation, and avoidance of aero-allergens that might influence their disease is often not practical. Thus the first-line management (see also Chapter 30) is usually symptomatic treatment with emollients and topical steroids, recognition and treatment of bacterial and viral skin infection, and use of sedating H<sub>1</sub> antihistamines at night. The situations in which antigen avoidance should be considered are:

1. **Severe disease.** Exclusion diets are highly disruptive to family life, and are potentially nutritionally hazardous, so it makes little sense to employ a diet when the condition is mild (< 10% of the skin surface area affected) and easily controlled with simple topical therapy. Such diets are more appropriate if 25% or more of the skin surface area is affected.
2. **History.** A history of immediate urticarial or gastrointestinal reactions to foods is common. It is sensible to avoid foods for which there is a clear history of an immediate allergic reaction.
3. **Multiple atopic disorders in infancy.** The occurrence of more than one atopic disorder appears to increase the possibility of an important allergic element. This is especially true if atopic features such as eczema, asthma or rhinitis are accompanied by gastrointestinal symptoms such as persistent loose stools or vomiting.
4. **Age.** Elimination diets are simpler to administer and control in infancy and results are better at this age.
5. **Severe eczema in exclusively breast-fed infants.** In one study, in six of 37 breast-fed infants eczema improved when the mother avoided cows' milk protein and egg and relapsed when these were reintroduced.<sup>28</sup> It is often difficult to predict which baby would respond to maternal dietary exclusion. It is reasonable to try maternal avoidance of cows' milk and egg in an infant with eczema who is being exclusively breast-fed. Other foods can provoke eczema in this way, but their detection relies on the suspicions of a parent or doctor followed by avoidance and later challenge.

## ANTIGEN AVOIDANCE IN ATOPIC DERMATITIS

### Diets

The important principles underlying any elimination diet are:

1. The diet should in the first instance be tried for a defined period of time (e.g. 6 weeks in patients with eczema) and not just imposed indefinitely.
2. At the end of this period the patient should be reassessed to see if the diet has been helpful. If it has not, then the diet should be discontinued. If the diet has helped, and the parents and doctor feel that the therapeutic benefit outweighs the inconvenience of the diet, then the items omitted should be reintroduced one by one (in eczema at the rate of about one new food every 5–7 d).
3. The help of a dietitian is important to ensure that specific food items have been properly excluded from the diet, and to ensure the nutritional adequacy of the diet.

There are a variety of exclusion diets available. Infants and toddlers are far more likely to benefit than older children.

### *Half-hearted attempts to 'have a go'*

The very small quantity of food that can provoke an adverse reaction means that the 'try cutting down his milk' type of tinkering with the diet is most unlikely to succeed. The advantage of a carefully conducted diet is that even if it fails, at least the parents will be satisfied in the knowledge that it was tried properly.

### *Complete avoidance of known triggers*

A trial of rigorous avoidance of known or suspected triggers is a logical first step. It is common to see a child with a clear history of intolerance to a food, but where the food is being incompletely avoided. In infants with eczema, specific avoidance of cows' milk, egg and/or wheat are most often considered. These diets are unlikely to be successful in the absence of history of the eczema being made worse by these foods.

### *Avoidance of 10 common food triggers*

The patient avoids approximately 10 common food triggers, plus foods for which there is a history of intolerance. The foods usually chosen for exclusion are cows' milk, egg, wheat, fish, legumes (pea, bean, soya, lentil), tomato, nuts, berries and currants, citrus fruit and food additives

**Table 33.4** Measures that kill the house dust mite and reduce levels of mite antigen in the home

1. Reducing indoor relative humidity below 50%  
High-efficiency dehumidifiers
2. Removal of dust mites and allergens  
Washing bed linen in hot water ( $\geq 55^{\circ}\text{C}$ )  
Adding benzyl benzoate (0.03%) to wash cycle  
Tumble drying bed linen ( $\geq 55^{\circ}\text{C}$  for more than 10 min)  
Dry cleaning  
Replace carpets, draperies and upholstery  
Vacuuming carpets  
Freezing toys and small items ( $< 17^{\circ}\text{C}$  for 24 h), then wash  
Dust with damp cloth
3. Encasements  
Mattress and pillow dust mite proof encasements

(for a discussion of these see separate section later). The chances of a useful clinical benefit are small.

### *The few-foods diet (so-called oligoantigenic diet)*

This consists of exclusion of all foods except for five or six items. These items should not include a food for which there is a history of intolerance. Such diets comprise a meat (usually lamb or turkey), three vegetables (e.g. potato, rice, and carrot or a brassica – cauliflower, cabbage, broccoli or sprouts), a fruit (usually pear) and possibly a breakfast cereal (e.g. Rice Krispies). There are scanty data on the outcome of few-foods diets. In one study, a few-foods diet was associated with marked improvement in 50% of patients (median age 2.9 years, range 0.4–14.8) with atopic eczema, but after 12 months' follow-up, the results were the same (marked improvement) in the group that improved, the group that failed to improve, and the group that tried a diet but were unable to cope.<sup>29</sup> In another study, 85 children (median age 2.3 years, range 0.3–13.3 years) with atopic eczema were randomly allocated to receive a few-foods diet supplemented with either a whey hydrolysate or a casein hydrolysate formula, or to remain on their usual diet and act as controls, for a 6-week period.<sup>30</sup> After 6 weeks, there was a significant reduction in all three groups in the percentage of surface area involved and skin severity score. Of those who participated, 16 (73%) of the 22 controls and 15 (58%) of the 24 who received the diet showed a greater than 20% improvement in the skin severity score. This is the only controlled study of a few-foods diet, and it failed to show benefit. However, the drawback to these two studies is the relatively high median age and the wide age range, which is important because it is general experience that the best results for elimination diets are in infants. Given the tendency for most children with food hypersensitivity to grow out of the problem by the age of 3 years, the inclusion of substantial numbers of older children in these studies unintentionally biased the results against finding benefit from a diet.

### *Elemental diet*

The application of an inpatient regimen of 4–6 weeks of a so-called elemental diet (e.g. Elemental O28, Vivonex or Tolerex) is the ultimate test of whether food intolerance is relevant or not, but until more data are available this approach must be regarded as experimental.<sup>31</sup> The drawbacks comprise the lack of a guarantee of success, family disruption associated with 2–3 months' hospitalization, loose stools (due to hyperosmolarity of the formula), weight loss and hypoalbuminemia.

### *House dust mite and pet avoidance*

House dust mites and pets can trigger atopic eczema. However, the number of patients who experience benefit solely from the avoidance of pets or mites appears to be small. As with elimination diets, there is no test that predicts benefit from avoidance measures. In some children, particularly those with troublesome facial eczema and periocular irritation worse first thing in the morning, the house dust mite in pillow cases and

mattresses may be a significant factor. Even though previous trials have not shown dust-proof covers to be useful in unselected patients with eczema, they may be helpful in these selected cases. A number of additional measures are recommended to kill house dust mites and remove mite antigen from homes (Table 33.4)<sup>32</sup> but none of these measures have been found to significantly affect the clinical severity of eczema. Some patients with atopic eczema are worse during the pollen season or after grass has been cut, but avoidance is impossible.

## RESPIRATORY TRACT

### ALLERGIC ASPECTS OF ASTHMA

There is no doubt that exposure to various triggers can provoke or worsen asthma in certain patients. Observations of children with unusually severe asthma who are sent to alpine resorts, where the exposure to house dust mites and pets is greatly reduced or abolished, are that somewhere between one and two thirds become completely asymptomatic and can discontinue all therapy. Return home is followed by relapse in most patients. In the past it was believed that this improvement was due to separation from parents and 'family tension', but the current doctrine is that the benefit is due to the avoidance of inhaled allergens. A history may help identify intermittent triggers that provoke attacks (e.g. cat dander), but may not identify allergens to which the patient is regularly exposed and which are responsible for maintaining the asthmatic state (e.g. house dust mites). However, there is a lack of objective investigations to establish the qualitative importance of allergy. For example, it is impossible to state, for asthmatic children of any specific age, in what proportion exposure to an animal provokes an attack of asthma, or what proportion will benefit from removal of a household pet. Some triggers are allergens, but others are not, so it is misleading to think of asthma solely as an allergic disease. Non-allergic triggers are discussed in Chapter 20.

### Trigger avoidance

It is impossible to avoid triggers such as cold weather, exercise, laughing and crying. Viral infections, pollens and fungal spores are ubiquitous, and total avoidance is impossible without unacceptable restrictions.

Avoidance of pets and pet antigens is theoretically possible but often unpopular or unacceptable to the family. Removal of the animal itself is insufficient, and if the level of pet antigen in the household is to be adequately reduced then also required are intensive carpet and furniture cleaning. Complete removal of cat antigen is especially difficult (if not impossible), and because of its adhesion to wall surfaces requires washing of the walls.

### Role of antigen avoidance in management of asthma

There are no objective data upon which to base clear recommendations, with the result that there are differences of opinion about the relevance of antigen avoidance. The cornerstone of the treatment of asthma is drug therapy, supplemented where possible or relevant by the avoidance of triggers. Even with the most enthusiastic approach to the identification and avoidance of triggers, it is rare for this alone to abolish symptoms. The major triggers that are at least potentially avoidable are house dust mites and pets. Since there is no clinical or laboratory test that can accurately identify those patients who will benefit from antigen avoidance, the only logical approach is to attempt a defined trial period of avoidance, including an assessment after an agreed period of time (e.g. 3 months) as to whether there has been any benefit.

### ALLERGIC RHINOCONJUNCTIVITIS

Allergic rhinoconjunctivitis may be either perennial or seasonal. Important triggers of perennial disease are house dust mite and pet danders. Seasonal rhinoconjunctivitis is most frequently caused by allergy to tree (spring), grass (summer) pollens or less frequently mould spores (*Cladosporium*, *Alternaria* and *Aspergillus*). Salicylate sensitivity occurs

mainly in adults and may start with symptoms of perennial rhinitis and then progress to include chronic sinusitis, nasal polyposis and asthma, which may be severe.<sup>21</sup>

Over 50% of patients have a combination of nasal and ocular symptoms. Nasal symptoms include sneezing, rhinorrhea and nasal blockage. Eye symptoms include itching, watering, redness, swelling and stinging. A severe seasonal form associated with cobblestoning of the conjunctiva, more common in boys is sometimes called 'vernal (spring) conjunctivitis'. During an exacerbation keratitis is common, causing photophobia and reduced visual acuity, and sometimes leading to an ulcer that may in turn cause permanent loss of vision. Asthmatic symptoms sometimes coexist with attacks of hay fever.

Avoidance of allergens is often not possible and therefore the mainstay of treatment is using medication to reduce the inflammatory effects of mast cell degranulation, particularly histamine. Nonsedating H<sub>1</sub> antihistamines are by far the simplest and most useful treatment for mild and moderate cases, given prophylactically during the pollen season. An advantage of H<sub>1</sub> antihistamines is that they help to prevent both nasal and eye symptoms.

Additional prophylactic medication for more troublesome nasal symptoms is mainly topical nasal corticosteroids. Systemic nasal decongestants are not recommended in children. Sodium cromoglycate nasal spray and oral montelukast are sometimes used, but are less effective than topical corticosteroids.

For allergic conjunctivitis, eye drops are often more effective than oral antihistamines but in more troublesome cases a combination should be used. Drops containing antihistamine, mast cell stabilizer (sodium cromoglycate), nonsteroidal anti-inflammatory agents and a combination of the above are available. Sodium cromoglycate works best if applied four times a day, which is demanding.

An exceptionally severe form of allergic conjunctivitis is known as vernal conjunctivitis, and for this steroid or cyclosporine drops may be justifiable, but these can only be prescribed under the supervision of an ophthalmologist, who can monitor for complications or adverse events side-effects such as corneal abrasions, glaucoma or cataracts.

Immunotherapy in selected children with severe allergic rhinoconjunctivitis due to grass pollen allergy can alleviate symptoms. It is worth considering where there is a poor response to oral antihistamines and topical treatments, and where the illness is having a major impact on the child's life. Referral to a specialist center for allergy testing and treatment is required.

## ADVERSE REACTIONS TO FOODS AND THE GASTROINTESTINAL TRACT

All eating causes reactions, for example satiety, the urge to defecate, a feeling of warmth, and weight gain. The mechanisms for food intolerance may be immunological (food allergy), metabolic (e.g. lactase deficiency), pharmacological (e.g. vasoactive amines), toxic (e.g. lectins in red kidney beans), irritant (e.g. curry) or unknown. Individuals vary in their tolerance of events.

The prevalence of reported food intolerance in children ranges widely from 6–18%,<sup>33,34</sup> a problem with these figures being that only about one third of parental reports of food intolerance can be confirmed when tested by blind food challenge. Intolerance to most other foods can occur; these are mainly responsible for immediate allergic reactions. Where there is doubt about a specific food intolerance, the only reliable way to confirm or refute the diagnosis is to perform a food challenge. The management consists of avoidance. The prognosis for food intolerance in young children is good. A prospective study showed that the offending food or fruit was back in the diet after only 9 months in half the cases, and virtually all the offending foods were back in the diet by the third birthday.<sup>35</sup>

## IgE-MEDIATED GASTROINTESTINAL HYPERSENSITIVITY DISORDERS

Symptoms of immediate gastrointestinal hypersensitivity are acute – usually occurring within minutes of consuming the food. Nausea and

vomiting is very common in IgE-mediated food allergy and help to rid the body of the triggering allergen. Diarrhea may follow several hours after the initial symptoms. The usual offenders are milk, egg, peanut, soy, wheat and seafood. Similar to other IgE-dependent allergic disorders, allergy to milk, egg, wheat and soy general resolve, whereas allergies to peanuts, tree nuts and seafood are more likely to persist. Allergens that are enzymes, for example in some fruit and vegetables, are rapidly degrading by salivary and gastric enzymes and therefore symptoms are often localized to the lips and oral cavity (oral allergy syndrome).<sup>36</sup> Oral allergy syndrome may be preceded by the onset of pollen-induced allergic rhinoconjunctivitis and is sometimes secondary to cross-reactivity between allergens of similar structure (see Table 33.5). These include oral pruritus, angioedema of the lips, tongue and palate. In around 9% of cases symptoms are systemic and in 1% of cases they may be severe.

## EOSINOPHILIC GASTROINTESTINAL DISORDERS

Eosinophilic gastrointestinal disorders (EGIDs) are defined as disorders that selectively effect the gut with eosinophil-rich inflammation in the absence of known causes for eosinophilia.<sup>37,38</sup> They need to be distinguished from drug reactions, parasitic infections (particularly strongyloides and ancylostoma), malignancies and inflammatory bowel disease. A family history of EGID was present in 10% of patients and 75% of cases are atopic. The prevalence is hard to estimate but seems to be as common as inflammatory bowel disease.

EGID is thought to have an allergic basis and the pathophysiology may involve either IgE or cell-mediated allergic responses. Clinical features and management vary depending on the segment of bowel affected (esophagus, stomach, small intestine, colon). Milk, egg, wheat, peanut and soy may trigger these disorders but in many cases multiple food allergies are involved. In 50% of cases there is a peripheral blood eosinophilia. Endoscopic appearance may be normal and the disease is often patchy. Diagnosis is dependent on the presence of an excessive eosinophilic infiltrate evaluated on multiple gut biopsies.

*Eosinophilic esophagitis* is associated with gastroesophageal reflux, vomiting, epigastric or chest pain, respiratory obstructive problems and dysphagia. The dysphagia, occurring in 85% of cases, may be severe enough to lead to impaction of food. Strictures and Barrett's esophagus may occur in chronic cases. Two thirds of patients are males and there is a high rate of atopic disease, particularly asthma. The condition has been thought of 'asthma of the esophagus'. Food allergens play a pathological role as dietary restriction or hydrolyzed formulae are associated with an improvement in 98% of children. Topical corticosteroids (the patient is instructed to swallow the dose from a metered-dose inhaler delivered without a spacer) provide long-term control but systemic steroids may be required for acute flares.

*Eosinophilic gastritis* and *gastroenteritis* are less well-defined entities and may present with vomiting, abdominal pain, anemia, failure to thrive and diarrhea, which may mimic Celiac disease. In such cases a jejunal biopsy usually shows some degree of villous atrophy. Treatment is similar to eosinophilic esophagitis with dietary restrictions and topical steroids (oral budesonide). The condition is often chronic waxing and waning.

Table 33.5 Common food allergy syndromes

Birch	Apples, cherries, peach, pear, nectarine, plum, apricot, hazelnut, walnut, almond, pecan, brazil (i.e. tree nuts), kiwi, carrot, celery, tomato, coconut, turnip, parsnip
Ragweed	Watermelon, cucumber, zucchini, banana
Mugwood	Celery, carrot, caraway, dill, parsley, fennel, green pepper
Grass	Potato, tomato, melon, peanut, orange, celery, kiwi
Latex	Banana, avocado, chestnut, kiwi

*Eosinophilic colitis (including cows' milk protein intolerance)* is the most common cause of bloody stools in infancy, is often due to cows' milk protein allergy and less commonly soy. Frequent loose stools occur in 25–75% of patients. In an uncommon but florid picture, infants can present with heavily bloodstained loose stools, sometimes accompanied by mucus. Acute abdominal pain (often but not always accompanied by vomiting or loose stools) can be a striking symptom. The acute presentation of blood in the stools and abdominal pain may mimic intussusception. Discomfort, crying or irritability are common and major features in infancy.

In contrast to eosinophilic esophagitis, eosinophilic colitis is a non-IgE mediated disease and thus RAST and skin prick tests are usually negative. In infants, exclusion of the offending food usually leads to resolution of the bloody diarrhea within 72 h and thus endoscopy and biopsy are reserved for refractory cases. The vast majority of infants outgrow the food intolerance by 1–3 years of age and therefore intermittent trials of reintroduction of the milk at 12 months old and then 6 months later is advised. In older children the prognosis is similar to eosinophilic gastroenteritis with a chronic course.

### Celiac disease

Celiac disease represents an immune response to a food protein (gluten in wheat, rye and barley) and therefore may be considered a food-allergic disorder.<sup>39</sup> Its prevalence is 1% in western populations. Symptoms include vomiting, diarrhea, anorexia and growth failure but are now recognized as often being more subtle or nonspecific. Thus the mean age of diagnosis has shifted from the first few years of life to middle adulthood. The  $\alpha$ -gliadin peptide of gluten is presented particularly well by dendritic cells expressing HLA-DQ2 and/or DQ8 and > 95% of patients have these HLA types.  $\alpha$ -gliadin cross-react with tissue transglutaminase 2 and stimulates the  $\gamma\delta$ T lymphocytic infiltrate and villous atrophy characteristic of this inflammatory enteropathy. Avoidance of dietary gluten leads to resolution of the disease, but this dietary restriction needs to be continued lifelong to prevent recurrences. Delay in removing gluten from the diet may be associated with an increased risk of other autoimmune diseases, particularly type I diabetes mellitus and autoimmune thyroid disease, as well as intestinal lymphoma. A detailed appraisal is given in Chapter 19.

### BEHAVIORAL PROBLEMS

Both hospital and community-based double-blind placebo-controlled studies have repeatedly failed to confirm any validity in the idea that food or food additives cause severe behavioral problems in otherwise healthy individuals. The avoidance of food additives seems to have only a very short-lived beneficial effect on hyperkinesia and other behavior problems, and any benefit from additive avoidance diets is likely to be a placebo response. One source of confusion has been the presence of atopic disease. If a food additive makes eczema or asthma worse, then the concentration span and behavior may also be expected to suffer, but there is no evidence that this is anything other than an indirect effect.

### IMPORTANT ALLERGENS IN CHILDREN

#### COWS' MILK PROTEIN

Cows' milk protein intolerance is a heterogeneous disorder and may present with symptoms of immediate (acute allergy, rarely even anaphylaxis) or delayed hypersensitivity reactions (EGID) (see section on the gastrointestinal tract earlier). Prevalence studies of intolerance to cows' milk protein vary from 1.9–7.5%. A most detailed study estimated a point prevalence of cows' milk protein intolerance in children with parentally perceived reactions at the age of 2.5 years at 1.1% (CI 0.8–1.6).<sup>40</sup>

The most common antigens in cows' milk are  $\alpha$ -lactoglobulin, casein,  $\alpha$ -lactalbumin, bovine serum albumin and bovine  $\alpha$ -globulin. Digestion may result in the production of additional antigens. The marked antigenic similarity between cows' and goats' milk proteins explains why

most children with cows' milk protein intolerance are intolerant to goats' milk. Intolerance to carbohydrates present in cows' milk and milk formulae is dealt with in Chapter 16.

The quantity of cows' milk required to produce an adverse reaction varies. Some patients develop anaphylaxis after ingestion of less than 1 mg of casein,  $\alpha$ -lactoglobulin or  $\alpha$ -lactalbumin. In contrast, Goldman et al<sup>41</sup> showed that 29 out of 89 children (33%) with cows' milk intolerance did not react to 100 ml of milk but only to 200 ml or more. The median reaction onset time in those who reacted to 100 ml milk challenges was 2 h, but the median reaction onset time in those who required larger amounts of milk to elicit reactions was 24 h.

Most cows' milk formula-fed infants with cows' milk protein intolerance develop symptoms in the first 3 months of life. The age of onset of the first symptoms in breast-fed babies depends on the age at which cows' milk is first introduced. A proportion of infants with cows' milk protein intolerance react adversely to traces of cows' milk protein in their mother's milk. Patients with cows' milk protein intolerance may be intolerant to other foods. In one hospital-based series of 100 children with cows' milk protein intolerance, over 50% exhibited intolerance to one or more other foods.<sup>42</sup> Approximately 8–14% of children with intolerance to cows' milk protein are also intolerant to soya protein.

### Clues to the diagnosis of cows' milk protein intolerance in the history

1. Symptoms occur, or are made worse, soon after ingestion of cows' milk protein. Multiple affected systems (e.g. gut, chest and skin) make the diagnosis more likely; single symptoms make it most unlikely.
2. Symptoms date from the time, or soon after the time, that breastfeeding was stopped or cows' milk protein was first introduced into the diet. (NB feeding changes often coincide with the onset of atopic disease, and do not prove a cause-and-effect relationship)
3. There is a family history of cows' milk protein intolerance.
4. The presence of severe atopic disease in an infant under the age of 12 months.
5. The observation that spilling cows' milk onto non-eczematous skin causes an urticarial rash.

### Making the diagnosis of cows' milk protein intolerance

Most patients whose symptoms commence within 20–30 min of cows' milk ingestion have a positive skin prick test, but most of those whose symptoms occur more slowly have negative skin prick tests. Skin prick tests and RAST tests are usually unhelpful, particularly if symptoms are delayed. A jejunal biopsy is unnecessary because it cannot replace the need for milk elimination and challenge, and the histological changes seen in the small intestine are not diagnostic for cows' milk protein intolerance.

The procedure required to diagnose cows' milk protein intolerance is:

1. a period of avoidance (2 d for those with symptoms occurring within 1 h of milk ingestion; 14–28 d for those with delayed-onset symptoms) causing loss of symptoms;
2. recurrence of symptoms on reintroduction of cows' milk protein;
3. loss of symptoms after second withdrawal of cows' milk protein;
4. Continued abatement of symptoms with continued avoidance of cows' milk protein.

This strategy must be accompanied by regular attempts to reintroduce cows' milk protein, for example yearly, to see if the patient has grown out of the intolerance.

### Failure of cows' milk exclusion

The reasons why a trial period of cows' milk elimination may fail are:

1. The patient has an alternative cause for the reported symptoms.
2. The period of elimination was too short.
3. Foods containing cows' milk protein have not been fully excluded from the diet.

4. The patient is intolerant to the cows' milk substitute that has been given. This is common with goat's milk or sheep's milk. About 8–14% of patients with cows' milk protein intolerance are also intolerant to soya. An unknown proportion are intolerant to whey hydrolysate formulae (these vary in their antigenicity), and there are rare cases of intolerance to casein hydrolysate formulae (Pregestimil or Nutramigen).
5. The patient has a coexisting or intercurrent disease, e.g. gastroenteritis.
6. The patient is intolerant to other items that have not been withdrawn from the diet or the environment.
7. The patient's symptoms are trivial and have been exaggerated, or alternatively do not exist at all and have either been imagined or fabricated by the parents. Complete fabrication of symptoms by parents is rare, but the mistaken belief that a child's symptoms are attributable to food intolerance is common.

### Milk challenge procedure

A challenge with cows' milk protein is carried out either to confirm the diagnosis or to see if the patient has grown out of the intolerance. If it is known that the child can tolerate small amounts of cows' milk at home then a formal challenge in hospital is not required, and the parents can continue to increase the quantity of cows' milk given at home.

It is vital to remember that during cows' milk protein challenge, symptoms may appear that had not been present previously, the most serious being anaphylactic shock. In Goldman et al's original study, three of 89 patients developed anaphylactic shock as a new symptom during milk challenge.<sup>42</sup> In a further five patients, anaphylaxis had been noted prior to milk challenge. Any strategy for cows' milk protein challenges has to take into account the risk of anaphylaxis.

### Milk challenge procedure for patients with no history of anaphylaxis after cows' milk ingestion

The first step, prior to the oral administration of cows' milk, is the topical application of milk to the child's skin, using the back. Some cows' milk is firmly rubbed onto the patient's skin with a piece of gauze or cotton wool, and the skin observed for 15 min. A positive reaction comprises a weal, surrounded by a red flare; redness without a weal is a negative response. If there is a positive response, the challenge procedure is halted, and cows' milk protein should be avoided for a further 12 months before repeating the test.

It is acknowledged that a positive rub test may sometimes be a false positive, but the above strategy is designed to protect the child, and the need to minimize the risks of anaphylaxis. A small number of centers bypass the application of milk (or other foods) to the skin as part of the challenge procedure, and as a precaution conduct the challenge in a high dependency or intensive care facility, with an i.v. line inserted and i.v. fluids running. Reasons for the former more cautious approach are: (1) if there is a significant risk of a life-threatening adverse reaction then it is safer to avoid doing the food challenge altogether, (2) the first-line treatment of anaphylaxis is intramuscular adrenaline, and (3) i.v. fluids are not an immediate requirement.

For the first 60 min of the procedure, a nurse, doctor or parent should be present; the patient must not be left alone. The observer is looking for signs of an adverse reaction, which are:

- rash around the mouth;
- urticarial rash;
- sneezing;
- vomiting;
- irritability and pallor;
- wheezing or coughing;
- loose stools;
- **stridor**;
- **collapse**.

After the first 60 min, the patient should be checked half hourly, provided a parent is present, or quarter hourly if no parent is present. The observer needs to know that the signs above are being sought, and that it

is just as important to remove the clothes and look for an urticarial rash as it is to perform the usual nursing observations of the temperature, pulse and respiration rate.

If any of the above signs appear, no further cows' milk should be given, and in the event of a rash, wheezing, stridor or collapse a doctor should be summoned.

The oral challenge procedure itself is:

1. Place one drop of ordinary cows' milk on the patient's tongue, and observe for 15 min.
2. If no reaction, give 5 ml of cows' milk and observe for 15 min.
3. If no reaction, give 10 ml of cows' milk and observe for 15 min.
4. If no reaction, give 30 ml of cows' milk and observe for 15 min.
5. If no reaction, give cows' milk freely, and give cows' milk protein-free solids as normal at meal times. Provided this does not exceed the usual intake volume, ensure the patient has taken at least 200 ml of cows' milk.

It is unclear how long observation in hospital should be continued. Rare cases are described in which severe reactions have developed late (e.g. 6 h after starting challenge) so parents must be warned that a reaction may develop later in the day, when the child is at home.

If any adverse reaction occurs, as well as stopping further cows' milk it is essential to monitor the patient very closely, as such patients are at special risk of suffering severe and possibly fatal collapse without warning. One may need to keep an infant in hospital overnight where a challenge has had to be stopped because of an adverse reaction. Such infants require close monitoring, including the use of an apnea alarm.

### Procedure for patients with previous history of anaphylaxis after cows' milk ingestion

Serious consideration should be given to whether a cows' milk challenge is really necessary. If it is being carried out to confirm the diagnosis it is best omitted, because the risks of misdiagnosis are likely to be outweighed by the hazards of the challenge procedure. If the challenge is being carried out to see if the patient has grown out of cows' milk protein intolerance, then it is recommended that at least 12 months have elapsed since the previous positive challenge or anaphylactic reaction. The challenge procedure is the same as detailed earlier.

### Natural history of cows' milk protein intolerance

Cows' milk protein intolerance often lasts only a few months, and in many cases it has disappeared completely by the age of 12 months, hence the need for milk challenge at the age of 12 months in patients who were diagnosed in infancy. Most children become tolerant to cows' milk protein by the age of 3 years, although some degree of intolerance persists, occasionally into adult life, in a small number of patients.

### Cows' milk-free diets

Cows' milk exclusion means the avoidance of all foods that contain cows' milk protein. A dietitian will be able to provide an appropriate diet sheet containing an up-to-date list of milk-free manufactured foods. Beef avoidance is unnecessary as the coexistence of intolerance to cows' milk and beef is unusual. Infants on a cows' milk-free diet require a cows' milk substitute. The choice is between formulae based on soya (bearing in mind that 8–14% of infants with cows' milk protein intolerance will also be intolerant to soya), casein hydrolysate (Pregestimil or Nutramigen) or amino acids (Neocate). The main drawback to casein hydrolysates or formulae based on amino acid is their poor palatability. The milks of other animals (goat, sheep) are inadvisable because of the high incidence of cross-sensitivity with cows' milk protein, their high solute content, and the risk of serious gastrointestinal infections due to unhygienic methods of collection and distribution. Non-infant formulae soya-based milks are unsuitable because of their low calcium, vitamin and energy content. In 2003, the UK Scientific Advisory Committee on Nutrition advised against the use of infant soya-based formulae because of their content of phytoestrogens, specifically isoflavones, which may theoretically affect reproductive health and fertility. There is currently no direct evidence from human studies to support this concern. If an

infant who has not been weaned is intolerant to both soya and casein hydrolysate, the options are donated human milk, an elemental diet, or in exceptional circumstances *i.v.* nutrition. After weaning has commenced, if milk substitutes are unsuitable then supplementation with calcium and maybe other nutrients will be required. Even where a soya or casein hydrolysate infant milk formula is provided, the calcium intake may fall below the recommended requirements. The importance of such low intakes of calcium is unknown, but there may be special risks for patients with atopic eczema. In these children intestinal absorption may be impaired because of an associated enteropathy, the absence of lactose from the diet may impair calcium absorption, and there is a risk of vitamin D deficiency and consequently diminished gastrointestinal calcium absorption in children with atopic eczema who are kept out of sunlight.

## EGG

The major allergens in egg white are ovalbumin, ovomucoid and ovomucoprotein, and all three are also present in much smaller quantities in egg yolk. Cooking reduces the allergenicity of eggs by 70%. Almost all children with egg intolerance can tolerate cooked chicken. The eggs of turkeys, duck and goose contain similar allergens to hen's eggs.

Egg intolerance is very common, and one population-based study found the estimated point prevalence of intolerance to egg in children aged 2½ years was 1.6% (CI 1.3–2.0%), with an upper estimate of the cumulative incidence by this age of 2.6% (CI 1.6–3.6).<sup>43</sup> It is particularly common in infants with atopic dermatitis. It is most common in the first 6 months of life, and the most frequent presentation is the rapid onset of symptoms minutes after an infant is given egg for the first time. Reactions mostly occur within minutes of eating egg, and consist of an erythematous rash around the mouth, swelling and urticaria of the oral mucosa and angioedema of the face, sometimes with wheezing, stridor, conjunctivitis, rhinitis, vomiting, loose stools and in severe cases anaphylaxis. Those with immediate reactions also exhibit urticaria after skin contact with egg.

The diagnosis of egg intolerance is made from the history. Skin prick tests and RAST tests, although providing information as to whether the child is allergic to raw egg protein, may be falsely positive (e.g. in children who can tolerate cooked egg contained in cake or biscuits, and in children who have outgrown their egg allergy). When the diagnosis is in doubt it can be confirmed by challenge, which would normally comprise ingestion of increasing quantities of egg-containing biscuit, and where this is tolerated hard-boiled egg. The management is to exclude egg in a form that leads to reactions (e.g. raw egg only, partly cooked egg, or all egg) from the diet.

Egg intolerance is not a contraindication to measles or measles–mumps–rubella (MMR) vaccination because modern measles vaccines are grown on fibroblasts and do not contain detectable quantities of egg protein. The MMR vaccine can be safely given to children with egg allergy. The majority of life-threatening allergic reactions to the MMR vaccine have been reported in children who are not allergic to eggs, and these are mainly explained by IgE-mediated gelatin allergy.<sup>44</sup> The same may not apply to other vaccines such as the influenza vaccine, which is grown in the allantoic cavity of chick eggs and which does contain traces of egg protein.

In the majority of cases, egg intolerance has disappeared by the age of 3 years. Where the presentation is after the age of 12 months, which is unusual, the duration of intolerance may be longer, and is occasionally life-long.

## SOYA

Soya protein is a permitted ingredient of flour in the UK, and this is not usually declared on manufactured food labels listing ingredients. Soya protein is widely distributed in manufactured foods including bread, pastry and sausages. Soya protein is also commonly employed as a meat extender and found in sausages, hamburgers and pie fillings.

Soya protein intolerance is less common than cows' milk protein intolerance. The clinical features and management of the two disorders are the same, but the widespread use of soya in manufactured foods means that soya protein avoidance is more difficult than cows' milk protein avoidance.

Soya and other beans can cause flatulence, abdominal pain and loose stools, which are due to the action of intestinal bacteria on poorly digestible oligosaccharides, mainly raffinose and stachyose.

## FISH AND SHELLFISH

Fish allergy is common in children, whereas shellfish allergy appears to be more prevalent in adults. Fish allergens are highly cross-reactive on *in vitro* testing with the exception of tuna fish, in keeping with the clinical association between codfish allergy and allergy to hake, carp, pike and whiting but not tuna.

Although most reactions to fish are caused by ingestion, reactions can also occur as a result of inhalation of fish aeroallergens at fish markets or when fish is being cooked. Reactions to food aeroallergens are either respiratory (asthma) or in the skin (urticaria). The latter has been labeled as *osmylogenic urticaria*; 'osmyls' are minute particles given off by odoriferous substances. Aas has reported from Norway that fish antigens could be found in house dust in most homes where fish is often eaten, and he suggested that this was a possible source for sensitization to fish.<sup>45</sup>

Anaphylaxis caused by the unexpected presence of casein after consuming salmon has been reported. Casein has been used in the processing of salmon, posing a threat to individuals who are intolerant to cows' milk protein.

## PEANUT AND TREE NUTS

### What is a nut?

There is much confusion as to what does or does not constitute a nut. Whereas most nuts come from trees, peanut, the most common nut to cause allergic reactions, is in fact a legume, and the seed pod grows underground (hence an alternative name, 'groundnut'). As far as allergic reactions are concerned, the key information is not the precise botanical origin or plant family but the degree to which the nut does or does not provoke allergic reactions. Allergic reactions to peanuts, walnuts, pecans, brazil nuts, hazelnuts, cashew nuts, pistachio nuts, almonds (strictly speaking a fruit) and macadamia nuts are all well recognized. In contrast, allergic reactions to coconuts, pine nuts, oyster nuts, sweet chestnuts and horse chestnuts are only very rarely reported, and these items do not need to be avoided in children with peanut allergy.

### Epidemiology and importance

Peanuts are a major cause of allergic reactions. The prevalence of peanut intolerance in western countries is approximately 0.5%. In a US survey<sup>46</sup> it was estimated that the prevalence of peanut and/or tree nut intolerance was 1.1% (95% CI, 1.0–1.4%). In another US survey, it was noted that peanuts and tree nuts accounted for 20 out of 32 (72%) total fatalities due to food-induced anaphylaxis.<sup>47</sup> Similar trends have been found in the UK.<sup>48</sup>

The main source of exposure to peanut and its products is consumption, but peanut oil (also known as arachis oil) has been used in some injectable, oral and topically applied pharmaceutical preparations. Because of concern that percutaneous absorption of peanut protein could cause sensitization to peanut, efforts have been made in recent years to remove arachis oil from topically applied pharmaceutical products.

The incidence of peanut intolerance is higher in siblings of affected individuals; in one study, three out of 39 siblings (7%) had peanut intolerance.<sup>49</sup> The concordance rate for peanut allergy in monozygotic twins is 64% compared with 7% in dizygotic twins, providing evidence for a strong genetic predisposition.<sup>1</sup> Nearly all patients who have had fatal or near-fatal reactions to nuts have other atopic diseases,

especially asthma, but often also atopic dermatitis and allergic rhinitis. The severity of the asthma in these fatalities is variable and may be relatively mild. Asthma has in the past been thought of as a risk factor for the development of potentially severe reactions, but this is probably misleading and it is likely that asthma and peanut allergy are simply different manifestations of the same atopic disease process.

### Peanut processing and its effects

The prevalence of peanut intolerance in China is low despite a high rate of peanut consumption. The method of frying or boiling peanuts, as practiced in China, reduces the allergenicity of peanuts compared with the method of dry roasting practiced widely in western countries.<sup>50</sup> Roasting uses higher temperatures that apparently increase the allergenic property of peanut proteins, and this may help to explain the difference in prevalence of peanut allergy observed in the two countries.

Untreated peanut oil contains peanut protein and consumption risks provoking adverse reactions in individuals with peanut intolerance. However processed and refined peanut oil, which has been subjected to degumming (separation of oil and water by centrifugation at 30–50 °C), refining with alkali and further centrifugation at 60–70 °C, bleaching with filters at 110 °C, and deodorization with steam under vacuum at 230–260 °C, does not contain peanut protein, and in one study refined peanut oil failed to provoke a reaction in any of 60 individuals with peanut intolerance.<sup>51</sup> However the marked variation in the degree of processing of peanut and other nut oils means that there will be marked variation in the nut protein content of various different types of refined nut oils.<sup>52</sup> It is worth noting that peanut oil may be used in the pharmaceutical industry, and has been used, for example, in vitamin A and D solutions.

Different cultivars of peanut are grown in many different parts of the world, but peanuts of different varieties from different parts of the world all appear to contain similar antigenic proteins.

### Cross-reactivity

In a study of 122 children with allergic reactions to peanuts and tree nuts, 68 had reactions to peanuts alone, 20 to tree nuts alone, and 34 had reactions to both peanuts and at least one tree nut.<sup>53</sup> Of those reacting to tree nuts, 34 had reactions to one, 12 to two, and 8 to three or more different tree nuts, the most common being walnut, almond and pecan. Although there is extensive cross-reactivity between peanuts and other legumes on skin prick testing and RAST testing, clinically important cross-reactivity is uncommon. Nevertheless the risk of confusion between different nuts provides an argument for the avoidance of all nuts in a child known to be allergic to one type of nut. On the other hand, in a clear allergy to a single nut in patients known to be tolerant to others, avoidance of all nuts is not required.

### Clinical features

Reactions can involve the skin (urticaria, angioedema), the respiratory tract (wheezing, throat tightness, coughing, dyspnea), and the gastrointestinal tract. Multiple organ systems may be affected. Accidental ingestion is common (30–50% over a 5-year period). In general the symptoms after accidental exposure are similar to those at an initial reaction.<sup>54</sup>

Modes of accidental ingestion include sharing food, hidden food ingredients,<sup>55</sup> cross-contamination (in kitchen utensils or in food manufacturing), and school craft projects using peanut butter.

The threshold dose required to produce a reaction varies. In one study of 14 individuals with peanut intolerance, the lowest dose of peanut to produce a convincing reaction was 2 mg, although individuals with peanut intolerance sometimes report short-lived symptoms after doses as low as 100 µg.<sup>56</sup> It is not uncommon for peanut-intolerant individuals to experience local urticaria after being kissed by someone who has eaten peanut. This is not specific for peanut intolerance; the same phenomenon is seen in individuals who are intolerant to other foods.

Acute allergic reactions to peanuts have been seen in neonates, and thus in some children, sensitization must occur in utero. At present there is no definitive evidence to suggest that avoidance of peanuts during

pregnancy and lactation will prevent the development of peanut allergy in the child. The severity of any reaction is in part related to the quantity of nut eaten. When patients with peanut intolerance are followed-up, and experience a further reaction resulting from accidental ingestion, most follow-up reactions are less severe than the index reaction.<sup>57</sup>

### Diagnosis

Although skin prick tests and RAST tests may provide useful supportive evidence of a peanut allergy in the absence of a clinical history, they should not be used to diagnose an allergy to peanut or any other food as false-positive reactions do occur and may inappropriately lead to children being labeled as food allergic when they are not. Furthermore, these tests cannot indicate the severity of symptoms. If the history suggests a nonlife-threatening allergy to a food but the skin prick test is negative then a food challenge should be considered as the definitive test of an allergy. If a life-threatening reaction to a food has occurred then food challenges should be avoided.

### Natural history

Whilst most children fairly rapidly grow out of some food intolerances, nut allergy has always been regarded as an exception, being lifelong in most cases. Recent claims that up to 20% of patients outgrow peanut allergy have often been based on studies of patients whose original diagnosis was questionable. There probably are a few genuine cases in which nut allergy is not permanent, but they are uncommon.

### Management

The management of nut allergy consists of education on avoiding the allergen, common traps being 'groundnut' (another name for peanut) and arachis oil (derived from peanuts). There are three additional treatment options – antihistamine for mild reactions, antihistamine plus inhaled adrenaline for moderate reactions, and antihistamine, adrenaline inhaler and adrenaline autoinjector for severe reactions. In the UK adrenaline inhalers (Medihaler Epi) are unavailable, and this means that adrenaline autoinjectors may need to be considered for some UK patients who have had moderately severe reactions.

Peanuts are cheap, readily available and are often used as a substitute for other nuts. For these reasons, even if there are no features of clinical cross-reactivity, patients who have peanut intolerance should in general avoid all tree nuts. Treatment of peanut allergy by immunotherapy using injections of peanut extract is not currently recommended.

### FOOD-PROVOKED EXERCISE-INDUCED ANAPHYLAXIS

Exercise-induced anaphylaxis is usually associated with a combination of cholinergic urticaria (widespread tiny 1–3 mm wheals with variable erythema that last 30–60 min and occur in association with sweating) often starting in the palms and soles before spreading. Signs of autonomic dysfunction such as nausea, vomiting and diarrhea, dilated pupils and hypotension may follow. Attacks may occur spontaneously, or in association with ingestion of specific foods such as celery, shellfish, peaches or wheat.<sup>58,59</sup> The mechanism of this uncommon exercise-induced anaphylaxis is obscure. Management includes warm-up and moderation in exercise, avoidance of food and NSAIDs prior to exercise and making sure the patient is with someone who knows of their condition. Nonsedating antihistamines are often helpful. Hypotension should be treated by lying the patient down with their feet raised.

### FOOD ADDITIVES

Food additives include coloring agents, preservatives, antioxidants, emulsifiers, stabilizers, sweeteners, other flavor modifiers and a large miscellaneous group of other agents. An obsession with food that is natural overlooks both the large number of toxic substances naturally occurring in food and the fact that most substances that provoke food intolerance are naturally occurring, such as eggs, cows' milk and nuts. There is an enormous discrepancy between the public's perception of food additive intolerance and objectively verified intolerance.<sup>60</sup>

### Tartrazine and benzoic acid

Tartrazine is a yellow coloring agent, and one of the group of azo dyes. It is used as a coloring agent in a wide range of foods and medicines. Benzoic acid and the related benzoates retard the growth of bacteria and yeasts, and are used as food preservatives. Double-blind placebo-controlled studies have demonstrated that tartrazine can provoke urticaria, asthma or rhinitis in a small number of atopic subjects.<sup>61</sup> Similar studies have shown that benzoates can provoke urticaria. There is a lack of objective information about whether benzoates can provoke asthma. Tartrazine or benzoate intolerance can be identified by history (particularly unreliable in suspected food additive intolerance), elimination and challenge. It is possible that repeated administration of tartrazine or the benzoates leads to tolerance, and the severity of adverse reaction may not always be severe enough to warrant avoidance.

### Sulfites

Sulfur dioxide and the sodium or potassium salts of sulfite or metabisulfite are widely used as food preservatives. Dried fruit is commonly treated with sulfur dioxide, and high levels of sulfite are sometimes found in wine, beer and salads in restaurants. Sulfites are sometimes used as preservatives in parenteral preparations of drugs, including several drugs used for the i.v. or inhalational treatment of asthma. Double-blind placebo-controlled studies have demonstrated that the oral administration of sulfite solutions can provoke bronchoconstriction in 35–70% of children with asthma.

A history of worsening of pre-existing asthma after consuming artificial drinks, eating in a restaurant or inhalation or injection of a drug containing sulfite raises the possibility of sulfite intolerance. Skin tests are unhelpful, and the diagnosis can only be confirmed by challenge, employing increasing doses of sulfite so as to establish the patient's threshold dose that can provoke asthma. Knowledge of the threshold enables the patient to avoid only those foods with a relatively high sulfite level, making a very restrictive diet unnecessary.

## HOUSE DUST

### House dust mites

The predominant allergens are digestive enzymes entrapped in mite fecal pellets, which are of a similar size to pollen grains. The main species of house dust mite in Europe is *Dermatophagoides pteronyssinus* and in the USA it is *Dermatophagoides farinae*. Mites feed on desquamated human skin scales, which are mainly shed in the bed and bedroom, where they can be found in mattresses, pillow cases, carpets, cuddly toys and upholstered furniture. The decisive factors that influence the number of mites are air humidity and temperature. Optimum conditions for mites are 70–80% relative humidity and an ambient temperature of 26 °C. Mites cannot reproduce when the relative humidity falls below 60%, and cannot survive for more than a few days in a relative humidity of below 40% if the temperature is above 25 °C. The relationship between the season and mite density in houses is attributable to seasonal changes in the ambient indoor humidity. In temperate areas, the number of mites is lowest in the winter, when central heating dries the indoor air. Lack of mites at higher altitudes (e.g. alpine resorts) is due to the lower relative humidity. Skin prick and RAST tests may be useful as supportive evidence where there is a history suggestive of an immediate-type hypersensitivity to house dust mite. Although it is possible to reduce levels of the house dust mite in the home (Table 33.4), these measures do not usually lead to an improvement in symptoms of eczema or asthma.

## LATEX

Natural latex is produced by nearly 2000 species of plants, although only the rubber tree *Hevea brasiliensis* is commercially valuable as a source of natural rubber. Proteins or peptides, which make up 1–2% of latex are responsible for allergic reactions and different patients appear to be sensitized to different groups of latex proteins.<sup>62</sup> The major rubber proteins are heveamines (proteins with chitinase and lysozyme properties),

and hevein, a fungotoxic protein with considerable structural homology with wheat germ agglutinin and other plant lectins.

Latex is used in the manufacture of a number of products in general and medical use, including gloves, catheters, condoms, balloons, rubber bands, toys and tyres. About 90% of harvested rubber is processed by acid coagulation at pH 4.5–4.8 into dry sheets or crumbled particles for manufacture of extruded rubber products (rubber thread); compression, transfer, or injection molded goods (rubber seals or diaphragms); or pneumatic tyres. The remaining 10% of harvested rubber is noncoagulated and ammoniated; it is used in the manufacture of rubber gloves and other 'dipped' products, such as condoms and balloons and it is these products that are responsible for most allergic reactions to natural rubber latex (see Table 33.6).

Latex antigens can be leached from rubber gloves by normal skin moisture, with subsequent adsorption onto corn starch powder inside the gloves. Latex allergen can also be adsorbed to powder inside gloves that have not been worn. When the gloves are donned or discarded, the corn starch particles with adsorbed latex allergens become airborne and can sensitize nearby persons by inhalation or can evoke symptoms in previously sensitized persons.

### Predisposing factors

Atopy is a significant risk factor in the development of latex allergy with two thirds of affected patients being atopic. Latex allergy is one disease that may affect providers of health care services more frequently than patients themselves. Other high-risk workers include housekeepers, doll manufacturers and tyre plant workers. High-risk patient groups are those requiring multiple surgical procedures, such as individuals with spina bifida, where the prevalence is reported as 18–64%.

### Reasons for increased prevalence of latex allergy

Other than increased awareness, possible explanations are: (1) the increased use of gloves during medical, dental and surgical procedures, owing to the risk of hepatitis and AIDS; (2) the replacement of mineral talc powder by cornstarch powder. Mineral talc is heavy and only transiently airborne, and has a high capacity to act as an allergen eliminator by binding firmly to latex allergens.

### Cross-reactions

Cross-reactions may occur between proteins in latex and various foods such as avocado, bananas, kiwi and chestnut; the so-called 'latex-fruit syndrome' (see Table 33.5).<sup>63,64</sup> Cross-reactions may also occur with the

Table 33.6 Relative risk of latex-containing products

<b>High risk</b>
Medical latex rubber gloves with powder
Latex rubber gloves for use at home
Balloons
Latex for modeling, dental impressions, etc.
<b>Medium risk</b>
Unpowdered gloves
Catheters
Rubber bands
Teats, dummies
Pencil erasers
Some medicines for injection in multi-dose vials
<b>Lower risk</b>
Tyres
Shoe soles
Hot water bottles
Squash balls, other rubber balls
Red or black rubber tubing or sheet
Condoms
Elastic threads in elasticated clothing

weeping fig *Ficus benjamini*, which is increasingly used for indoor decoration. The existence of cross-reacting allergenic structures in plant-derived products such as latex, fruit and enzymes may explain extensive allergenic reactivity.

### Clinical manifestations

The most common reaction to latex products is non-immunological, *irritant contact dermatitis*, the development of dry, irritated areas on the skin caused by the effects of repeated hand washing, detergents or sanitizers, or powders added to gloves. *Allergic contact dermatitis* appears 1–2 d after contact with the offending product such as rubber gloves, shoes, sports equipment and medical devices. The dermatitis is a cell-mediated delayed-type hypersensitivity reaction to low molecular weight accelerators and antioxidants in the rubber product. Examples of rubber product components that cause contact dermatitis are thiurams, carbamates, benzothiazoles, thioureas and amine derivatives. Patients may also present with acute urticaria. Inhalation of latex allergen-coated cornstarch particles from powdered gloves can cause *rhinitis* and *asthma* in latex-allergic individuals, mainly adults who manufacture gloves and health care workers. Latex-allergic individuals can rarely experience *anaphylaxis*, occasionally fatal in a variety of medical care situations and as a result of blowing into balloons or using rubber-handled squash racquets. Finally, latex-allergic individuals can react to food that has been contaminated by latex, for example by food handlers wearing latex gloves.

### Diagnosis of latex allergy

Diagnosis depends on the clinical history, coupled with examination and laboratory tests. Latex-specific IgE tests result in up to 25% false-negative and 27% false-positive results and must be interpreted with caution.

### Management

The mainstay of management is avoidance, especially of powdered latex gloves, which are the major contributors of transferable allergen.<sup>65</sup>

### STINGING INSECT VENOM

Stinging insect allergy has a prevalence of 0.3–3% within the general population. It is more common in adults than in children, and males than females. Insects of the order *Hymenoptera* (vespids [wasps] and apids [bees]) sting and these insects are most active in summer and early autumn. The venoms contain proteins such as phospholipase and hyaluronidase.

Normal local reactions consist of pain, swelling and erythema. Larger local reactions can be confused with cellulitis, which is uncommon after insect stings. These are more extensive and may peak at 48 h and last as long as 1–2 weeks. Malaise and nausea may also develop. Symptomatic treatment is with NSAIDs and antihistamines. Oral prednisolone for 2–3 d may also be helpful. People who develop large local reactions to stings typically continue to have similar reactions after subsequent stings. The risk of anaphylaxis following large local reactions is < 5% and patients do not require venom skin tests and are not candidates for immunotherapy.

The most common symptoms of acute systemic IgE-mediated reactions are dermal (urticaria and angioedema). Life-threatening symptoms include edema of the upper airway, circulatory collapse and shock, which can occur at any age.<sup>66</sup> There have been no deaths from insect stings in children and young adults (< 20 years old) in the UK. Deaths are most likely to occur in adults with concurrent pathology (e.g. coronary vascular disease) or those on certain drugs (ACE inhibitors; beta-blockers, tricyclic antidepressants). Just over half of deaths in the UK have been from shock, one third from upper airway obstruction, 10% from asthma.

The risk of systemic IgE-mediated reactions is highest if the second sting occurs 2–8 weeks after the first and decreases with time, being very low > 5 years after the last sting. Children who have had systemic IgE-mediated reactions (skin, respiratory or cardiovascular symptoms)

should have blood taken for specific IgE to the insect and be referred to a pediatric allergist. These children should be prescribed an injectable adrenaline device and appropriate training given. They should be told that early adrenaline administration after a sting is important, as patients in established shock are unlikely to respond to this treatment. First-aid should concentrate on lying the patient down with their legs up and calling an ambulance. Venom immunotherapy typically involves a 3–5-year course of desensitizing injections and is rarely indicated in children.

## DRUGS

### Epidemiology

Prospective studies have estimated that the incidence of serious adverse drug reactions in hospitalized patients is 6.7% and the incidence of fatal drug reactions is 0.32%. Whereas most adverse drug reactions are non-allergic in nature, 6–10% may be attributed to an immune mechanism involving either antibodies or T cells. Drug reactions that are immunologically mediated: (1) require a period of sensitization, (2) occur in a small proportion of the population, (3) are elicited at drug doses far below the therapeutic range, and (4) in most instances subside after drug discontinuation.

The mean age of allergic drug reactions is approximately 40 years, allergic drug reactions in childhood being much less common than in adulthood. Many patients who are said to have drug allergies are not allergic to the drug. For instance, 80–90% of patients who report a penicillin allergy are not truly allergic when assessed by skin testing, and virtually all patients with a negative skin test result can take penicillin without serious sequelae.<sup>67</sup> In children, most of the reactions that coincide with drug administration are exanthema, which are usually due to the underlying disease.

### Clinical spectrum of disease

True allergic reactions are restricted to a limited number of syndromes that are generally accepted as allergic in nature, such as anaphylaxis, Stevens–Johnson syndrome, angioedema and urticaria, contact sensitivity and various exanthema, among others. Skin reactions are the most frequent symptoms of adverse drug reactions, occurring in nearly 80% of patients and are most commonly observed with ampicillin, amoxicillin and co-trimoxazole. Beta-lactam antibiotics are the most frequent pharmacological group involved in allergic drug reactions. NSAIDs, minor analgesics and other antibiotics (e.g. co-trimoxazole) are other drugs implicated. Anesthetic agents may cause immediate-type allergic reactions: muscle relaxants are implicated in 60% of cases, suxamethonium being responsible for 39% of these.<sup>68</sup>

### Drug antigenicity
