Glucoamylase	Maltose Glucose oligomers	Glucose Glucose

and subsequently split, after insertion in the brush border, into two separate functional units. Damage to the villi results in loss of disaccharidase activity with lactase being the most susceptible enzyme.

Undigested carbohydrate is fermented by colonic bacteria and salvaged as short chain fatty acids. If however the carbohydrate load is large, the osmotic pull will draw fluid into the lumen, causing diarrhea.

### Digestion of proteins

Ingested proteins are all very large molecules which must be broken down to their constituent amino acids or di- and tripeptides before absorption can occur. The process of protein digestion involves the initial extraction of protein from food due to mastication and the mechanical activity of the stomach and denaturation of the protein, which is promoted by the low pH of the stomach. The subsequent hydrolysis of the denatured protein is brought about by four major groups of enzymes: the pepsins secreted by the chief cells of the gastric glands and trypsin, elastase and chymotrypsins, which are all secreted by the acinar cells of the pancreas. All four enzymes are secreted as proenzymes with hydrogen ions promoting the activation of pepsin and the enzyme enterokinase and trypsin activating the other three. The presence of enterokinase, which is found on the brush border membrane of the proximal small intestine, is vital for the activation of these pancreatic proteinases. Luminal digestion is completed by the action of amino- and carboxypeptidases which cleave the terminal amino acids of the peptides. This results in a mixture of small peptides and free amino acids being presented to the brush border membrane. The larger peptides are further hydrolyzed by brush border-bound peptidases leaving free amino acids, dipeptides and tripeptides for absorption.

### Digestion of lipids

Dietary lipids are mainly in the form of triglycerides but phospholipids and cholesterol esters are also present in smaller amounts. Lipid digestion occurs mainly in the small intestine under the influence of bile salts, which form an emulsion of the ingested fat and of pancreatic lipase, which hydrolyzes the ester links at the 1 and 3 position of the triacylglycerol to yield monoacylglycerol and free fatty acid.

The presence of an adequate concentration of bile salts in the lumen of the small intestine ( $> 2$  mmol/L) is of vital importance, as a failure to form a fat emulsion with small micelles (approximately  $1 \mu\text{m}$  in diameter) severely reduces the surface area of contact between the lipase and the fat with resulting maldigestion. Inadequate bile salt concentrations can occur where there is an obstruction to biliary flow, deconjugation by luminal bacteria or where the total bile salt pool is depleted by bile salt malabsorption due to ileal resection.

Pancreatic lipase is quantitatively the most important enzyme in the digestion of triacylglycerols but lingual and gastric lipase are also present. Gastric lipase may be important in the hydrolysis of lipids with short and medium chain fatty acids, and in the preterm and newborn infant; where pancreatic exocrine function is very poorly developed it is likely that lingual and gastric lipase are the major enzymes of lipid digestion, helped in breast-fed babies by breast milk lipase. Ingested phospholipids

are hydrolyzed by pancreatic phospholipase and cholesterol esters are hydrolyzed by pancreatic cholesterol esterases.

The resulting monoacylglycerols, free fatty acids and cholesterol are absorbed by the epithelial cells of the small intestine. The fat-soluble vitamins A, D, E and K are absorbed from micelles and where the production of micelles is compromised by low bile salt concentrations, fat-soluble vitamin malabsorption is likely to occur. Following the digestion and absorption of the lipid from the micelles the bile salts are reabsorbed by the terminal ileum and recycled through an enterohepatic circulation.

## INTESTINAL ABSORPTION

The absorptive surface area of the small intestinal mucosa is greatly enhanced by the mucosal folds and by the presence of villi. The differentiated villous cells are responsible for the absorption of electrolytes and the products of the luminal and brush border digestion of food. Water is transported passively and moves down its osmotic gradient through a paracellular path. The epithelial cells are polarized with a brush border membrane facing the lumen of the intestine, a tight junction joining the lateral border of adjacent enterocytes and a basolateral membrane which is in close contact with the vasculature of the villi (Fig. 19.5).

The membranes of cells are very rich in lipid and thus while free fatty acids and monoacylglycerols can readily pass into epithelial cells, water-soluble compounds such as monosaccharides, amino acids, dipeptides and electrolytes all require specific transport processes to facilitate absorption.

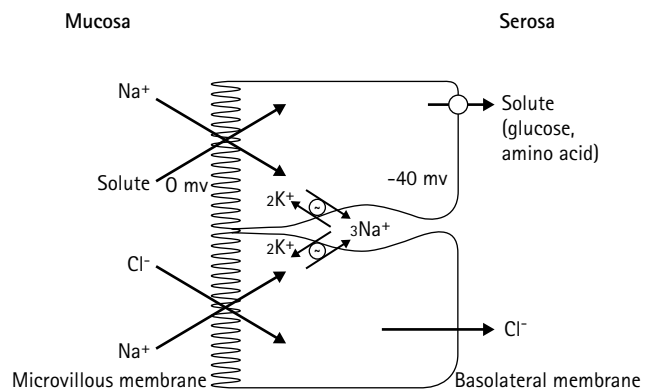

### Electrolyte absorption

The direction of movement of an electrolyte across a cell membrane is determined by the electrical and chemical gradient which exists across that membrane. In the villous cells of the small intestine there is a strong electrochemical gradient for  $\text{Na}^+$  across the brush border membrane with the inside of the cell  $-40$  mV relative to the luminal surface and the intracellular  $\text{Na}^+$  concentration being much lower than that found externally (Fig. 19.5). This gradient is maintained by the activity of the basolateral membrane  $\text{Na}^+/\text{K}^+$  ATPase which pumps  $\text{Na}^+$  out of the cell at the expense of the hydrolysis of ATP.

Sodium absorption may be either electroneutral when the absorption of  $\text{Na}^+$  and  $\text{Cl}^-$  is coupled, or electrogenic when it is linked to the absorption of a solute such as glucose or an amino acid. Once absorbed the  $\text{Na}^+$  is actively pumped out of the cell by  $\text{Na}^+/\text{K}^+$  ATPase and the  $\text{Cl}^-$  is able to leave down its electrochemical gradient.  $\text{K}^+$  is transported across the small intestine by a passive process while  $\text{HCO}_3^-$  is absorbed across the jejunum by a  $\text{Na}^+$ -dependent process.

### Solute absorption

The absorption of glucose and galactose across the brush border membrane occurs by a carrier-mediated process which is driven by the  $\text{Na}^+$  gradient across the cell, while fructose is absorbed by a  $\text{Na}^+$ -independent

**Fig. 19.5** A diagrammatic view of the  $\text{Na}^+$ ,  $\text{Cl}^-$  and solute absorption across the enterocyte of the small intestinal villi. Water moves passively between the cells down an osmotic gradient.

mechanism. Similarly group-specific active Na<sup>+</sup>-coupled cotransport is responsible for the absorption of free amino acids and unhydrolyzed short peptides.

The presence of a luminal solute enhances the absorption of Na<sup>+</sup> and water by the small intestine. This explains the success of glucose electrolyte solution in the oral rehydration of children with diarrheal disease.

### SMALL INTESTINAL MOTILITY

In the fasting state small intestinal motor activity is characterized by a highly organized band of propagative activity which moves down the intestine from the stomach to the ileum, called the migrating motor complex.<sup>31</sup> This activity develops between 2 and 4 h after a meal and recurs, every 25 min in the term infant and every 90 min in the older child, until disrupted by the next meal. The exact role of the migrating motor complex is uncertain but it has been postulated that it helps clear the small intestine of undigested food debris between meals and this may in part explain the very high incidence of bacterial overgrowth in patients where this activity is absent.

Following the ingestion of food the rate of transit through the small intestine is slowed to allow the complete digestion and absorption of the luminal contents. The rate of slowing is dependent on the energy density of the meal with lipids exerting a greater inhibitory effect than carbohydrates or protein. If undigested lipid reaches the ileum a powerful entero-entero reflex called the 'ileal brake' reflexly decreases the rate of gastric emptying and the degree of propagated intestinal motor activity, a situation which might pertain in patients with cystic fibrosis. Mouth to cecal transit time as measured by the breath hydrogen method is increased from 60 to 90 min in the fasting state to 3–4 h postprandially.

### IMMUNE DEFENCES

The gastrointestinal tract, as with other mucosal surfaces, acts as an important interface between the external environment and the internal milieu of the individual. On the one hand it has to allow the uninterrupted passage of nutrients while on the other it acts as a major barrier to the entry of toxic macromolecules derived from the microbiological flora of the gut or from ingested food (Table 19.10).

#### Non-immunological mechanisms

Gastric acid has an important role in initiating the digestion of ingested protein and in activating the intraluminal proteases. The colonization of the small intestine by bacteria may be enhanced by reduced gastric acidity and the failure to fully digest large macromolecules may facilitate the absorption of large unaltered proteins. Normal peristaltic small intestinal motor activity is required to clear the small intestine of food debris between meals and to prevent colonization by bacteria. The mucosal

surface, which comprises the microvillous membrane and overlying mucus, acts as a physical barrier to the attachment and uptake of luminal antigen and bacteria.

### Immunological mechanisms

The specific immunological response to absorbed antigen is expressed by the production of secretory antibodies, systemic antibodies and by activation of the cellular immune system.

The secretory response is initiated by the absorption of antigen across specialized epithelial cells (M cells) which overlie lymphoid aggregates in the small intestine. This antigen is then passed to the underlying lymphoid tissue where, with the help of T lymphocytes, B lymphocytes are activated to become IgA-producing cells. These cells initially proliferate and then migrate through the thoracic duct into the systemic circulation. The plasma cells then move back into the lamina propria where dimeric IgA, and to a lesser extent IgG, is produced prior to processing by the epithelial cells and secretion into the lumen in their secretory form. Secretory IgA is also produced by the salivary and mammary glands. A systemic immune response will occur in response to some antigens with the production of IgG, IgE and IgD.

T cells are also activated by the absorption of foreign antigen and these follow a path similar to that described earlier, back into the lamina propria. Along with these activated lymphocytes, mast cells and macrophages are also available to initiate a cell-mediated response within the intestinal mucosa.

A failure of activation or conversely an overactivation of these immune defences will result in the development of gastrointestinal disease.

### MALABSORPTION

Malabsorption may result either from a failure of the intraluminal digestion of food or from a defect of mucosal function which prevents the absorption of nutrients. The range of conditions which can cause malabsorption is extensive and is listed in Table 19.11. The presenting signs and symptoms are also very variable and may include diarrhea, vomiting, abdominal distension and weight loss. Some children, however, do not have symptoms directly referable to the gastrointestinal tract and may present with evidence of nutritional or other deficiency states.

A good history, with particular reference to the dietary and family history, is vital in assessing any child with suspected malabsorption. The age of the child is also important as food allergy is most likely to present in the first 6 months of life while celiac disease can only develop after gluten products have been introduced into the diet. One might expect diarrhea to be a universal feature in a child with malabsorption but such is the reserve capacity of the small intestine and the ability of the colon to absorb fluids and electrolytes, that this is not always the case. Failure to thrive, anemia and nongastrointestinal symptoms such as chest problems in cystic fibrosis should be sought. The sections below outline the major causes of malabsorption along with a guide to diagnosis and treatment.

### CELIAC DISEASE

Although first described in children over 100 years ago it was only in 1950 that Dicke noticed the association between celiac disease and the dietary protein gluten, and it was still later in 1957 that the enteropathy associated with this condition was first described following peroral jejunal biopsy. The enteropathy associated with celiac disease involves predominantly the proximal small intestine and following the removal of gluten from the diet it resolves completely.

In the last decade there has been a dramatic change in our understanding of celiac disease brought about largely by the introduction of screening tests which have unmasked a large population with lesser symptoms or sometimes none at all.<sup>32</sup>

**Pathophysiology**

Celiac disease is a multifactorial condition where environmental, genetic and immunological factors interact to produce damage to the mucosa of the proximal small intestine.

**Genetic**

The human leukocyte antigen (HLA) DQ2 is found in 80% of patients with type I diabetes who develop celiac disease and in almost 100% of Down syndrome children who have celiac disease. HLA DQ8 is found in almost all the remaining patients. HLAs DQ2 or DQ8 occur in about 30% of the general population. The prevalence of celiac disease is approximately 10% in first-degree family members with 40% concordance in HLA matched siblings and 70% in monozygotic twins.

**Environmental**

The exposure of the small intestine to gluten from wheat, barley or rye is a prerequisite for the development of celiac disease. The small amount of gluten found in oats may also cause problems for some patients. The amount of gluten in the diet is also a factor in the time of presentation and the type of symptoms the patient may experience. In Sweden where the weaning diet contains large amounts of gluten, children with celiac disease present most commonly with classical symptoms of diarrhea and failure to thrive between the age of 1 and 2 years. In contrast in Denmark, where the weaning diet has much less gluten, children present between 7 and 9 years with milder symptoms such as anemia or abdominal pain.

**Immunological**

The contact of gluten with the small intestinal mucosa activates a cellular immune response in which T cells are activated and cytokines are released. The net result of this is that the mucosa is damaged and heavily infiltrated with inflammatory cells. The villus structure is completely lost and the crypts hypertrophy in an attempt to repair the damage. This transformation is outlined in Figure 19.6. There is also a humoral immune response which leads to the production of antibodies against

Fig. 19.6 A light micrograph (magnified  $\times 240$ , stain hematoxylin and eosin) of a jejunal biopsy in (a) a normal child and (b) a child with untreated celiac disease. (Reproduced by kind permission of G. Anderson)

grain peptides (antigliadin) and connective tissue autoantigens (antiendomysial, antireticulin). It is unlikely that these play a part in the tissue damage.

### Presenting symptoms

The classical form of celiac disease presents with severe diarrhea, abdominal distension, weight loss, anemia and a general debilitation. This is most commonly found in younger patients while in older children there is a tendency for symptoms to be milder. Such symptoms might include abdominal pain, mild anemia, linear growth failure, delayed menarche or pubertal delay. The older child is often free of diarrhea.

Celiac disease can be present in association with enamel defects of the teeth or with dermatitis herpetiformis, an itchy vesicular rash of the skin. There is now an irrefutable association between celiac disease and other autoimmune conditions such as type 1 diabetes mellitus<sup>33,34</sup> and hyperthyroidism and with genetic abnormalities such as Down syndrome and Turner syndrome. Frequently it is the associated condition that is diagnosed first and it has been suggested that patients with the above conditions should all be screened for celiac disease at diagnosis. Before screening these at-risk groups, it is important to fully counsel the children/families as to the relative risk of untreated celiac disease and the need for a confirmatory biopsy and gluten-free diet if testing is positive.

### Epidemiology

Generally celiac disease is uncommon in black African, Japanese and Chinese populations. Previously it was thought that the prevalence of celiac disease in Europe was about 1 in 2000. With the possibility of screening populations for celiac antibodies it is now being realized that the true prevalence is probably 10–20 times higher at approximately 1 in 100–200. This situation has been described as the 'celiac iceberg' in which only a small percentage of patients are diagnosed and 'visible above the waterline' while the majority are undiagnosed and 'hidden' from view. This is illustrated schematically in Figure 19.7. Silent celiac patients will have positive celiac antibodies and histological evidence of celiac disease but will not have overt symptoms. These children are often labeled asymptomatic but when diagnosed and started on treatment, many feel better and only report symptoms in retrospect. Other children, so-called latent celiacs, have positive celiac antibodies but have a normal or near-normal duodenal mucosa. If followed, many of these children go on to develop classical histological changes in their small intestine in subsequent years.

### Screening tests

The starting point is either with a patient in whom there is a clinical suspicion of celiac disease or a patient diagnosed as having a condition which is associated with a greatly increased risk of developing celiac

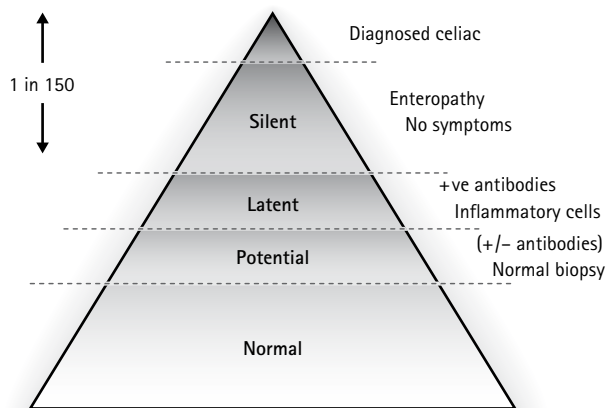

Fig. 19.7 The 'celiac iceberg'. Approximately 90% of people with celiac disease are presently undiagnosed.

Table 19.12 Conditions associated with an increased prevalence of celiac disease

Condition	Percentage
Type 1 diabetes	1–10%
Autoimmune thyroid disease	
Children	8%
Adults	3%
Turner syndrome	8%
Down syndrome	4–12%
First-degree relative of known celiac	6%
General population	0.2–1%

disease (see Table 19.12). The former group all need further investigation while screening of the latter at-risk groups requires full counseling of the child and families as to the relative risk of untreated celiac disease (see page 618) and the need for a confirmatory biopsy and gluten-free diet if testing is positive. Up to 50% of so-called 'asymptomatic' patients, identified from screening programs as having celiac disease, receive benefit in terms of improved symptoms and quality of life from treatment of their celiac disease.

The preferred screening test for celiac disease is the measurement of the IgA anti tissue transglutaminase (anti-tTG) combined with total IgA estimation. If the anti-tTG assay is not available the measurement of the IgA antiendomysial antibody (AEA) can be substituted. 0.3% of the general population is IgA deficient although this rises 10-fold in patients with celiac disease to 3%. This association between celiac disease and IgA deficiency means that screening with a single IgA antibody will lead to false-negative results in deficient patients. In IgA-deficient patients there is the option of testing for IgG anti t-TG or IgG AEA but these tests are less readily available and less sensitive and specific than the IgA antibodies. Where a strong clinical suspicion exists the practitioner should proceed to biopsy even in the presence of negative antibodies. The sensitivity and specificity results with these tests are over 90% but this will vary depending on the reagent kits used and on the laboratory. At present none of the screening regimens have 100% sensitivity and specificity and as such **all positive results require confirmation with a small bowel biopsy**.

In type I diabetes screening is generally recommended, with full consent, at the time of diagnosis and at 2-yearly intervals thereafter. It is known that celiac disease may still develop many years after the initial presentation. In the asymptomatic, antibody-negative child HLA typing may help to clarify which patients may subsequently develop celiac disease. Patients who are HLA DQ2/DQ8 positive should continue to undergo surveillance or if symptomatic undergo biopsy. Alternatively those who are negative are most unlikely to develop celiac disease and do not require further screening. This also applies to all at-risk groups.

### Diagnosis

The only diagnostic test for celiac disease is small intestinal biopsy. From the time of their introduction in the 1950s biopsies of the jejunum were carried out using Crosby or Watson capsules. This technique, which required the capsules to be swallowed and the child sedated, was very unpleasant for the child and due to problems with the capsule firing, was not always successful. Now all pediatric centers have adopted upper intestinal endoscopy as the primary method for intestinal biopsy. This is a relatively rapid and reliable method of collecting mucosal samples from the distal duodenum and if four or more biopsies are taken from the second part of the duodenum or beyond, the diagnostic yield is comparable to the traditional capsule biopsy.

Because of our changing understanding of celiac disease guidelines for diagnosis and management are constantly evolving. The North American Society of Pediatric Gastroenterology Hepatology and Nutrition (NASPGHAN) published updated guidelines in 2005 which represents the first major guideline revision since the widespread use of antibody screening.<sup>35</sup>

The primary criterion for making a diagnosis of celiac disease is the presence of the characteristic crypt hyperplastic subtotal villus atrophy on small intestinal mucosal biopsy (see Fig. 19.6b). It is vitally important that the child has an adequate amount of gluten in the diet and under no circumstances should a gluten-free diet be started prior to biopsy. In symptomatic patients a clear-cut clinical remission on starting a gluten-free diet should be seen. In all patients the anti-tTG or AEA should become negative 6–12 months after starting treatment and if this is not the case it implies that dietary exclusion of gluten has been incomplete.

In patients where there is diagnostic doubt or no initial biopsy has been taken, a gluten challenge is required. This is often the case in children under 2 years of age where other causes of enteropathy such as food allergy can confuse the diagnostic picture. After 3 months on gluten the antibodies should be rechecked. If positive or if symptomatic earlier, the biopsy should be done. If negative the challenge should be continued. The gluten challenge should be carried out between the ages of 6–10 years or after the pubertal growth spurt.

### Treatment

The treatment of celiac disease is with life-long exclusion of gluten from the diet. This essentially means avoiding all wheat, barley and rye products. Tolerance of oats is generally good if products free from contamination with other cereals can be provided. The education of the child and their parents in this diet needs the expert help of a pediatric dietitian. Many gluten-free products are commercially available and this goes some way to making what is essentially a very restrictive diet, a little easier to tolerate.

Some newly diagnosed children, particularly those with a classical presentation, may be severely malnourished at the time of diagnosis. Addition nutritional supplementation will be required and in the very lethargic child, short-term nasogastric feeding may be required until the child is able to feed. Because of the risk of osteoporosis, all patients with celiac disease require a good calcium intake and often require calcium supplements.

### Consequences of untreated celiac disease

Because most patients with celiac disease are presently undiagnosed (nine out of 10) and many may have little in the way of symptoms, it has been argued by some that there is little point in screening at-risk groups. Untreated celiac disease however can lead to anemia, osteoporosis, reproductive problems and worryingly an increased risk of intestinal malignancy. In children who do not comply with their gluten-free diet school performance is poorer.

Untreated celiac disease does appear to be linked to an increased incidence of gastrointestinal neoplasm (1.8-fold risk) although the rate from recent studies is not as high as previously reported.<sup>36,37</sup> Most of this risk appears to be in the first year after diagnosis of celiac disease with lymphoproliferative (4.8-fold risk) disorders being the most common. Interestingly the risk of breast cancer (0.35-fold risk) is reduced in patients with celiac disease.

### FOOD ALLERGY

Food allergy most commonly develops in the first few months of life with the most common allergens being cows' milk protein, although soya protein and a wide range of other dietary proteins may also be responsible. This sensitization develops most commonly in atopic individuals with a family history of food allergy or clear evidence of another atopic symptom such as eczema, asthma and urticaria. In many of these children, although their intolerance generally resolves between the age of 18 months and 5 years, symptoms of asthma and hay fever frequently follow. In older patients sensitization may follow an enteric infection leading to persistent intestinal symptoms long after the pathogen has been cleared.

In healthy individuals oral tolerance to dietary protein develops through the suppression of lymphocytes within the intestinal mucosa.<sup>38</sup>

This occurs when a large antigen load is presented to the immune system by the epithelium without co-stimulation and in the case of low-dose antigen, processing by the M cell from the Peyer's patches leads to the production of suppressor lymphocytes which home in on the lamina propria. Where mucosal integrity is compromised these mechanisms break down and sensitization to food allergens may develop. Mucosal integrity will be disrupted by enteric infection but it is clear that a close interaction between the epithelial cell and the gut flora is also important in maintaining integrity. It has recently been shown that the administration of the probiotic *Lactobacillus* GG, which promotes the colonization of the gut by 'healthy bacteria', to the mother before and the infant after birth, reduced the subsequent development of atopic disease.<sup>39,40</sup>

### Cows' milk protein intolerance

This condition develops most commonly within the first 6 months of life and occurs predominantly in formula-fed babies or babies receiving cows' milk in weaning foods. Breast-fed babies are also at risk as cows' milk protein is secreted at lactation if the mother's diet contains cows' milk. The most common symptoms at presentation are of vomiting, diarrhea and poor weight gain with eczema frequently present in babies and asthma or hay fever in older children.<sup>41</sup> Rectal bleeding due to an allergic colitis may be a presenting symptom in some infants.

### Diagnosis

The diagnosis is made from the history and from the characteristic improvement in symptoms with exclusion of cows' milk protein from the diet. Jejunal biopsy is likely to reveal a patchy partial villous atrophy with eosinophilic infiltrate, although in some patients the enteropathy may be more severe and be difficult to distinguish histologically from celiac disease. Jejunal biopsy however is not required in most patients as the condition usually responds well to an exclusion diet and is self-limiting, but if there is severe failure to thrive or a failure to respond to a cows' milk-free diet a jejunal biopsy is essential to exclude any other more serious pathology. A full blood count may reveal evidence of a peripheral eosinophilia, serum immunoglobulins may show a raised IgE and a low IgA and skin test or RAST may reveal positive reactions to food and environmental allergens. RAST has a poor sensitivity in childhood food allergy as up to 50% of allergic reactions are non-IgE mediated. There is also a high false-negative rate and in many patients who are quite clearly food allergic they may still be negative. This can be improved significantly by skin patch testing, which will detect non-IgE-mediated allergy. The clinical response to challenge and withdrawal remains the gold standard for diagnosing allergic disease in children.

### Management

It is usual to exclude cows' milk protein from the diet and as many atopic children also react to egg protein a combined milk and egg exclusion is frequently required. In breast-fed babies the mother should be put on a milk-free diet and started on a calcium supplement. It is essential that the diet is supervised by a dietitian to ensure that adequate calories and calcium remain in the diet. A complete milk substitute based on a whey or casein hydrolysate should be prescribed, and where the infant has been weaned the mother should be instructed on a diet containing milk- and egg-free solids. The use of soya formula can lead to sensitization as 30% of children allergic to cows' milk protein also react to soya and such formulae are generally not recommended in young children under 6 months of age, because of their phytosterols content. A small number of patients will even fail to tolerate a hydrolyzed formula and an elemental feed may be substituted. Some older children refuse to take these milk substitutes because of the taste and under such circumstances, if the diet is otherwise adequate, an oral calcium substitute should be prescribed. Alternatively if the intake is poor, the feed can be given by nasogastric tube.

Most children will improve quickly after starting their diet but it may take many months for full catch-up growth to occur in children who have been failing to thrive. The natural history of this condition is one of spontaneous remission but in some children further intolerances may develop.

## Multiple food intolerances

Although cows' milk protein, soya and egg are most commonly responsible for food intolerances in children, wheat, colorings, preservatives and sugar have all been implicated. In the very atopic child almost any dietary intolerance is possible. In addition to the gastrointestinal and atopic symptoms described earlier for cows' milk protein intolerance, behavior disturbance and hyperactivity may occur in some children.

It should be possible to discover which foods are responsible for the symptoms by taking a good dietary history, and an appropriate exclusion diet should be devised. In some children, however, it is difficult to isolate which foods are causing the problem and under these circumstances two further dietary options are available. The diet can be restricted to five or six foods which are felt least likely to cause allergic reactions. If symptoms resolve, new foods can then be introduced one at a time at weekly intervals. Alternatively the patient can proceed straight to an elemental, amino acid based feed which in older children will almost certainly have to be administered by nasogastric tube. Both of these diets are a very major undertaking for the family and where symptoms are less severe the use of oral sodium chromoglycate may be helpful in suppressing allergic symptoms.

## Eosinophilic gastroenteritis

It is likely that a fair degree of overlap exists between the allergic conditions described earlier and eosinophilic gastroenteritis. The condition is characterized by an eosinophilic infiltrate which can involve the stomach and/or small intestine and which appears to be triggered by the presence of dietary antigens. Three forms of the condition, each involving a different layer of the intestine, have been described.

The mucosal form is characterized by protein loss with hypoalbuminemia and edema. Damage to the antral and duodenal mucosa will result in blood loss and anemia while jejunal damage leads to an enteropathy with malabsorption. Where the muscle layer is involved symptoms of intestinal obstruction occur and in the serosal form of the condition an eosinophilic ascites may develop. Most patients are likely to have the markers of atopy, which are outlined earlier.

Diagnosis will be suggested by the history of atopy with abdominal pain, diarrhea, vomiting, weight loss and edema. Some patients, however, may have no abdominal symptoms. Upper gastrointestinal endoscopy is invaluable for detecting antral and duodenal lesions and for confirming the diagnosis by mucosal biopsy. Barium contrast studies may show evidence of inflammation in the mucosal form or luminal obstruction in cases involving the enteric smooth muscle. Protein loss from the intestine may be detected by measuring the level of alpha-1 antitrypsin in the stool.

Treatment with dietary exclusion is frequently all that is required in the mucosal form but where there is transmural or serosal inflammation, oral corticosteroids may also be required. The level of therapy required will vary from patient to patient but those with mucosal disease are likely to be the most responsive to therapy. Where intestinal obstruction occurs, surgery with local resection is likely to be required.

## POSTENTERITIS ENTEROPATHY

While most enteric infections are self-limiting and are free of long-term sequelae, some organisms damage the mucosal surface of the gut, resulting in a persistence of symptoms long after the original infective organism has been cleared. This postenteritis syndrome can be caused by viruses such as adenovirus or by bacterial pathogens such as the enteropathogenic *Escherichia coli* which totally denude the mucosa of villi. The consequences of acute enteric infections and their management are discussed more fully later in this chapter (see p. 627).

## CONGENITAL ENTEROPATHIES

Intractable diarrhea presenting from the time of birth may be caused by inborn errors which result either in a disruption of enterocyte absorptive or secretory function, or where structural genes are damaged, leading

to an enteropathy of the small intestinal mucosa. Microvillus inclusion disease (microvillus atrophy) is the best characterized of these congenital enteropathies but other forms include intestinal epithelial dysplasia (tufting enteropathy) and syndromic forms which are associated with dysmorphic features.<sup>42</sup>

Microvillus atrophy is characterized by a hypoplastic villous atrophy associated with depletion and shortening of the microvilli over the villous epithelium. This condition can be differentiated from other congenital enteropathies by the presence of smudging of stains which outline the microvillous membrane and by electron micrographs which show the presence of characteristic microvillous inclusions in the villous enterocytes. Patients who survive with this condition are likely to remain dependent on PN for a prolonged period as no specific treatment other than intestinal transplantation is available.

For children with the other forms of congenital enteropathy the lack of understanding of the underlying cause makes treatment and prognostication difficult. Nutritional support with predigested hypoallergenic feeds and i.v. alimentation can greatly prolong life but will frequently not alter the underlying disorder.

## AUTOIMMUNE ENTEROPATHY

In a small number of patients with intractable diarrhea and an enteropathy the presence of enterocyte autoantibodies has been described. Autoimmune enteropathy presents with intractable watery and sometimes bloody diarrhea between 3 months and 2 years of age.<sup>43</sup> In some of these patients other organ-specific autoantibodies or autoimmune diseases have also been found, making it likely that the intestinal disease is caused by an autoimmune process. Treatment of these children with hypoallergenic diets, steroids and immunosuppressive drugs, such as azathioprine, cyclosporin or tacrolimus, is successful in some cases.

## PROTEIN-LOSING ENTEROPATHY

Small amounts of albumin pass into the gut each day and under the influence of pancreatic enzymes are digested and reabsorbed. In response to an increased loss into the gut the liver is able to compensate by increasing the rate of albumin synthesis by up to a factor of two. Above this level, however, the patient becomes increasingly hypoproteinemic. Albumin and IgG are the first to fall and in severe protein-losing enteropathies between 10% and 50% of the plasma albumin pool may be lost into the gut each day.

## Etiology

Protein-losing enteropathy may arise either as a consequence of the increased permeability of the intestine to plasma proteins or as a result of disordered intestinal or mesenteric lymph flow which leads to the loss of lymphocytes and fat, in addition to protein, into the intestine. Protein loss due to increased permeability is most marked in hypertrophic gastritis, eosinophilic gastroenteritis and in some forms of intestinal polyposis but any condition which results in severe damage or inflammation to the lining of the gut is likely to result in increased luminal protein loss. Lymphangiectasia is the most common cause of disordered lymph flow. The conditions associated with protein-losing enteropathy are listed in Table 19.13.

## Clinical features and diagnosis

The clinical features are of peripheral edema and ascites, when the serum albumin falls below 20 g/L, in addition to those of the underlying condition. The diagnosis of a protein-losing enteropathy is confirmed by the detection of increased amounts of protein in the stool in the face of a low serum albumin. The increased losses can be shown by increased levels of fecal alpha-1 antitrypsin. The cause of the protein loss, which may be from the stomach, small intestine or large intestine, can best be defined by endoscopy and biopsy.

**Table 19.13** Causes of protein-losing enteropathy

1. Increased mucosal permeability to protein
  - a. Hypertrophic gastritis
  - b. Eosinophilic gastroenteritis
  - c. Polyposis
  - d. Inflammatory disease
    - (i) Crohn's disease
    - (ii) Ulcerative colitis
    - (iii) Enterocolitis
    - (iv) Pseudomembranous colitis
    - (v) Radiation enteritis
    - (vi) Graft-versus-host disease
    - (vii) Autoimmune enteropathy
  - e. Celiac disease
  - f. Nephrotic syndrome
  - g. Esophagitis
2. Altered lymph flow
  - a. Primary intestinal lymphangiectasia
  - b. Secondary intestinal lymphangiectasia
    - (i) Congestive cardiac failure
    - (ii) Constrictive pericarditis
    - (iii) Lymphoma
    - (iv) Tuberculous adenitis
    - (v) Volvulus

The treatment is that of the underlying condition but 20% albumin infusion may be required in the short term to correct the hypoalbuminemia and edema.

## INTESTINAL LYMPHANGIECTASIA

The lymphatics of the small intestine play a vital role in the absorption of fat, being responsible for the transport of chylomicrons from the mucosal cells, via the thoracic duct to the venous system. This lymphatic fluid is also rich in protein and in lymphocytes. In intestinal lymphangiectasia these lymphatic channels become blocked, and as a consequence protein and lymphocytes are lost into the gut while fat and fat-soluble vitamins are malabsorbed.

The condition may be either congenital when it is frequently associated with other abnormalities of lymphatic development, such as peripheral lymphedema, or it may arise secondary to acquired lymphatic obstruction from congestive cardiac failure, constrictive pericarditis, malrotation or infiltration of the lymphatics by neoplastic processes. Examination of the jejunal mucosa under a dissecting microscope reveals pale villi of normal length. On higher magnification the lymphatics of the lamina propria and submucosa are distended and filled with lipid staining material.

Patients are likely to present with diarrhea, abdominal distension with hypoproteinemia leading to edema and ascites. The loss of lymphatic cells will result in lymphopenia and an increased susceptibility to infections. Fat-soluble vitamin deficiencies are likely to lead to rickets and clotting abnormalities. The diagnosis is confirmed by the characteristic jejunal biopsy findings in a patient with lymphopenia and a protein-losing enteropathy.

If the primary cause of the lymphangiectasia cannot be remedied treatment involves the use of a high-protein diet to compensate for the large stool losses. The substitution in the diet of long-chain by medium-chain fats which are absorbed directly into the portal venous circulation reduces the protein loss. In some patients regular albumin infusions may be required to control hypoproteinemia.

## IMMUNE DEFICIENCY AND GUT DISEASE

The normal immune function of the small intestine plays a major part in preventing both the absorption of foreign proteins and the penetration of enteric pathogens across the lining of the gut. While the immunodeficiencies

**Table 19.14** Immune deficiency leading to gastrointestinal disease

1. Antibody defect
  - a. X-linked agammaglobulinemia
  - b. IgA deficiency
2. Combined immunodeficiency
  - a. Common variable immunodeficiency
  - b. Severe combined immunodeficiency
3. Defect of phagocytosis
  - a. X-linked chronic granulomatous disease
4. Immunodeficiency as part of a syndrome
  - a. Wiskott–Aldrich syndrome
  - b. DiGeorge syndrome
  - c. IPEX syndrome
5. Acquired immune deficiency syndrome

themselves very rarely cause any primary damage to the gut, the consequences of the sensitization of the gut to foreign proteins or of recurrent enteric infections can lead to structural damage to the small intestinal mucosa with the development of malabsorption and diarrhea and as a consequence, failure to thrive. The immunodeficiencies which can lead to compromised intestinal function are listed in [Table 19.14](#).

While the majority of children with IgA deficiency may have no symptoms, the incidence of food allergy and of celiac disease is increased as is infection with *Giardia lamblia*. In agammaglobulinemia and common variable immunodeficiency (CVI), as well as giardiasis, bacterial overgrowth and nonspecific colitis can occur. Where T cell function is compromised in CVI, chronic fungal infection and a nonspecific enterocolitis may develop. Chronic granulomatous disease can cause liver and perianal abscesses, and an enterocolitis which can mimic Crohn's disease; a granulomatous narrowing of the gastric antrum has also been reported.

In both Wiskott–Aldrich and DiGeorge syndrome there is T cell dysfunction, the former associated with severe eczema and thrombocytopenia and the latter associated with esophageal, parathyroid and cardiac defects. A less common immunodeficiency associated with gastrointestinal disease is the IPEX syndrome, an X-linked condition with severe autoimmune enteropathy, autoimmune polyendocrinopathies and hemolytic anemia. Acquired immune deficiency syndrome (AIDS) frequently presents with opportunistic intestinal infection with *Cryptosporidium*, *Candida*, *Salmonella* or cytomegalovirus.

The diagnosis and treatment of these immune deficiencies is more fully described in Chapter 27. When gut disease occurs, therapy should be aimed at the primary disorder, at treating the enteric infection and at supporting nutrition with elemental feeds or even PN.

Immunodeficiencies may themselves occur as a consequence of primary gastrointestinal disease and this in turn can feed back to potentiate the initial disorder. This can occur in any severely malnourished child, in patients where gut protein loss results in hypoproteinemia and hypogammaglobulinemia, and in acrodermatitis enteropathica where zinc deficiency suppresses immune function.

## SHORT GUT SYNDROME

Resection of part of the small intestine is not uncommonly required in neonates who develop an acute surgical problem ([Table 19.15](#)). Similarly

**Table 19.15** Causes of the short bowel syndrome in the neonate

1. Small intestinal malrotation with volvulus
2. Jejunal and ileal atresias
3. Meconium ileus
4. Omphalocele or gastroschisis with volvulus
5. Internal hernias
6. Necrotizing enterocolitis
7. Congenital short small bowel

in the older child intestinal resection may be required following trauma or volvulus formation. The consequences of such a resection depend very much on the length of gut resected, the part of the small intestine resected, whether the ileocecal valve and colon are still present and on the nutritional state of the patient.<sup>44</sup> Loss of more than 30 cm of intestine is likely to have nutritional consequences to the infant. The remaining bowel, however, has great powers of adaptation and it is possible for as little as 20 cm of small intestine with an intact ileocecal valve to adapt adequately over many months or years to support life by enteral nutrition.

### Clinical features

As a consequence of the loss of intestinal surface area the child develops diarrhea and the absorption of all nutrients, minerals and vitamins is reduced. This is likely to lead to weight loss and the development of specific nutritional deficiencies.

Loss of the terminal ileum will lead to malabsorption and depletion of the bile salt pool and failed vitamin B<sub>12</sub> absorption will over a period of years lead to the development of a deficiency state. If duodenal bile salt concentration falls below 2 mmol/L, micelle formation may be inhibited, leading to malabsorption of long chain fats, and the passage of bile salts into the colon will result in intestinal secretion, which will compound the diarrhea. The ileum is also rich in enteroglucagon, a potent trophic factor in intestinal adaptation, and where the ileum has been resected the adaptive response may be further delayed or blunted.

The ileocecal valve has a vital role in preventing the reflux of colonic flora into the small intestine and when the valve is resected bacterial overgrowth of the small intestine is an almost inevitable sequela. This leads to mucosal damage and the deconjugation of bile salts with resulting disruption of lipid solubilization and intestinal secretion. Without an ileocecal valve the length of gut that is needed to support life is probably more than doubled and this is further increased if the colon has also been extensively resected.

The small intestine also has an important role in the metabolism of gastrin and where a large length of jejunum is resected hypergastrinemia with increased gastric secretion can occur. This not only increases the fluid load on the intestine but also lowers the duodenal pH and as a result reduces bile salt solubility and the activity of the digestive enzymes.

### Management

During the period of adaptation which follows an intestinal resection the turnover of regenerative cells in the crypts of the small intestine increases and as a consequence the length of villi increases. With time this leads to an increase in the absorptive capacity of the residual small intestine. This process, however, may take many months and the mainstay in management is the promotion of the adaptive response and the nutritional support of these patients during this period.

One of the most potent trophic factors in promoting adaptation is the presence of food within the gastrointestinal tract. Starvation is known to produce a partial villous atrophy which is reversed by re-feeding. In short gut syndrome it is therefore most important that enteral feeding is maintained at a level which is able to stimulate the adaptive response while at the same time not causing torrential diarrhea. Because of the reduced digestive and absorptive capacity of the small intestine it is usual to feed these infants with a predigested feed, synthetic elemental feed or a modular feed to which carbohydrate and fat can be added individually as tolerated.

There is also a need to control the many complications of short gut syndrome in order to further increase the absorptive and digestive capacity of the gut. These treatments are listed in Table 19.16. In some infants where very little small intestine remains, or where the adaptive response has been blunted by loss of the ileum and ileocecal valve, the child may remain dependent on PN and under such circumstances efforts should be made to institute this therapy at home. These most severe patients may also be candidates for intestinal transplantation (see pp. 632–33).

**Table 19.16** Complications in short gut syndrome and their treatment

Complications	Treatment
Bacterial overgrowth	Antibiotics Resect stricture or stagnant loop
Gastric hypersecretion	Histamine 2 blockers
Rapid transit	Loperamide
Malabsorption of fats	Medium chain triglycerides in feeds
Bile salt diarrhea	Bile salt chelator: cholestyramine
Poor growth	Increase parenteral/enteral nutrition

## INBORN ERRORS OF DIGESTION AND ABSORPTION

Although most causes of gastrointestinal disease are acquired, there are a number of specific inborn errors of intestinal function which interfere with the normal digestion and absorption of nutrients. Although these disorders are generally uncommon it is important to be aware of their existence as failure to recognize their signs and symptoms may have severe consequences for the child. A knowledge of normal intestinal physiology is important if the clinical consequences of these defects are to be understood.

### CARBOHYDRATE MALABSORPTION

Carbohydrates will be malabsorbed if there is a failure of luminal or brush border digestion or a defect in the transport proteins which facilitate the absorption of monosaccharides. The most common inborn error involving carbohydrate digestion is cystic fibrosis, in which luminal levels of pancreatic amylase are markedly reduced. Of the disaccharidases outlined in Table 19.9, specific defects of lactase, sucrase–isomaltase and trehalase have all been reported although the latter defect is of no clinical significance.

The presence of increased concentrations of disaccharides in the lumen of the small intestine leads to an osmotic diarrhea that results in abdominal distension with large water and electrolyte losses which can be life threatening in young infants.

### Lactase deficiency

Primary lactase deficiency is very uncommon and presents with profuse watery diarrhea soon after the introduction of milk feeds. The diagnosis can be suspected from the clinical history and the response to a lactose-free diet, although it can only be confirmed by the measurement of brush border lactase activity. The condition is thought to be inherited in an autosomal recessive fashion.

In many African and Asian races, adult levels of lactase activity fall far below those found in European races. This has previously been labeled 'late-onset lactase deficiency', but given that most of these individuals do not have any symptoms, it is probably incorrect to say that they are deficient. Transient lactase deficiency commonly occurs as a result of damage to the intestinal mucosa from a primary infective agent.

### Sucrase–isomaltase deficiency

The incidence of this deficiency is probably very low although it is said to affect up to 10% of Greenland Eskimos. The condition probably occurs in a number of distinct genetic forms and this may in part explain the variability in its clinical presentation.<sup>45</sup> Symptoms of diarrhea and failure to thrive usually develop following the introduction of sucrose or complex carbohydrate into the diet, but in some children the symptoms may be very mild and the condition goes undiagnosed. As sucrase also contributes to a large part of the brush border maltase activity the use of refined formula feeds which all contain glucose polymer invariably results in an increase in the diarrhea.

In response to an oral sucrose load, exhaled breath hydrogen rises and sucrose can be detected by sugar chromatography of the loose stools. Jejunal biopsy will show normal mucosal morphology but

histochemical studies reveal low or absent enzyme activity. Dietary removal of sucrose and complex carbohydrate results in an immediate symptomatic recovery.

### Glucose–galactose malabsorption

The condition results from a defect in the transport protein which is responsible for sodium–glucose and sodium–galactose linked co-transport.<sup>46</sup> Diarrhea develops shortly after the first feed and persists until glucose and galactose are removed from the diet. In contrast fructose absorption is normal and sodium–amino acid co-transport is preserved. In some children the degree of glucose intolerance decreases with increasing age. The inheritance is autosomal recessive and is treated with the fructose-containing feed, Galactamin 19.

### LIPID MALABSORPTION

Lipid malabsorption with steatorrhea will result from failed luminal solubilization and digestion of triglycerides, as occurs in pancreatic insufficiency, biliary disease and short gut syndrome, and from failure of mucosal fat transport as occurs in abetalipoproteinemia and hypobetalipoproteinemia.

### Abetalipoproteinemia

This autosomal recessive condition which was first described in 1950 is characterized by the presence from birth of steatorrhea, acanthocytosis on the peripheral blood film and failure to thrive. If diagnosis is delayed signs of ataxia and retinopathy may develop in the second decade.

Failure to synthesize apoprotein B means that chylomicrons cannot be manufactured and exported into the lymphatics. Lipid electrophoresis reveals absent serum low density lipoprotein (LDL), very low density lipoprotein (VLDL) and chylomicrons and as a consequence serum triglyceride and cholesterol levels are low. Jejunal biopsy reveals fat-laden enterocytes.

There is now strong evidence that the neurological signs result from chronic vitamin E deficiency and if treatment is started promptly with a low-fat diet, large oral supplements of vitamin E (100 mg/kg/24 h) along with supplements of the other fat-soluble vitamins, the development of ataxic symptoms and mental deterioration can be prevented.

### PROTEIN MALABSORPTION

The digestion of proteins is dependent on the action of proteases which are secreted by the stomach, pancreas and the intestinal mucosa. Inborn errors of these enzymes are very uncommon although specific deficiencies of trypsinogen and enterokinase have been reported. Both these conditions result in failure to thrive, hypoproteinemia, edema, anemia and neutropenia, and following the introduction of a protein hydrolysate feed with oral pancreatic supplements there is a marked improvement in symptoms.

Defects of brush border amino acid absorption tend to have few clinical consequences as the particular amino acid can still be absorbed as part of a dipeptide. This explains why cystinuria and iminoglycinuria do not result in the development of any nutritional deficiencies and why in Hartnup disease symptoms tend to develop only when the diet is otherwise compromised. Defects of basolateral transport appear, however, to have more severe clinical consequences.

### Hartnup disease

A defect in the transport of free neutral amino acids across the brush border of the small intestine and the proximal renal tubules of the kidney leads to a pellagra-like skin rash in areas exposed to sunlight with associated diarrhea and a dementing psychiatric illness. These features are the result of low levels of tryptophan leading to the decreased production of nicotinamide. Treatment with nicotinamide supplementation controls the symptoms of pellagra, which spontaneously become less severe with increasing age.

### Lysinuric protein intolerance

In this disorder there is impaired absorption of the dibasic amino acids lysine, ornithine and arginine across the basolateral membrane of intestinal, hepatic and renal tubular cells. The patients present with severe failure to thrive, diarrhea, hepatosplenomegaly and aversion to high protein foods by 1 year of age. Developmental delay and mental retardation occur if there have been prolonged episodes of hyperammonemia. This can occur following a protein load due to the low level of urea cycle intermediates, and as a consequence treatment with oral citrulline can in part prevent this problem arising.

## DISORDERS OF ELECTROLYTE AND MINERAL ABSORPTION

### Congenital chloride diarrhea

This condition is characterized by severe watery diarrhea with hypochloremia, hypokalemia and metabolic alkalosis.<sup>47</sup> This autosomal recessive condition is characterized by a defect in  $\text{Cl}^-/\text{HCO}_3^+$  transport in the ileum and colon with the resulting loss of large amounts of  $\text{Cl}^-$  in the stool.  $\text{Na}^+$  is also lost in the stool and as a consequence the patients develop secondary hyperaldosteronism with urinary sparing of  $\text{Na}^+$  and loss of  $\text{K}^+$ . This secretion starts in utero and is associated with maternal polyhydramnios, which frequently results in premature delivery. In the neonatal period the presence of diarrhea may be missed, leading to confusion with Bartter syndrome, in which the  $\text{Cl}^-$  loss is primarily renal and not intestinal. If the salt losses are not corrected the infant will become increasingly dehydrated and may die. Alkalosis is not present at birth and only develops over the subsequent weeks. Those infants who survive without adequate electrolyte replacement are invariably growth retarded with hypotonia and developmentally delayed as a consequence of chronic salt depletion.

The diagnosis is made from the high  $\text{Cl}^-$  content of the stool with levels  $> 90 \text{ mmol/L}$  exceeding the sum of the  $\text{Na}^+$  and  $\text{K}^+$  concentrations. Blood gases will show a metabolic alkalosis, serum  $\text{Cl}^-$  and  $\text{K}^+$  are low while the  $\text{Na}^+$  level is likely to be normal. Urinary electrolytes will show very low or absent  $\text{Na}^+$  and  $\text{Cl}^-$  excretion with markedly raised  $\text{K}^+$  losses in the face of hypokalemia.

Treatment is with oral electrolyte supplements in the form of both  $\text{NaCl}$  and  $\text{KCl}$  given in amounts large enough to suppress the hyperaldosteronism, maintain urinary  $\text{Cl}^-$  excretion and correct the electrolyte deficiency. This treatment does not influence the diarrhea but results in the normal growth and development of the child.

### Congenital sodium diarrhea

Diarrhea secondary to a defect of  $\text{Na}^+/\text{H}^+$  exchange can present in newborn babies in a manner very similar to congenital chloride diarrhea. The watery stools however contain more sodium than chloride and the child will develop a metabolic acidosis. Treatment with sodium citrate and oral rehydration solutions maintains fluid and electrolyte balance.

### Acrodermatitis enteropathica

This is an autosomal recessive condition characterized by a specific defect in the absorption of zinc by the histologically normal small intestinal mucosa. The resulting zinc deficiency leads to a florid rash over the perineum (Fig. 19.8), buttocks and oral region with associated diarrhea, infection, alopecia and behavioral disturbance. The clinical features are reversed promptly by treatment with oral zinc supplements, which need to be taken life-long.

### Primary hypomagnesemia

This autosomal recessive condition results from the defective absorption of magnesium by the small intestine and leads in the first few weeks of life to tetany and generalized convulsions associated with hypomagnesemia and hypocalcemia. On a normal diet the patient is in negative magnesium balance but this can be reversed by giving oral magnesium supplements. These supplements increase serum levels of both magnesium and calcium but unfortunately frequently induce diarrhea.

Fig. 19.8 The napkin area of a child with acrodermatitis enteropathica. (Reproduced by kind permission of P J Milla)

## INVESTIGATIONS OF THE SMALL INTESTINE

A wide range of tests are available to look at the structure and function of the small intestine. Each test has its own specific indications and limitations and with the correct choice of investigations the maximum relevant information can be obtained with the minimum of invasive investigations.

### RADIOLOGY

Plain abdominal X-ray is of value in detecting intestinal obstruction and the presence of free gas will also be seen if perforation has occurred. The barium follow-through or small bowel enema is the investigation of choice to define the anatomy of the small intestine and to demonstrate the gross mucosal pattern. This examination will define the rotation of the small intestine and allow the detection of blind loops, strictures and duplication cysts. Contrast studies are also invaluable in detecting small bowel involvement in Crohn's disease, intestinal polyps and infiltrative lesions of the small bowel such as non-Hodgkin's lymphoma.

The ectopic gastric mucosa in Meckel's diverticulum can be outlined with a  $^{99}\text{Tc}$  pertechnetate scan and mucosal inflammation can be detected with the autologous labeling of leukocytes with  $^{99}\text{Tc}$  hexametazime (HMPAO).

Celiac axis angiography is only very rarely required to define the site of intestinal hemorrhage from a vascular malformation.

### SMALL INTESTINAL BIOPSY

The development of peroral small intestinal biopsy using the Watson or Crosby capsule in the late 1950s led to major advances in the diagnosis and management of small intestinal disease. This method has now been largely superseded by the use of upper gastrointestinal endoscopy for small bowel biopsy. Biopsies need to be taken from the distal second or third part of the duodenum in order to avoid the presence of Brunner's glands, which are found more proximally. This technique has the advantage that the area for biopsy can be directly visualized, other pathologies may be detected at endoscopy and with the development of small instruments, biopsies in preterm infants are now possible. A limitation is that biopsies tend to be small and more difficult to orientate but this problem can be largely overcome by taking multiple biopsies.

If the biopsy material is correctly stored it is possible to carry out the quantitative measurement of brush border disaccharides by histochemical methods, to characterize the infiltrate in the lamina propria

with immunostaining, and with electron microscopy the characteristic lesion of microvillous atrophy can be seen.

Serial mucosal biopsy is also valuable in monitoring the therapeutic response to therapy.

### CAPSULE ENDOSCOPY

Traditional endoscopic techniques allow direct examination of the duodenum at upper endoscopy and of the terminal ileum during colonoscopy. Push endoscopy, a technique used more widely in adult practice, should allow direct examination beyond the duodeno-jejunal flexure. Direct visualization of the entire length of the small intestine is now available using the technique of capsule endoscopy, where a video camera 'pill' is swallowed and continuous images are transmitted to a data recording device as it passes along the length of the small intestine.<sup>26</sup> This technique is particularly valuable in the detection of intestinal polyps, small bowel Crohn's disease and occult intestinal bleeding. In younger children down to the age of about 6 years the capsule can be passed during an endoscopic procedure if it cannot be swallowed.

### NUTRIENT LOSS IN STOOL

Alpha-1 antitrypsin is a protein which is resistant to digestion by the gut and excretion in the feces is a reliable marker of stool protein loss. Fat loss can be quantified by the homogenization and separation of fat within fecal material by centrifugation of spot stool samples. The steatocrit refers to the fat content as a percentage of the total solid matter in the stool. Carbohydrate loss in the stool is discussed more fully in the section on stool chromatography.

### BREATH HYDROGEN

When bacteria in the colon come in contact with undigested carbohydrate it is fermented with the production of hydrogen, which is exhaled in the breath. By the use of a suitable carbohydrate load this phenomenon can be used to measure mouth to cecal transit time, the absorption of a range of mono- and disaccharides and to detect colonization of the small intestine by bacteria.

Lactulose is a naturally occurring carbohydrate which is not absorbed or digested by the human small intestine but is readily fermented by colonic bacteria to produce hydrogen. Therefore the time between an oral dose (250 mg/kg) and a rise in the basal level of breath hydrogen is an indication of mouth to cecal transit time. If an oral load of glucose (2 g/kg) is given to a healthy fasting subject the monosaccharide should be completely absorbed by the small intestine and no breath hydrogen peak will occur. In a patient with glucose-galactose malabsorption the glucose will pass straight into the colon causing a large peak in breath hydrogen along with abdominal pain and diarrhea. Finally, in a patient with bacterial overgrowth the glucose will be fermented almost immediately it leaves the stomach producing a very brisk and early rise in breath hydrogen.

### STOOL CHROMATOGRAPHY

Whenever a patient has osmotic diarrhea it is likely that the stool will contain sugars. While reducing sugars can be crudely detected using clinitest tablets, the quantification and characterization of these sugars by stool chromatography can be very useful, when taken along with the carbohydrate content of the child's feed or a specific oral load, in defining the cause of the underlying disorder. Two classic examples are the child with sucrase-isomaltase deficiency who, following the ingestion of complex carbohydrate, has loose stool containing limit dextrins, maltotriose and maltose and the baby with glucose-galactose malabsorption who, following a milk feed, has diarrhea containing glucose and galactose.

Specimens require immediate transport to the laboratory so that further digestion of sugars by colonic bacteria is prevented.

## DUODENAL INTUBATION

When bacterial overgrowth is suspected, intubation with aspiration of duodenal juices is essential to confirm the diagnosis and define the sensitivities of the organisms present. Aspiration will similarly allow the concentration and pattern of luminal bile salts to be measured. The technique used to measure pancreatic function is described in the section on the pancreas.

## GASTROINTESTINAL TUMORS

### JUVENILE POLYPS

The most common polyp found in childhood is the juvenile polyp. These inflammatory lesions are found most frequently in the rectosigmoid but may develop more proximally and in 50% of cases more than one may be found. They present most frequently with painless rectal bleeding, in children between the ages of 2 and 5, although rarely they may present with recurrent abdominal pain and intussusception. These polyps do not undergo malignant change although if more than 10 lesions are seen, juvenile polyposis coli should be suspected. This condition can be differentiated from familial polyposis coli by the earlier age of onset and the presence of inflammatory, rather than adenomatous, polyps.<sup>48</sup>

The diagnosis can be confirmed by flexible colonoscopy and at the same examination the polyps can be diathermied and removed for histological examination.

### FAMILIAL ADENOMATOUS POLYPOSIS (FAP)

This autosomal dominant condition is characterized by multiple adenomatous polyps throughout the large intestine and is likely to present insidiously with diarrhea, blood and mucus in the stools. The polyps, which generally appear after puberty, slowly enlarge with time until they invariably undergo malignant change. The children of affected adults should be offered genetic screening and with the recognition of mutations in the FAP gene on chromosome 5q21 and the association with congenital hypertrophy of the retinal pigment epithelium (CHRPE), patients at high risk of developing the condition can be detected. Those at high risk require regular colonoscopic screening from the age of 12 years. Although the rate of polyp growth may be slowed by nonsteroidal anti-inflammatory drugs (NSAIDs), for the majority of individuals total colectomy in early adulthood is still the treatment of choice.

In Gardner syndrome adenomatous polyps are seen throughout the gut in association with bone osteomas and epidermoid cysts.

### PEUTZ–JEGHERS SYNDROME

In this autosomal dominant condition multiple hamartomatous polyps are distributed throughout the jejunum, ileum and large intestine of children in association with pigmentation of the oral mucosa and the skin of the perioral region, the digits and the anus. The condition presents with anemia due to blood loss or with obstruction secondary to intussusception. The risk of gastrointestinal cancer is increased 15-fold in this condition and up to 50% of untreated patients will die of cancer by the age of 57 years.

### PSEUDOPOLYPS

In response to any inflammatory reaction the intestinal mucosa may become swollen and a polyp-like structure will be formed. As a result of enteric infections or allergy, lymphoid hyperplasia of the ileum may occur and in conditions such as ulcerative colitis and Crohn's disease exuberant mucosal inflammation leads to pseudopolyp formation. The true nature of the lesions can be defined by mucosal biopsy.

### HEMANGIOMAS

Intestinal hemangiomas, which are frequently multiple, are a well-recognized cause of rectal bleeding. Small colonic lesions can be

sclerosed during endoscopic examination but laparotomy may be required for large angiomas and small intestinal lesions. In the blue rubber bleb nevus syndrome skin lesions may be associated with luminal lesions within the intestine.

## MALIGNANT TUMORS

Fortunately, malignant tumors of the intestine are very rare in childhood and in particular colonic and gastric neoplasms, which are so common in adult life, are hardly ever seen.

Small intestinal lymphoma of the nonHodgkin's type is, however, occasionally seen. These tumors may be unifocal and present with obstruction or intussusception of the ileocecal region, or more commonly they are multifocal and present with ascites. Lymphoma is more likely to occur in children with immunodeficiency or following infection with the Epstein–Barr virus (EBV) while in adults there is a clear association with untreated celiac disease. If a laparotomy is required for intestinal obstruction the diagnosis can be made from the histology of the resected specimen but under other circumstances bone marrow aspiration and cytological examination of ascitic fluid is required.

## THE PANCREAS

### CYSTIC FIBROSIS

Cystic fibrosis is an autosomal recessive condition which affects approximately 1 in every 2000 live Caucasian births.<sup>49,50</sup> The underlying defect results from one of a number of possible mutations, in a chloride transporter protein which lines ductular epithelium. This results in inspissation of mucus in the ducts of the pancreas and in the bronchial and biliary trees with the resulting development of pancreatic insufficiency, chronic respiratory disease and biliary cirrhosis. In this section discussion will be confined to the effects of cystic fibrosis on the pancreas and intestine (Table 19.17) as the pulmonary (see Ch. 20) and hepatic (see p. 652) consequences are discussed elsewhere.

### Pancreatic insufficiency

The inspissated concretions result in distension of the ducts and acini of the pancreas, which with time progress to the formation of small cysts with destruction and fibrosis of the exocrine tissue. As a consequence of this the output of pancreatic enzymes and bicarbonate falls, leading to pancreatic insufficiency. In some patients endocrine pancreatic tissue is also damaged with the development of diabetes mellitus. Approximately 85% of patients with cystic fibrosis have pancreatic insufficiency with resulting malabsorption and steatorrhea, while in the remaining 15%, although not normal, the pancreas has adequate reserve capacity. Signs of pancreatic insuffi-

| f. Distal intestinal obstruction syndrome |

ciency are usually present within the first 2 years of life with the passage of foul, bulky pale stools. In the majority of untreated children, growth is abnormal and fat-soluble vitamin deficiencies are likely to develop.

As a consequence of chronic steatorrhea, bile salts are lost in the stool, leading to depletion of the bile salt pool, which may be further compounded if liver disease reduces the rate of synthesis. The resulting reduction in bile salt concentration will not only reduce the solubilization of lipids in the duodenum but may also reduce the solubilization of cholesterol and predispose to the formation of gall stones.

### Meconium ileus

Cystic fibrosis may present in the first day or two of life with vomiting and abdominal distension due to meconium ileus. This obstruction to the small intestine with thick tenacious meconium may be complicated by volvulus, atresia or peritonitis. Plain abdominal X-ray will show dilated loops of intestine with meconium, outlined by trapped air, present in the obstructed segment of bowel and gastrografin enema will reveal a microcolon distal to the obstruction. The enema may be of benefit in the nonsurgical clearance of the meconium (see Ch. 37).

Difficulty in passing stool may also lead to rectal prolapse.

### Distal intestinal obstruction syndrome

This condition, which is sometimes also referred to as meconium ileus equivalent, is a common problem known to occur in up to 15% of patients with cystic fibrosis. It is most common in adolescence and is characterized by recurrent episodes of subacute or occasionally acute obstruction with abdominal pain, vomiting and anorexia. Marked fecal loading may be detected by abdominal palpation or plain abdominal X-ray. If treatment with laxatives fails, the use of mucolytic drugs or balanced intestinal lavage should be considered.

### Diagnosis of cystic fibrosis

The main diagnostic test for cystic fibrosis is the sweat test, which measures the increased sodium content found in the sweat of children with cystic fibrosis. The vast majority of healthy children have a sweat sodium less than 45 mmol/L while in cystic fibrosis it is greater than 74 mmol/L in 99% of cases. A modification of this test measures the sweat osmolality, which is greater than 125 mOsmol/L in cystic fibrosis.

Many mutations have been described for the cystic fibrosis gene. If the patient's DNA is tested against the most common 20 mutations for the study population, it is possible to get a diagnostic accuracy of about 99%. Screening for cystic fibrosis in newborn babies can be carried out by heterozygote screening of mothers using genetic techniques or by immunoreactive trypsin measurement of a blood spot from a Guthrie card after birth.

### Treatment

As far as the intestinal complications of cystic fibrosis are concerned the main treatment for pancreatic insufficiency is with oral pancreatic supplements. Although only 10% of normal lipase activity is required to prevent steatorrhea, the majority of ingested supplements are inactivated by the low pH of the stomach and as a consequence symptoms may persist. This may be overcome by incorporating the pancreatic supplements within a pH-sensitive microsphere. The dose required by each patient is likely to vary greatly, although an inadequate dose will result in a failure to relieve symptoms while an excessive dose may lead to perianal excoriation or some children may develop thickening of the colonic mucosa with the development of obstruction.

The nutritional intake of patients with cystic fibrosis is frequently less than recommended for their age and given that their requirements may be increased due to chronic infection or the increased work of breathing, it is perhaps not surprising that many children grow poorly. With improved dietary advice and the use of nutritional supplements children with cystic fibrosis are now growing better and as a consequence they are surviving longer. Where supplements cannot be given enterally, nasogastric or gastrostomy feeding may be helpful. Oral fat-soluble vitamin supplements, in particular vitamin E, are also required.

### SHWACHMAN SYNDROME

After cystic fibrosis, Shwachman syndrome is probably the next most common cause of pancreatic insufficiency in childhood.<sup>51</sup> This autosomal recessive condition is due to a mutation on chromosome 7q11. Although the gene product is not known, the gene is expressed widely in the pancreas and bone marrow. The condition is characterized by the presence of neutropenia, short stature and bony changes in addition to pancreatic insufficiency. The neutropenia may occur cyclically as may the thrombocytopenia, which is seen in two thirds of patients. Arrest in proliferation of the myeloid series may be seen on bone marrow aspiration and leukemic transformation has been reported in a number of patients. Bony abnormalities with metaphyseal chondrodysplasia are frequently seen with involvement of the femoral neck.

The diagnosis should be considered in any child with pancreatic insufficiency, a normal sweat test and neutropenia. Treatment is with pancreatic supplements and fat-soluble vitamins and where symptomatic neutropenia persists, the use of human granulocyte colony stimulating factor should be considered. The patients are particularly prone to recurrent infections and antibiotic prophylaxis may be of some benefit.

### ACUTE AND CHRONIC PANCREATITIS

Pancreatitis is uncommon in childhood with idiopathic (23%) and trauma being the most common causes. Obstruction to the pancreatic duct, loss of vascular integrity and a direct insult to the parenchymal cells are all factors which can lead to the development of pancreatitis. Hereditary causes are the most common reason for chronic pancreatitis; mutations in the cationic trypsinogen gene, the cystic fibrosis transmembrane conductance regulator (CFTR) and the serine protein inhibitor (SPINK1) have all been implicated. Some hereditary cases may be due to a defect which prevents the inactivation of pancreatic enzymes with resulting autodigestion.<sup>52</sup> The causes of pancreatitis are listed in Table 19.18.

## Presentation

Attacks of pancreatitis are characterized by severe epigastric or umbilical pain which tends to be constant rather than colicky and which can radiate to the back or shoulders.<sup>53</sup> The pain is exacerbated by food and is not relieved by antacids. The patient will find abdominal movement uncomfortable and if the pancreatitis is severe, hemorrhagic bruising of the flanks with a paralytic ileus may develop. When the course is prolonged the condition may be complicated by circulatory collapse, hyperglycemia, hypocalcemia or by the formation of pleural effusions and pancreatic pseudocysts. The diagnosis is confirmed by markedly raised levels of serum amylase.

## Treatment

The management of acute pancreatitis is conservative. All oral feeds should be stopped and i.v. fluids should be given to correct any fluid losses and to provide normal requirements. Acute pancreatitis can be very painful, requiring adequate analgesia and where the patient is vomiting a nasogastric tube should be passed. An acute attack will normally last for between 3 d and 5 d but if the attack is more prolonged total PN should be started and treatment with a somatostatin analogue should be considered. The patient should be monitored for the development of complications and serial abdominal ultrasounds will allow fluid collections to be detected at an early stage. Pseudocysts which fail to resolve spontaneously will need to be drained.

In both acute and chronic pancreatitis if an underlying cause has been defined, this should be appropriately treated. Where a duct abnormality has been isolated reconstructive surgery may be of benefit and if a localized area of the pancreas is responsible for recurrent attacks, a partial pancreatectomy should be considered.

## INVESTIGATION OF THE PANCREAS

The most commonly used indirect measure of pancreatic function in childhood is the sweat test, which was discussed in the section on cystic fibrosis (see p. 625). The remaining investigations can be divided into blood tests which measure the level of pancreatic enzymes (i.e. amylase), tests which measure fecal fat or enzyme activity, more direct measures of pancreatic function and radiological imaging methods.

### Pancreatic function tests

These tests can be divided into the traditional tests which require duodenal intubation and the newer tubeless function tests. The traditional tests remain the most accurate although they are also the most invasive. They involve the collection of duodenal juice during a basal fasting period followed by the stimulation of the pancreas with cholecystokinin (1–2 iu/kg) and then secretin (1–2 iu/kg) with the further collection of duodenal juice. In pancreatic insufficiency the stimulated levels of lipase and trypsin are reduced and the juice fails to alkalize following stimulation with secretin. The tubeless tests rely on the pancreatic enzymes cleaving an ingested compound (bentiromide or fluorescein dilaurate) and the amount subsequently collected in the urine is a measure of pancreatic function.

Stool elastase activity is a non-invasive measure of pancreatic function which although not as accurate as the intubation technique described earlier, is easy to carry out. Pancreatic lipase activity can also be indirectly measured by the labeling of a fatty substrate with C<sup>13</sup> and measuring the appearance of the stable isotope in the breath.

### Radiology

Ultrasound is a very useful non-invasive imaging method in pancreatitis as it will show pancreatic edema during the acute attack, outline any fluid collections and allow gallbladder disease to be excluded. Where more detailed imaging is required of the structure of the pancreas, computerized tomographic (CT) techniques using X-ray and magnetic resonance imaging (MRI) may be used. In chronic pancreatitis where imaging of the pancreatic ducts is required to exclude a malformation or stricture, endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP) can be used.

Any abnormality of the structure of the duodenum will be seen on a barium study.

## DISORDERS OF GASTROINTESTINAL MOTILITY

Disorders of gastrointestinal motility are very common in childhood and are responsible for such diverse conditions as gastroesophageal reflux, irritable bowel syndrome and chronic constipation. Normal contractile activity relies on the coordinated action of the intestinal smooth muscle, its enteric and central neural connections and the humoral environment of the gut. Diseases exist in which damage to the enteric nervous system (Hirschsprung disease) or smooth muscle severely compromises the luminal transit of food and present with the symptoms of intestinal obstruction. The central nervous system has an important role in the modulation of intestinal motility with central insults commonly resulting in vomiting or even paralytic ileus. Lesser disturbances such as stress may lead to vomiting, abdominal pain and diarrhea.<sup>54</sup>

## ESOPHAGUS AND STOMACH

Motility disorders of the esophagus and stomach have already been discussed in their respective sections (pp. 604 and 605).

## INTESTINAL PSEUDO-OBSTRUCTION

Intestinal pseudo-obstruction is a clinical syndrome characterized by the signs and symptoms of intestinal obstruction in a patient with no evidence of an obstructing lesion. Pseudo-obstruction occurs most commonly as a primary disorder in childhood; it may be familial but may occasionally present in adolescence as a secondary manifestation of some other disease such as diabetes mellitus. The disorder tends to be generalized, involving either the smooth muscle or the enteric nerves of the entire length of the intestine.

A quarter of children present at birth and by 1 year two thirds have developed symptoms of abdominal distension, vomiting, constipation and failure to thrive. Frequently it is only after laparotomy that the condition is diagnosed. Associated abnormalities of the urinary tract such as megacystis and megaureter are found in some patients and an association with malrotation of the small intestine has been reported. Diagnosis can be made from the history and from intestinal manometry, which shows either a disruption or loss of cyclical fasting motor activity. A full-thickness biopsy is required for a definitive diagnosis.

The condition is complicated by bacterial overgrowth of the small intestine and is punctuated by repeated episodes of obstruction. In some patients this can be significantly improved by the formation of a defunctioning ileostomy. Nutrition is frequently compromised and in the most severe cases survival without total PN may not be possible.

## LARGE INTESTINE

Colonic motility disorders will present in the neonatal period with the delayed passage of meconium and symptoms of intestinal obstruction if severe, or may be delayed for many months or years when they are more likely to present with chronic constipation. Hirschsprung disease (see Ch. 37), hypo- and hyperganglionosis are now all well-recognized entities but unfortunately the nature of the structural or functional disorder in children with chronic constipation due to other causes is less well defined.

Treatment is symptomatic with oral laxatives in milder cases. In more severe cases, regular enemas may be required and in some patients the use of regular intestinal lavage through a continent cecostomy is effective. Where these techniques fail a defunctioning stoma or resection of the affected bowel may be required.

## ACUTE INFECTIVE DIARRHEA

Acute infective diarrhea is one of the major causes of morbidity and mortality in childhood in the world today, killing up to 3 million children

each year. In resource rich countries each child under 5 years has one to two episodes each year and over 10% of all hospital admissions in this age group are with acute diarrhea. In developing countries the much higher incidence of diarrheal illness is a consequence of the combined effect of contaminated water supplies, the preparation of bottle feeds under unhygienic conditions and from malnutrition, which frequently occurs in these children at the time of weaning.

Most acute diarrheal illnesses in well-nourished children are self-limiting and resolve within a few days. However, when frequent reinfection occurs, the child may develop a state of chronic diarrhea which will inevitably result in further malnutrition and an increased susceptibility to recurrent infection. It is this vicious cycle of events which along with the acute effects of dehydration leads to the significant mortality from this condition in developing countries.

## ETIOLOGY AND PATHOGENESIS

The infective agent in acute diarrhea cannot always be isolated but with improvements in diagnostic techniques a pathogen can be isolated in up to 80% of cases. Viral agents are the most common cause of acute infective diarrhea in childhood, followed by bacteria and then protozoal infection. The causes of acute infective diarrhea are shown in Table 19.19.

In the young infant who is most at risk from the complications of acute diarrhea a number of protective mechanisms exist to limit the effect of infective pathogens. The acid content of the stomach and IgA secreted by the small intestine and in breast milk will limit the growth of bacteria in the upper small intestine and the resulting predominance of bifidobacteria in feces may inhibit colonization by enteric pathogens. These factors all lead to a reduced incidence of acute enteric infection in breast-fed infants. Modification of the intestinal flora with probiotics may be of benefit both in preventing and reducing the severity of acute infective diarrhea.<sup>55</sup>

### Viral infection

The agent most commonly responsible for acute infantile gastroenteritis is the rotavirus. The rotavirus selectively attacks the mature enterocytes at the tips of the small intestinal villi, which are killed and shed into the lumen. This leads to the increased production of immature crypt-like cells with shortening of the villi. These cells have greatly reduced absorptive and disaccharidase activity and this loss of normal small intestinal function combined with the active secretion of fluids and electrolytes, leads to the production of diarrhea. Following the clearance of the viral pathogen the functional mucosal abnormalities resolve.

Table 19.19 Causes of acute infective diarrhea

Viruses	
	Rotavirus
	Astrovirus
	Adenovirus
	Parvovirus-like (i.e. Norwalk agent)
	Coronavirus
Bacteria	
	<i>Campylobacter</i> sp.
	<i>Salmonella</i> sp.
	<i>Escherichia coli</i>
	<i>Shigella</i> sp.
	<i>Yersinia enterocolitica</i>
	<i>Vibrio cholerae</i>
	<i>Clostridium difficile</i>
Protozoa	
	<i>Giardia lamblia</i>
	<i>Cryptosporidium</i>
	<i>Entamoeba histolytica</i>

### Bacterial infection

Four major mechanisms are responsible for the effects of bacterial pathogens. Organisms such as *Vibrio cholerae* and some strains of *Escherichia coli* synthesize proteins called enterotoxins, which are able to promote intestinal secretion. The preservation of electrogenic sodium-linked solute co-transport in these patients is exploited by the use of sodium- and glucose-containing oral rehydration solutions (ORSs), which are able to promote net intestinal absorption in the face of active secretion.

Enteropathogenic organisms such as some strains of *E. coli* adhere to the brush border membrane of the small intestine causing severe mucosal damage which may take many weeks to recover and such children may require parenteral nutritional support during the intervening period. *Shigella* species and *E. coli* serotypes O124 and O164 possess enteroinvasive properties leading to the development of watery diarrhea and dysentery with bacterial invasion of the colonic mucosa, while some bacteria, such as *Clostridium difficile* also produce cytotoxins, which have a direct toxic effect on enterocytes.

## CLINICAL FEATURES

Acute infective diarrhea characteristically results in a combination of nausea, vomiting, abdominal pain and diarrhea. In some children the symptoms may be relatively trivial while in others dehydration and metabolic disturbances may be life threatening. Symptoms appear generally to be most severe in younger and in malnourished infants who also run the risk of becoming septicemic with some bacterial pathogens. Bloody diarrhea frequently occurs in *Shigella*, *Salmonella*, *Campylobacter* and *E. coli* O157 infection. In children infected with *E. coli* O157 monitoring for signs of hemolytic uremic syndrome (HUS) and renal failure are required, particularly those under the age of 5 years, who are most vulnerable to this complication. Diarrhea and vomiting may also occur in a number of other medical conditions and it is important to consider systemic infection, metabolic disorders, surgical problems and other gastrointestinal disorders in the differential diagnosis of such patients.

The most serious consequence of acute diarrhea and vomiting is dehydration. The severity of the dehydration (see Table 19.20), which can be assessed clinically, determines the best treatment for the child. Children on high-solute diets, who develop diarrhea, may develop hypernatremic dehydration in which case the signs of dehydration are less obvious although lethargy and irritability may develop earlier.

Loss of bicarbonate and potassium in the stool, poor tissue perfusion, hypoglycemia, ketosis and renal failure may all lead to severe metabolic derangement. Symptoms of lethargy and irritability are particularly marked in hypernatremic dehydration and its rapid correction with i.v. fluids may lead to cerebral edema as a result of fluid shifts across the blood-brain barrier. This can result in convulsions or even death.

## MANAGEMENT

The management of children with acute infective diarrhea hinges upon the treatment of their dehydration.<sup>56-59</sup> The treatment required depends very much on the severity of their dehydration and on the facilities

Table 19.20 Assessment of the severity of dehydration

	No dehydration	5% dehydration	10%+ dehydration
Condition	Well, alert	Restless, irritable	Lethargic, unconscious
Eyes	Normal	Sunken	Very sunken and dry
Tears	Present	Absent	Absent
Mouth and tongue	Moist	Dry	Very dry
Thirst	Not thirsty	Thirsty, drinks eagerly	Drinks poorly
Skin pinch	Goes back quickly	Goes back slowly	Goes back very slowly

which are available. Most mild cases can be treated at home by their family practitioner with ORS but where dehydration is more severe, social circumstances are poor or where other complicating medical factors are present, hospital admission is required. Even in moderate dehydration, ORS remains the treatment of choice although this therapy is underused in developed countries, where i.v. therapy is often used inappropriately. Additionally the practitioner has to consider how best to feed these infants during both the acute and recovery phase of their illness. Generally drug therapy has no role in the management of acute diarrhea.

### Oral rehydration therapy

The management of acute diarrhea was revolutionized by the introduction of ORS over 30 years ago. This treatment continues to be the mainstay of therapy and by preventing the patient becoming dehydrated; it has greatly reduced the morbidity and mortality. While most children with acute diarrhea will have active intestinal secretion, their ability to absorb fluid and electrolytes is largely preserved. As outlined in [Figure 19.5](#), the absorption of sodium and glucose across the luminal surface of the enterocyte is facilitated by a transmembrane cotransport system. Solutions containing sodium and glucose in an optimum concentration are absorbed at an accelerated rate and where this is greater than the fluid losses incurred by the diarrheal process, dehydration can be prevented. It must be remembered that ORS does not stop the diarrhea and this is probably one of the reasons why its acceptance in developed countries is sometimes poor, as parents want any treatment to be a 'quick fix' to their child's problems.

The main recommendations for the treatment of acute diarrhea have come from the World Health Organization (WHO). Their oral rehydration solution contained 111 mmol/L of glucose and 90 mmol/L of sodium ([Table 19.21](#)). There has however been concern that in developed countries where cholera is an uncommon cause of diarrhea, this sodium concentration is too high and a concentration of 60 mmol/L has been suggested by the European Society for Pediatric Gastroenterology and Nutrition. It has also recently been shown that the traditional ORS, which has a slightly hyperosmolar osmolality of 311 mOsmol/L, may not be as effective as solutions with a lower osmolality of 210–260 mOsmol/L. This has resulted in revised recommendations by the WHO suggesting that rehydration solutions should contain 75 mmol/L of sodium and 75 mmol/L of glucose with a resulting osmolality of 245 mOsmol/L.<sup>57</sup> It must be remembered that fruit juices and colas are entirely unsuitable as ORS as they contain large amounts of sugar and very small amounts of electrolytes.

### Fluid replacement therapy

When assessing how best to treat a child with infective diarrhea, first severity of the patient's dehydration should be assessed ([Table 19.20](#)). The majority of children presenting for medical attention in resource rich countries are not yet dehydrated and the aim of treatment should be to prevent this occurring. Such children are often reluctant to take ORS and a normal age-appropriate diet should be continued. Unweaned infants should continue either with breast-feeding or undiluted formula

feed. The diet of older children should contain complex carbohydrate and meat but large amounts of fat or simple sugars should be avoided. There is increasing evidence that not only is the continued use of diet safe in children with infective diarrhea but through the trophic effect on the intestinal mucosa, a more rapid recovery of symptoms is promoted.

Children who are dehydrated and not shocked should be rapidly rehydrated with ORS. They should receive 50 ml/kg in the first 4 h with an additional 10 ml/kg for each stool and supplements for vomiting. In the more severely dehydrated child up to 100 ml/kg can be given in the first 4 h. By giving frequent small sips, vomiting can be reduced. If the child will not take adequate volumes of ORS, administration by nasogastric tube is preferable to i.v. administration in the nonshocked child who is not vomiting. Once the child is rehydrated, normal diet should be resumed as for the nondehydrated child.

I.v. rehydration is required if the patient is shocked or where repeated vomiting prevents adequate oral rehydration. The shocked patient should receive 20 ml/kg boluses of normal saline until the signs of shock resolve. ORS should be introduced at the earliest opportunity to continue the rehydration of the patient and food intake should be started as soon as it is likely to be tolerated. If continued i.v. rehydration is required, a 5% deficit should be corrected over 24 h and a 10% deficit ([Table 19.20](#)) over 48 h with a 0.45% saline/dextrose solution.

### Other therapies

Generally antibiotics have no place in the management of acute infective diarrhea, the exception being *Shigella*, *V. cholerae*, *Clostridium difficile* and *Giardia*. Similarly antimotility drugs, many of which are opiate derivatived, should not be given. There is now increasing evidence that probiotic therapy is beneficial in the treatment of acute infective diarrhea. A large European multicenter study has shown that *Lactobacillus rhamnosus* strain GG given with ORS reduces the length of diarrhea and the time of hospital stay.<sup>55</sup>

### Complications

Acute infective diarrhea may be complicated by the extraintestinal spread of the infection with the development of intestinal perforation, abscess formation, septicemia and meningitis. If dehydration is pronounced acute renal failure may develop and if hypernatremia is corrected too rapidly cerebral edema with convulsions is likely to occur. This complication is less common when ORS is used as fluid shifts occur more slowly. In some children severe damage to the intestinal mucosa will lead to the development of diarrhea which persists long after the original pathogen has been cleared.

### CONCLUSIONS

There have been many changes and advancements in the management of acute infective diarrhea in the last 10 years. There is clear agreement that ORS is the preferred method of rehydration, that diet should be introduced at an early stage and that drugs have very little role in the treatment of this problem. These points are summarized in [Table 19.22](#).

**Table 19.21** Major constituents of appropriate oral rehydration solutions (mmol/L) compared to inappropriate preparations. World Health Organization (WHO), European Society of Paediatric Gastroenterology Hepatology and Nutrition (ESPGHAN)

	Glucose (or other sugar)	Sodium	Potassium	Base	Osmolality
WHO (original)	110	90	20	30	311
ESPGHAN	74–111	60	20	10	225–260
WHO (revised 2001)	75	75	20	10	245
<i>Solution not suitable for ORS</i>					
Cola	700	2	0	13	750
Apple juice	690	3	32	0	730

**Table 19.22** Principles of treatment of acute gastroenteritis (Adapted from Szajewska, 2000<sup>66</sup>)

1. Use of ORS for dehydration
2. Use hypotonic ORS, Na 60–75 mmol/L (see Table 19.21)
3. Fast oral rehydration, over 3–4 h
4. Rapid realimentation with normal feeding thereafter
5. Use of special formula is unjustified
6. Use of diluted formula is unjustified
7. Continuation of breast-feeding at all times
8. Supplementation of ORS for ongoing losses
9. No unnecessary medications

## PROTRACTED DIARRHOEA IN EARLY INFANCY

Protracted diarrhea may be defined as the passage of four or more watery stools per day persisting for at least 2 weeks. This definition encompasses a wide variety of disorders (Table 19.23) and a definitive diagnosis may only be made in approximately 70% of cases. In most instances, the protracted diarrhea appears to follow an episode of acute gastroenteritis in early infancy, although by the time of presentation to hospital it may be impossible to isolate an infective agent from the stool. Furthermore, unless the situation is managed effectively at an early stage, a cycle of malabsorption and malnutrition may result which will further compromise intestinal function and perpetuate the diarrhea.<sup>42</sup>

One proposed sequence of events is that an acute infective insult may sensitize the intestine to foreign proteins (usually cows' milk protein), and subsequent ingestion of the offending food antigen causes further damage to the intestinal mucosa thus continuing the diarrhea (see also Ch. 33). Although the resulting enteropathy may be caused primarily by the protein content of the milk feed, disaccharide intolerance (particularly lactose) may also develop and the institution of an appropriate exclusion diet will often result in resolution of the diarrhea. In this situation, an exclusion diet may be necessary only for 2 or 3 months, after which a normal weaning diet can be reintroduced. In some cases, particularly in the developing world, bacterial overgrowth of the small intestine may be an added complication and bacterial toxins themselves may impair mucosal function.

Celiac disease, cystic fibrosis, selective inborn errors of absorption and immunodeficiency states may all present with intractable diarrhea of infancy. These conditions are discussed elsewhere in this chapter.

Less common causes include autoimmune enteropathy, while in some children there may be a family history suggesting an inborn error

**Table 19.23** Causes of protracted diarrhea in early infancy

1. Food sensitivity/postenteritis syndrome
2. Cystic fibrosis
3. Celiac disease
4. Microvillous inclusion disease
5. Congenital chloride losing diarrhea
6. Congenital short bowel
7. Inborn error of carbohydrate absorption
  - a. Sucrase–isomaltase deficiency
  - b. Glucose–galactose malabsorption
8. Immunodeficiency
9. Hormone-secreting tumor (i.e. VIPoma)
10. Autoimmune enteropathy
11. Bacterial overgrowth
12. Nonaccidental injury (laxative administration)
13. Idiopathic

as a causative factor. A proportion of these infants may suffer from congenital chloride-losing diarrhea or intestinal microvillus inclusion disease.<sup>60</sup> Where intestinal secretion is present in utero there may be a history of polyhydramnios or premature labor.

## INVESTIGATIONS

Collection and examination of the stool is vital and a careful search for intestinal pathogens (bacteria, viruses, parasites) should be undertaken at an early stage. The stools should be analyzed for the presence of reducing substances (> 1%) and stool electrolytes and osmolality should be measured to determine whether the diarrhea is osmotic or secretory in nature (Table 19.24). Chromatography of a fresh stool specimen may help in the diagnosis of inborn errors of carbohydrate absorption and in determining the osmotically active substances within the stool. Valuable information may also be obtained by fasting the child as this is likely to result in a marked diminution of osmotic diarrhea with little change in secretory diarrhea. It is essential to collect and measure the volume of all stools as this will influence the amount and the nature of fluid replacement therapy.

Jejunal biopsy is invaluable in detailing the morphology of the small intestinal epithelium and a sweat test can rule out cystic fibrosis. Blood tests are of limited value although peripheral blood eosinophilia may be present in children with food protein sensitivity and investigation of immune function may reveal specific abnormalities in the child with diarrhea due to immunodeficiency. Measurement of electrolytes and acid–base balance is important in the day-to-day management of fluid balance and may be abnormal in children with congenital chloride-losing diarrhea. If the cause of the diarrhea is not immediately evident serum should be sent for gut-autoantibody estimation to exclude gut autoimmune disease, and circulating gut hormones should be measured to exclude a hormone-secreting tumor. Serum and urine toxicology should be checked if laxative abuse by the mother is suspected.

Radiological studies are rarely informative but barium meal and follow-through will exclude malrotation and may occasionally demonstrate a blind loop. Endoscopic evaluation of the upper and lower gastrointestinal tract is often helpful and multiple biopsies may be taken for examination by light and electron microscopy in addition to obtaining fluid from the lumen of the gut, which should be screened for the presence of pathogens.

## TREATMENT

The management of the infant with protracted diarrhea depends on the cause and the severity of the condition. In many cases dietary manipulation is the mainstay of management as appropriate exclusion diets often reduce the volume of diarrhea. A hypoallergenic feed should be used, either as a complete amino acid based feed (Neocate, Scientific Hospital Supplies), peptide based (Nutramingen, Mead Johnston) or as a modular feed where the protein, carbohydrate and fat content can be varied independently. The assistance of an experienced pediatric dietitian is essential in the management of any infant with protracted diarrhea. Those infants who are severely malnourished or who do not respond to enteral feeding and dietetic management may, in addition, need a period of i.v. feeding. If this fails to resolve the problem, long-term PN or even gut transplantation need to be considered.

In certain situations drug therapy may be beneficial. If there is evidence of bacterial overgrowth and bile salt degradation, colestyramine and antibiotics may help the situation. Antisecretory agents such as

**Table 19.24** Stool analysis in osmotic and secretory diarrhea

	Osmotic	Secretory
Osmolality (mOsmol/L)	400	290
Na <sup>+</sup> (mmol/L)	30	105
K <sup>+</sup> (mmol/L)	30	40
(Na <sup>+</sup> + K <sup>+</sup> ) × 2	120	290
Solute gap (mmol/L)	280	0

chlorpromazine, octreotide and loperamide may be beneficial in some cases where the primary pathology is not reversible.

In general terms, for those children who present several weeks or months after birth the prognosis is good, while for those who present at birth with an intractable secretory diarrhea the prognosis is poor and the mortality rate high.

## INTESTINAL FAILURE

### DEFINITION AND PREVALENCE

Intestinal failure is defined as the inability of the alimentary tract to digest and absorb sufficient nutrients to maintain normal fluid balance, growth and health. Acute intestinal failure is relatively common and self-limiting, for example, surgical treatment for an ileal atresia, or an episode of rotavirus gastroenteritis. Chronic intestinal failure resulting in dependence on i.v. feeding/PN is less common and is variously defined as intestinal failure persisting for 4, 6 or 8 weeks. In the United Kingdom period prevalence varies from 4.5 per million population in Wales to 14.3 per million in Scotland, 12.5 per million in Northern Ireland and 9.5 per million in England. This does not take account of the number of patients, especially children, who remain hospitalized long term, because of social factors or complications related to intestinal failure. Whatever the precise number of children affected, the prevalence of treated intestinal failure is increasing. The administration of PN either at home or in hospital is complex with many potential, even life-threatening complications, which means that patients with intestinal failure benefit from early referral to a multidisciplinary team experienced in the management of this highly technical therapy.<sup>61-63</sup>

### ETIOLOGY

The vast range in functions and huge physical dimensions of the gastrointestinal system, mean that the possible causes of intestinal failure are numerous and often overlap with disorders in other systems. Broadly, there are three categories of intestinal failure: disorders related to reduced surface area or intestinal mass (e.g. short gut syndrome), disorders of motility (e.g. Hirschsprung disease) and disorders of the mucosa (e.g. microvillus inclusion disease) (Table 19.25). Intestinal failure may be caused by a primary disease of the gastrointestinal tract or it may be secondary to disease in other systems (e.g. immunodeficiency).

### Clinical presentation at different ages

#### *Congenital*

Intestinal failure may present antenatally or in the neonatal period, where it tends to have a congenital cause. Polyhydramnios is an important sign common in conditions in which the gastrointestinal tract produces excess secretions as in microvillus inclusion disease. The antenatal ultrasound

may show distended loops of bowel in the second trimester in babies who develop features of pseudo-obstruction, and gastroschisis can be diagnosed from 12 to 14 weeks' gestation. Antenatal diagnosis is important as it allows the parents to be prepared and for delivery to take place in a unit with rapid access to a neonatal surgical facility.

The cardinal symptoms of intestinal failure are vomiting (with or without bile), abdominal distension, protracted diarrhea, and constipation. These symptoms will be rapidly followed by dehydration, weight loss, shock and renal failure (Table 19.26). Perhaps the most sinister symptom in babies is that of a secretory diarrhea such as occurs in microvillus inclusion disease. In this condition large volume watery diarrhea is uninfluenced by restricted intake. Such diarrhea can be mistaken for urine, with the result that the severity of illness is not recognized until renal failure develops. Another diagnostic pitfall is when the symptoms are intermittent, as can occur in midgut malrotation and which may present at any age with pain and vomiting with spontaneous remissions when the associated volvulus untwists and frees the mesenteric blood supply. Once a midgut volvulus is recognized it is usual to proceed to an operation to fix the bowel (Ladds procedure) and prevent ischemia of the midgut.

Malabsorption may be the predominant problem in children with short gut or mucosal disorders; this is manifested by diarrhea which is exacerbated by feeding. Clinical signs of malabsorption include: excoeriated perineum secondary to carbohydrate malabsorption, edema secondary to protein-losing enteropathy and bulky offensive stools secondary to fat malabsorption.

The presence of opportunistic infections such *Candida* species and *Cryptosporidium parvum* indicates the possibility of immune deficiency either primary or acquired as a result of infection by human immunodeficiency virus (HIV). Granulomas may be present on mucosal biopsy, which may suggest an autoimmune enteropathy if Crohn's disease and mycobacterial infection have been excluded.

#### *Acquired*

During infancy and childhood the causes of intestinal failure are usually of an acquired nature such as ischemia, trauma and food antigen intolerance (celiac disease usually presents in patients from 9 months of age and older). Fabricated or induced illness is an important diagnosis to consider in a child whose symptoms were not apparent until months or years after birth and in whom the disease appears to be relentlessly progressive despite visits to more than one expert center. Usually such cases do not have a clear diagnosis, but have been labeled 'atypical pseudo-obstruction' or 'protracted diarrhea'.<sup>64</sup>

### INVESTIGATIONS

A detailed history and examination including height, weight, midarm circumference, triceps skin fold and head circumference should be carried

Table 19.25 Causes of intestinal failure. Examples in brackets (also see Table 19.23)

	Primary gastrointestinal disorders	Secondary gastrointestinal disorders
Reduced surface area or mass	Gastroschisis Small bowel atresia Mid-gut volvulus Necrotizing enterocolitis Crohn's disease	Gardener syndrome Meconium ileus equivalent (cystic fibrosis) Vascular accident (mesenteric artery thrombosis)
Motility disorder	Aganglionosis (Hirschsprung disease) Megacystis microcolon syndrome	Tumors secreting vasoactive substances (VIPoma) Inappropriate use of purgatives (Munchausen by proxy)
Mucosal lesion	Microvillous inclusion disease Abnormal electrolyte or solute transporters Congenital disaccharidase deficiency Lymphangiectasia Enteropathies (celiac disease, autoimmune) Crohn's disease	Postgastroenteritis viral disease (rotavirus) Ischemia re-perfusion injury after cardiac bypass Mucositis secondary to chemotherapy Graft versus host disease Immune deficiency (see also Table 19.14)

**Table 19.26** Symptoms and signs of intestinal failure

Early	Late
Polyhydramnios	Weight loss
Vomiting	Malabsorption (see also <a href="#">Table 19.11</a> )
Diarrhea	Food aversion
Perineal ulceration	Micronutrient deficiency including zinc
Abdominal distension (and pain)	Water and fat-soluble vitamin deficiency
Weight loss	Abdominal pain (colicky)
Electrolyte imbalance	Edema
Convulsions	Opportunistic infection

out. Blood and urine tests should be done with the aim of identifying the extent of illness, devising a management plan and making a diagnosis ([Table 19.27](#)). In addition radiology, histopathology and evaluation of intestinal motility are key investigations in arriving at a diagnosis.<sup>63</sup>

## MANAGEMENT

### Multidisciplinary team

Children with intestinal failure will require urgent resuscitation, initially rehydration with saline and glucose and usually followed by PN if it is clear that intestinal failure is either life threatening or likely to persist for some weeks. Most hospitals have guidelines for prescribing PN which should avoid over- and underprovision of calories since both can cause liver dysfunction. After initial resuscitation a team consisting of dietitian, specialist nurse, pharmacist, pediatric gastroenterologist, radiologist and surgeon should establish the diagnosis, prognosis and plan treatment. For patients with a purely medical cause for intestinal failure, the role of the surgeon will be limited to careful placement of central venous feeding catheters to minimize trauma to major veins

and the superior vena cava in particular. However, patients with short gut will require frequent review by the multidisciplinary team as the maturing and adapting intestine becomes capable of absorbing greater volumes of feed, which should be supervised by a pediatric dietician. If intestinal adaptation does not occur, the presence of strictures, blind ending loops and dilated nonpropulsive bowel should be considered, since well-timed surgery will facilitate reduced dependency on parenteral nutrition.<sup>62</sup>

### Dietetic management

In brief four main themes can be identified:

1. Establish oral feeding including sucking and chewing as soon as practical. Even if the quantity of nutrition consumed is negligible, the positive effects on development in speech, social skills and physiology of the upper intestinal tract are great. When it is available, breast milk is ideal, otherwise a hydrolysate is frequently used initially (e.g. Peptijunior, Pregestimil, Neocate) for neonates who have immature pancreatic function and an intestinal mucosal barrier which is still highly permeable to foreign proteins.
2. Initiate continuous nasogastric tube feeding in short gut patients in order to promote intestinal adaptation. Oral feeding is also important and the usual compromise is to offer bottle or bolus feeds during the day and feed by infusion pump for 12–18 h overnight.
3. If feed tolerance is poor consider the use of a modular feed in which the carbohydrate, fat and protein components can be varied independently of each other to achieve a more digestible feed (e.g. less carbohydrate for infants with short gut, medium chain fat for children with lymphangiectasia). Pharmaceutical agents to improve gastric emptying (e.g. domperidone), or to slow transit time (e.g. loperamide 50–200 µg per kg per dose, two to four times per day) can be used in conjunction with manipulations to the feed.
4. Keep micronutrient balance (e.g. fat-soluble vitamins and trace elements) and sodium balance under regular review in case supplements to the feed are necessary.

**Table 19.27** Investigations in intestinal failure: acute (less than 4 weeks old); chronic (more than 4 weeks old)

	Acute (less than 4 weeks old)	Chronic (more than 4 weeks old)
Key clinical facts to be elicited	Vomiting related to feeding or not Bile present in vomitus? Presence of pain Nature of diarrhea: watery, offensive, blood present?	Symptoms are static, improving worsening? Which is the dominant symptom? Does the diarrhea reduce when nil by mouth (osmotic), or is it similar in fasting and fed state (secretory)
Biochemistry	Blood Urine Stool	Liver function tests, parathyroid hormone Urinary sodium:potassium ratio Stool electrolytes (? sodium losing diarrhea; see also <a href="#">Table 19.24</a> ) Intestinal transit time by the appearance of orally administered pigment in stool (e.g. Carmine red) Fecal alpha-1 antitrypsin concentration
Hematology	Full blood count (polycythemia ?dehydrated) blood film (?fragmented cells as in hemolytic uremic syndrome)	Full blood count, anemia, also note neutropenia (Shwachman syndrome), lymphopenia (lymphangiectasia) Coagulation profile (? vitamin K malabsorption)
Radiology	Plain abdominal X-ray (gas pattern, intramural gas?, calcification) Abdominal ultrasound to identify cystic lesions, e.g. pancreatic pseudocyst	Small bowel contrast study (provides information about malrotation, reflux, motility disorders) Scintiscanning (gastric emptying) Abdominal ultrasound to identify portal hypertension Venogram if difficulty with central venous access
Manometry		Esophageal, upper small bowel and rectal manometry, depending on likely site of lesion
Histopathology	Mucosal biopsy Full thickness biopsy of large bowel and proximal bowel if indicated	Duodenal or jejunal tissue for disaccharidase measurement Liver biopsy, repeat intestinal mucosal biopsy

## Avoidance of complications

### Infection

The child with intestinal failure is susceptible to serious infections mainly via the i.v. feeding catheter. Skin organisms which have colonized the catheter via the hub and access ports can cause major systemic upset in the presence of the PN solutions. Less frequently bacteria from the bowel appear to translocate to the circulation. Infection from any source however is a risk factor for hepatic impairment, especially in the preterm infant who will become chronically cholestatic after two or three infections when such infections occur within months of birth.<sup>65</sup> Sepsis at any age diminishes transport of bile from hepatocytes into bile canaliculi, leading to retention of bile salts, which itself leads to disruption of hepatocyte function.<sup>66</sup> Other risk factors include overprovision of nutrients, which is associated with depletion of glutathione, induction of steatosis, and lipids especially if the daily infusion rate exceeds 3.5 g/kg. Avoiding sepsis depends on good hygiene and restricting the number of individuals who have access to the feeding catheter. In France it has been shown that patients discharged home on PN had one tenth the incidence of central line infections compared to hospitalized patients.

### Hepatic

In patients fed by the i.v. route, purified nutrients consisting of simple glucose, essential amino acids, and triglyceride (derived from soya oil) are delivered to the hepatic sinusoids via the hepatic artery without the benefit of intestinally derived growth factors. This may explain the frequently observed phenomenon of fatty liver in parenterally fed patients (see also Table 19.28). Patients who are fed exclusively by the parenteral route are more likely to experience cholestasis. Total enteral starvation deprives the liver of intestinally derived growth factors and hormones including cholecystokinin and is associated with reduced portal blood flow, reduced bile secretion at canalicular level and impaired motility of the large bile ducts. Other risk factors for cholestasis include:

1. Prematurity since the immature liver is unsuited structurally (paucity of bile ductules) and physiologically (detoxification and conjugation and transsulfuration pathways are inadequate<sup>66</sup>) to handle nutrients which have not been processed by the placenta or only partly digested in the immature intestine. The majority of babies less than 28 weeks' gestation who receive PN after surgery become cholestatic;<sup>65</sup>
2. Emergency abdominal surgery, especially if it leads to short gut syndrome;
3. Lack of a multidisciplinary care team.<sup>61,67</sup>

Avoiding liver damage therefore depends on establishment of oral feeding as soon as possible, rigorous hand washing routine and a low threshold for suspecting and treating infection.

### Thromboembolism and thrombosis

This is more commonly a complication of long-term PN, although there are case reports of extensive thrombosis of the inferior vena cava occurring a few days after insertion of a femoral line. A review of patients at Great Ormond Street Hospital, England showed that 30% of patients on long-term PN had evidence of pulmonary embolus, and around 10% of children referred for small bowel transplantation had superior vena cava thrombosis; most such children have a history of 10 or more insertions of the feeding catheter.<sup>68</sup> Strategies for avoiding this complication have been reviewed by European Society of Paediatric Gastroenterology Hepatology and Nutrition (ESPGHAN) and the following treatments

are used: oral warfarin, oral aspirin, heparin added to the vamin component of the PN solution. The use of ultrasound to locate veins, and the designation of a senior surgeon to be responsible for line insertion are recommended good practice.

### Social isolation

The nursing skills which parents are obliged to learn and the need to protect their child from accidental damage to his feeding catheter mean that some families are disinclined to travel outside their home except for hospital visits. The involvement of a social worker, specialist nurse and play specialist are vital in encouraging the child and family to integrate in society, to benefit from education and to make adequate developmental progress despite the restrictions of PN. Contact with self-help groups such as Patients on Intravenous and Nasogastric Nutrition Therapy (PINNT), who have a children's section, Half-PINNT and the Children's Liver Disease Foundation (CLDF) can be encouraged (see [Charities and Organizations](#), p. 654).

## Surgical

### Nontransplant surgery

This consists of a range of surgical operations ranging from those which are consequent on the primary procedure such as closure of a stoma previously created to treat a bowel perforation, to identification and repair of strictures, to reconstruction of residual intestine. The indications and timing for reconnection surgery are usually clear, but intestinal lengthening and tapering operations remain somewhat controversial. Since some poor early experiences in which prolonged surgery was carried out in infants already experiencing hepatic complications, it is now recognized that longitudinal intestinal lengthening and tapering operations (the Bianchi procedure) are more successful in children with dilated nonpropulsive bowel who are at least 12 months old and in whom intestinal adaptation appears to be static. Nontransplant surgery for short gut is likely to proliferate as innovative surgeons describe techniques such as the creation of artificial strictures and reverse segments for expanding the residual bowel prior to lengthening and tapering.<sup>69</sup> Patients who have been referred for possible small bowel transplantation may be suitable for this kind of nontransplant surgery, so it is important for specialist teams to network even when operating in different institutions.<sup>62</sup>

### Isolated liver transplantation in short bowel syndrome

For a small group of patients who could be expected to be weaned off PN by the age of 5 years because they have at least 40 cm residual small bowel and have tolerated significant amounts of enteral nutrition, the option of isolated liver transplant rather than combined liver and bowel transplant, could be considered if they develop liver failure whilst still dependant on PN. This is a challenging group with a prolonged postoperative recovery time who require careful selection and the involvement of a multi-disciplinary team.<sup>62,63,66,67,69</sup>

### Small bowel transplantation

The small bowel, being a hollow viscous contaminated with bacteria, liable to autolysis and prone to intense rejection, has proved to be difficult to transplant, but experience is increasing rapidly with 180 patients per year receiving grafts, and results are improving to the point where they are starting to parallel the outcome of i.v. nutrition.<sup>70</sup> Since 2000, breakthroughs in the form of monoclonal antibodies targeting the receptors for triggering rejection (anti-CD 25 receptors on T lymphocytes) and the other therapies for depleting lymphocytes such as: (1) administering humanized monoclonal anti-thymocyte globulin, (2) pre-treatment of the recipient with Campath, and (3) pre-treatment of the small bowel allograft with anti-lymphocyte globulin have been described. The main gain in these new approaches is the reduction in tacrolimus and steroid exposure and is associated with 1-year survival rates in the order of 80–100%.

The 3- and 5-year survival reported from the Intestinal Transplant Registry remains at 50%; however, results are somewhat better in

**Table 19.28** Complications of parenteral nutrition upon the liver

Biliary sludge, gall stones and occasionally cholecystitis
Steatosis which may be intense and lead to hepatomegaly and fibrosis
Fibrosis which may be portal and within the parenchyma ('pericellular fibrosis')
Cirrhosis and portal hypertension

individual busier centers (Pittsburgh, Omaha, Miami) where 25–50 transplants per center are performed annually and in which 3-year survival has exceeded 65% since 2001.<sup>70,71</sup> Nevertheless, this still means that the transplant option is generally reserved for patients with life-threatening complications such as PN-related liver disease or recurrent line sepsis.

**Indications for referral.** Most transplant centers are prepared to review patients with intestinal failure at any stage, but recommend early referral if the child is becoming progressively jaundiced (i.e. if plasma bilirubin is in excess of 100  $\mu\text{m/L}$ ), where there are problems with maintaining fluid balance despite the provision of PN, or if there are complications associated with placing a feeding catheter.<sup>72</sup> Results from the international transplant registry and the UK<sup>67</sup> clearly show that delayed referrals have an adverse impact on survival: the difference in survival between adult patients who are hospitalized (40–60%) versus those who are still at home (80–100% survival) when called to transplant makes it almost unethical to delay evaluating patients for small bowel transplantation once they start experiencing complications on home PN. Patients who have developed a thrombosis of the superior vena cava may become impossible to cannulate safely and require stenting of the superior vena cava<sup>68</sup> to maintain them prior to isolated bowel transplant provided their liver function is satisfactory. Failure to progress with intestinal adaptation and tolerance of enteral feeds in patients with short gut may also prompt a referral.

**Types of intestinal transplants** (see Fig. 19.9). Of the 989 intestinal transplants carried out in 923 individuals and reported to the Intestinal Transplant Registry 2003 (<http://www.intestinaltransplantregistry.org/>), 606 were children. Half ( $n = 306$ ) were combined procedures with liver and bowel, 37% were isolated small bowel transplants and about 13% multivisceral involving variously stomach, colon, pancreas, kidney combined with small bowel and liver grafts. In infants for whom small donors are very scarce, a technique to cut down the size of organs from donors up to five times the size of the patient has been developed<sup>73</sup> (see Fig. 19.9c). The survival after isolated bowel transplant is better in the first 12 months (90% compared with 70% for combined liver and bowel transplants), but the long-term complications of rejection and opportunistic infections are similar, resulting in a 3–5-year graft survival, which is no different when compared to combined liver and bowel grafts.

**Complications.** The complications related to small bowel transplantation are numerous.<sup>74</sup> Early complications are generally related to the surgery and the consequences of organ preservation and reperfusion. These include perforation of native bowel and transplanted bowel (30% in pediatric series), bile leaks, pancreatitis, stomal prolapse, ileus and translocation of enteric bacteria to the liver and systemically via the portal vein. Unlike isolated liver transplantation, thrombosis of the splanchnic vasculature (i.e. portal vein, hepatic artery) is almost unheard of because the anastomoses are large, usually being made between the aorta on the arterial side and inferior vena cava on the venous side.

**Fig. 19.9** Anatomical sketch of (a) isolated small bowel allograft, (b) combined liver and small bowel allograft, and (c) reduced en-bloc liver and small bowel allograft. (Line drawing by J de Ville de Goyet)

Early medical complications include generalized edema secondary to fluid retention, ileus secondary to morphine, acute cellular rejection of the small bowel allograft and infection by enteric bacteria. Rejection of the small bowel is common and causes fever, deterioration in absorption of feed and changes in the morphology of the mucosa (apoptosis combined with a mixed inflammatory infiltrate). Severe rejection is less common since the advent of monoclonal antibodies active against T cell receptors which mediate rejection, but it is important to treat promptly as untreated rejection may progress rapidly to severe rejection in 12–48 h. This can be life threatening with full-thickness lesions associated with bloody diarrhea, peritonitis and systemic sepsis from escaping enteric bacteria.

The long-term complications are mainly related to opportunistic infections including cytomegalovirus, cryptosporidiosis, mucosal fungal infections and EBV. The EBV is a particularly important complication for children after intestinal transplantation in whom it is often a primary infection. In the context of selective T lymphocyte inhibition induced by tacrolimus treatment, the B lymphocytes infected with the EBV proliferate greatly and may become malignant, resulting in post-transplant lymphoproliferative disease (PTLD). Up to 30% of small bowel transplant recipients in the transplant program in Pittsburgh developed PTLD within 2 years of transplantation with half (15% overall) eventually died from this complication. Optimal management requires routine testing for EBV genome copies in blood using PCR techniques and the use of antiviral agents such as ganciclovir and rituximab (an anti-CD20 antibody which destroys B lymphocytes) which has brought about an improvement in the outcome of PTLD since 2000. Chronic rejection appears to be a vascular phenomenon in which the mesentery of the distal bowel in particular becomes infiltrated with inflammatory cells, leading to occlusion and ischemia. The early symptoms are subtle, resembling an intermittent distal ileal obstruction syndrome. Small bowel transplant recipients also experience the usual childhood infections such as otitis media and viral gastroenteritis, notably rotavirus and adenovirus; the latter can be severe and necessitate a temporary resumption of PN to hasten recovery.

**Outcome.** Historically, one in five small bowel transplant recipients did not survive the early postoperative period, reflecting their poor condition at the time of surgery. However, those children who are discharged from hospital do well, with 90% completely independent of PN and maintaining normal growth rates. The number of appliances such as Broviac lines, nasogastric tubes, gastrostomy tubes, and stoma bags reduces steadily in the 3 years after transplant. Most families report a sense of greater freedom and improved quality of life compared with that which they experienced with i.v. feeding before the transplant.

## INTESTINAL FAILURE AND QUALITY OF LIFE

Measurement tools for quality of life are numerous,<sup>75</sup> but the most commonly used ones appear to be questionnaires in which the subject chooses one of five possible choices in response to questions about emotions (hopes and fears), physical function, pain, relationships (e.g. The General Health Questionnaire [GHQ], The Nottingham Short Form-36, The Euro-Qol Questionnaire), and semi-structured questionnaires which allow a more individualized response by the subject. In children on PN, it is clear that families cope with the demands of home PN by developing obsessive/neurotic traits and that there is a high incidence of depression among them compared with the general population. In the case of children after small bowel transplant, a study from the Nebraska medical center showed an improved quality of life as rated by the children themselves after the transplant, although their parents expressed different perceptions and did not score so highly for quality of life.<sup>76</sup>

## PROGNOSIS

Although chronic intestinal failure is a disabling condition with long-term implications for the child's development and carers, medical

advances have improved survival and allowed such children to be kept alive and even discharged home with good quality of life.<sup>63</sup> In children without major complications the 5-year survival rate is around 95%.<sup>67</sup> In contrast, children who develop serious complications, especially cholestasis, are at risk of early death from overwhelming sepsis. Of 55 children assessed at the Birmingham Children's Hospital (England) and considered to fulfill criteria for intestinal transplantation between 1993 and 2003, 20 died of infection and/or liver failure before they could be transplanted. Children with intestinal failure who are experiencing a delay in being discharged on home PN, or deteriorating despite home PN, should be referred for assessment by a multidisciplinary team, which includes gastroenterologists working with a transplant team, to allow them to have the opportunity to have their intestinal failure treated by the full range of medical and surgical options in an integrated manner up to and including intestinal transplantation.<sup>62,70</sup>

## THE COLON

### STRUCTURE

The colon is a long hollow tube which, with the exception of the sigmoid, which has a short mesentery, lies retroperitoneally. Along its length from the ileocecal valve to the anus the mucosa is lined by a cuboidal epithelium which is indented with crypts. The mature colon has no villi and no brush border disaccharidase activity. Submucosal and myenteric nerve plexuses are present, similar to those in the small intestine, but the smooth muscle layers differ in that the longitudinal layer is incomplete, forming three tenia coli.

### FUNCTION

The large intestine fulfills both storage and salvage functions. The colon stores the intestinal contents prior to excretion, but it is also an organ of conservation which reduces liquid ileal effluent to solid feces excreted via the anus. It plays an important role in the salvage of electrolytes and water, and in addition, the salvage of nutrients in the form of short chain fatty acids.

#### *Absorption*

Although it is clear that the majority of water and electrolyte absorption occurs in the small intestine, it is often the adequacy of colonic function which determines whether the child experiences diarrhea, and whether or not there is net loss of water and electrolytes from the body. In small intestinal disease there is an increase in the volume of fluid arriving at the ileocecal valve but the colon has a reserve reabsorptive capacity which can adequately absorb the excess ileal effluent. When there is massive small intestinal secretion, the reserve reabsorptive capacity of the colon may be overwhelmed, resulting in diarrhea. In addition, in disorders which compromise colonic function such as inflammatory bowel disease (IBD), diarrhea may occur as a result of either reduced colonic absorptive capacity or frank colonic secretion.<sup>77</sup>

The importance of the colonic sodium absorptive mechanism is demonstrated clinically by the high rate of sodium supplementation necessary for normal growth in infants with ileostomies. The majority of sodium absorption occurs via an active, electrogenic mechanism, while chloride is absorbed down its electrochemical gradient. Potassium is secreted into the lumen, largely in response to electrochemical gradients and, in older children bicarbonate is secreted into the colonic lumen via an exchange mechanism with chloride. It has previously been shown that colonic sodium absorptive processes are already highly efficient in preterm infants and there is evidence that circulating aldosterone levels may be important in the regulation of these mechanisms.<sup>78</sup> In addition to its role in the absorption of water and electrolytes, the colon may also salvage extra nutrient energy from the contents of the gastrointestinal tract via the absorption of short chain fatty acids such as acetate, butyrate and propionate. These are produced by colonic bacterial fermentation of unabsorbed dietary carbohydrate and studies have shown that they are rapidly absorbed from the large intestine, providing a significant

additional source of energy, and also that they promote further colonic salt and water absorption.

The salvage of electrolytes, water and nutrients requires sophisticated integration of the functions of bacterial digestion, epithelial transport and motor activity of the colonic muscle layers. Details of colonic motility patterns are scanty in childhood, although a major proportion of the total mouth to anus transit time occurs in the large intestine.

## INFLAMMATORY BOWEL DISEASE

Although infective agents are the commonest cause of IBD in a worldwide context, the term will be used in this section to describe chronic inflammation of the gastrointestinal tract in the absence of a detectable pathogenic agent. Included in this definition in descending order of importance are Crohn's disease, ulcerative colitis and allergic colitis. In addition, the term 'indeterminate colitis' has been employed to describe children with colitis which is impossible to precisely categorize at presentation: the final diagnosis may often only become evident in these patients with the lapse of time and further, or repeated, investigation.

### EPIDEMIOLOGY

The prevalence of Crohn's disease in both Wales and Scotland<sup>79,80</sup> appears to have increased in the 1980s and 1990s, with the incidence of Crohn's being at least twice as common as ulcerative colitis. In Sweden, the incidence of pediatric IBD has also increased over a 10-year period,<sup>81</sup> although in contrast to the UK this was primarily an increase in ulcerative colitis. A prospective study of pediatric IBD in the British Isles, from the British Paediatric Surveillance Unit (BPSU), has suggested an estimated incidence of IBD of 5.3 per 100 000 children under the age of 16, equivalent to about 700 new cases per annum in the UK, with Crohn's disease again being twice as common as ulcerative colitis.<sup>82</sup> This study suggests that 10% of patients may be of Asian origin (an over-representation compared with the overall population) with some 5% of patients from the Afro-Caribbean population. There is a slight male preponderance (58%). In childhood the peak in incidence is between 11 and 13 years, although 13% of cases in the recent BPSU study developed in children aged less than 10 years. Although Crohn's disease and ulcerative colitis may present in early childhood, it seems likely that many cases of colitis presenting in the first 2 years of life may be related to food allergy that responds to an appropriate exclusion diet, and with a favorable long-term prognosis.<sup>83</sup>

### ETIOLOGY/PATHOPHYSIOLOGY

The etiology and pathogenesis of Crohn's disease and ulcerative colitis are unknown despite many theories and much painstaking research work.<sup>84,85</sup> There is no doubt that there is a genetic preponderance for both diseases and twin studies suggest a much higher concordance in monozygotic than in dizygotic twins. It is likely that Crohn's disease and ulcerative colitis are related polygenic diseases,<sup>86</sup> and genome-wide linkage studies have identified a number of possible susceptibility genes, involving several chromosomes with some loci being more specific for UC and some for CD including the CARD15 gene (previously known as NOD2) on chromosome 16q.<sup>87</sup> Some genes influence disease susceptibility while others only affect the course of the disease and more research is needed on the significance of the genotype and phenotype interactions.

Multiple immunological abnormalities have been described in patients with IBD but none has convincingly been shown to be a primary pathogenetic event. Environmental factors such as bacterial pathogens or their products, dietary components and intercurrent infections appear necessary to trigger and maintain the diseases and may well interact with specific genes. The basic problem appears to be an over-stimulation or over-reaction of the mucosal immune system to a particular antigenic stimulus in genetically susceptible individuals although the antigenic stimulus, such as a microorganism or food antigen, may vary from case to case. Though there has been controversy over the role of the measles virus, and indeed the measles mumps rubella (MMR) vac-

cine, there is no convincing evidence that this is related to the development of IBD. Infectious agents have been postulated as playing a major role but so far the evidence is inconclusive. There is no conclusive evidence for causal associations for any environmental exposure in the etiology of Crohn's disease or ulcerative colitis, although there is strong evidence incriminating dietary allergens, particularly dairy produce and soya milk, in the pathogenesis of allergic colitis in younger children.

Studies have, however, shown that intestinal permeability may be increased in Crohn's disease and it is conceivable that this could result in an increase in absorption of antigens from the gut, which may be important in the pathogenesis of the disease. Finally, it has been suggested that psychosomatic factors may be important and a 'colitis personality' was previously defined. However, several studies have not supported this concept and it is hardly surprising that there may be a higher incidence of emotional problems and depression found in sufferers and their families as a consequence of their chronic, debilitating disease. Thus adequate psychological and emotional support from health care staff is of paramount importance in the management of children with IBD. Adequate communication is vital, and several self-help groups publish helpful booklets and can provide additional support and information for the child and family (see [Charities and Organizations](#), p. 654).

## CROHN'S DISEASE

### Pathology

The disease may involve any part of the gastrointestinal tract from the lips to the perianal area, and normal bowel may be found in between affected areas. The inflammation is transmural, often extending from the mucosa to the serosal surface, resulting in sinus tracts or fistulae formation. In childhood disease, terminal ileitis is common with variable involvement of the colon in 50–70% and the recent UK British Paediatric Surveillance Unit study<sup>82</sup> suggested that one third of patients have small intestinal disease, one third ileocolitis and one third colitis, with total colitis being more common (50%) than segmental colitis or isolated proctitis. Macroscopically, the bowel mucosa may look inflamed, and small shallow, aphthoid or linear ulcers may be present. Later on in the disease, deeper fissures may occur, leading to the classic 'cobblestone' appearance of the mucosa, as well as stricturing of the bowel. Histologically, there is transmural inflammation and the diagnostic hallmark is the finding of noncaseating epithelioid granulomata with giant cells which may not be present in all affected tissues.

### Clinical features

The insidious onset and subtle nature of the symptoms and signs of Crohn's disease often result in a considerable delay in diagnosis with left-sided colonic disease being usually diagnosed more rapidly than diffuse small intestinal disease. The manifestations of the disease depend upon the site of involvement but periumbilical, colicky abdominal pain, diarrhea with or without blood and growth failure are the commonest forms of presentation. Occasionally more subtle manifestations, such as oropharyngeal disease, perianal skin tags and fissuring or growth failure, may be the first signs of the disorder in the absence of overt gastrointestinal symptoms. The diarrhea in Crohn's disease is likely to be due to a combination of several factors which may include mucosal dysfunction, bile acid malabsorption, bacterial overgrowth and protein exudation from inflamed bowel.

On examination, it is important to ascertain whether extraintestinal manifestations of Crohn's disease are present. Thus there may be intermittent pyrexia, clinical anemia, arthralgia and arthritis, uveitis, finger clubbing, perianal disease (skin tags, bluish discoloration, fissures, fistulae), oral ulceration, skin manifestations (erythema nodosum and pyoderma gangrenosum), signs of liver dysfunction and evidence of growth failure and delayed sexual maturation. Examination of the abdomen may reveal generalized or localized tenderness and occasionally an ill-defined palpable mass. The importance of growth retardation and pubertal delay must be emphasized as it may occur in up to 30% of children with Crohn's disease and may be present well before the diagnosis is made.<sup>88</sup> There is little evidence that this is due to a primary endocrine disturbance

and the most likely reason for growth failure is nutritional deprivation or a direct effect of inflammatory molecules such as cytokines on the growing skeleton. Growth failure must be detected earlier as there is evidence that this can be successfully reversed by prompt treatment.<sup>89</sup>

Osteopenia has been recognized as an important complication of IBD, particularly in children with Crohn's disease and, although the mechanisms are not yet fully elucidated, the cause appears to be a combination of both the disease itself and drug treatment with steroids.<sup>90</sup>

### Diagnosis

Laboratory assessment involves the search for infective agents in the stools of patients with Crohn's disease presenting with diarrhea. Hematological investigation often reveals iron-deficiency anemia and acute phase reactants such as erythrocyte sedimentation rate (ESR) and C reactive protein (CRP) may be elevated, although not universally. Thrombocytosis and hypoalbuminemia may also be present and these appear to be more reliable markers of disease activity. Plasma zinc levels are frequently low and liver function tests may be abnormal. It should, however, be remembered that alkaline phosphatase is a zinc-dependent enzyme which may be spuriously depressed in the presence of zinc deficiency. Recent studies also suggest that measurement of stool calprotectin, a protein secreted into the gut by lymphocytes, is a reliable indicator of intestinal inflammation.<sup>91</sup>

Radiological assessment is important and plain abdominal X-rays may reveal evidence of intestinal obstruction or bowel dilatation. A barium meal and follow-through is vital in order to assess the small bowel and, although a small bowel meal (via a transpyloric tube) is the most sensitive technique, this is not always acceptable as it may be particularly uncomfortable for the child. The presence of skip lesions, with narrowing of the lumen, thickening and fissuring ('rose-thorn ulcers') of the bowel wall and fistulae formation are all highly suggestive of Crohn's disease (Fig. 19.10).

Technetium white cell scanning has been suggested as a useful investigation for initial screening/follow-up but there is continued debate about the sensitivity and specificity of this investigation.<sup>92</sup> With proper bowel preparation, magnetic resonance imaging of the small intestine is possible and virtual colonoscopy using computerized tomographic scan-

Fig. 19.10 Extensive narrowing of the ileum in a child with small intestinal Crohn's disease. (Reproduced by kind permission of P J Milla)

ning is available in some centers. Small bowel disease may be detected by capsule endoscopy although this investigation is contraindicated if a stricture is present. The main weakness of all these techniques is that they do not allow mucosal biopsy.

Endoscopy remains the most important tool for assessing both the upper gastrointestinal tract and colon (Fig. 19.11), and colonoscopy has superseded the barium enema as the primary investigation of the lower bowel. Several authors have suggested that upper intestinal endoscopy should be performed at the same time as colonoscopy, as a majority of patients with IBD may show histological abnormalities in the upper gastrointestinal tract, which may be useful in diagnosis.

## Treatment

The goal of therapy is both to induce and maintain a remission of active disease and also to correct malnutrition and promote growth. Two main treatment modalities are available, one being drug therapy and the other nutritional therapy. They can if necessary be combined. They are

(a)

(b)

Fig. 19.11 The colonoscopic appearance in (a) a normal child with the mucosal blood vessels clearly seen and (b) in a child with Crohn's disease showing 'snail tract' ulceration and loss of the vascular pattern of the mucosa. (Reproduced by kind permission of P J Milla)

probably both equally effective with drug therapy being preferred where disease is localized to the colon, weight has been maintained and compliance with nutritional therapy is likely to be problematic. Where there has been significant weight loss prior to diagnosis and small bowel disease is present, nutritional therapy is to be encouraged. Where these treatments fail surgical intervention may be required.

## Drug therapy

There is no convincing evidence that any drug alters the long-term natural history of Crohn's disease, but several agents have a place in the treatment of the disorder. Steroids may induce remission in over 70% of patients and prednisolone should be given in an initial dose of 2 mg/kg/d (max. 40–60 mg) with a gradual reduction after 2–4 weeks, preferably to an alternate-day regimen in order to minimize the growth-suppressive side-effects. There is no good evidence that low-dose steroid therapy can maintain remission and, if possible, steroid therapy should be gradually reduced over a further 6–8 weeks and stopped if the disease is quiescent.<sup>93</sup>

5 amino salicylic acid (5ASA) drugs such as mesalazine slow release (15–20 mg/kg [max. 1 g] three times a day) and sulfasalazine (50–80 mg/kg/d) are useful in the treatment of active Crohn's colitis in inducing remission, although there is little evidence that continuous therapy will maintain remission. The pure 5ASA preparations such as mesalazine have fewer site-effects than sulphasalazine and are therefore now used as the preparation of first choice. There is an increasing use of immunomodulatory drugs, such as azathioprine and 6-mercaptopurine, which allow reduction or cessation of steroids and also help to maintain remission. However, although very useful, such drugs are potentially hazardous and their use should be monitored carefully. Metronidazole may be effective in colonic and particularly perianal disease although peripheral neuropathy may develop with its long-term use. In children who are acutely toxic and systemically unwell on presentation, it is reasonable to start i.v. broad-spectrum antibiotics, including metronidazole, in addition to i.v. steroids until the disease begins to remit. Where perianal disease is troublesome topical treatment with tacrolimus 0.1% may be helpful.

There are potential advances in the use of new biological drugs such as anti-TNF alpha monoclonal antibodies. Inflammatory cytokines (such as TNF alpha) tend to be consistently elevated in the mucosa and the anti-TNF alpha monoclonal antibody shows promise as an agent which, through blockage of TNF, will reduce disease activity in patients resistant to conventional treatment. However, its place in the treatment of children with Crohn's disease is presently being established and concerns still remain about its long-term safety.

## Nutritional therapy

Nutritional therapy is recognized as a very important therapeutic modality in Crohn's disease, not only in the correction of specific nutrient deficiencies, but also in the reduction of disease activity and the reversal of growth failure. Patients may need specific therapy with iron, folate, vitamin B<sub>12</sub> and zinc in addition to ensuring an adequate energy intake via the oral or nasogastric route or indeed via i.v. feeding. Furthermore, nutritional therapy has been shown to be effective in inducing remission of active disease<sup>94</sup> and both enteral and parenteral routes may be used. Over the last decade, there has been increasing use by pediatric gastroenterologists (though less use by adult gastroenterologists) of enteral nutrition as a primary therapy to induce remission. An analysis of five randomized clinical trials comprising 147 children showed that enteral nutrition was as effective as corticosteroids in inducing remission;<sup>95</sup> however there is still debate as to the appropriate place of enteral therapy in the treatment of Crohn's disease and randomized trials involving large numbers of patients are necessary. Several questions remain unanswered, i.e. how the enteral therapy works, whether a polymeric diet is as effective as an elemental diet, whether or not large intestinal disease is treated as effectively as small intestinal disease and the role of on-going maintenance – there is some evidence that intermittent

periods of enteral feeding may maintain remission, but these results need to be confirmed.

### Surgical treatment

The indications for surgical intervention in Crohn's disease include intestinal obstruction, fistula formation, hemorrhage and perforation, and a failure of medical therapy, particularly where there is growth failure. The surgical results in Crohn's disease are most encouraging in children with localized ileal disease,<sup>96</sup> although children with both large and small bowel disease may require reoperation at a later date. Elective surgery is perhaps most important in children nearing puberty with specific growth problems and it is very important to use as an option when the disease is not too extensive and it is feasible to resect the diseased bowel. The early use of surgery can be vital during the narrow window of therapeutic opportunity before the pubertal growth spurt is complete. Colectomy in ulcerative colitis is curative while in Crohn's disease, although surgery may modify the immediate outcome, it does not prevent recurrence.

### Prognosis

The prognosis for childhood Crohn's disease is reasonably optimistic and, although the morbidity is relatively high, the mortality is low. Psychosocial aspects particularly those influencing quality of life are being investigated in the childhood IBD population.

The risk of colorectal carcinoma in children with Crohn's colitis is not well defined although there is a suggestion that the incidence is slightly increased when compared with a control population. Long-term follow-up studies are needed to clarify this point and in the meantime the large intestine in patients with persistent colitis should be inspected regularly by colonoscopy through adult life.

## ULCERATIVE COLITIS

### Pathology

Ulcerative colitis is an inflammatory disease of the large intestinal mucosa and the abnormal changes are seen most commonly in the rectum and distal colon, although the whole colon may be affected. Indeed, pancolitis is the most common form (62%) while disease of the left colon (22%) or rectum (16%) occurs less frequently. Unlike Crohn's disease, the inflammation is continuous and it is usually limited to the colonic mucosa. Macroscopically the mucosa is friable and granular, and ulceration may be present in association with a bloody or mucopurulent exudate. The ulceration, which is often patchy, may be interspersed with areas of regenerating epithelium, resulting in pseudopolyp formation. In addition, there may be an inflammatory reaction in the distal ileum, so-called 'backwash ileitis'. The characteristic histological features are an acute and chronic inflammatory cell infiltrate in the lamina propria, distortion of crypt architecture, the presence of crypt abscesses and goblet cell depletion.

### Clinical features

The commonest presenting features are diarrhea, often associated with blood and mucus, and tenesmus with lower abdominal pain, which is relieved by defecation. Attacks may be graded as mild, moderate or severe depending upon stool frequency, abdominal tenderness, fever and the degree of anemia and hypoalbuminemia. It is important to recognize that 5–10% of patients with ulcerative colitis may present with fulminating colitis associated with toxic megacolon, and a plain abdominal X-ray should be performed to look for the presence of a dilated colon (usually exceeding 6 cm in diameter).

On examination the only positive findings may be minimal lower abdominal tenderness, although in severe disease the child may be pyrexial, dehydrated, anemic and profoundly toxic. It is important to look carefully for evidence of extraintestinal manifestations which are similar to those of Crohn's disease, although growth retardation occurs less frequently in ulcerative colitis and affects less than 20% of patients at presentation.

### Diagnosis

Infective agents such as *Shigella*, *Salmonella*, *Campylobacter*, *Yersinia* and *Entamoeba* may cause an acute or chronic colitis, and it is vital to look carefully for pathogens in the stool and perform appropriate serological tests. Further laboratory assessment may reveal anemia, raised levels of ESR and CRP, leukocytosis and hypoalbuminemia which may reflect the disease activity. Radiological investigations should include plain abdominal X-ray, in patients with severe disease, and a good colonoscopy examination makes barium enema examination unnecessary. Endoscopic evaluation of the whole colon is very useful in assessing both the severity and extent of inflammation. However, the procedure should be deferred, or at least limited, in patients with acute severe colitis because of the risk of toxic megacolon and perforation.

### Treatment

Therapy is directed towards inducing and maintaining remission in mild or moderate disease and may be life saving in fulminating colitis. Patients with mild disease are best treated with mesalazine slow release (15–20 mg/kg [max. 1g] three times a day) or sulfasalazine (50–80 mg/kg/d) and, in those children with disease confined to the distal colon, a topical steroid or 5ASA preparation may be useful. Moderately severe disease (bloody diarrhea five times/d, abdominal pain, fever) may require the addition of oral steroids (prednisolone 1–2 mg/kg/d, max. 40–60 mg) in order to induce remission, and this dose should be gradually reduced after 2 weeks if the child's condition is improving. Antispasmodic medication and agents which decrease gut motility should not be given as they may precipitate the development of toxic megacolon.

Severe, fulminating colitis is a medical emergency which is easily underestimated. The child should receive nothing by mouth and i.v. therapy is always indicated. The patient will usually need rehydration and blood transfusion, and regular albumin infusions are often required. All children should receive i.v. hydrocortisone (10 mg/kg/d) and broad-spectrum antibiotics (ceftriaxone and metronidazole) and, if malnourished, PN should be instituted at an early stage. Many children with severe colitis will respond to this aggressive medical therapy within 7–10 d, but if by this time there is no improvement rescue therapy with i.v. cyclosporin should be considered. If the child develops a complication such as toxic megacolon, colonic hemorrhage or perforation, then surgery is necessary. In addition to emergency surgery for complications of acute disease, elective surgery may be required if there is a failure of medical therapy, severe growth retardation unresponsive to improved nutrition or severe colonic dysplasia with the risk of adenocarcinoma formation in long-standing colitis. The surgical procedures available for the child include a proctocolectomy with ileostomy or ileal reservoir, or a colectomy with rectal mucosectomy and endorectal pull-through.

As regards the maintenance of remission, there is good evidence that continued therapy with a 5ASA is superior to placebo in preventing relapse although, in some patients, alternate-day steroids may also be required. Immunosuppressive drugs are proving to be useful in patients with intractable disease.

In contrast to Crohn's disease, there is less compelling evidence that aggressive nutritional therapy alone, either enteral or parenteral, is effective in inducing remission in ulcerative colitis, although the correction of malnutrition and specific nutritional deficiencies is mandatory in all patients.

### Prognosis

Approximately 90% of patients with ulcerative colitis presenting in childhood or adolescence will experience one or more relapses of their disease after initial treatment. The majority will be able to lead a relatively normal life despite chronic disease but some 20% will be chronically incapacitated. The prognosis is best for isolated, distal colitis, with only 10% progressing to pancolitis; overall, approximately 30% of patients will eventually require colectomy. There is an increased risk of developing large intestinal adenocarcinoma in patients with long-standing ulcerative colitis, although the risk is probably considerably less than previously thought.<sup>97</sup> The advent of flexible endoscopy has made possible

Careful, regular surveillance of the colonic mucosa and colonoscopy and biopsy should be performed at regular intervals in older patients with long-standing colitis.

## RECTAL BLEEDING

The passage of small amounts of blood per rectum is not uncommon in childhood and is rarely of sinister significance, being often due to a simple anal fissure or self-limiting infective colitis. It is important to determine whether it is bright red blood that has been passed, around, after or mingled with the stool as in the case of bleeding from the colon, or whether the blood is altered, or indeed melena, which may signify a more proximal source of bleeding. It is also helpful to determine whether there is mucus or slime in the stool or if there is associated diarrhea or constipation, abdominal pain or perianal pain on defecation.

Clinical examination should attempt to assess the degree of blood loss and whether anemia is present. Adequate visualization of the perianal region is mandatory and the use of a pediatric proctoscope may yield important diagnostic clues. General examination includes a detailed examination of the skin for evidence of purpura and telangiectases, circumoral pigmentation, and evidence of arthritis and renal abnormalities should be sought. Although direct visualization of the stool may reveal fresh blood or melena, chemical testing may be required when occult bleeding from a more proximal source is present. A number of kits are available for the testing of occult fecal blood, although most are highly sensitive and are likely to give false-positive results, particularly if the child is receiving vitamin C supplements or food high in peroxidase activity such as uncooked vegetables.

### Etiology

Table 19.29 outlines some of the commoner causes of rectal bleeding in childhood. It is important at any age (particularly in the neonatal period) to exclude swallowed blood as a cause of rectal bleeding. The etiology of bleeding per rectum is influenced by the age of the patient and also by the mode of clinical presentation. Thus, a child with chronic constipation who passes bright red blood on the surface of the stool may have an associated anal fissure, while the infant with intussusception may present with colicky abdominal pain, shock and the passage of 'red currant jelly stools'. Acute vomiting and bloody diarrhea may herald the onset of intestinal infection and the presence of hematuria and proteinuria may suggest Henoch-Schönlein purpura or the hemolytic uremic syndrome. Chronic blood loss with the painless passage of bright red blood is suggestive of a colonic polyp or hamartoma and a detailed family history may be helpful.

Table 19.29 Causes of rectal bleeding in childhood

1. Anal fissure
2. Infective colitis
  - a. *Shigella*
  - b. *Salmonella*
  - c. *Campylobacter*
  - d. *Escherichia coli* O157
3. Allergic colitis
4. Intestinal polyps
  - a. Juvenile polyps
  - b. Familial polyposis coli
  - c. Peutz-Jeghers syndrome
  - d. Gardner syndrome
5. Generalized bleeding diathesis
6. Inflammatory bowel disease
7. Rectal prolapse
8. Intussusception
9. Meckel's diverticulum/gut duplication
10. Henoch-Schönlein purpura
11. Hemangioma/angiodysplasia/telangiectasia
12. Upper gastrointestinal bleeding

## Investigation and treatment

The pattern of investigation will depend upon the urgency of the clinical presentation. Thus an infant who is shocked and passing bright red blood per rectum will need resuscitation and an urgent plain abdominal X-ray or ultrasound and possibly an air contrast enema to exclude intussusception. Usually the presentation is less acute and initial laboratory assessment should include a full blood count, ESR, serum iron and ferritin estimation, serum electrolytes and clotting studies. In cases of bloody diarrhea, stool culture is mandatory and plain abdominal X-ray may be helpful. The most useful investigation is colonoscopy, which after scrupulous bowel preparation will provide direct visualization of the colonic mucosa and allow multiple biopsies to be obtained for histology. Furthermore, the procedure may be therapeutic as smaller polyps may be removed at colonoscopy by diathermy.

Isotope scanning using technetium may identify ectopic gastric mucosa in either a Meckel's diverticulum or in a duplication of the intestine, and labeling of red blood cells with the isotope may also be useful in detecting the site of active, but occult, gastrointestinal blood loss. In the last resort, in selected cases of severe chronic unexplained iron-deficiency anemia associated with positive fecal occult blood, it may be necessary to perform angiography to localize the source of bleeding and rarely laparotomy and intraoperative endoscopy is indicated. Capsule endoscopy may be helpful in visualizing more proximal sources of bleeding.

## CHRONIC GASTROINTESTINAL SYMPTOMS

### RECURRENT ABDOMINAL PAIN

Recurrent abdominal pain is a relatively common pediatric problem, occurring primarily in older children and adolescents. The term generally describes recurrent and moderately severe episodes of abdominal pain over a period of at least 3 months which may lead to absence from school and may affect the child's lifestyle. Typically the pain is nonspecific although most children describe colicky, periumbilical discomfort. Most importantly the child is healthy in between these episodes and physical examination is normal; 10–20% of schoolchildren are affected.<sup>98</sup>

### Etiology and pathogenesis

Although early studies showed that in only 7% of cases is an organic cause found to explain the pain, it is increasingly recognized that many conditions may cause such pain, such as constipation, abdominal migraine,<sup>99</sup> gastritis and peptic ulcer associated with *H. pylori* and the irritable bowel syndrome<sup>100</sup> (Table 19.30). As clinical examination is usually normal, it is vital to take a detailed and comprehensive history which may provide clues as to the etiology of the pain.

Table 19.30 Organic causes of recurrent abdominal pain in childhood

1. Gastrointestinal
  - a. Constipation
  - b. Peptic ulceration/gastritis
  - c. Gastroesophageal reflux
  - d. Anatomical abnormalities
    - (i) Meckel's diverticulum
    - (ii) Malrotation
  - e. Inflammatory bowel disease
  - f. Food intolerance
  - g. Infection (e.g. *Yersinia ileitis*)
  - h. Pancreatitis
  - i. Hepatobiliary disease
2. Others
  - a. Migraine
  - b. Urinary tract disorder
    - (i) Chronic infection
    - (ii) Hydronephrosis
    - (iii) Calculi

Where the pain has lasted for more than 6 months with no associated weight loss, bleeding or diarrhoea, a non-organic cause is most likely. Psychological disturbances including over-reaction to normal life events and family dysfunction have often been considered important in the pathogenesis of the symptoms. However, studies have failed to show any psychological differences among children with recurrent abdominal pain compared with control subjects, although a proportion of these children and their families may benefit from psychological or family therapy.

## Management

Blanket investigation is no substitute for a careful history and examination although selective laboratory and radiological testing may be necessary, based on the pediatrician's clinical assessment. Routine urine testing and culture is mandatory and a full blood count and ESR may be helpful in excluding anemia and inflammatory conditions. If the child's symptoms are suggestive of pancreatitis, then a serum amylase may be useful when the child is experiencing pain, and liver function tests may be abnormal in children with pain due to hepatobiliary disease. Radiological investigations are usually unhelpful although a plain abdominal film will reveal calcification and gross constipation which may not be evident clinically. An abdominal ultrasound can be of use, particularly if urinary symptoms are suspected, but only rarely is it necessary to perform barium studies in order to exclude malrotation and IBD. Screening for *H. pylori* infection (see pp. 609–10) may not be helpful in children with generalized abdominal pain but where symptoms suggest peptic ulcer disease, upper gastrointestinal endoscopy and biopsy will be required.

Treatment will depend on the clinical assessment and on the results of investigations undertaken. It is important to exclude constipation as therapeutic intervention may alleviate the child's pain. In children where there is a typical history of abdominal migraine,<sup>101</sup> a trial of anti-migraine prophylaxis such as pizotifen and/or the exclusion of cheese, chocolate, citrus fruit and caffeine (the 4Cs) is sometimes justified, particularly if the child is missing a substantial amount of schooling. In the majority of cases, however, none of these measures is indicated and the most important therapeutic maneuver is to reassure the child and his parents that there is no serious organic disease present. It is often helpful to emphasize that the disorder is common in childhood and that the symptoms are likely to improve with age. It is important also to explain that although there is no obvious organic cause for the pain, it is not suggested that the pain is imaginary; rather it can be useful to admit that we as physicians do not understand why the pain is occurring, but do know that stress and emotional upheaval will tend to exacerbate the symptoms. In some children who present with intractable symptoms it is helpful to enlist the services of either a child psychologist or psychiatrist at an early stage so that a joint approach can be made in the exclusion of organic and non-organic causes for the recurrent abdominal pain.

## Prognosis

Prospective follow-up studies have been undertaken in children with recurrent abdominal pain and these suggest that a substantial proportion of children may continue to suffer in adult life from the symptoms of IBS. Furthermore it has been suggested that in children who develop symptoms at an early age and in whom treatment is delayed, the prognosis may be worse. It is tempting to speculate that recurrent abdominal pain in childhood and the IBS found in later life are manifestations of the same condition, although further large prospective studies are needed to clarify this point.

## INFANTILE COLIC

Infantile colic is a condition which is difficult to classify and define. It is used to describe the baby who, in the first few weeks of life, has frequent spells of inconsolable crying, usually occurring in the evening, and often associated with excessive flatus. The infant appears to be suffering abdominal pain although the 'colic' is intermittent and

usually self-limiting, often subsiding after 3 months of age. The disorder occurs equally in boys and girls and may occur in up to 20% of all babies in the first few months of life. The pathogenesis of the disorder is still unclear and several etiologic theories have been proposed including psychosocial factors, a failure of parent–infant interaction and milk allergy.<sup>102</sup>

Although the pathogenesis of the disorder is unclear, all the evidence points to an intestinal origin for the discomfort, and fundamental physiological and clinical research needs to be undertaken in order to understand the phenomenon more clearly.

As regards management, the most important therapeutic maneuver is to carefully examine the baby and reassure the parents that colic is common, self-limiting and without harmful long-term effects. Many remedies have been tried but the sheer number of treatment options testifies to the fact that none works particularly well. However, for the parents who are at the end of their tether, it may be worth a trial of simple measures such as gripe or peppermint water, and where a child is clearly atopic a cow's milk exclusion may be of benefit; a whey-based hydrolysate formula is the feed of choice. Counseling and support of the parents, however, remains the mainstay of management.<sup>103</sup>

Although the condition is usually self-limiting by 3 months of age, some children continue to experience colic throughout the first year of life and go on to develop recurrent abdominal pain and the irritable bowel syndrome in later life.

## CHRONIC CONSTIPATION

Although often regarded as a less than glamorous and rather insignificant problem by many physicians, chronic constipation is of great importance to the child and his family. It should be stressed that early accurate assessment and prompt treatment of constipation is vital to the child's well-being and lifestyle, as delays in management will only exacerbate the problem and perpetuate the child's lack of self-esteem and feelings of hopelessness. Furthermore it has been shown that constipation may cause reversible urinary tract abnormalities that may predispose the child to urinary tract infection and enuresis.<sup>104</sup>

The term 'constipation' is used to describe difficulty or delay in the passage of stools, which may progress to a chronic state where defecation is infrequent and the bowel motions passed are hard pellets or firm and very bulky; in addition there may be leakage of fecal liquid around the hard compacted stools in the dilated rectum causing soiling, which is distressing for the child and may result in inappropriate referral to a child psychiatrist. It is important to distinguish chronic constipation and associated overflow incontinence from true encopresis, which is the voluntary passage of normal stools in an inappropriate fashion or place. Normal bowel frequency varies widely although the average baby passes three to six stools per day in the neonatal period, one to two stools per day at 1 year of life and approximately one stool per day, or every other day, in the preschool years.<sup>105</sup>

## Pathophysiology and clinical features

Although the vast majority of children presenting with constipation have no serious underlying organic pathology, it is generally true that the younger the child, the more likely it is that the problem is due to a congenital abnormality of the lower bowel. It is particularly important to diagnose Hirschsprung disease (see Ch. 37) at an early stage, as the infant is at risk from developing an associated and severe life-threatening enterocolitis. Such children almost always have symptoms of constipation dating from before 3 months of age with the majority presenting in the first few days of life. Most children with chronic constipation, however, present in the preschool years with symptoms that may have been present for several months and sometimes several years. In these children it is unlikely that organic disease is present although the organic pathologies shown in Table 19.31 should be considered. A careful history and examination, particularly of the perianal region, is crucial in the evaluation of the problem, and the need for further investigation is dictated by the clinical assessment.

Table 19.31 Organic causes of constipation

1. Dietary
2. Dehydration
3. Intestinal obstruction
4. Anal fissure/stenosis
5. Hirschsprung disease
6. Hypo/hyperganglionosis
7. Cerebral palsy
8. Spinal cord lesion
9. Cystic fibrosis
10. Food allergy
11. Hypothyroidism
12. Hypercalcemia
13. Hypokalemia
14. Lead poisoning
15. Renal failure

By the time most children present to the pediatrician, an enlarged megacolon full of hard feces is present. The child is usually otherwise well although abdominal pain and occasionally nausea and vomiting may be associated with chronic constipation. The original genesis of the constipation is often difficult to pinpoint and several initiating factors may have been involved such as a loss of appetite during an acute illness, the prescription of constipating medications following a bout of diarrhea, pain from an anal fissure, a stressful life event, difficult toilet training made worse by inadequate facilities at school or aggressive management by parents determined to see their child toilet trained at a very early age. It has also become clear that chronic constipation may be a manifestation of food intolerance and this should be considered in a child or family with a strong history of atopy.

Chronic constipation is most often the end result of a sequence of events which starts with an episode of acute constipation which is inadequately treated. Adequate bowel evacuation relies on the child experiencing the urge to defecate consequent on the distension of the rectum with feces. If this urge is suppressed, for whatever reason, retained feces become hard and painful to expel, the rectum becomes distended, reducing rectal sensation, and the urge to defecate is diminished. A consequence of this chain of events is persistent fecal loading, a capacious rectum and frequent overflow soiling caused by fluid stool passing around the hard feces and staining the child's pants. As a result of these symptoms the parents may adopt a punitive approach towards the child which may compound an already unfortunate situation.

The problem of chronic constipation in children with neurological disability such as cerebral palsy, or spinal cord abnormalities such as myelomeningocele, is especially intractable due to a combination of reduced sensation, weakness of the muscles of the pelvic floor and abdominal wall, and also particular abnormalities of gastrointestinal motility in these patients. These difficulties should be anticipated and appropriate measures taken at an early stage.

### Management

Prompt management of children with acute constipation may prevent the development of chronic constipation and the vicious cycle outlined earlier.<sup>106</sup> In the baby with delayed passage of meconium and continuing constipation, Hirschsprung disease should be excluded by rectal suction biopsy at an early stage. Investigation of older children and exclusion of the rare organic causes of chronic constipation will depend on the clinical features following a careful history and examination. Laboratory assessment is usually not warranted, but a plain abdominal film may occasionally be helpful in assessing the degree of constipation and the size of the rectum, and also to demonstrate the fact to the child and his parents. General measures such as ensuring an adequate fluid and fiber intake are important and the advice of a pediatric dietitian is helpful in this regard. If anal stenosis is present, then repeated gentle anal

dilatation, or an anal stretch under anesthesia, may be of benefit. It is important to carefully examine the perianal region for the presence of an anal fissure as the application of local anesthetic preparations may encourage the child to open his bowels.

It is important to explain to the child and his parents the sequence of events leading to chronic constipation and to outline the aims of therapy, which are designed to clear the enlarged rectum and distal colon of feces, and subsequently keep it empty. It should be stressed that the situation is not the child's or family's fault and that treatment may involve many months of therapy. It is vital to provide a reassuring approach that the situation will improve, although setbacks and further bouts of constipation may be encountered during this period. It is not adequate to prescribe a 2-week course of laxatives and tell the family that the situation will improve with time. In practical terms, the initial therapeutic goal is to empty the rectum and distal colon and this can usually be achieved by oral disimpaction regimens although occasionally there is a need for enemas. This can often be undertaken on an outpatient basis if the general practitioner or health visitor is enthusiastic, but sometimes it is necessary to admit the child to hospital for 2 or 3 days for the disimpaction regimen and also to establish that the bowel is empty with an abdominal radiograph prior to starting maintenance laxative therapy. Once the large intestine is empty, oral laxatives should be prescribed in adequate doses to ensure that the child's bowels are open at least once a day. This can be achieved by a combination of a stool softener such as lactulose with a stimulant aperient such as senna, although a macrogol preparation such as Movicol (Norgine) is becoming the treatment of choice. If the initial dose of laxatives is inadequate, it should be increased; if the laxatives result in diarrhea the dose should be reduced. With time, however, sensation will return to the rectum as its size decreases, and the amount of laxative medication can eventually be decreased and finally stopped.

In addition to medical therapy, it is usually beneficial to institute a behavioral program based on simple rewards such as a modified star chart, where the child is rewarded for a normal, daily bowel action. This is coupled with advice that the child should be able to visit the toilet in a relaxed atmosphere at regular times and it is helpful to see the child regularly in the outpatient clinic, initially at fortnightly intervals, to provide continuing support and encouragement. The child should be encouraged to drink plenty of fluids and to eat a good balanced diet containing fruit and vegetables.

Treatment of children with chronic neurological disease and spinal cord lesions poses particular difficulties and early institution of regular suppositories and oral laxative therapy may be helpful. Furthermore, the development of an enema continence catheter or the use of an anterior continence enema (ACE procedure) whereby the colon is emptied on a regular basis is providing a useful adjunct in patients with constipation and fecal incontinence who experience little or no rectal sensation.

Overall the long-term prognosis for functional chronic constipation is excellent and this should be emphasized to the child, the parent and the physician.

### Short segment Hirschsprung disease

In a small proportion of children who present in childhood with a history of chronic constipation dating from birth and associated with the delayed passage of meconium, a diagnosis of short segment Hirschsprung disease is made. In these children anorectal manometry is abnormal but rectal biopsy may be unremarkable. The term 'internal sphincter spasm' may be a more appropriate term for this condition with treatment involving a full anal sphincter stretch and internal sphincterotomy performed under general anesthesia.

In some children with chronic constipation rectal biopsy may show either an increase or decrease in the number of ganglion cells. Such hypo- or hyperganglionosis undoubtedly can result in altered colonic motility which leads to chronic constipation and the development of a megacolon.

## CHRONIC NONSPECIFIC DIARRHEA

The syndrome of chronic nonspecific diarrhea (CNSD, previously known as toddler diarrhea or irritable colon of childhood) is now recognized to be the commonest cause of diarrhea without failure to thrive in early childhood; the mechanisms underlying the disorder are largely unknown and speculative, thus making it difficult to advise with confidence about management. It has been suggested that CNSD is self-limiting in 90% of cases, although others have reported a high incidence of constipation on follow-up and a significant history of functional bowel disorders in close family members.<sup>107</sup> Indeed it seems likely that CNSD may be merely part of a spectrum of gastrointestinal motility disorders that includes colic in infancy, recurrent abdominal pain in older children and IBS in adults.

### Clinical features

Children with CNSD present with loose stools usually between the ages of 6 months and 5 years. The condition is commoner in boys and a careful history will usually elicit the characteristic features of a variable pattern of stool consistency and frequency, often following an initial episode of acute gastroenteritis, with firmer stools passed in the morning and decreasing in consistency later in the day. Occasionally there may be a history of alternating diarrhea and constipation and the presence of undigested foods (especially peas and carrots), with or without mucus, is typical of the disorder. The diarrhea is often exacerbated by a high roughage diet, fruit and sugary drinks. The absolute characteristic of the condition is the absence of faltering growth, and it is of paramount importance to carefully document the child's height and weight on presentation and at subsequent follow-up. If the child is failing to gain weight and height, the diagnosis must be suspect and further investigation is then warranted.

### Etiology and pathogenesis

Although the precise pathophysiological mechanisms operating in CNSD are unknown, several possible etiological factors have been suggested. It is important to exclude excessive intake of fruit juices as a cause of diarrhea. Food allergy can cause similar symptoms in childhood and, although circumstantial evidence for this may be present in the form of a strong personal or family history of atopy, the most important diagnostic test is the response to an elimination diet and challenge. It has been suggested that a low dietary fat intake is a possible cause of CNSD as gastric emptying and gut transit time may be slowed by increasing dietary fat intake. It is thus conceivable that a diet low in fat causes rapid gastric emptying with increased propagative motor activity resulting in the formation of loose stools.

Abnormal intestinal secretion has been implicated in the causation of CNSD as has a primary motility disturbance. It has been suggested that some children with CNSD may demonstrate a significantly higher incidence of environmental indicators of personal or family stress compared with matched controls,<sup>108</sup> which is in keeping with the anecdotal experience of many clinicians.

### Diagnosis

CNSD is primarily a diagnosis of exclusion although there are certain positive clinical features, already described, which may provide a pointer to the diagnosis. The prime feature is that the child is healthy and growing normally. In some children there may be a family history of functional bowel disorders, or indeed a personal or family history of food intolerance. It is important to exclude both urinary and enteric infection although food intolerance and the postenteritis syndrome are the main differential diagnoses. Any evidence of malabsorption, atypical clinical features or failure to thrive should prompt further investigation.

### Treatment

In the majority of cases, simple reassurance is all that is required. It is important to explain to the parent that, apart from the loose stools, the child is otherwise well and thriving, and the problem is likely to improve.

It is also useful to explore the probable etiology of the disorder, which may be explained in terms of deranged motility which will improve with time. It is very important to emphasize that growth and general health will be normal in the future, and there will be no delay in achieving continence. Most parents will accept with relief the fact that their child has no serious disease, but for parents who feel that the problem is too difficult to manage, further measures may be necessary.

It is important to advise the parents to avoid giving an excessive intake of fruit juices or squash. Dietary treatment may be beneficial and, in those children with a strong personal or family history of atopy or in whom chronic diarrhea was manifested following an episode of acute gastroenteritis, a trial of an exclusion diet (usually cows' milk and egg free) may be helpful. The services of an experienced pediatric dietician are invaluable, and the diet must be adhered to for at least 1 month before any decisions are taken about its efficacy. If there is an improvement in symptoms, the diet is continued for at least 3 months before trying to gradually reintroduce the excluded foods. Some pediatricians have achieved success by increasing the child's fat intake so that 50% of the calories are derived from fat.

There is evidence that loperamide may provide symptomatic improvement and it can be used intermittently. All drugs, however, have significant side-effects and they should be prescribed only in carefully selected cases.

### Prognosis

Overall parents can be reassured that the prognosis for their child with CNSD is very good. In the past, the condition has been described as benign and self-limiting and although it is known that diarrhea may persist after toilet training, it usually becomes less obvious to the parents who no longer have to change dirty nappies. It is possible that a proportion of children who manifest CNSD may represent one end of a spectrum of familial functional bowel disorders which will re-emerge as continuing gastrointestinal complaints as they become older.

## INVESTIGATION OF THE COLON

Investigation of colonic anatomy and physiology has in the past been difficult, largely owing to the relative inaccessibility of the large intestine and the fact that investigation has involved the use of invasive techniques and exposure to radiation. Those investigative techniques in most common usage are described later.

### Radiology

The plain abdominal film (supine and/or erect) can be very useful in the investigation of acute and chronic gastrointestinal disease. Thus the presence of fluid levels may indicate intestinal obstruction, and free gas in the peritoneal cavity may represent intestinal perforation. Repeated plain abdominal films are an essential part of the management of toxic megacolon associated with colonic inflammatory disease such as fulminant ulcerative colitis.

Barium enema examination is now used much less frequently to study colonic anatomy since the advent of colonoscopy, although it may yield useful diagnostic information as well as being potentially therapeutic in cases of intussusception. The indications for barium enema examination include neonatal intestinal obstruction and intussusception. The use of double contrast barium enema technique is preferable for demonstrating colonic polyps or subtle mucosal disease, although it can be an uncomfortable examination for the child and almost all the indications for such investigation have been superseded by colonoscopy. The need for barium enema examination in Hirschsprung disease has largely been replaced by the use of rectal suction biopsy.

Radioisotopic scanning after injection of technetium-labeled leukocytes may have a part to play in the diagnosis of the site and extent of inflammatory disease<sup>109</sup> and occasionally patients with unexplained lower gastrointestinal blood loss may require investigation by a <sup>99m</sup>Tc-labeled red blood cell scan or selective angiography of the inferior mesenteric artery.

## Rectal suction biopsy

Biopsy of the rectal mucosa and submucosa is the most useful technique for diagnosing Hirschsprung disease but it also may be helpful in the diagnosis of neural lipidoses and amyloidosis. The technique is usually carried out under sedation, and multiple biopsies at varying intervals from the anal margin can be taken. The biopsies are studied for the presence or absence of ganglion cells and for the activity of cholinesterase.<sup>110</sup>

## Colonoscopy

The use of flexible endoscopy in pediatric practice has revolutionized the investigation of large intestinal disease in childhood.<sup>111</sup> Using the technique it is possible to traverse and visualize the whole colon and also to obtain multiple biopsies for histological assessment.

Proctoscopy can be performed easily at the bedside in older children and the use of an auroscope may be useful in neonates. Rigid sigmoidoscopy is uncomfortable for the child and this technique has been superseded by the use of small diameter flexible pediatric colonoscopes. Colonoscopy may be performed under sedation using a combination of pethidine and midazolam given intravenously immediately prior to the procedure. Alternatively a short general anesthetic may be more comfortable for the patient, easier for the operator and reduce recovery time. For an adequate inspection of the colon to be undertaken, it is vital that bowel preparation is effective and this may require the administration of 'clear fluids' for 24 h before the examination in addition to generous doses of laxatives and occasional recourse to rectal washouts. The procedure is generally well tolerated and the experience of centers using the technique in childhood has been that the complication rate is minimal.

Virtual colonoscopy using magnetic resonance imaging is not yet widely used in children with colonic disease. The inability to directly visualize the mucosa and to take mucosal biopsy means that endoscopic colonoscopy is likely to remain the gold standard for the investigation of intestinal inflammation.

## Motility studies

Anorectal manometry is a useful technique for distinguishing the different causes of constipation and is particularly helpful in the diagnosis of short segment Hirschsprung disease where the characteristic abnormality of failed internal sphincter relaxation is seen. Large bowel transit can be measured by the ingestion of multiple radio-opaque markers followed by a plain abdominal film at 48 h and 72 h. More detailed investigation of colonic motility is at present only available in research centers.

## HEPATIC AND BILIARY DISEASE

### ANATOMICAL STRUCTURE AND FUNCTION OF THE LIVER

The anatomical site and structural organization of the liver are designed to maintain close homeostatic control of the constituents of portal blood when returned to the hepatic venous system. Substrates from the portal system are rapidly taken into the liver cells, metabolized, and their products stored or transferred as required into the blood and bile. Blood-, bile- and lymph-containing channels transport nutrients, metabolites, antigens, antibodies, hormones and drugs to and from hepatocytes, and also to the other specialized liver cells, the Kupffer cell, the sinusoidal endothelial cell, the stellate cells and to the cells of the biliary tree.

The basic functional unit of the liver is the acinus, being the parenchyma receiving its blood supply from a hepatic artery and portal vein in a single portal tract. Traversing the sinusoids, specialized capillaries lined by Kupffer and endothelial cells which contain fenestra allow ready access of plasma and its contents to the surface of the hepatocyte (Fig. 19.12).<sup>112</sup> The sinusoids drain to the central vein of the hepatic lobule, and into the inferior vena cava. The hepatocytes near the portal tracts receive more oxygen, nutrients and hormones, have a higher metabolic rate, synthesize more proteins and regenerate more rapidly than those nearer the central vein, which are particularly susceptible to hypoxic and toxic injury. This structure can regain its pristine condition when

Fig. 19.12 A diagrammatic representation of the liver sinusoids and their blood supply. A–F represent sites of possible sphincters involved in controlling blood flow through the hepatic sinusoids. (Reproduced from *Liver Disorders in Childhood*<sup>112</sup> by kind permission of Elsevier Science Ltd.)

destroyed by acute toxins such as paracetamol or type A viral hepatitis but persisting injury with infiltration by cells of the reticuloendothelial system sets in train deposition of extracellular matrix components leading ultimately to irretrievable disruption of the acinar relationships by cirrhosis, with consequences for homeostatic function.

## CLINICAL ASSESSMENT OF LIVER DYSFUNCTION

Unfortunately, the sensitivity and specificity of many clinical symptoms and signs in liver disease are low so disease may be present without detectable signs or symptoms and those present may not be specific to liver disease. Thus, for example, it is possible to have chronic viral hepatitis B for decades preceding to cirrhosis without any external or even biochemical evidence. Features with some degree of sensitivity in established liver disease are:

- Jaundice with dark urine implies cholestasis. The urine of infants should not contain significant color or stain the nappy. Yellow sclerae also suggest cholestatic jaundice but are often difficult to detect in small infants and those with scleral pigment.
- Liver palms are not often seen in the first year of life.
- Splenomegaly indicating portal hypertension, although as children get older a larger spleen can be accommodated beneath the ribs, further reducing the sensitivity of this sign.
- Coagulopathy in the context of cholestasis may represent failure of absorption of sufficient vitamin K particularly leading to vitamin K deficiency bleeding of the newborn when intracranial bleeding is associated with severe long-term morbidity. Infants should not normally suffer spontaneous bleeding and fresh blood from sites such as the umbilicus or nares should always prompt a search for evidence of liver disease. Jaundice may be so mild as to be disregarded in such cases. When coagulopathy is not responsive to vitamin K, coagulation factors are being consumed intravascularly or not being formed. Thus in the patient with liver disease and coagulopathy unresponsive to vitamin K but without consumptive coagulopathy liver synthetic failure must be present. This criterion is the most sensitive for liver failure in children. Hypoglycemia and encephalopathy are less so.
- White stools, or stools the color of cream cheese or uncooked pastry are clearly abnormal. Those with mild degrees of green pigment or pale yellow or a pale buff brown color may also evidence reduced bile flow. Particular emphasis should be placed on examining stool and urine personally, as the history particularly from first-time parents can be misleading.
- Hepatomegaly is likely to be associated with liver disease, hepatic mass, infiltration or cardiac failure. Normal infants may have up to 2 cm of liver edge palpable parallel to and below the costal margin with soft texture. Riedel's lobe is seldom encountered

in practice. Firm/hard texture and an irregular inferior margin strongly suggest established liver disease with fibrosis/cirrhosis. Changed liver conformation with prominence in the midline but an impalpable right lobe suggests collapse, regeneration and the development of cirrhosis. A liver of this shape is also found in the Budd–Chiari syndrome as a consequence of caudate hypertrophy. Tenderness of a smooth liver suggests rapid recent increase in liver size, e.g. acute hepatitis or cardiac failure.

Severity of liver dysfunction can be considered in three broad categories. These are:

1. cholestasis, implying impairment of bile flow with reduction of intraluminal bile salt concentration, conjugated hyperbilirubinemia and raised serum bile acids causing pruritus;
2. portal hypertension (PHT) with associated hypersplenism and the effects of porto systemic shunting (if present);
3. hepatocellular impairment with evidence of failure of synthetic and homeostatic function.

Clinical and basic laboratory findings can be interpreted according to this classification although some such as ascites are represented in more than one category (Tables 19.32 and 19.33). Transudative ascites can result from a combination of increased portal pressure and low plasma oncotic pressure (implying low serum albumin). Serum albumin reflects liver synthetic function but also depends on nutritional status and losses, e.g. via the gastrointestinal tract or kidneys. Thus it is necessary to consider all clinical features supported by laboratory parameters in order to evaluate the severity of liver disease.

**Table 19.32** The clinical features of liver disease and their significance

Clinical features	Cholestasis	PHT	Cell function
Jaundice	Conjugated	–	Mixed if severe
Pruritus	+	–	–
Leuconychia	+	–	–
Clubbing	+	–	–
Fat-soluble vitamin deficiency	+	–	–
Xanthomas	+ but not in PFIC	–	–
Splenomegaly	–	–	+
Clubbing	+	–	–
Cutaneous shunts	–	+	–
Other cutaneous stigmata	–	+	+
Hypersplenism	–	+	–
Cyanosis – hepatopulmonary syndrome	–	+	–
Esophageal varices	–	+	–
Ascites	–	+	+
Encephalopathy	–	+	+
Dependent edema	–	–	+
Malnutrition	+	+	+

PFIC, progressive familial intrahepatic cholestasis; PHT, portal hypertension

## Ultrasound

Ultrasonography has become a mainstay in examining liver parenchyma texture, anatomical structures, portal and arterial blood flow and intrahepatic lesions. Particular examples are cysts, abscesses, solid tumors, hemangiomas, dilatation of the biliary tree from choledochal cysts and tumors. Calculi, sludge and polyps in the gallbladder can be visualized. Parenchymal echotexture may be altered with cirrhosis, edema in acute hepatitis, in storage disorders and with fatty or malignant infiltration. Splenomegaly and portal and hepatic arterial flow patterns can be evidence of portal hypertension. It is unhelpful in diagnosing biliary atresia other than it may show an absent or irregular small gallbladder.

## Other imaging

CT scanning, MRI, cholangiography and angiography, percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography are informative although their safe and/or effective use requires specialist diagnostic imaging expertise.

## Percutaneous liver biopsy

Skilled histological interpretation, histochemical and biochemical analysis and bacterial, fungal or viral culture of liver biopsy tissue may be of crucial diagnostic importance, giving information on the severity of liver damage and also in assessing the requirements for therapy in chronic hepatitis. An ultrasound scan, to exclude a focal liver lesion or bile duct dilatation, is required before a biopsy. If the following contraindications are observed the risk of significant bleeding is of the order of 1 in 5–10 000:INR (international normalized ratio for prothrombin time) greater than 1.3, platelet count of less than  $70 \times 10^9/L$ , the presence of clinical ascites, hydatid cyst or abscess in the right lobe of liver, angiomatous malformation of liver and hepatocellular carcinoma but not hepatoblastoma. It should only be undertaken with adequate vascular access by trained personnel having immediate surgical support.

## NEONATAL CHOLESTASIS SYNDROME

Hepatitis in infancy is characterized by clinical and laboratory features of hepatic inflammation with conjugated hyperbilirubinemia.<sup>113</sup> It must be suspected in any jaundiced infant, particularly if the urine is yellow, or if jaundice persists beyond 14 days of age. Specimens of stool must be saved in a container excluding light and examined for pigment by the clinician personally according to the description earlier (Clinical assessment, p. 642). If the stools contain no yellow or green pigment, cholestasis is complete and biliary atresia must be suspected.

Occasionally, infants will present with bleeding diathesis, hypoglycemia, fluid retention or malabsorption. The most important investigation is INR following administration of parenteral vitamin K, which if it remains abnormal indicates acute liver failure (ALF).

The prognosis is that of the associated disorder (see remainder of chapter), with positive family history, consanguinity and normal serum gamma-glutamyltranspeptidase (gamma-GT) predictors of the development of progressive intrahepatic cholestasis. Chronic liver disease rarely occurs in cholestasis associated with acute infections, or when disease remains cryptogenic after full investigation.

**Table 19.33** Laboratory features of liver disease and their significance

Laboratory features	Cholestasis	PHT	Cell function
Serum bilirubin	Conjugated	–	Mixed
Serum albumin	N	N (low in severe enteropathy)	Low
Serum cholesterol	High except in FIC	N	Low
Prothrombin time/ratio	N if vitamin K replete	N*	Prolonged if severe

N, normal; PHT, portal hypertension

\*Implies minor prolongation seen in portal vein thrombosis

## Differential diagnosis

Three management priorities can be identified:

1. to prevent complications such as vitamin K deficiency bleeding and hypoglycemia;
2. to identify treatable bacterial, metabolic, endocrine or hematological disorders and initiate treatment (Tables 19.34 and 19.35);
3. to diagnose biliary atresia as early as possible so as to optimize the surgical outcome.

Biliary atresia must be considered in any infant remaining jaundiced beyond 14 days of age. Evidence of consanguinity or liver disease in siblings suggests the possibility of familial, genetic, metabolic or hemolytic disease. Physical abnormalities are occasionally very helpful (Table 19.36).

Vitamin K deficiency bleeding, hypoglycemia, septicemia, urinary tract infection, syphilis and herpes simplex infections, listeriosis and toxoplasmosis all have effective treatments. Galactosemia (low RBC galactose-1-phosphate uridyl transferase activity), fructosemia (often a history of dietary exposure to honey can be obtained) and tyrosinemia (urinary succinylacetone excretion) should also be excluded immediately since dietary treatment is available. Inborn errors of bile acid

10. Erythrophagocytic reticulosis
11. Neonatal hemochromatosis
12. Defects in synthesis of primary bile acids
13. Variants of progressive intrahepatic cholestasis (PFIC)

**Table 19.36** Helpful physical findings in neonatal cholestasis

Physical signs	Disorder suggested
IUGR, skin lesions, purpura, choroidoretinitis, myocarditis	Congenital infections
Cataracts	Galactosemia, hypoparathyroidism
Multiple and characteristic abnormalities	Trisomy 21, 18, 13, Lawrence–Moon–Biedl, Beckwith–Wiedemann syndromes
Mass beneath liver	Choledochal cyst
Ascites, bile stained hernia and umbilicus	Spontaneous perforation of the bile ducts
Murmur, characteristic facies, embryotoxon	Alagille syndrome
Cutaneous hemangioma	Hemangioendothelioma of liver
Situs inversus, cardiac defect 'cor triatum'	Biliary atresia
Optic nerve hypoplasia, wandering eye movements, micropenis	Hypopituitarism

synthesis can respond to primary bile acid treatment. Early diagnosis of alpha-1 antitrypsin deficiency (see Ch. 20 p 648) cystic fibrosis and Niemann–Pick C clarifies the prognosis and allows genetic counseling. Associated endocrine disorders (Table 19.37) must also be excluded on the basis of the clinical findings and appropriate laboratory investigations. Current subgroups of progressive familial intrahepatic cholestasis (PFIC)<sup>114</sup> appear in Table 19.38.

A percutaneous liver biopsy is usually required for diagnosis. Some of the material obtained must be frozen at  $-70^{\circ}\text{C}$  for subsequent biochemical analysis for inherited disorders (Table 19.35) if indicated by the liver histology or other investigations. Outstanding results of investigations for conditions including congenital infections (Table 19.39) should not delay diagnosis of surgically correctable disorders, particularly biliary atresia.

If percutaneous liver biopsy shows increased edema, fibrosis and bile duct reduplication with bile plugs, biliary atresia is highly likely although this appearance can also be found in some genetic and endocrine disorders and after PN, in some infants who will ultimately develop bile duct hypoplasia and in some of the conditions within the spectrum of intrahepatic cholestasis shown in Table 19.38.

## Paucity of interlobular bile ducts (intrahepatic biliary hypoplasia)

The above diagnosis is based on a decrease in the number of interlobular bile ducts seen in portal tracts (ratio  $< 0.06$ ) on liver biopsy. It is found in prematurity, with neonatal hepatitis of CMV inter alia, and with right-sided cardiovascular anomalies, classically peripheral pulmonary stenosis, skeletal and ocular anomalies defining Alagille syndrome (AS). Diagnosis of AS is supported by the typical facies: triangular face shape, deep-set eyes, overhanging forehead, a straight nose which in profile is in the same plane as the forehead and a small pointed chin, posterior embryotoxon and vertebral arch defects on spinal radiographs. Long-

e. <i>Toxoplasma gondii</i>
f. Tuberculosis
g. Malaria

standing cholestasis causes jaundice, pruritus, hypercholesterolemia and xanthelasma. AS is inherited in an autosomal dominant fashion, with one of a wide variety of Jagged 1 mutations on chromosome 20q shown in most affected families studied. Phenotypic expression is variable. Jaundice is usually evident from the neonatal period. The long-term prognosis is uncertain but 30% may progress to cirrhosis and 5–10% die from liver disease.<sup>115,116</sup> In one series 25% died from cardiac involvement or infection. The treatment is that of chronic cholestasis with particular emphasis on adequacy of vitamin E replacement and the control of pruritus. Intolerably low quality of life may be an indication for liver transplantation.

### Liver disease associated with parenteral nutrition

Prolonged i.v. PN, particularly in early infancy causes cholestasis and hepatocellular damage which may progress if PN cannot be stopped.<sup>117</sup> The mechanism remains unclear. Prevalence increases with the degree of prematurity, growth retardation before birth sepsis, hypoxia, shock, cardiac failure, intra-abdominal surgery and potentially hepatotoxic drugs, the duration of PN and the absence of enteral intake. Inspissated bile syndrome is an important complication, when ursodeoxycholic acid and cholecystokinin may be beneficial in promoting bile flow.

### Clinical features and laboratory findings

Infants show early conjugated hyperbilirubinemia with elevated biochemical tests of liver function. It is important to consider other causes of cholestasis before incriminating PN. If it can be withdrawn the jaundice settles, although liver function tests may remain abnormal for over 6 months.

### Disorders requiring urgent surgical treatment

Biliary atresia (BA) is a destructive sclerosing inflammatory process with onset about the time of birth. Obstruction of the extrahepatic bile ducts extending into the major intrahepatic bile ducts leads to severe progressive cholestasis and cirrhosis. If surgery is to be successful it must be performed before complete intrahepatic occlusion occurs. By 6–10 weeks of age the portal blood pressure is increased by incipient or established cirrhosis. The mean age at death in untreated cases is 11 months, with less than 5% surviving beyond 2 years.

### Clinical features

Prolonged jaundice while always present may be very mild, and urine is always yellow. The stools contain no yellow or green pigment, but in up to 30% of infants with BA, stools are pigmented in the first weeks after birth before bile flow is completely obstructed. There is hepatomegaly often with splenomegaly. All too frequently the infant's apparent well-being causes health workers to overlook biliary atresia in the early weeks, when surgery is most likely to be successful. The incidence in the prematurely born or light-for-gestational age infant is the same as full term.

### Laboratory investigations

There is no single test to guarantee a pre-laparotomy diagnosis of BA. Percutaneous liver biopsy showing the features described earlier in all portal tracts is over 90% sensitive and specific if alpha-1 antitrypsin deficiency, cystic fibrosis and AS have been excluded. Radionuclide studies such as <sup>99m</sup>Tc-tagged iminodiacetic acid derivative (IDA) are only of value in excluding biliary atresia by showing continuity between the biliary system and gastrointestinal tract. ERCP is helpful in diagnosing ambiguous cases.

Diagnosis of BA is confirmed at laparotomy, which should only be undertaken by a surgeon performing at least five Kasai portoenterostomies per year who can assess changes in the porta hepatis and proceed to portoenterostomy. Currently there are only surgeons in three such centers in the UK. An anastomosis is fashioned between the area of the porta hepatis from which the inflamed bile duct remnants have been resected and a Roux-en-Y loop is fashioned, allowing bile to drain from the main hepatic bile ducts directly into the bowel. Good bile flow can be achieved in 70% operated on by 60 days of age but in only 20–30% following later surgery.<sup>118</sup>

### Complications

Cholangitis occurs in a significant minority of cases in the first 2 years after surgery, characterized by fever, recurrence or aggravation of jaundice and occasionally features of septicemia. Blood culture, ascitic aspirate and possibly liver biopsy to identify the organism responsible, should precede i.v. antibiotic therapy, which is continued for 7–14 d. Recurrent cholangitis has an adverse effect on liver function and prognosis indicating early and aggressive treatment. Prophylactic antibiotics are of no proven value.

Portal hypertension is present in almost all cases of BA at the time of initial surgery. At 5 years of age approximately 50% will have esophageal varices but only 10–15% will have alimentary bleeding when band ligation is the treatment of choice. All patients have a degree of malabsorption in the first year indicating dietary supplements with medium chain triglycerides and glucose polymers. Supplements of fat-soluble vitamins E, D, K and A are essential.

### Prognosis

The prognosis of BA has been transformed by the Kasai operation followed by liver transplantation if necessary. Following the Kasai procedure a normal serum bilirubin is found in 65% of patients with approaching 90% 10-year survival and a good quality of life. Overall there is no evidence of portal hypertension in 25%, 10% with normal transaminases and 15% with abnormal transaminases, 40% will have varying degrees of portal hypertension, almost all with good quality of life. Subsequent liver transplantation will be required by 35% and with this combined approach mortality can be reduced to less than 5% compared with universal mortality 30 years ago.<sup>119</sup>

### Choledochal cyst

In this disorder there is enlargement or dilatation of part or all the extrahepatic +/- intrahepatic biliary system. Bile flow may be obstructed causing histological changes similar to those of BA. Cholangitis, cyst rupture, pancreatitis, gall stones and carcinoma of the cyst wall are important complications. Incidental antenatal diagnosis by ultrasound occurs infrequently. In infancy it presents with features of neonatal cholestasis. In older children there may be recurrent upper abdominal pain, recurrent jaundice and/or a palpable cystic mass but the classical triad is rare. Diagnosis is by ultrasonography and other imaging, usually MRCP. The treatment is surgical removal with biliary drainage via a Roux-en-Y loop. Intrahepatic elements of the cyst are associated with a poorer prognosis with increased risk of developing biliary cirrhosis.

### Spontaneous perforation of the bile duct

Perforation occurs at the junction of the cystic duct and common hepatic duct in infants. The etiology is unclear but may represent the consequence of a choledochal malformation. Mild jaundice, acholic stools, failure to thrive and biliary ascites with bile-stained hernia and umbilicus are the clinical features. Treatment entails surgical drainage of the biliary system into a Roux-en-Y loop.

## HEPATITIS AND LIVER INFECTIONS

Acute and chronic inflammation of the liver with varying degrees of hepatocellular necrosis may be due to a wide range of causes including viral infections, drugs and toxins, metabolic and infiltrative conditions, and autoimmunity. Chronic low-grade hepatitis may progress to cirrhosis despite repeatedly measured normal serum transaminases.

### Viral hepatitis (see also Ch. 28)

The term 'viral hepatitis' is usually applied to infections caused by viruses with a high degree of hepatotropism. Five distinct agents can be identified at present.

### Acute viral hepatitis type A (HAV)

Following ingestion of enterovirus type 72 (picorna), the virus becomes established in the liver, spills into the biliary system and is excreted in the stools. Stool virus concentration is highest 7d before the onset of biochemical hepatitis, falls rapidly but may still be detected months later in patients with a relapsing course. The diagnosis is confirmed by finding specific HAV IgM antibodies appearing as early as 7d after exposure, reaching peak concentrations at 20–40d and usually clearing by 60d. Infection occurs predominantly in early childhood and is related to overcrowding and poor hygiene. In northern Europe only 10–15% becomes infected in childhood. Children under 2 years are very unlikely to become icteric; the likelihood of severe hepatitis increases with age.

### Clinical features

The incubation period varies from 15 to 40d, followed by a preicteric stage which may be accompanied by anorexia, nausea, vomiting, fever, headache, lassitude, dull intermittent upper abdominal pain and loose stools. The liver may be enlarged and tender, and the spleen enlarged. Jaundice and pruritus may develop with dark urine and pale stools. Jaundice usually lasts for 2 weeks, but may persist for months or follow a relapsing course. Chronic liver disease does not occur although transient liver nodularity with portal hypertension can occasionally persist for up to 1 year. Rare complications include ALF, bone marrow aplasia, pancreatitis, myocarditis and polyneuropathy.

### Prevention

Provision of drinking water uncontaminated by feces and safe disposal of sewage are essential in the prevention of this disorder. Person-to-person spread may be minimized by scrupulous hand washing after defecation and before handling food. Two doses of hepatitis A vaccine 14d apart are extremely safe, providing over 95% protection.

### Viral hepatitis type B (HBV)

Hepatitis B (HBV) is a DNA-containing virus of the hepadna group that can integrate into the hepatocyte genome.<sup>120</sup> In up to 10% of adults, less than 20% of 2–3-year-olds, 80% of infants aged 6 months or less and up to 90% of newborns, infection leads to a chronic infective carrier state, associated with normal liver structure and function or a range of pathological abnormalities including chronic hepatitis, cirrhosis and hepatocellular carcinoma. Patients with HBV may be superinfected by the delta virus (HDV).

### Serological responses in HBV infection

Viral antigens and antibodies to them may be present so transiently that they are never detected or they may persist in high concentrations indefinitely. The antigens and antibodies used in clinical practice are given in Table 19.40. There may be an interval following the disappearance of an antigen before its antibody becomes detectable or both may be present together. Immunosuppressed children with hepatitis B infection usually have massive viral replication within the liver but may lack serological responses. HBV DNA may be detectable by very sensitive techniques even after successful anti-e seroconversion occurring spontaneously or induced by interferon treatment.

### Clinical features

The acute and chronic responses to HBV infection in childhood are given in Table 19.41. The risk of serious sequelae is higher in males than in females. Those with anicteric hepatitis and minimal elevation of serum transaminases appear to be at greater risk of becoming chronically infected. The population chronic carrier rate varies from 0.1% in northern Europe and North America to 10% in southern European

Table 19.40 Serological markers in viral hepatitis type B

Marker	Clinical significance
HBsAg	Acute or chronic hepatitis B infection
HBsAb	Immunity to hepatitis B, postinfective or with active or passive immunization
HBcAb IgM	High titer: acute hepatitis, recent infection Low titer: chronic infection
HBcAb IgG	Past exposure to hepatitis B
HBeAg	Highly infectious state, high risk of progressive liver disease
HBeAb	Less infective state in the HBsAb-positive patient with low risk of progressive liver disease
HBV DNA by direct DNA hybridization	Quantification of viral replication

**Table 19.41** Clinical expression of hepatitis B virus in childhood

1. Asymptomatic development of HBsAb
2. Acute hepatitis, anicteric or icteric
3. Papular acrodermatitis
4. Acute liver failure
5. Acute hepatitis proceeding to chronic hepatitis or cirrhosis
6. Disorders associated with circulating immune complexes
  - a. Glomerulonephritis
  - b. Periarthritis
  - c. Pericarditis
  - d. Arthritis
7. Chronic hepatitis
8. Cirrhosis
9. Hepatocellular carcinoma

11. Carrier state with immune disorders
  - a. Down syndrome
  - b. Malignant disease and its treatment
  - c. Renal failure
  - d. Immunosuppression with transplantation

and Mediterranean countries and as high as 20% in parts of Africa and South-East Asia.

Only 5% of infections in early infancy are symptomatic, as opposed to 40% in later life. The clinical features of acute HBV are similar to those of HAV but the incubation period ranges from 30 to 180 d and the onset more insidious. Often infection is asymptomatic and the carrier state is only detected by serological testing.

#### **Natural history of HBV infection**

It has been estimated that 20–25% of those infected in infancy are still positive in the fourth decade. HBe clearance rate varies between 2% per year for those infected in earlier infancy to 20% of children infected later in life. The conversion to anti-HBs in carriers is much rarer at between 0% and 2% per year.

Neither the clinical features nor biochemical tests of liver function predict the histological findings. Cross-sectional studies of children with HBV in Europe show 'interface' hepatitis in about 50%, with portal hepatitis in 33%, the remainder having chronic lobular hepatitis or minimal changes. Histological diagnosis of cirrhosis is made in approximately 5% but as many as one third may become cirrhotic. Those with active CAH are more prone to develop cirrhosis with complications, particularly if super-infected by delta virus. Hepatocellular carcinoma, associated with HBV infection, accounted for 13% of childhood cancers in Taiwan seen in children as young as 8 months but has almost disappeared since the introduction of neonatal vaccination against HBV. Children with chronic persistent hepatitis or chronic lobular hepatitis have a good prognosis over a period of 15 years in terms of developing cirrhosis.<sup>121</sup>

#### **Prevention of HBV**

Blood, saliva, urine and other secretions are infectious. All blood and blood-derived products should be screened for hepatitis B. Wearing disposable gloves and hand washing after handling blood or excretions minimize the risk of infection. Highly immunogenic synthetic vaccines should be used to protect family members of index cases and medical and paramedical personnel. Hyperimmune gamma-globulin to HBV (HBIG) must be given immediately after accidental inoculation of hepatitis B-positive blood.

The combined use of HBIG in a dose of 200 iu, with active immunization starting within 48 h of delivery with further doses at 1, 2 and 12 months, is very effective in producing high anti-HBs titers. Further doses are recommended later if the anti-HBs titer falls below 100 iu/L. This schedule is applied in the UK to all infants of mothers who are found to be HBsAg positive by screening during pregnancy, including those who

are HBe antibody positive. In areas of high prevalence it is cost effective to protect all newborns with vaccination alone rather than set up a system to identify those at risk and this regimen has been recommended universally by the WHO. Where infection is acquired after the neonatal period, vaccination at 3 months would seem to be cost effective. Instead of the UK recommended dose of 20 mg, doses as low as 2 mg given intradermally or intramuscularly are almost as effective.

#### **Therapy of chronic hepatitis**

In European children, treatment with interferon alpha 2b, 3 MU/m<sup>2</sup> for 3 months increased anti-HBe seroconversion rates over 12 months from 13% in controls to 40%. Pretreatment with steroids is not beneficial. The long-term clinical and histological benefit is assumed but unproven. No benefit has been shown of combined lamivudine interferon treatment. Lamivudine may have a role in reducing viral load in patients with abnormal immunity or those who cannot tolerate interferon. The role of other antivirals in children is under evaluation.

#### **Viral hepatitis delta (HDV)**

HDV is a defective RNA virus that requires HBV core Ag to replicate. It may be transmitted by parenteral inoculation or close body contact but is rare in the UK and in children. Subjects may be simultaneously infected with HBV or HBV carriers may be superinfected. When acquired simultaneously with HBV it may cause acute hepatitis from asymptomatic infection to ALF. Usually a chronic HBV carrier state does not follow. Superinfection of HBV carriers causes a serious exacerbation with progression to ALF, chronic active hepatitis or cirrhosis. It is confirmed by detecting antibodies to the delta virus. There is no effective treatment. HBV vaccination should limit its spread.

#### **Viral hepatitis type C (HCV)**

It has been shown that this 9500-RNA-base *Flavivirus* was responsible for up to 90% of post-transfusion hepatitis in North America prior to the screening of blood products. Infection in childhood was almost entirely acquired from unscreened blood products before 1989. It has now become rare with new infections by vertical transmission occurring in 5% of pregnancies of infected mothers. No vaccine is currently available.<sup>122</sup>

#### **Natural history of HCV infection**

The consequences of infection for adults are becoming clearer and it is assumed that they are similar for children. A mild hepatitis typically follows infection and an incubation period of about 60 d. Only 30% are icteric and ALF occurs exceedingly rarely. Perhaps 30–40% of immunocompetent patients will clear the virus while developing anti-HCV antibodies. The remainder will have chronic infection with anti-HCV antibodies and RNA polymerase chain reaction (PCR) positivity. Of these the majority will have mild liver disease such as minimal change or chronic persistent hepatitis with normal or occasionally abnormal transaminases. Liver disease is slowly progressive with cirrhosis developing over 20 years in 5–25% with one third taking 50 years or longer to develop cirrhosis. Concomitant liver diseases such as drug-induced, iron overload, HBV or alcohol will increase the rate of progression. Genotype 1 tends to progress more quickly and hepatocellular carcinoma occurs in 1–10%. Non-immunocompetent patients are more likely to develop chronic infection with antibodies to HCV being negative. The presence of HCV RNA can be used to demonstrate infection and the response to treatment.<sup>123</sup>

#### **Treatment**

Interferon with ribavirin treatment has been used with benefit in adults, but should only be undertaken by specialist centers under a research protocol in children. Sustained virological response (SVR), implying lack of viremia with associated improvement of inflammatory liver damage at least 12 months after completion of treatment, is the current outcome measure. Virus genotype 1 or 4 should be treated for 48 weeks and 2 or 3 for 24 weeks. SVR for genotype 1 is 30–40% and for 2 and 3

60%+. Side-effects with both drugs are frequent. Pegylated interferon promises even better results.<sup>124</sup>

### Prevention of cross-infection

HCV is blood borne and despite being less infectious than HBV requires scrupulous antiseptics for spilled blood. Patients' razors and toothbrushes should be separated from others'. Counseling of sexual infectious risk, as 5% per partner, is required. HCV can also be detected in breast milk but breast-feeding is not contraindicated.

### Viral hepatitis E (HEV)

This enterically transmitted 30nm RNA virus is responsible for epidemics of hepatitis in the Middle East and Asia. Icteric disease occurs in 1–3% of infections. The prognosis is usually good but mortality is recognized in pregnant women and in association with other liver diseases including Wilson disease. Chronicity has not been documented but a relapsing course may occur.

## NONVIRAL INFECTIONS

### Hepatic abscesses

Hepatic abscesses may be caused by almost any bacteria or fungi, in association with any septicemic state, particularly with portal pyemia from appendix abscess and Crohn's disease that may be associated with portal vein thrombosis. Patients at risk include those with primary or secondary immune deficiencies, particularly chronic granulomatous disease. Secondary infection of another hepatic lesion such as bile duct obstruction, or sickle cell infarct may occur.

### Clinical features

There are frequently no clinical or biochemical features of liver disease, but high spiking fever is universal and abdominal pain frequent. Diagnosis rests on ultrasonic detection of the lesion but CT scan is necessary to demonstrate possible appendix abscess and exclude associated malignancy. Successful management requires prolonged appropriate antibiotics as determined by culture of material aspirated from the lesion with ultrasonically guided drainage. Surgical drainage is required if there is associated peritonitis, bile duct obstruction or if chronic abscesses with established walls are present.

### Hepatic amebiasis

This disorder has a high prevalence in children in endemic areas. Malaise, fever, rigors and tender hepatomegaly are usual. It is unusual to obtain a history of diarrhea. Secondary bacterial infection may be present. Diagnosis is based on finding living ameba in the stools or gut biopsy and positive serological tests.

### Treatment

Metronidazole (50mg/kg/24h in three doses for 10d) is the treatment of choice. Therapeutic needle aspiration or surgical drainage may be necessary when rupture of the abscess seems imminent or the liver lesion enlarges in spite of drug treatment.

### Hydatid disease

Hydatid disease is usually caused by the larval stage of the dog tapeworm *Echinococcus granulosus*. Rarely the fox tapeworm, *Echinococcus multilocularis*, may be responsible.

### Clinical features

Infection is usually acquired asymptotically in early childhood. Earlier signs are discomfort in the right hypochondrium or hepatomegaly. Rarely rupture into the biliary system may cause cholangitis; sudden collapse may be caused by rupture into the peritoneum. Diagnosis is based on serological tests. Secondary bacterial infection may produce a liver abscess. Treatment is surgical resection. Patients with *E. multilocularis* or those too ill for surgery may respond to mebendazole or albendazole.

### Schistosomiasis

Hepatic features are firm hepatomegaly, portal hypertension with splenomegaly, ascites and/or Hematemesis. Liver disease may occur as early as 2 years after initial infection. The recovery of ova in stools or rectal mucosa proves infection as positive serology does not distinguish past from present infection. The treatment is praziquantel. Alimentary bleeding due to portal hypertension should be treated by injection sclerotherapy or banding, not by portosystemic shunting.

### Liver infestations

The liver and biliary system may be damaged by infestation with *Fasciola hepatica* (sheep), *Clonorchis sinensis* (freshwater fish), *Opisthorchis felineus* and *Opisthorchis viverrin* (cat) and by larvae of the roundworm *Ascaris*. All cause cholangitis which may become suppurative and be complicated by bile duct obstruction, calculus formation, bile duct carcinoma, biliary cirrhosis and portal hypertension.

## CHRONIC LIVER DISEASE

Chronic liver disease implies evidence of liver damage persisting longer than 6 months likely to lead to cirrhotic change and its complications. It may develop asymptotically, insidiously and without physical signs. Paradoxically, the presentation may appear acute when features of decompensation appear suddenly or when a relapsing course presents with severe exacerbation. Liver biopsy to aid in etiological diagnosis and assess progress of disease should be performed unless there is a specific contraindication. If there is evidence of hepatitis B infection biopsy should be delayed for 6 months to allow spontaneous remission.

### Features suggesting chronicity

Chronic hepatitis should be suspected in the following situations:

1. relapse of an apparent acute hepatitis;
2. clinical or biochemical features of hepatitis persisting beyond 8 weeks;
3. hepatitis occurring after a history of neonatal cholestasis;
4. signs such as a small or hard liver, enlarged left or collapsed right lobe of liver, or others shown in [Table 19.32](#).

### Autoimmune liver diseases

Autoimmune chronic active hepatitis (AIH) and sclerosing cholangitis (AISC) are recognized to be part of an overlap syndrome.<sup>125</sup> At presentation, when patients may have aggressive hepatitis, occasionally ALF, or cirrhosis, it may be difficult to distinguish from Wilson disease. High serum immunoglobulins with IgG greater than 16 g/L, low concentrations of C4, and the presence of one or more non-organ-specific antibodies, particularly anti-nuclear, anti-smooth muscle are found in SMA/ANA antibody-positive AIH (type 1) and AISC. Anti-liver/kidney microsomal (LKM) antibodies define type 2 AIH, very rarely associated with AISC and occasionally with normal serum IgG level. IBD may be present in up to 30% of all patients. Presence of anti-gastric parietal cell antibodies is a marker of possible autoimmune polyendocrinopathy.

### Drug treatment

Prednisolone in a dose of 2mg/kg/d up to a maximum 50mg/kg/d is given initially and continued until serum transaminase values fall by 80% or to less than 100IU/L. Over the course of 2–3 months the dose is gradually reduced to that which will have no side-effects whilst maintaining normal transaminases, typically 0.1 mg/kg/d. Ursodeoxycholic acid 15–20mg/kg/d is given for AISC. If the reduction of the steroid dose is associated with a rise in transaminase level, azathioprine 0.5 mg/kg/d is added and the dose increased gradually to 1.5 mg/kg/d. Weekly full blood counts and platelet counts are essential early in azathioprine therapy. Mycophenolate mofetil is a powerful second-line steroid sparing alternative to azathioprine. LKM antibody-positive patients will require indefinite treatment, while a minority of SMA/ANA-positive

patients can slowly reduce and stop steroids after 2–4 years of normal transaminase levels.

The majority of patients have cirrhosis at the time of diagnosis but over 90% can be maintained in biochemical remission by immunosuppressive therapy with stable liver function and without side-effects of medication over a 20-year period. Patients with AISC have a marginally increased risk of need for liver transplantation during that period.

### Sclectrosing cholangitis

Sclectrosing cholangitis is a chronic obliterative inflammation in the intrahepatic and/or extrahepatic biliary system shown as irregularities in the outline of the ducts with areas of stricturing and dilatation (beading) on cholangiography. The various types are listed in Table 19.42.

#### Treatment

Symptomatic treatment includes adequate replacement of fat-soluble vitamins and cholestyramine for pruritus. Ursodeoxycholic acid may be beneficial. Dietary, drug and/or surgical treatment of bowel disease associated with AISC and AIH is necessary but does not influence the biliary pathology.

### Wilson disease

This inborn error of metabolism is characterized by defective biliary copper excretion. The spectrum of mutations causing a defective transport protein, ATP7B has been described.<sup>126</sup> Wilson disease may simulate virtually any form of liver disease from the age of 2 years onwards but typically presents in adolescence with ALF or severe hepatitis. Coombs negative hemolytic anemia or evidence of renal tubular damage often with hypophosphatemia suggests the diagnosis. In 80% the serum ceruloplasmin value is less than 20 g/dl (1.25 μmol/L). Biopsy liver copper concentration is > 250 mg/g of dry weight. Kayser–Fleischer rings may be identified by slit lamp examination in children over the age of 7. The gold standard for diagnosis is urinary copper excretion requiring both 1.2 mmol/24 h and more than 25 mmol/24 h with 1 g of penicillamine.

#### Treatment

The prognosis of Wilson disease at treatment is predicted by the total score according to Table 19.43. A score > 9 is associated with an early death (< 2 months) without liver transplantation. Patients with score < 6 should respond satisfactorily to penicillamine (5 mg/kg/d increased by 5 mg/kg/d at 2-weekly intervals to 20 mg/kg/d) and zinc sulfate 100–300 mg three times a day after meals given at different times from the penicillamine. Patients with scores of 6–9 require close monitoring. Recovery on treatment may take 12 months or longer.

It is essential to screen families of patients with Wilson disease to enable early treatment. Serum transaminases, copper, ceruloplasmin and urinary penicillamine challenge are required for all first-degree relatives. Genetic markers are available, but with more than 100 alleles described genetic tests are frequently uninformative.

Table 19.42 Classification of sclerosing cholangitis

1. Autoimmune (with or without chronic inflammatory bowel disease) with high serum immunoglobulins and non-organ-specific autoantibodies, C4 concentration normal and circulating T lymphocytes displaying IL-2R < 5%
2. Following cholestasis in infancy or with family history or consanguinity (neonatal sclerosing cholangitis)  
Associated with:
  3. Langerhans' cell histiocytosis
  4. Immune deficiency states, particularly HIV and CD40 ligand deficiency
  5. Cystic fibrosis
  6. Biliary surgery, or trauma
  7. Ischemia after liver transplantation or in sickle cell disease
  8. Primary (with or without chronic inflammatory bowel disease with normal serum immunoglobulins and no autoantibodies)

Table 19.43 Prognostic score in Wilson disease

Bilirubin (μmol/L)	Aspartate amino-transferase	Prothrombin time INR (u/L)	Prognostic score
N < 20	N < 40	N < 1.3	
< 100	< 100	< 1.3	0
101–150	101–150	1.3–1.6	1
151–200	151–200	1.7–2.0	2
201–300	201–300	2.1–2.5	3
> 300	> 300	> 2.5	4

N, normal

### Other copper-associated liver diseases

Indian childhood cirrhosis was largely confined to the Indian subcontinent and was characterized by necrosis of hepatocytes containing Mallory's hyaline and orcein-staining copper-associated protein due to accumulation of copper in the liver. Over 80% died within 6 months. Elimination of exposure to dietary copper has resulted in near elimination of the disease. Rare non-Indian cases have been described both with and without excessive environmental exposure to copper but with similar poor prognosis.

### Non-alcoholic steatohepatitis (NASH)

This condition, long recognized in adult practice, is becoming increasingly prevalent in children.<sup>127</sup> Presentation is with incidentally discovered raised serum transaminases or fat as brightness on liver ultrasound. Children are usually obese with a high fat and refined carbohydrate diet and sedentary lifestyle. The diagnosis is by exclusion of other liver disease associated with fat in the liver and by the characteristic liver biopsy features of inflammation, macrovesicular fat and occasional fibrosis. Other causes of fatty infiltration include Wilson disease, alpha-1 antitrypsin deficiency, HCV, and milder forms of glycogen storage disease. A glucose tolerance test is mandatory. Treatments suggested have included antibiotics against bacterial translocation, antioxidants and metformin, but dietary and lifestyle changes to reduce weight are the mainstay of management. Progressive liver fibrosis will be found in 5–10%.

### ACUTE LIVER FAILURE

The adult terminology 'fulminant liver failure' based on the onset of encephalopathy is not helpful in pediatrics as in infants and small children severe liver failure may occur without apparent encephalopathy.<sup>128</sup> ALF is preferred for children with a 'de novo' liver injury causing coagulopathy without disseminated intravascular coagulation or vitamin K deficiency. Two minority subgroups may be defined, one with hyperacute presentation of duration less than 1 week and typically low levels of jaundice, and one with subacute presentation of more than 8 weeks. ALF is a rare, complex, multisystem disorder with a mortality of 30–100%. Life-threatening complications include septicemia, especially from fungi, and raised intracranial pressure secondary to encephalopathy proceeding to impaired cerebral blood flow. In ALF, but possibly not the subacute subgroup, if the patient survives, the liver usually regains normal histology and function.

#### Diagnosis

The differential diagnosis of ALF is shown in Table 19.44. Although no diagnosis is possible in up to 40% of cases the search for a diagnosis should not delay transfer of the patient to a center with facilities and experience of managing ALF.

#### Clinical features

The grades of hepatic encephalopathy are shown in Table 19.45. Prognostic features for ALF other than paracetamol toxicity and Wilson disease appear in Table 19.46. The prognosis for ALF from Wilson disease appears in Table 19.43. Adverse prognostic markers for paracetamol toxicity include metabolic acidosis, renal dysfunction and encephalopathy

Table 19.44 The causes of acute liver failure

1. Infective

Table 19.45 The grade of hepatic encephalopathy

Grade of encephalopathy	Features
1	Lethargy, minor reductions in consciousness or motor function, vomiting
2	Stupor, irrational hyperactivity, combative behavior
3	Unresponsive to command but responds to pain
4	Unresponsive to command, extensor posturing and rigidity, brainstem depression with respiratory and vasomotor failure

Table 19.46 Prognostic markers in acute liver failure

Prognostic factor	Risk of mortality
INR $\geq$ 4.0	93%
Serum bilirubin $>$ 235 $\mu$ mol/L	92%
Age $<$ 2 years	96%
WBC $\geq$ $9 \times 10^9$ /L	93%
Encephalopathy grade 3 or 4	90%+
Drug etiology	90%+
Etiology unknown	90%+
HBV	70–90%
HAV	50–70%
3 or more adverse factors	100%

but not transaminase level. Unlike ALF of other causes, INR of  $>$  4.0 does not necessarily herald a poor prognosis in paracetamol toxicity.

### Indications for liver transplantation

Since the 5-year survival following liver transplantation for children with ALF is approximately 70%, transplantation is indicated when the prognosis of the liver failure is worse than that of transplantation,<sup>129</sup> assuming no other influences on the overall prognosis of the underlying condition, e.g. respiratory chain disorders with central nervous system complications.

### Treatment

Intensive care aimed at preventing and treating complications is essential until the liver function recovers or transplantation can be performed. Early arrangements should be made to transfer the child to a pediatric intensive care unit (PICU) with the experience to manage the multisystem complications and to proceed to liver transplantation if indicated. *Sedatives must not be given unless patients are to be ventilated.* Vitamin K is given to optimize coagulation. Hypoglycemia must be prevented by i.v. glucose. Protein intake is restricted to 0.5 g/kg/d. Lactulose may precipitate diarrhea without altering the outcome. Ranitidine given intravenously may prevent bleeding from gastric erosions. Prophylactic antibiotics and antifungals are indicated as 40% of cases have early covert sepsis.

### Reye syndrome and Reye-like ALF

Reye syndrome is an increasingly rare, acute, frequently fatal encephalopathy of unknown cause occurring in children of any age characterized by a self-limiting abnormality of mitochondrial structure and function. It occurs following an unremarkable viral infection of the respiratory or gastrointestinal tract. Aspirin may play a role although Reye syndrome has been disappearing in countries where aspirin is still given to children at a similar rate as in countries where it has been prohibited. Reye syndrome must be distinguished from an increasing range of inborn errors of metabolism that present in a similar fashion, particularly urea cycle disorders, fatty acid oxidation disorders, e.g. medium chain acyl CoA dehydrogenase deficiency, organic acidemias and mitochondrial respiratory chain disorders (see Ch. 26). Respiratory chain disorders are increasingly recognized as causing encephalopathy often with fits followed by ALF perhaps precipitated by sodium valproate. They are often distinguished by high serum transaminases and mild or initially absent jaundice.<sup>130</sup> Classical Reye syndrome does not have very high serum transaminases. In all these conditions liver transplantation is not usually required despite the severity of the initial coagulopathy and may be contraindicated in view of the neurological sequelae. Prevention of further episodes and genetic counseling are required after diagnosis.

In Reye syndrome encephalopathy with prominent vomiting may proceed over 4–60 h to brain death. Diagnosis of Reye syndrome or Reye-like conditions must be suspected in any encephalopathy if there is laboratory evidence of liver involvement such as raised serum transaminases, hyperammonemia, hypoglycemia or prolonged INR.

### Treatment

Mortality is as high as 40% with a considerable proportion of survivors being left with brain damage or with progressive encephalopathy in those with respiratory chain disorders. The patient should be nursed in a fashion that minimizes increases in intracranial pressure while being transferred to a specialist PICU. At presentation it is essential to collect and store serum (at  $-70^{\circ}\text{C}$ ) and urine in order to diagnose Reye-like disorders.

### Hemophagocytic lymphohistiocytosis

This rare condition is due to uncontrolled activation of the immune system, particularly by viral infection, and results in aggressive tissue damage by histiocytes and possible liver failure. Lymphadenopathy and hepatosplenomegaly are frequently present. Inflammatory markers particularly triglycerides and ferritin are elevated, fibrinogen is low, and cytopenia is indicative of disseminated intravascular coagulation and bone marrow involvement.<sup>131</sup> Recent work has shown abnormalities of apoptosis in infected cells being the primary defect with perforin gene abnormalities in 30%. Treatment includes anti-T cell globulin and etoposide. Prognosis is poor and particularly grave in infants.

### CIRRHOSIS

The main pathophysiological effects are impaired hepatic function and portal hypertension. Hepatocellular carcinoma may develop. Although the diagnosis of cirrhosis implies an irreversible and usually progressive pathological change, it may be compatible with normal growth and activity for many years. There are two broad pathological categories: biliary cirrhosis and so-called postnecrotic cirrhosis. Genetic factors contribute to both pathological varieties (Table 19.47).

Table 19.47 Causes of cirrhosis in childhood

1. Biliary	
a. Biliary atresia	i. Cholangitis due to:
b. Intrahepatic biliary hypoplasia	(i) <i>Fasciola</i>
c. Choledochal cyst	(ii) <i>Clonorchis sinensis</i>
d. Cystic fibrosis	(iii) <i>Ascaris</i>
e. PFIC	j. Pancreatic tumors
f. Bile duct stenosis or obstruction	k. Langerhans' cell histiocytosis
g. Choledocholithiasis	
h. Sclerosing cholangitis	
2. Postnecrotic	
a. Hepatitis in infancy	
b. Auto-immune chronic active hepatitis	
c. Acute viral hepatitis (viral hepatitis, B, C, delta, non-A non-B)	
d. Hepatitis due to drugs, e.g. actinomycin D, methotrexate	
e. Toxins, e.g. aflatoxin, copper, copper associated liver diseases	
3. Genetic disorders	
a. Wilson disease	l. Defects in fatty acid oxidation
b. Galactosemia	m. Sickle cell disease
c. Fructosemia	n. Thalassemia
d. Glycogen storage disease type IV	o. Hepatic porphyria
e. Hurler syndrome	p. Hemochromatosis, idiopathic
f. alpha-1-antitrypsin deficiency	q. Hemochromatosis secondary to chronic hemolytic disease
g. Tyrosinemia	r. Defects in primary bile salt synthesis
h. Cystinosis	
i. Gaucher disease	
j. Wolman disease	
k. Niemann-Pick disease type C	
4. Venous congestion	
a. Constrictive pericarditis	e. Venacaval webs
b. Ebstein's anomaly	f. Veno-occlusive disease
c. Congestive cardiac failure	g. Radiation
d. Budd-Chiari syndrome	

PFIC, progressive familial intrahepatic cholestasis

### Clinical and laboratory features

Clinical and nonspecific laboratory features are described earlier. Five disorders may cause particular diagnostic difficulty: extrahepatic portal hypertension, congenital hepatic fibrosis, constrictive pericarditis, sclerosing cholangitis and infiltrative disorders such as reticulosos.

### Management

Based on the history, examination findings and standard investigations listed in Table 19.48, a differential diagnosis may be possible prior to performing a liver biopsy. In considering the genetic disorders, consideration must be given to those with effective treatment, e.g. Wilson disease and AIH, and to identify surgically correctable abnormalities of the biliary tree, e.g. choledochal cyst. The further aim of management is to minimize further liver damage by treating the cause of liver disease and preventing or controlling complications (Table 19.49).

Portal hypertension (see later) causes splenomegaly, ascites and alimentary bleeding. Splenomegaly and hypersplenism rarely require intervention. Ascites may respond to spironolactone 4–7 mg/kg/d. If there is hyponatremia, water restriction is essential. It is rarely possible to reduce the sodium intake to less than 0.5 mmol/kg/d. If these measures are unsuccessful albumin infusions with furosemide (frusemide) 0.5–1 mg/kg/d may control ascites for 7–21 d. Paracentesis may be necessary if there is severe abdominal distension or respiratory embarrassment, followed by 20% i.v. albumin 5 ml/kg. It is essential to monitor the patient's weight, abdominal girth, urinary output of water and sodium and to measure the serum urea and creatinine when managing ascites.

### Treatment of alimentary bleeding

Following small initial bleeds, shock requiring rapid blood transfusion may occur. The child should be immediately admitted to the nearest hospital with resuscitation facilities. Bleeding decreases hepatic perfusion

Table 19.48 First-line investigations in children with evidence of chronic liver disease

FBC reticulocytes, film, INR, APTT, fibrinogen, cross match, Coombs test
Renal, bone, liver, lipid profiles, amylase, CK, blood glucose, lactate urate
Blood gases
Ferritin, copper, caeruloplasmin, zinc
Alpha-fetoprotein
Alpha-1-antitrypsin phenotype
CF alleles, sweat test
Immunoglobulins, complement C3 & C4, autoantibody screen
Serology for hepatitis B HBSAg, eAg, HCV Ab, HCV RNA PCR, CMV, EBV
24-hour urine copper collection and penicillamine challenge
CXR (cardiac echo if constrictive pericarditis is possible)
Liver and spleen ultrasound

Table 19.49 Complications of cirrhosis

1. Portal hypertension and hypersplenism
2. Bleeding diathesis
3. Hypoxemia
4. Increased susceptibility to infection
5. Hyperdynamic circulation (cardiac failure)
6. Ascites
7. Spontaneous bacterial peritonitis
8. Pulmonary hypertension
9. Hepatoma
10. Malnutrition
11. Gallstone formation
12. Renal failure
13. Hepatic encephalopathy
14. Endocrine changes
15. Impaired hepatic metabolism of drugs and hormones
16. Impaired neurodevelopment, particularly gross motor

with the possibility of ischemic hepatitis and hepatic encephalopathy. On admission, a baseline assessment of the clinical state should be made, blood cross-matched, and a secure i.v. line established. I.v. octreotide 25 µg/h is indicated. A Sengstaken–Blakemore tube of suitable size should be available and chilled to facilitate insertion by an experienced operator. Oral ranitidine and sucralfate reduce the risk of bleeding from gastric erosions. I.v. vitamin K should be given. As soon as the patient is stable, transfer to a unit equipped to manage the causes and complications of portal hypertension is required. Endoscopy is essential to determine the cause and source of bleeding, which may be gastric erosions or peptic ulceration rather than varices with band ligation or injection sclerotherapy if necessary.<sup>132</sup> Propranolol 1 mg/kg/d in two doses may reduce the frequency of subsequent bleeds. Emergency portosystemic shunting is rarely required.

### Spontaneous bacterial peritonitis

This potentially lethal complication of ascites may present with signs of peritonitis and fever. Blood culture and diagnostic ascitic tap are required for early diagnosis and antibiotics against *Streptococcus pneumoniae* and Gram-negative organisms are given. With high risk of recurrence prophylactic antibiotics and consideration of liver transplantation are required.

### Chronic hepatic encephalopathy

Chronic hepatic encephalopathy is a complex neuropsychiatric syndrome with major portosystemic shunting usually complicating cirrhosis with portal hypertension.<sup>133</sup> It is characterized by intellectual impairment, personality change and clouding of consciousness. Sleep patterns may be disturbed. Causes of hepatic encephalopathy and compounding factors are given in Table 19.50.

#### Treatment

The objectives of treatment are to prevent accumulation of ammonia and other vasoactive or false neurotransmitter substances in the gut, to remove or correct identifiable precipitating factors and to try to improve liver function. Protein intake should be reduced to 0.5–1 g/kg of body weight initially but then increased if tolerated. Sodium benzoate may be beneficial.

### Nutritional complications of severe liver disease

Cirrhosis and portal hypertension may be associated with a characteristic habitus having a full abdomen with thin limbs. Body weight underestimates the severity of derangement of body composition. Anorexia and fluid retention complicate management.<sup>134</sup>

#### Dietary management of cholestasis and cirrhosis

The calorie requirements may be up to 40% above recommended daily intake for weight. The diet must contain sufficient protein (up to 4 g/kg/d), essential fatty acids, minerals, trace elements and vitamins. Anorexia is frequently a problem, which may be aggravated by restricted fluid and/or salt intake. Fat malabsorption of varying severity is frequent. Water- and fat-soluble vitamin supplements are required. If hepatic

encephalopathy develops, dietary protein should be stopped and gradually reintroduced up to the maximum tolerated, while sodium benzoate is given. There is no proven advantage in using branched chain amino acids. Nutritional requirements are shown in Table 19.51.

### Pulmonary complications

Hepatopulmonary syndrome (HPS) presents insidiously as exertional dyspnea followed by cyanosis.<sup>135</sup> Type 1 HPS implies pulmonary capillary vasodilatation and type 2 new vessel intrapulmonary shunts both with ventilation/perfusion mismatch. The degree of shunting does not correlate with the severity of the liver damage or portal hypertension but may relate to the degree of portosystemic shunting. Hypoxia is only partially relieved by increasing inspired oxygen concentration but is cured by liver transplantation. Portopulmonary hypertension may develop due to pulmonary vasoconstriction, the converse of the dilatation of HPS.<sup>136</sup>

### Hepatorenal failure

Oliguric renal failure without structural abnormalities in the kidney (functional renal failure) is frequently a terminal event in advanced cirrhosis. There is a slow development of uremia, oliguria, and hyponatremia with a low urinary sodium concentration. Glomerular filtration may show transient improvement with inotropes or vasopressin analogues. Liver transplantation is the definitive treatment.

## PORTAL HYPERTENSION

### Portal vein obstruction

The portal vein may be obstructed by infective or thrombotic disorders or by a congenital abnormality. The presenting features are asymptomatic splenomegaly, alimentary bleeding with portal hypertension at any age throughout childhood or adult life, and rarely ascites and failure to thrive. The diagnosis is suspected by the finding of portal hypertension or esophageal varices in a patient with splenomegaly without clinical or biochemical evidence of liver disease. The diagnosis is confirmed by ultrasonography or angiography. The treatment is that of bleeding esophageal or rectal varices.<sup>132</sup> There is an increased frequency of bleeding during adolescence.<sup>137</sup>

### Congenital hepatic fibrosis

The clinical features are those of portal hypertension, hepatomegaly and occasionally cholangitis. Liver function tests are usually normal. Diagnosis requires an adequate liver biopsy showing wide bands of fibrous tissue linking portal tracts but clearly demarcated from the hepatic parenchyma. The bands contain irregularly shaped clefts lined by bile duct epithelial cells. Portal veins are sparse. There is little inflammatory cell infiltrate unless there is associated cholangitis. There is frequently significant associated renal disease, particularly infantile polycystic disease and renal excretion scans are essential. A wide range of dysmorphic syndromes is associated including Senior–Loken syndrome, Lawrence–Moon–Biedl syndrome and neurofibromatosis. Alimentary bleeding from varices is treated by band ligation, and cholangitis with appropriate antibiotics. Rarely liver transplantation is indicated for biliary cirrhosis secondary to chronic cholangitis.

### Cystic fibrosis (see Ch. 20)

Clinical syndromes include:

1. prolonged conjugated hyperbilirubinemia in infancy presenting as a hepatitis syndrome sometimes difficult to distinguish from biliary atresia;
2. massive hepatic steatosis which reverses as nutrition improves;
3. cirrhosis with portal hypertension and variceal hemorrhage, hypersplenism or splenic pain;
4. biliary abnormalities take the form of micro gallbladder present in up to a third, with gallstones in as many as 12%. Up to 40% of patients with CF have evidence of liver disease.

Table 19.50 Causes of hepatic encephalopathy

1. End-stage chronic parenchymal disease
2. Acute or subacute liver failure
3. Liver disease with severe portosystemic shunting
4. Precipitating factors
  - a. Sedative medications
  - b. Hypoglycemia
  - c. Hypokalemia
  - d. Hypovolemia
  - e. Sepsis
  - f. GI bleeding
  - g. Hypoxia
  - h. High-protein diet

Table 19.51 Nutritional requirements – vitamins and minerals

Nutritional element	Daily requirement	Products/source	Means of administration	Comments/monitoring
Vitamin A	<10 kg 5000 IU >10 kg 10 000 IU IM – 50 000 IU	Ketovite liquid & tabs, Abidec	Oral	IM supplement only in severe refractory deficiency Serum retinol/ RBP $\geq$ 0.8
Vitamin D	25-OHD: 2–5 $\mu$ g/kg IM – 30 000 IU 1–3 monthly	Ketovite liquid & tabs, Abidec have calciferol 400 iu/d IM calciferol	Oral/IM	Supplementation with oral products containing calciferol may suffice. Refractory cases may require 25-OHD or IM preps 25-OHD serum levels > 20 ng/ml
Vitamin E	TPGS* 25 iu/kg IM 10 mg/kg (max. 200 mg) every 3 weeks	TPGS from Eastman–Kodak or Orphan Europe. Others include Ketovite liquid & tabs, Abidec, Ephyral	Oral	Vit. E/total lipids $\geq$ 0.6 mg/g Vit. E < 30 $\mu$ g/ml Look for reflexes!
Vitamin K	2 mg/d Weekly 5 mg: 5–10 kg 10 mg > 10 kg IM – 5–10 mg every 2 weeks	Konaktion MM Micellar formulation or menadiol Phytomenadione	Oral IM	Prothrombin time PIVKA II < 3 ng/ml
Water-soluble vitamins	Twice RDA	Children's multivitamins, Ketovite liquid & tabs	Oral	Supplement as needed
Minerals			Oral	Supplement as needed
Calcium	25–100 mg/kg			
Selenium	1–2 $\mu$ g /kg			
Zinc	1 mg/kg			
Phosphate	25–50 mg/kg			
Total lipid/MCT	30–50% of energy of which 30–70% MCT	Depending on product and level of malabsorption	As formula	
PUFA/LCP	Probably > 10% total energy	Rapeseed oil Egg yolk Walnut oil Fish oil Sunflower oil Soybean oil	Walnut oil added to feed/given separately	Products unpalatable Levels difficult to measure and interpret. Most centers lack access to clinical measurement
Protein	2–4 g/kg (min. 2 g/kg)	Whey protein	As formula	Avoid semi-elemental diet/hydrolysates if not necessary. Treat hyper-ammonemia instead of reducing protein intake
BCAA	10% total AAs			
Energy	RDA for age or up to 150% of requirement for weight	2/3 as CHO and 1/3 as lipids approx.	As formula	
Carbohydrate		CHO polymer	As formula	Usually lactose free
Na/K	Minimum/2–3 mmol/kg		As formula	

Treatment is aimed at improving nutrition, particularly deficiency of fat-soluble vitamins, and the management of portal hypertension. Ursodeoxycholic acid (15–20 mg/kg/d) improves transaminases, serum bile acids and ultrasound findings but is of uncertain effect on prognosis.<sup>138</sup> Surgery may be required for symptomatic gall stones. Liver transplantation has also been performed with good results but no large series has clarified indications and outcomes.

## LIVER TUMORS

Primary liver tumors are rare and occur at approximately one tenth of the frequency of neuroblastoma. Malignant tumors include hepatoblastoma and hepatocellular carcinoma, both of which are usually

accompanied by a high alpha-fetoprotein level, fibrolamellar hepatoma (accompanied by transcobalamin markers), rhabdomyosarcoma and cholangiocarcinoma. Other tumors appear in Table 19.52.<sup>139</sup> Infantile hemangioendothelioma may present in two forms: 'sump' effect with consumptive features of Kasabach–Merritt syndrome and 'shunt' like with high output cardiac failure. The others present with abdominal distension, hepatomegaly, abdominal pain or rarely complications of the tumor, such as virilization. Diagnosis is supported by the demonstration of a space-occupying lesion within the liver by imaging.

Malignant tumors are treated with appropriate chemotherapeutic agents followed by resection. Hemangioendothelioma is treated by surgical hepatic artery ligation in congestive cardiac failure. Such surgery should be confined to specialist centers.

Table 19.52 Tumors of the liver in childhood

	Benign/malignant
Hepatoblastoma <sup>141</sup>	M
Hepatoma/HCC including fibrolamellar HCC	M
Small cell tumor of infancy	M
Biliary rhabdomyosarcoma	M
Lymphoma	M
Neuroblastoma (including 4S)	M (spontaneous remission)
Secondary carcinomas/sarcomas	M
Hemangioendothelioma/angiosarcoma	B/M
Mesenchymal hamartoma	B
Adenoma	B
Focal nodular hyperplasia/nodular regenerative hyperplasia	B
Inflammatory pseudotumor	B

## LIVER TRANSPLANTATION

With 5-year survival rates as high as 90% for chronic liver diseases, orthotopic liver transplantation should be considered in any child with acute or chronic liver disease if death within 1 year is likely, or as a consequence of liver disease when the quality of life has deteriorated to unacceptable levels, or if irreversible damage to the central nervous system or other organs is likely as a consequence of liver disease. Transplantation must be considered in ALF or subALF and in selected children with an increasing range of metabolic disorders (Table 19.53). Auxiliary transplants may be most suitable for some of these latter indications. Full consideration must be given to other forms of treatment and the presence of relative contraindications. The results are better in children transplanted in a good nutritional state and if the procedure is elective.<sup>140</sup>

## Complications

Complications are those of major surgery involving multiple vascular and biliary anastomoses, of rejection and the effects of long-term anti-rejection drugs. Rejection occurs in up to 70% but is resistant to treatment with steroids in about 15%. In patients with poor graft function, opportunistic infections remain a high risk while those on modest doses of anti-rejection drugs are at risk of infections with community-acquired and gastrointestinal organisms. Between 1 and 6 months, cytomegalovirus, and opportunistic infection with organisms such as *Nocardia* and *Pneumocystis* may occur. EBV infection may lead to post-transplant lymphoproliferative disease, particularly but not exclusively in patients

Table 19.53 Indications for liver transplantation

Indications for liver transplantation	Examples
Decompensation of cirrhosis	Uncontrollable ascites Encephalopathy Failure to thrive Coagulopathy unresponsive to vitamin K
Untreatable complications of portal hypertension	Hepatorenal syndrome Hepatopulmonary syndrome
Poor quality of life	Pruritus Lethargy
Life-threatening complications	Varices refractory to all other treatments
Selected liver tumors	Unresectable chemosensitive hepatoblastoma Benign but unresectable tumors
Extra-hepatic manifestations of hepatic inborn errors of metabolism	Crigler-Najjar type 1 Primary oxaluria Propionic acidemia
Acute liver failure	INR > 4 Grade 3 or 4 encephalopathy Children under 2 years

who have received exceptional total immunosuppression for rejection. Tacrolimus and cyclosporine have reduced the risk of infective complications but with major side-effects including chronic renal dysfunction, neurotoxicity, glucose intolerance and cosmetic considerations.

The longest survivor to date remains well 25 years after transplant, and the majority of survivors have a good quality of life. Life-long immunosuppressive therapy with expert medical supervision is required. The supply of suitable donor organs remains a major limiting factor in liver transplantation in childhood despite improvements from reducing organs, splitting organs between two recipients and using part of the liver of live related donors. Selecting the appropriate time for surgery can be difficult, being a compromise between early enough to receive a liver while in good condition and not undertaking transplant with its risks of complications before it is clearly necessary. Thus, it is essential that patients who may become candidates for transplantation should be referred at the earliest possible stage to units with the expertise to advise on the optimum timing.

## INTRODUCTION

Acute respiratory illness is among the most common reasons for admission to medical pediatric beds in industrialized countries and, together with acute gastroenteritis, acute respiratory infections (ARIs) remain among the most common causes of death and serious morbidity in young children in resource limited and emerging economies (Fig. 20.1). Despite a high worldwide prevalence of ARIs, the infective agents differ in that bacterial infections, including tuberculosis, are common in resource limited countries while viral infections are more commonly associated with ARIs in resource rich economies. In temperate countries there is also a marked seasonality of ARIs with a significant rise in prevalence in the winter months, falling to relatively low levels in

Fig. 20.1 Causes of death in children under 5 years. UNICEF under 5 mortality statistics, 2000–2003. ([www.childinfo.org/areas/childmortality/](http://www.childinfo.org/areas/childmortality/))

Fig. 20.2 Laboratory reports to CDSC of infections due to respiratory syncytial virus, England and Wales. RSV laboratory reports, 4-weekly by date of report 1990–2006. Source: UK Health Protection Agency ([www.hpa.org.uk/infections/topics\\_az/rsv/graphmenu.htm](http://www.hpa.org.uk/infections/topics_az/rsv/graphmenu.htm)).

the summer – so much so that many acute medical pediatric units have low occupancy rates in the summer months. This seasonal pattern of illness is most dramatically seen for respiratory syncytial virus (RSV) bronchiolitis (Fig. 20.2). Whereas serious morbidity and mortality from respiratory disease has fallen to very low levels in resource rich economies, the total burden of respiratory disease remains high with a shift from life threatening ARIs to an increased incidence of asthma and related atopic disease. Worldwide comparisons of asthma prevalence using carefully standardized methodology have shown a high prevalence in resource rich, industrialized countries and generally low prevalence in resource limited countries.<sup>1</sup> The increasing prevalence of asthma and allergic disorders that was consistently reported over several decades in a number of resource rich countries, including the UK,<sup>2,3</sup> with some, although not all, recent studies suggesting that the rate of increase is slowing in the UK,<sup>4</sup> Europe<sup>5</sup> and elsewhere.<sup>6</sup> The reasons for what has been termed the ‘asthma epidemic’ have still not been fully elucidated but, since the proposition that a rise in allergic diseases could be linked to reductions in the burden of infections – the so-called hygiene hypothesis,<sup>7,8</sup> there has been accumulating evidence to support a role for bacterial-derived endotoxin exposure in programming the developing immune system to reduce the risk of allergic disease,<sup>9</sup> possibly by interactions with specific genetic polymorphisms in the innate immune system.<sup>10</sup> This raises the possibility of development of targeted interventions for the primary or secondary prevention of asthma in genetically predisposed individuals.

## IN RESOURCE RICH ECONOMIES

The marked reduction in the prevalence of life threatening ARIs in resource rich countries in the last 50 years reflects an improved standard of living, immunization against tuberculosis, pertussis, diphtheria, measles and *Haemophilus influenzae*, and the introduction of effective

antimicrobial drugs. For those children with life threatening disease, technological advances in managing respiratory failure have also had their impact. Targets for further reductions in the burden of illness, particularly in the youngest age groups, would be the elimination of RSV infection by an effective vaccine and a reduction in exposure to cigarette smoke in utero and in early childhood. Whereas the work load for acute asthma in hospitals has been diminishing, the burden in primary care remains at high levels with the highest annual incidence, in proportion to the at risk population, in the youngest age groups (Fig. 20.3). Ecological analyses have suggested that the early and sustained use of prophylactic therapy, particularly inhaled corticosteroids (ICSs), has contributed to this reduction in hospital admissions, although this beneficial outcome needs to be balanced by concerns about the possible systemic effects of long term use of ICSs.<sup>11</sup> Recent controlled trials of inhaled corticosteroids for infant wheeze have not demonstrated that this is an efficacious strategy to alter the natural history of asthma after treatment is stopped.<sup>12-14</sup>

In resource rich economies improvements in therapeutic options, including age appropriate inhalation delivery devices, antibiotics and organization of care, have resulted in increasing actuarial survival for conditions that in previous generations and epochs were invariably fatal in childhood. This increased survival applies to a number of conditions, including cystic fibrosis, unusual congenital anomalies such as congenital diaphragmatic hernia and respiratory complications of other conditions such as extreme prematurity and neuromuscular disorders (see p. 727 – Chronic lung disease of prematurity, and p. 687 – Sleep and respiratory disorders). In cystic fibrosis, for example, a strong cohort effect on actuarial survival, although modulated by socioeconomic factors, has become apparent since the disease was first characterized in the 1940s (Fig. 20.4).<sup>15,16</sup> The recent introduction in the UK of universal newborn screening for cystic fibrosis may also contribute to improved survival during childhood.<sup>17</sup> The increased survival of children with significant lung disease, or with neuromuscular disorders and associated respiratory impairment, has effectively exported much morbidity and mortality into adult life. These medical ‘successes’ have placed increased burdens on affected individuals and their families and, in order to maintain a satisfactory quality of life, more attention is now being given to psychosocial aspects of disease and to palliative care (see Ch. 35). Quality of life instruments are being increasingly used to assess the impact of disease and in assessing therapeutic interventions.<sup>18,19</sup>

## IN RESOURCE LIMITED AND EMERGING ECONOMIES

Respiratory disease is a prevalent cause of mortality in resource limited countries and a major contributor to child deaths in Africa and South East Asia (see Fig. 20.1). In a global health context these potentially avoidable causes of death have moved up the political agenda and the UN Millennium Summit in 2000 agreed a number of goals to reduce the burden of infectious diseases, including ARIs, setting defined targets for

Fig. 20.3 Annual incidence of physician-diagnosed asthma in Scottish General Practices 1998. Data from the General Practice Data Evaluation Project (GDEP) Scotland.

Fig. 20.4 Actuarial survival of patients with cystic fibrosis by birth cohort. Source: Elborn et al.<sup>16</sup>

their reduction. One such target is to combat HIV/AIDS, malaria and other infectious diseases, including tuberculosis (TB). The World Health Organization (WHO) declared TB a global emergency in 1993 and set targets to detect 70% of new infectious (smear positive) cases of TB worldwide, to successfully treat 85% of all cases detected and to halve TB prevalence and death rates. Although progress has been made on mortality using strategies such as directly observed treatment strategy (DOTS), factors such as the AIDS epidemic and the emergence of drug resistant strains of *Mycobacterium tuberculosis* have contributed to the still growing burden of new cases worldwide (Fig. 20.5).

Deaths from pneumonia can also be significantly reduced if the WHO guidelines are fully implemented. The WHO program requires identification of children with clinical evidence of pneumonia followed by early introduction of antibiotics and advice on use of fluids and adequate nutrition. This program can be delivered relatively inexpensively by village health workers who are trained to identify signs of pneumonia, including rapid breathing and chest indrawing, and who use appropriate antibiotics and discourage the use of commercial cough remedies, some of which contain harmful ingredients. The benefits of such programs can be dramatic (Fig. 20.6).

## FETAL PROGRAMMING OF LUNG DISEASE IN CHILDREN AND ADULTS

There is growing evidence that fetal life and early childhood are critical periods of development for many diseases that present during childhood and adult life. In humans and other long-gestation species, the development of lung architecture occurs during fetal and early postnatal life. A number of epidemiological studies have demonstrated associations between prenatal factors that restrict intrauterine growth and respiratory symptoms in infancy. This observation led to speculation that factors which impair fetal growth may also constrain fetal lung development, resulting in permanent changes to lung architecture. Longitudinal follow-up of birth and childhood cohorts to adolescent and adult life has suggested that pulmonary function decrements that are established in early childhood track with somatic growth to adulthood,<sup>20,21</sup> suggesting that some late-onset diseases, such as chronic obstructive pulmonary disease (COPD), may have their origins in childhood.<sup>22</sup> Work in fetal lambs with imposed growth restriction during late gestation has demonstrated structural and mechanical abnormalities of the lungs but no effects on surfactant protein expression in these animals.<sup>23</sup> Barker et al.<sup>24</sup> described an association between low birth weight and lung function decrements in over 5000 adult males. Furthermore, respiratory infection during early childhood was associated with further decrements in adult lung function in this population, suggesting that either impaired lung function at birth was associated with predisposition to pulmonary infections during infancy or that respiratory infections, such as pneumonia and whooping cough, cause airway and lung remodeling which further impairs lung function. A follow-up study of lung function in

infancy has demonstrated reduced forced expiratory flows at the age of 2 months in infants who subsequently developed pneumonia,<sup>25</sup> supporting a role for predisposition to infections in infants who already have pre-existing lung function impairment. Other epidemiological studies have confirmed an association between respiratory infections during infancy and early childhood and later functional abnormalities consistent with airway obstruction in adults.<sup>26</sup>

## GENETIC DETERMINANTS

### Cystic fibrosis

Pulmonary disease may accompany a number of genetic disorders in children and some pulmonary diseases have a genetic basis, although this is seldom based on simple Mendelian inheritance but may have polygenic or multifactorial etiology. A clear exception to this is cystic fibrosis, which results from a variety of mutations in a single gene located on chromosome 7q (see p. 706 – Cystic fibrosis).

### Asthma

Asthma is a complex, polygenic disease that results from the exposure of genetically susceptible individuals to environmental triggers, possibly at critical stages of development. Linkage studies and genome-wide searches have identified a number of potential candidate genes for asthma and atopy.<sup>27,28</sup> Although variants in over 60 genes have been

associated with asthma and related traits, candidate gene studies have demonstrated considerable heterogeneity of associations with asthma and many have failed to replicate in independent samples.<sup>29</sup> Also, the rate of increase in asthma prevalence in the UK and other Western countries is inconsistent with major shifts in population genetics. Therefore, attention has focused on identification of environmental exposures that may be causally implicated in the etiology of asthma and atopy.

### Non-cystic fibrosis bronchiectasis

The approach to bronchiectasis in children without cystic fibrosis (non-CF bronchiectasis) has changed in emphasis from the role of childhood infections, such as pertussis, tuberculosis and complicated measles, to the role of intrinsic defects with an inherited basis. Although deficiency of protease inhibitors, primarily alpha1-antitrypsin, is often included in the work-up of these children, it is not a condition that presents in this way. Primary ciliary dyskinesia (PCD), however, is increasingly recognized in children with chronic suppurative lung disease and bronchiectasis. PCD is generally observed to follow an autosomal recessive mode of inheritance, although dominant and X-linked inheritances have been described. Linkage studies of separate populations with PCD have mapped loci to a number of chromosomes and a genome-wide screen has demonstrated extensive locus heterogeneity in PCD.<sup>30</sup> Candidate genes for the disease include those encoding the intermediate and heavy dynein chains, e.g. DNAI2 and DNAH5.<sup>31</sup> There is also increasing recognition of the importance of nodal cilia in determining laterality,<sup>32</sup> underpinning the observed association of PCD with congenital heart disease, including atrial isomerism and disorders of laterality, such as situs inversus.

Immune deficiency is another important risk factor for bronchiectasis. A survey of 150 patients, mainly adults, with bronchiectasis, during which systematic investigations for possible heritable causes were performed, identified 12 subjects with abnormalities of immune function, including common variable immune deficiency (CVID), IgM deficiency and isolated IgG subclass deficiencies.<sup>33</sup>

### Other lung disorders

Other pulmonary diseases that have a genetic basis but rarely present during childhood include interstitial lung disease in association with collagen disorders, such as lupus erythematosus, and sarcoidosis. There is increasing interest in the origins of COPD, which has been demonstrated in several studies to cluster within families, independent of smoking status. It is possible that mechanisms such as oxidative lung injury due to deficiencies of components of the antioxidant defenses, such as superoxide dismutase and glutathione-S-transferases, are responsible

for respiratory morbidity in childhood that is the antecedent of COPD in adults. Increasing knowledge of the genetic and cellular regulation of pulmonary inflammation and defense is likely to lead to new insights into the origins of pulmonary diseases. The challenge will be to recognize individuals at risk and to develop effective interventions to prevent the onset or alter the natural history of some of these conditions.

## ENVIRONMENTAL RISK FACTORS

### Tobacco smoke exposure

A series of systematic reviews demonstrated consistent relationships between parents' smoking and respiratory illnesses and symptoms and middle ear disease in children with odds ratios between 1.2 and 1.6.<sup>34</sup> The odds were greater for preschool children and higher for maternal compared with paternal smoking. The latter observation might be explained by increased exposure to maternal rather than paternal smoking among preschool children. Alternatively, a prenatal effect of maternal smoking on the developing fetal lungs might be responsible. One of the difficulties of disentangling the interrelationships of prenatal and postnatal tobacco smoke exposure on children's respiratory symptoms in epidemiological studies is the observation that prenatal maternal smoking is almost always associated with postnatal tobacco smoke exposure.

Several studies have demonstrated an association between prenatal tobacco smoke exposure and decrements in pulmonary function in infants soon after delivery and before the onset of symptoms. Such decrements appear to be associated with respiratory symptoms during the first year after birth<sup>35–37</sup> and it seems likely that in utero smoke exposure causes growth restraint of fetal airways. The longer term effects of such fetal growth restraint have yet to be determined. Recent studies have attempted to examine the differential effects of intrauterine and postnatal tobacco smoke exposure on the outcomes of asthma and wheezing in later childhood. Gilliland et al<sup>38</sup> have demonstrated associations between in utero exposure and physician diagnosed asthma in later childhood but, although current or past environmental (postnatal) exposure was related to wheezing symptoms, there was no significant relationship with asthma. The authors speculated that environmental exposure may act as a cofactor for attacks of wheezing but did not appear to be a factor that induced asthma in this population.

Parental smoking has also been demonstrated in several case control and cohort studies<sup>39</sup> to be significantly associated with sudden infant death syndrome. Maternal smoking was associated with increased risk and a dose response effect has been demonstrated in several studies, suggesting a casual relationship, and, although smoking rates vary with socioeconomic status, the risk appears to be consistent across socioeconomic groups. Fleming et al in a study of sudden infant death after the 'Back to Sleep' campaign in the UK calculated an odds ratio of sudden infant death syndrome (SIDS) for maternal smoking during pregnancy of 2.1 with an additional independent effect of paternal smoking.<sup>40</sup> The mechanisms for this effect have not been elucidated but fetal lung growth restraint or effects of smoking on neurological responses to thermal, hypoxic or hypercapnic stress have been postulated. Recent pathological studies of infants dying of SIDS have demonstrated increased thickness of the airway wall in infants of mothers who smoked compared with infants of nonsmoking mothers, suggesting that airway obstruction may be an important mechanism.

Many studies have concentrated on the respiratory health effects of passive exposure to tobacco smoke in children. However, active smoking by children remains a significant health problem. In the UK, smoking becomes detectable in the 10–12 year age range and approximately one quarter of 15 year olds are reported to smoke.<sup>41</sup> A survey of 14–16-year-old children revealed that 30% had been active smokers in the previous 12 months, with 14.1% reporting regular smoking.<sup>42</sup> Similar figures are reported from the USA, although with encouraging signs of a downward trend in recent years.<sup>43</sup> Trials of smoking cessation targeted specifically at adolescents have recently been reviewed, suggesting that complex approaches may be required for these to be effective.<sup>44</sup>

### Social deprivation (see also Chs 2 and 3)

#### Resource limited countries

Using the World Bank definition of \$1/person/day, it is estimated that 2.1 billion of the world's population live in conditions of absolute poverty below this threshold. Diseases associated with poverty are primarily infectious diseases, which are linked to inadequate income, lack of access to clean water and sanitation, malnutrition and poor access to medical services. In resource limited countries the commonest causes of death in children under 5 years of age are lower respiratory infections, diarrheal illnesses and measles. In 2000, acute lower respiratory tract infections accounted for 1.89 million deaths in children under 5 in the resource limited world,<sup>45</sup> with approximately 40% estimated to be related to malnutrition. Some resource limited countries have achieved lower rates of poverty-related ill health by government interventions in health, education and social security, and also by active programs to increase the level of female literacy in their populations.

#### Resource rich countries

In the UK, adults and children of lower socioeconomic status have also been demonstrated to be at higher risk of communicable diseases, particularly respiratory infections.<sup>46</sup> A longitudinal study of a UK cohort born in 1946 demonstrated that a poor home environment, parental bronchitis and atmospheric pollution were the best predictors of lower respiratory tract infections in the first 2 years after birth and these factors, together with later smoking and childhood respiratory infections, were the best predictors of lower respiratory tract diseases in adults.<sup>47</sup> It is possible that increased infections in socially disadvantaged populations are related to crowding and increased exposure to infectious agents or to alterations in host immunity, possibly related to nutritional status. One of the characteristic diseases of social deprivation, tuberculosis (see Ch. 28) has shown a reversal of the decline in notified cases in the UK (Public Health Laboratory Service; [www.phls.co.uk](http://www.phls.co.uk)) with the largest number of cases reported from urban regions, particularly London. The annual incidence of tuberculosis in children in the UK is currently around 3.5 per 100 000 with a doubling of cases in London reported between 1993 and 1998.<sup>48</sup> In contrast to the adult population in which the majority of cases occur in males, the sex distribution in children appears to be even. Studies of variations in tuberculosis rates between electoral wards in inner cities have suggested that the country of birth was the single most explanatory variable, with measures of poverty being of only secondary importance.<sup>49,50</sup>

#### Early respiratory infections

In addition to potential protective effects on later development of asthma and related allergic disease (see p. 690 – Asthma), viral respiratory infections have also been proposed as contributors to the development of obstructive airways disease. A number of studies have reported persistent or recurrent wheezing after RSV bronchiolitis in infants. Sigurs et al<sup>51</sup> demonstrated a significant risk of asthma and allergic sensitization at the age of 7½ years in children who had been hospitalized with RSV bronchiolitis during infancy compared with matched controls. However, there is still debate about whether RSV causes asthma or whether severe RSV infection is a manifestation of pre-existing risk factors for both bronchiolitis and asthma.<sup>52</sup> It is hoped that randomized controlled trials (RCTs) of RSV prophylaxis will be able to address some of these questions but these are currently restricted to high risk infants.

#### Diet

The prenatal effects of maternal famine were studied in a Dutch population exposed to the famine of 1944–45. The prevalence of obstructive airways diseases in the offspring of famine-exposed mothers was higher, particularly when the exposure occurred in early gestation. This effect did not appear to be mediated through increased prevalence of atopic disease in this population, suggesting that impairment of fetal lung development was an important factor.

A number of dietary constituents have been examined in relation to their potential role in the etiology of lung diseases, including fatty acids,

antioxidants and sodium intake. The observation that Eskimos had a low prevalence of lung disease and a diet high in oily fish prompted speculation that *n*-3 fatty acids, which competitively inhibit the metabolism of arachidonic acid, may be protective against asthma.<sup>53</sup> However, there is only weak evidence for this and no intervention studies have yet been done.

Oxidative damage to the lungs, mediated through oxygen free radicals, is believed to be important in the pathogenesis of asthma and COPD. Fruit is a major source of antioxidant vitamins and epidemiological associations between fruit intake and lung function in adults have been established. A positive association between fresh fruit consumption and lung function has also been demonstrated in children.<sup>54</sup> Selenium is essential to the activity of glutathione peroxidase enzymes that are involved in the lung's antioxidant defenses. Low serum concentrations of selenium have been demonstrated in subjects with asthma but it is unclear whether selenium deficiency contributes to the development of asthma or if selenium consumption occurs as a consequence of oxidant injury. An ecological study of asthma and allergy (ISAAC) did not demonstrate an increased prevalence in countries in which selenium deficiency is endemic<sup>55</sup> compared with areas with abundant dietary selenium sources. A systematic review of selenium supplementation in asthma identified only one RCT. This suggested improvements in clinical control when asthma treatment was supplemented by selenium but there were no objective correlates of this improvement.<sup>56</sup> Low dose vitamin A supplementation has been examined for its possible protective role in the development of lower respiratory infections in children. Intervention studies in resource limited countries had suggested that this effect was strongly related to nutritional status with decreased acute lower respiratory infections observed in underweight children only.<sup>57,58</sup> However, a recent review of vitamin A supplementation in nonmeasles-related pneumonia concluded that there was no evidence of reduction in mortality or measures of morbidity.<sup>59</sup>

Regional differences in asthma mortality have been correlated with table salt purchase, leading to the possibility that dietary sodium may be an important factor in asthma pathogenesis. However, dietary salt intake in children has been associated with increased bronchial responsiveness to methacholine but not with a diagnosis of asthma or with exercise induced bronchospasm.<sup>60</sup> A recent systematic review of a number of small trials of dietary salt reduction or exclusion in asthma concluded that there was insufficient evidence on which to base current recommendations.<sup>61</sup>

### Atmospheric pollution (including indoor pollution)

There is clear evidence that atmospheric pollution may exacerbate respiratory symptoms in human subjects but what is less clear is whether specific pollutants have a causal role in the pathogenesis of respiratory diseases. The principal pollutants of the external (outdoor) environment include nitrogen oxides (NO, NO<sub>2</sub>), ozone, sulphur dioxide (SO<sub>2</sub>) and particulates from the burning of fossil fuels. Hospital admission rates for respiratory diseases, especially pneumonia, have been demonstrated to be correlated with high atmospheric concentrations of particulates (PM<sub>10</sub>), NO<sub>2</sub> and ozone<sup>62</sup> and effects of NO<sub>2</sub>, carbon monoxide (CO) and SO<sub>2</sub> on general practice consultations for asthma have been found to be stronger in children than adults.<sup>63</sup> The well documented rise in the prevalence of asthma in industrialized countries has coincided with a general increase in the density of road traffic in the majority of these countries. Therefore, a number of studies have investigated the possibility that traffic pollution is an exposure that initiates asthma in previously unaffected individuals but with conflicting results. A landmark study of this aspect of lung disease in children was undertaken following the German reunification in 1989. This allowed a study of two genetically similar populations exposed to different levels of atmospheric pollution with higher concentrations of industrial pollutants (SO<sub>2</sub> and particulates) in Leipzig, East Germany compared with Munich, West Germany where traffic density was higher. The results of this study demonstrated a higher lifetime prevalence of asthma and a greater prevalence of sensitization to common aeroallergens in the West

German population compared with the East German population, suggesting that prolonged exposure to industrial pollutants was not associated with the development of asthma or allergy.<sup>64</sup> The same group studied the relationships between traffic density and respiratory health of children in several school districts in Munich and, although demonstrating associations between traffic density and small decrements in lung function, found no association between high traffic density and either lifetime prevalence of asthma or bronchial responsiveness to cold air.<sup>65</sup> It should be borne in mind that geographical comparisons such as this are prone to confounding by other differences in exposures between the populations, such as indoor environment and lifestyle variations. The importance of the indoor environment for respiratory diseases has been highlighted in observational studies of populations in resource limited countries that rely on burning fossil fuels for domestic energy: this practice appears to be associated with increased respiratory infections and obstructive airways diseases in children,<sup>66</sup> although no controlled studies have been done and few have measured exposures directly. An association between gas cooking and asthma in children has been described<sup>67</sup> and Burr et al<sup>68</sup> have described an increased 12-month prevalence of wheeze in 12–14 year olds in association with the use of bottled gas, paraffin and other unusual domestic fuels for heating. However, of all the potential indoor pollutants to which children may be exposed, it is likely that parental tobacco smoke exposure has the single greatest effect on their respiratory health.

## DEVELOPMENT OF THE RESPIRATORY SYSTEM

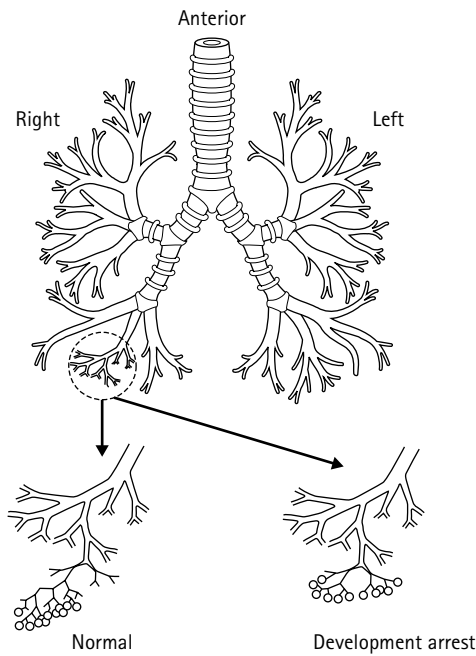

### FETAL AND PERINATAL DEVELOPMENT

#### Structural development

Lung growth and development commences in early intrauterine life with the development of the trachea from the primitive esophagus at approximately 5 weeks of gestational age. The right and left lung buds develop at about 7 weeks and the formation of the main lobar structures is already evident by 9 weeks. This process of branching airway development continues through the first trimester of pregnancy and is largely complete by 16 weeks of gestational age. By this time the lungs have a glandular appearance with alveoli emerging over the next 8–10 weeks, increasing in complexity and surface area up to and beyond term.<sup>69,70</sup> Arguments concerning the duration of alveolar development have depended on the distinction of saccules and alveoli and on techniques for counting alveolar number in postmortem lungs. Approximately 50% of alveoli are present at term with 85% complete by 2–3 years of age, a process accompanied by a reduction in interstitial tissue and the remodeling of capillaries into a single network, and with an enormous thinning of the blood–gas barrier. A network of elastin strands form the 'skeleton' (likened to a fishnet) between which the new alveoli are formed. Normal fetal breathing movements are important in promoting this growth. Adverse influences on this ordered sequence of development will have important and different consequences for future respiratory health of the individual depending on their timing and duration. Generally the earlier the insult the more profound the long term consequences.

#### Implications for disease

Many adverse intrauterine influences, e.g. congenital diaphragmatic hernia<sup>71</sup> and renal agenesis and oligohydramnios<sup>72</sup> can have devastating effects on subsequent lung growth and development. Insults during the early phase of airway development will reduce branching and will inevitably lead to reductions in the number of alveoli that can bud from a reduced number of terminal bronchioles (Fig. 20.7). This can also be inferred from physiological measurements in infants with impairment of intrauterine growth due to diaphragmatic hernia or reduced fetal breathing movements associated with spinal muscular atrophy of intrauterine origin.<sup>73</sup> The importance of fetal breathing movements has been demonstrated in a series of elegant experiments in laboratory animals in which the relative contributions of fetal breathing and the volume of amniotic fluid have been demonstrated.<sup>74</sup> As pulmonary vascular

**Fig. 20.7** Representation of the bronchial tree in a normal newborn infant and in an infant with intrauterine pulmonary hypoplasia in whom peripheral airways development has been impaired. Note the implication for reduced alveoli.

development follows the development of the airways it is hardly surprising that pulmonary perfusion anomalies have also been observed in the survivors of diaphragmatic hernia repair despite what appears to be a satisfactory radiological outcome.<sup>75</sup> Although the intrauterine insults described above are dramatic, they are thankfully relatively rare in population terms. What may be more relevant for population respiratory health are the more subtle influences on lung growth and development in utero and in early life. Such associations between early respiratory symptoms and adverse environmental exposures have been inferred by the association between low birth weight and subsequent respiratory health and in particular chronic respiratory lung disease of adulthood.<sup>24</sup> The most clearly identified adverse exposure at a whole population level is fetal tobacco smoke exposure associated with maternal smoking in pregnancy. Whereas postnatal or environmental tobacco smoke (ETS) exposure has a significant influence on respiratory morbidity in the young,<sup>76</sup> the effects of prenatal exposure are likely to be more long lasting. Studies which have assessed lung function soon after birth, when the effects of ETS would be expected to be small, have shown evidence of reduced airway function.<sup>77,78</sup> Whereas it is clearly not possible to identify the exact mechanisms of these effects in humans, animal studies have shown that fetal ETS significantly reduces cell division in the lung (as evidenced by reduced DNA), alveolar number and the amount of connective tissue within the lung.<sup>79,80</sup>

The structures of the airways themselves also have important functional consequences. Cartilaginous structures appear in segmental bronchi at 10–12 weeks of gestational age but continue to develop in small bronchi until after birth. Generalized bronchomalacia or local disorders affecting the trachea and bronchi are associated with several important disorders, including tracheomalacia, stovepipe trachea and lobar emphysema. Airway smooth muscle, contrary to popular belief, is found at term down to the smallest terminal and respiratory bronchioles and consequently failure of wheezing illnesses to respond to bronchodilators cannot be ascribed to the absence of smooth muscle at this level. Vascular modeling after birth may be disturbed as a result of widespread perinatal lung damage such as chronic lung disease of prematurity (see p. 727), or in association with congenital heart disease (see Ch. 21, p. 765), leading to persistence of high pulmonary vascular resistance

and pulmonary hypertension. A number of major developmental defects in the nasopharynx may lead to respiratory obstruction, infection or recurrent aspiration. These include choanal atresia or stenosis, palatal anomalies and, at a cellular level, ciliary dyskinesia. These, as well as mid-facial syndromes, Down syndrome and neuromuscular disorders, can lead to obstructive apnea or sleep-disordered breathing problems (see p. 687 – Sleep and respiratory disorders).

### The chest wall

The chest wall is defined as the structures which surround the lung and which have significant influences on lung growth and function. It includes the rib cage, the diaphragm and the abdominal contents together with the paraspinal and accessory muscles of respiration. The diaphragm becomes a complete membrane by 8 weeks of gestation and the abdominal wall is complete at 9 weeks, allowing the establishment of effective fetal breathing. At birth, however, the proportion of fatigue resistant (Type 1) striated muscle fibers is approximately 10%, much less than the 50% found in adults. The proportion is even less in pre-term infants and along with the instability of the chest wall explains in part the tendency of preterm infants to develop respiratory failure and to suffer from apnea. The diaphragm is also inserted more directly into the chest wall with a reduced area of apposition (or alignment with the lower rib cage) than that found in mature subjects and this again results in a relative functional impairment in the infant and very young child. The chest wall has important influences on the function of the underlying lungs both in maintaining lung volume at rest (the lung tends to seek a lower volume whereas the chest wall recoils outwards) and in its role as the 'respiratory pump'. During growth and development important changes occur in the function of the chest wall, not only at rest but also during respiratory efforts that affect underlying lung function (see below).

### POSTNATAL DEVELOPMENT

Alveolization is virtually complete by 3 years of age, after which the lungs grow as a result of stretch, mainly due to the associated growth of the rib cage. This can be seen in the different patterns of alveolar growth assessed from postmortem pathological studies and physiological lung volumes measured during respiratory maneuvers (Fig. 20.8). This disparity emphasizes the significant influence of the chest wall on the function of the underlying lung. The stretch and subsequent growth of volume of the lung results in what has been termed 'dysynaptic' growth. In infancy the airways are relatively large in relation to the total lung volume, a ratio which falls progressively during subsequent

**Fig. 20.8** Increase in lung volume in boys contrasting in vivo to post mortem measurements. Measurements in vivo are of total lung capacity and are influenced by increasing inspiratory effort with age. Measurements post mortem made at the same distending pressure of 3.3 kPa.

growth. This feature of physiological lung growth results in a gradual fall in the contribution of peripheral airway resistance to overall airway resistance, a feature which also contributes to the severe nature of lower respiratory illnesses and an increased tendency to develop symptomatic airway obstruction in infancy and early childhood. Another feature during growth and development is that females appear to have more patent airways (lower resistance) than males, as seen in physiological measurements,<sup>81,82</sup> and in the increased risk of significant respiratory morbidity in boys. This relative female advantage reverses during puberty and is in part explained by the increased stretch of the underlying lung that is associated with increased muscular development and thoracic expansion in males at that time.

Large airways are supported by cartilage in order to resist collapse during expiration whereas smaller peripheral airways within the lung have no such support but rely on the distending pressure within the lung parenchyma to remain patent. In infancy and early childhood this distending pressure is low and in the region of 0.15 kPa at the end of quiet expiration. In the young healthy adult these pressures increase to between 0.5 and 1.0 kPa, differences which can be largely attributed to increasing chest wall recoil associated with maturation. A highly compliant (or floppy) chest wall is an advantage in utero in that the low lung distending pressure reduces the amount of lung liquid that needs to be cleared by lymphatic drainage soon after birth. However, in the transition to air breathing the highly compliant and unstable ribcage has significant functional consequences. Whereas it is the chest wall that determines the distribution of ventilation and airway function in infancy and early childhood, it is the gradual loss of the elastic recoil of structures within the lungs themselves that is associated with increasing peripheral airway closure and reduced airway function in the elderly (Fig. 20.9).

The thoracic configuration is also different in infants and young children in that the ribs are more horizontally placed with less potential for thoracic expansion than in older children and adults.<sup>83</sup> As a consequence infants and very young children rely more on diaphragmatic activity and this, in combination with a more direct insertion into the ribcage and a reduced number of Type 1 muscle fibers (slow twitch high oxidative fibers), places the infant and young child at significant risk of developing respiratory failure when presented with an added respiratory load. Any additional impairment of the chest wall itself, e.g. in association with scoliosis or neuromuscular disorders, will only augment this relative inefficiency of the respiratory system in early life.

The upper airway of the infant and young child is also structurally different from that of the mature child or adult in that the posterior

Fig. 20.9 Interaction between outward recoil of chest wall and inward recoil of the underlying lung. The reduced chest wall recoil in the infant results in low transpulmonary pressures whereas in the elderly reduced lung recoil has the same effect. Low transpulmonary pressures result in increasing risks of peripheral (small) airways closure.

Fig. 20.10 Growth of facial skeleton from childhood to adult life. The relative hypoplasia of the facial skeleton and sinuses renders the infant and very young child prone to upper airway obstruction as a consequence of a crowded hypopharynx.<sup>84</sup>

nasopharynx is relatively crowded and therefore vulnerable to obstruction. The immaturity of the facial skeleton, particularly the mid-facial skeleton in the infant and young child, results in the relative backward displacement of the tongue. Together with the hypertrophy of the tonsillar tissue that occurs in early childhood, it is hardly surprising that upper respiratory airway obstruction is a common clinical feature in early life (Fig. 20.10).

### Gas exchange

The immediate process of adaptation at birth takes about 5 h but in premature infants a significant alveolar to arterial oxygen difference  $[(A-a) DO_2]$  persists up to term largely due to intrapulmonary anatomical shunt through non-alveolized vessels. Persistence of a significant  $(A-a) DO_2$  through the first year is largely due to the ventilation/perfusion imbalance described below. Thus the mean arterial oxygen tension  $PO_2$  for a term infant for the first week of life is 10 kPa, giving an approximate  $(A-a) DO_2$  of 4 kPa compared with 1 kPa for an adult. Oxygen consumption per kg and hence alveolar ventilation in the newborn is two to three times adult values. The suboptimal gas exchange in subsequent infancy and early childhood is largely due to the poor support offered by the compliant chest wall to the underlying lungs (see Fig. 20.9) with subsequent closure of small airways in dependent parts of the lungs (the lung bases when posture is upright) and shunting of blood through nonventilated areas.<sup>85</sup>

Developmental disorders of gas exchange are not common. Severe lung hypoplasia may impose limits in the newborn period which diminish with growth. Incomplete collateral ventilation (the canals of Lambert are not apparent in lungs from preschool children) may lead to atelectasis and hence impaired gas exchange in disease.

## RESPIRATORY PHYSIOLOGY, PATHOPHYSIOLOGY AND THE MEASUREMENT OF RESPIRATORY FUNCTION

The principal function of the respiratory system is gas exchange: oxygenation of the blood and the removal of carbon dioxide. A knowledge of the means whereby this is achieved forms the basis for understanding many of the clinical features of respiratory disease and of lung function tests. Although the principles of disturbed pathophysiology are no different in children and adults, growth and development add further dimensions both to the interpretation of data and to the challenge of making the measurements.

### RESPIRATORY FUNCTION TESTS

A decision to carry out respiratory function tests will generally have followed clinical assessment and can often usefully be combined with other

investigations. The tests should be performed by an operator experienced in dealing with children, who can allay their anxiety and turn natural inquisitiveness and playfulness to advantage. A positive approach, with lots of encouragement and the insight to abandon a session before failure to cooperate turns into panic, are essential virtues.

For most simple procedures the equipment found in any adult lung function laboratory will be adequate. In infancy most measurements can only be made in specialized laboratories and will not be dealt with here. Preschool children form another challenging group, where specially adapted equipment may be needed and where the repeatability of measurements is not as good as in older children and adults. However, spirometric measurements, for example, can be performed in children as young as 4 years of age with suitable equipment and experience and peak flow can occasionally be measured in 3 year olds. In view of these challenges there is a burgeoning interest in tidal breathing techniques in this young age group.<sup>86,87</sup>

## Interpretation

Lung function is most closely related to body length or height but with small additional effects of age and sex, particularly around puberty, and of ethnic group. In the presence of scoliosis, arm span can be substituted directly for length. Body weight is a poor reference standard, since its variation in disease can be extreme. The significance of individual measurements in relation to the population is found by reference to a graph, table or appropriate prediction equations.<sup>81,82</sup> For sequential measurements in an individual, the confidence limits or coefficient of variation for repeated measurements must be sought.

## AIRWAY FUNCTION

As most lung problems in infancy and childhood are associated with airway obstruction, measurements that reflect airway caliber and function are of particular relevance.

The conducting airways extend from the tip of the nose to the terminal bronchioles and are physiologically very active, constantly varying their caliber and the nature of their secretions in response to changing environmental exposures.

The volume of the conducting airways constitutes a dead space (i.e. the volume of the lungs which although ventilated does not contribute to alveolar gas exchange; it measures about 2.2 ml/kg throughout life<sup>80</sup>). Disorders of airway structure such as bronchiectasis lead to an increase in anatomical dead space. In addition, the ventilation of underperfused regions of the lung, such as the apices in the erect posture, leads to another form of dead space referred to as physiological dead space.

Airway resistance ( $R_{aw}$ ) is a function of gas flow and pressure: airway resistance = pressure/flow. The reciprocal of  $R_{aw}$ , airway conductance

( $G_{aw}$ ), is often used, since its relationship with lung volume is linear, rather than curvilinear as with  $R_{aw}$ . In peripheral airways, because the total cross-sectional area of the enormous number of airways is large, gas velocity and resistance is low. In the most distal respiratory bronchioles, alveolar ducts and alveolar spaces, gas molecules move by diffusive processes. In the larger central airways, where flow rates are high, the pattern of gaseous movement is transitional (somewhere between ordered laminar and turbulent flow) with a consequent steep increase of resistance with increasing flow. In nose-breathing infants, about 50% of the total resistance is nasal, 25% is in the glottis and large central airways, and the remainder in the peripheral airways. This distribution of resistance together with the relatively crowded upper airway (see p. 663 – Postnatal development) renders infants particularly prone to develop upper airway obstruction. The highly compliant chest wall and consequent tendency to peripheral airway closure, particularly at lung bases (see p. 663 – Postnatal development) also renders the infant prone to small airway obstruction (e.g. bronchiolitis) in contrast to older children and adults in whom the small airways represent a clinically 'silent zone'.

During forced expiration intrapulmonary airways progressively close as lung volume falls. Towards the lung periphery small airway patency relies on the tension within the surrounding connective tissue elements, a tension which in turn is dependent on the degree of lung stretch or inflation. During forced expiration a point is reached where the pressures within and surrounding the airway reach equality, the equal pressure point (EPP), and when flow becomes effort independent. EPP is usually reached somewhere near the mid-point of a forced expiratory effort whereas in diseases associated with increased lung compliance (reduced lung recoil), or in airway obstruction, the EPP occurs closer to the lung periphery and expired flow rates become limited earlier during expiration. This produces the concave flow volume curve so characteristic of moderate to severe asthma or cystic fibrosis (Fig. 20.11) whereas obstruction in larger airways reduces peak expiratory flow rates (Fig. 20.11). During forced inspiration the airways remain widely patent throughout and as a consequence inspiratory flow is more symmetrical. The exceptions to this rule are in fixed large airway obstruction, in profound neuromuscular weakness, or where the site of the obstruction is extrathoracic. Variable large airway obstruction such as in obstructive sleep apnea may be associated with characteristic oscillations (Fig. 20.11).

Inflammation, excessive mucus secretion and active contraction of airway smooth muscle all lead to increased airflow obstruction. Although these processes may be part of normal defense mechanisms in the lungs, one of the characteristic features of asthma is an exaggerated airway responsiveness (i.e. reversible airway narrowing in response to either allergic or non-immunological irritant factors). The degree of airway responsiveness can be measured by standardized challenge procedures

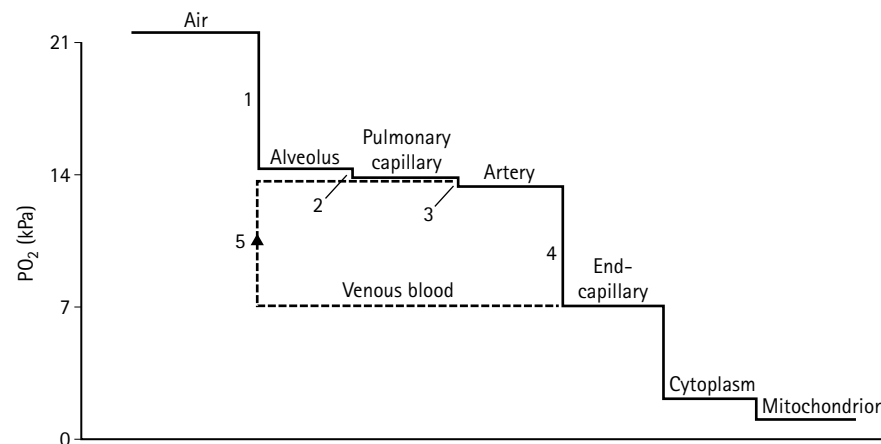

Fig. 20.11 Flow-volume curves. Maximum forced expiratory and inspiratory flow volume curves, showing patterns characteristic of airflow obstruction at various sites.

based, for instance, on exercise or inhalation challenge with cold dry air, hypertonic or hypotonic saline or with pharmacological agents such as histamine or methacholine (see p. 689 – Asthma).

### Measurement of airflow obstruction

Forced expiratory maneuvers, which require a maximum expiratory effort from total lung capacity, form the basis of the most useful tests of airway obstruction. The peak expiratory flow (PEF), the forced expiratory volume in the first second of expiration (FEV<sub>1</sub>) and the indices derived from the maximum expiratory flow volume (MEFV) curve are the most commonly performed. The best of three efforts (after two practice blows for novices) should be recorded, the two most important features being the completeness of the maximum expiratory effort at the start of each procedure and whether the effort is sustained to residual volume (RV), as evidenced by a smooth progress of flow until it meets the volume axis (Fig. 20.11). Most children from 4 years old can perform a PEF maneuver, although they may not be able to meet the recommended adult standards of less than 5% variability for other forced measurements (FEV<sub>1</sub>, MEFV curve). In young children, the whole vital capacity may be exhaled in under 1 s and in this group, FEV<sub>0.75</sub> or FEV<sub>0.5</sub> have been suggested as more sensitive indices of obstruction.

Airway obstruction is indicated by a reduction in the ratio FEV<sub>1</sub>/forced vital capacity (FVC) (or FEV<sub>0.75</sub>/FVC) since airway obstruction will prolong the expiratory time constant of the lungs and reduce the rate of emptying. The FEV<sub>1</sub>/FVC ratio normally decreases with age, from over 90% in the youngest children in whom it can be measured to over 75% in young adults.

The shape of the expiratory flow–volume curve provides additional information, which is not available from the traditional volume–time plot (Fig. 20.11). Compensatory changes in lung volume with airways disease or its treatment may explain apparent changes in forced flow expiratory rate as airway caliber is modified by lung stretch. The maximal expiratory procedure itself may induce airway obstruction in children with reactive airways although this effect is transient and is responsive to inhaled bronchodilators.

Methods for measuring airflow obstruction which do not depend on respiratory effort, and which have therefore been adapted for use in infants and young children, include the plethysmographic determination of airway resistance and the measurement of total respiratory system resistance (impedance) by a forced oscillation and interrupter techniques.<sup>84</sup> Like PEF these methods mainly reflect large airway function and are especially sensitive to glottic narrowing and (in nose-breathing infants) to nasal obstruction.

### Peak flow measurements

Objective evidence of the severity and nature of airway obstruction in wheezy children of school age can be obtained from twice-daily peak flow measurements that can easily be made at home using a peak flow meter. Although this kind of monitoring can be useful in assessing responses in clinical trials and in large scale epidemiological studies, its contribution to asthma management at the individual patient level is disappointing (see p. 689 – Asthma). However, peak flow measurements made at home can be of value in providing objective evidence of the severity or absence of reported asthma. A single isolated value of peak flow (or of any other measure of lung function) is of little use in the assessment of severity since variability, even within a 24-h period, can be considerable.

### Measurement of bronchial responsiveness (bronchial provocation tests)

Bronchial provocation tests rarely help in the diagnosis of asthma as they are neither specific nor sensitive for asthma. They may be used in order to assess the importance of airway responsiveness in a patient with atypical symptoms (e.g. chronic cough) or in patients with other forms of airway obstruction (e.g. cystic fibrosis, bronchiectasis). Their main use is as a research tool in whole population studies or in assessing

the response to prophylactic anti-asthma therapy. Children under the age of 6 can be tested only under the conditions of a research laboratory. Simple, repeatable measurement techniques (FEV<sub>1</sub>, PEF) are the reference norms for bronchial provocation tests but increasingly techniques that reflect airways resistance, including specific resistance, and interrupter techniques are being employed.<sup>84</sup>

There are three broad categories of challenge test: pharmacological challenge by aerosol, bronchial provocation with aerosolized antigen and exercise (or isocapnic hyperventilation) challenge. In order to determine the degree of responsiveness, pharmacological or exercise challenge are usually used. Exercise is said to be specific for asthma, whereas a response to pharmacological challenge also occurs in other lung disorders. Antigen provocation is a risky procedure confined to research laboratories.

Pharmacological challenge with solutions of histamine, methacholine or adenosine is performed by administering increasing concentrations of aerosol by jet nebulizer at regular intervals, until at least a 20% fall in PEF or FEV<sub>1</sub> has been produced (or the maximum concentration has been reached). By interpolation on a graph the concentration which provokes a 20% fall in PEF or FEV<sub>1</sub> (PC<sub>20</sub>) can be calculated. The PC<sub>20</sub> or the cumulative dose (PD<sub>20</sub>) is an index of bronchial responsiveness. There is a continuum of values of PC<sub>20</sub> from the lowest in severe, labile asthma to the highest in normal individuals. Many factors influence asthmatics, such as environmental antigen exposure (pollen, dust mite), time of day and recent medication. In children with other forms of chronic bronchial obstruction (e.g. cystic fibrosis), bronchial responsiveness appears to become greater as their airway obstruction worsens.

Exercise-induced asthma (EIA) can be reproducibly induced by having a child run for 5–6 min at a rate sufficient to produce a heart rate of >170 beats/min, ideally on a treadmill in an air-conditioned laboratory. The fall in PEF or FEV<sub>1</sub> can be expressed as a percentage of the baseline value, to provide an index of EIA (upper limit of normal about 15%). Again, a number of clinical variables (a recent cold) and laboratory conditions (air temperature and humidity) may affect the result; outdoor tests of a similar type are very poorly repeatable. Used as a diagnostic aid, EIA has poor sensitivity and specificity. Exercise tests can be used to study the protective effects of drugs given before challenge and to demonstrate their value to the child and family. They can also be used to show that some children get ‘short of breath’ when they exercise, not because of EIA but simply because they are unfit!

### Normal (reference) values

The choice of reference norms remains controversial. Whereas many equipment manufacturers use composite reference values,<sup>81</sup> there may be important racial and regional differences that need to be accounted for. For example, reference values for Caucasian European children may not be appropriate for children of African origin<sup>88</sup> and even within Europe differences in flow rates have been reported between studies from Northern and South-Eastern Europe.<sup>89</sup> Another particular problem is in predicting expected values in children and adolescents who fall between the published reference norms for children, usually up to 18 years of age, and those of adults, usually starting at about 18 years. A possible solution to these problems has been suggested by the European Respiratory Society Standardisation Report of 1989 which provided all the summary equations up to that point in time. This report suggested that individual centers should perform lung function measurement in a sample of 50–100 normal, healthy children from their own population and then identify and use the published norms that most closely fit these local values.

## THE AIRSPACES: LUNG VOLUME AND COMPLIANCE

### Physiology

As described above (p. 663 – Postnatal development) the elasticity of the lung and chest wall (i.e. compliance: change in volume for a given change in pressure) is such that at high volumes, the respiratory system tends to deflate and at low volumes to expand, reaching equilibrium at

Table 20.1 Lung function patterns (for spirometry)

Setting	Vital capacity	Peak flow	FEV <sub>1</sub> /FVC	MEF <sub>50</sub>	MIF <sub>50</sub>
Poor effort/weakness	Reduced	Reduced	Normal	Normal	Reduced
Mild asthma/cystic fibrosis	Normal	Normal	Normal	Reduced	Normal
Severe asthma/cystic fibrosis	Reduced	Reduced	Reduced	Reduced	Normal

the functional residual capacity (FRC) where the outward recoil of the chest wall and inward recoil of the lungs are at equilibrium.

In pulmonary fibrosis where the lungs are less compliant (stiffer), the inward recoil forces of the lungs are greater and FRC is reduced. Conversely in emphysema (where the lungs are 'stretched') the inward recoil forces are lower and hence FRC is increased. Peripheral airway obstruction with 'gas trapping', as seen in chronic asthma and cystic fibrosis, results in overstretch of the lung and an increase in FRC. Static lung volumes, total lung capacity (TLC) and residual volume (RV) depend on several factors including lung compliance, chest wall compliance, respiratory muscle strength and the caliber of the small intrapulmonary airways. These may all be important in relation to changes in the vital capacity (VC) in disease and need to be interpreted together with expiratory flow rates (Table 20.1).

### Measurement of lung volume and compliance

Lung volume is most commonly estimated by clinical examination aided by chest radiography. On formal laboratory testing, the distinction is often made between dynamic lung volumes produced by respiratory effort (e.g. FVC) and static lung volumes measuring absolute lung volumes (e.g. FRC, RV and TLC). Static lung volumes and lung compliance are less often measured and require a specialized lung function laboratory.<sup>82</sup>

The VC is a most useful, repeatable measurement, although almost any disturbance of lung function will lead to its reduction (Fig. 20.12). FVC can be reduced by poor or inefficient inspiratory or expiratory efforts due to chest wall disorders, such as scoliosis, to neuromuscular disorders or as a consequence of premature airway closure resulting in gas trapping and an elevated RV (Table 20.1; Fig. 20.12). Lung volumes may also be valuable in following the course of patients with these disorders. There are two methods of measuring static lung volumes: by the plethysmographic technique and by dilution of an inert non-absorbable gas such as helium. The former technique measures all the gas in the thoracic cage, whether or not it is in communication with airways, using

Fig. 20.12 Causes of reduced vital capacity. The length of the arrows indicates the vital capacity and the position indicates the changes in total lung capacity (TLC) and residual volume (RV) for each condition in relation to normal. The horizontal line across each arrow indicates the usual end-expiratory curve (functional residual capacity, FRC).

simple physical principles (Boyle's law). The latter technique, relying on equilibration of gas concentrations between the gas in the lungs and in a mixture of air and a known initial concentration of helium, tends to underestimate the volume of those parts of the lung which are very poorly ventilated (i.e. in the presence of obstructed airways). Both techniques require cooperative subjects and are rarely reliable under the age of 6 apart from in sleeping or sedated infants.

## VENTILATION AND PERFUSION

### Physiology

During tidal breathing, air is distributed within the lungs according to local variations in airway resistance and lung compliance. In the upright subject, because of the weight of the lungs (density about 0.2 g/ml), the pleural pressure is more negative near the apex so that the airspaces are relatively overdistended compared with those near the base. In infants the low chest wall recoil results in a reversal of the normal apex to base gradient in ventilation (see p. 663 – Postnatal development). Disease may also affect the regional distribution of ventilation by affecting the chest wall (e.g. spinal muscular atrophy, severe rickets in infancy), the diaphragm (e.g. congenital diaphragmatic hernia, eventration or paralysis), the airways (e.g. bronchiectasis, asthma) or the airspaces (e.g. lobar pneumonia, pulmonary edema).

The matching of ventilation to pulmonary perfusion mainly takes place at alveolar level with the airways playing a smaller part in this homeostatic mechanism. Alveolar hypoxia induces local pulmonary arteriolar constriction by a nitric oxide-dependent mechanism, cutting down the local blood supply. The effect is amplified by acidosis. The particular problems of the perinatal period are described in Chapter 12.

In older children, a sustained increase in pulmonary resistance, usually associated with severe chronic and generalized disease (e.g. chronic lung disease of prematurity, terminal cystic fibrosis), may lead to cor pulmonale.

Mismatching of ventilation ( $\dot{V}$ ) and perfusion ( $\dot{Q}$ ) occurs in acute lung disease before adaptation has occurred and in severe chronic disease, beyond the limits of adaptation. Its effects are wasted ventilation (excessive dead space ventilation) on the one hand, and hypoxemia (due to right-to-left intrapulmonary shunting) on the other. Hypoxemia due to mild  $\dot{V}/\dot{Q}$  imbalance, as well as that due to alveolar hypoventilation, is largely corrected by increased inspired oxygen concentrations.

### Tests of the distribution of ventilation and perfusion

Regional distribution of ventilation and perfusion can be studied fairly simply in standard nuclear medicine facilities, using radionuclide-labeled gas and microspheres and a gamma camera (see p. 671 – Special investigations – imaging). Other tests remain research procedures.

## GAS TRANSFER AND GAS TRANSPORT

### Physiology

Within the alveoli, gas movement takes place by diffusion. Transfer of oxygen from alveolus ( $\text{PaO}_2$  14 kPa) into the pulmonary capillary and of carbon dioxide in the reverse direction ( $\text{PaCO}_2$  5 kPa) take place by passive diffusion down partial pressure gradients.

The gradient of  $\text{PO}_2$  can be thought of as running from alveolus to mitochondrion. Oxygen is transported as oxyhemoglobin. The quantity of oxygen carried depends on the  $\text{PaO}_2$  (and its characteristic sigmoid relationship with oxygen saturation), the hemoglobin concentration

and the cardiac output: oxygen delivered = oxygen content of blood  $\times$  cardiac output. Thus oxygen delivery will be reduced by anemia, hypoxemia or diminished cardiac output. Metabolic acidosis (anaerobic metabolism leading to lactic acid production) is one consequence of impaired oxygen delivery.

The oxygen dissociation curve is also affected by a number of other factors: the dominant class of hemoglobin (e.g. HbF in the newborn), adaptive variations in intracellular 2,3-diphosphoglycerate (2,3-DPG) concentration with chronic anemia and arterial pH and PaCO<sub>2</sub> (the Bohr effect).

The transport of CO<sub>2</sub> is much more robust, since the CO<sub>2</sub> content of blood is almost linearly related to PCO<sub>2</sub> over the clinical range. Respiratory acidosis results from hypercapnia.

Respiratory failure is a general term used to imply a breakdown of the supply of oxygen and removal of CO<sub>2</sub>. A single definition which covers the whole pediatric range would be inappropriate, since degrees of acute disturbance of blood gases which may have dire clinical consequences in a preterm neonate may have little effect in a chronically sick older child. In newborns when the labile fetal circulation shunts through fetal channels, a low PaO<sub>2</sub> may indicate a complex failure of ventilation and circulation which it would be inappropriate to label as 'respiratory' (see Ch. 12).

## Terminology

### Hypoxemia

Hypoxemia (PaO<sub>2</sub> at sea level in postneonates of < 12 kPa) may have several causes (Fig. 20.13; Table 20.2). At altitude the oxygen content of inspired air is reduced and the PO<sub>2</sub> will fall. However, acclimatization principally by hyperventilation and the development of polycythemia preserves the oxygen content of arterial blood.

Alveolar hypoventilation, with resultant hypoxemia and hypercapnia, may be due to mechanical factors (stiff or obstructed lungs), weakness of respiratory muscles or a defect of the control of breathing.

Shunt refers to systemic venous blood which effectively bypasses ventilated portions of lung. There are two main varieties of right-to-left shunt: intracardiac shunt and intrapulmonary shunt. In childhood, the main extrapulmonary cause of shunt is cyanotic congenital heart disease. Breathing 100% oxygen for at least 5 min (the nitrogen washout test) is useful for diagnosing this 'central' shunting. In order to under-

stand this test, the shape of the hemoglobin–oxygen dissociation curve should be borne in mind. Even if the PO<sub>2</sub> of pulmonary venous blood is > 55 kPa (400 mmHg), the content of oxygen in that blood will be hardly greater than if the PO<sub>2</sub> is 13 kPa (100 mmHg). When mixed with shunted blood of low oxygen content the PO<sub>2</sub> will fall dramatically. Even when the lungs are completely normal, the presence of a very small central shunt will prevent a significant rise in PO<sub>2</sub> when breathing 100% oxygen. A rise in PaO<sub>2</sub> to 20 kPa (150 mmHg) makes cyanotic heart disease an unlikely cause of hypoxemia. On the other hand, if breathing 100% oxygen (for a minimum of 5 min) does successfully elevate the PaO<sub>2</sub>, the hypoxemia in air is likely to have been due to intrapulmonary shunting (regions of low  $\dot{V}/\dot{Q}$  ratio) or hypoventilation. A specific exception to this rule is the situation of pulmonary hypertension in the newborn, when oxygen therapy, by reducing pulmonary vascular resistance, can abolish the extrapulmonary right-to-left shunt through fetal channels, causing the hypoxemia to resolve for 'vascular' rather than 'pulmonary' reasons.

Ventilation perfusion  $\dot{V}/\dot{Q}$  mismatching is by far the commonest cause of hypoxemia in pulmonary disease. Blood leaving alveolar units which are underventilated but well perfused will have a low O<sub>2</sub> content and a raised CO<sub>2</sub> content. For the reasons mentioned above, the total PaO<sub>2</sub> will fall and hyperventilation results. CO<sub>2</sub> is washed out of the well-ventilated lung units. As the CO<sub>2</sub> content of blood bears an almost linear relationship to PaCO<sub>2</sub>, the reduction in CO<sub>2</sub> content of blood leaving well-ventilated units offsets the rise in that leaving poorly ventilated alveoli. However, no matter how good the ventilation of healthy alveolar units, the O<sub>2</sub> content of blood leaving them remains the same and does not offset the reduced content of those leaving poorly ventilated alveoli. Hypoxemia due to  $\dot{V}/\dot{Q}$  imbalance will therefore be unaltered by hyperventilation, an increased ventilatory drive will persist and the PaCO<sub>2</sub> may fall. (This is sometimes referred to as type I respiratory failure.)

This is the situation in the early stages of acute asthma and bronchiolitis. Increasing the inspired oxygen concentration will improve the oxygen content of poorly ventilated areas and the PaO<sub>2</sub> will rise as a result. Patients are able to compensate for the increase in dead space initially by increasing overall minute ventilation but eventually they may become exhausted or, because of worsening disease, the dead space may rise. In either case alveolar hypoventilation results and the PaCO<sub>2</sub> will eventually rise (type II respiratory failure).

Fig. 20.13 Oxygen 'waterfall' in health and disease. Under normal circumstances oxygen is transported down a gradient between atmospheric air and the mitochondria where it is consumed.

**Table 20.2** Oxygen 'waterfall' in disease: hypoxia. Various causes of hypoxemia have their effect at different steps in the waterfall. Increase in inspired oxygen concentration (FiO<sub>2</sub>; the hyperoxia test) will usually correct the first two causes of hypoxemia. The level of PaCO<sub>2</sub> depends on the degree of compensatory hyperventilation which is possible; in severe lung disease, hypercapnia may develop

Cause of hypoxia	Effect of increase in FiO <sub>2</sub>	Value of PaCO <sub>2</sub>
1. Decreased alveolar ventilation 2. Impaired diffusion	Correction of hypoxemia Correction of hypoxemia	Increase Decrease (unless severe imbalance)
3. Right–left shunt and ventilation/perfusion imbalance	No change if pure right–left shunt	Decrease (unless severe shunting)
4. Decreased oxygen delivery*	No change	Decrease (due to metabolic acidosis)
5. Demand for oxygen exceeding supply**	Depends on cause	Increased mixed venous PCO <sub>2</sub>

\* PaO<sub>2</sub> may be normal under these circumstances; not true for hypoxemia

\*\* Refers to the fall in mixed venous (pulmonary artery) PO<sub>2</sub>; PaO<sub>2</sub> may be normal

### Alveolar hypoventilation

Alveolar hypoventilation in the presence of normal lungs or severe ventilation perfusion mismatching, as described under hypoxemia, results in *hypercapnia*, a rise in PaCO<sub>2</sub>. Hypercapnia should always be taken very seriously. In acute respiratory disease the PaCO<sub>2</sub> may remain normal or low for some time but may eventually rise very quickly. Children in whom this happens are very often exhausted and may well require ventilatory support. With chronic hypercapnia, central insensitivity results as cerebrospinal fluid (CSF) pH is buffered by a rise in bicarbonate. Administration of an oxygen-enriched gas to a patient not receiving assisted ventilation may result in a further dangerous increase in PaCO<sub>2</sub> because of removal of the hypoxemic drive to respiration. In practice this is extremely uncommon in children as chronic type II respiratory failure is rare. Oxygen should therefore never be withheld from children with acute respiratory disease.

### Alveolar–arterial PO<sub>2</sub> difference

(A–a) DO<sub>2</sub> is a measure of the degree of right-to-left shunt (of all types).

In respiratory failure of whatever cause the PaO<sub>2</sub> falls while the patient is breathing air. When accompanied by alveolar hypoventilation the PaCO<sub>2</sub> rises. An assessment of respiratory failure may be made by use of the alveolar air equation:

$$P_{A}O_2 = P_{i}O_2 - (P_{A}CO_2/R) + F$$

where P<sub>A</sub>O<sub>2</sub> is the partial pressure of oxygen in the alveoli, P<sub>i</sub>O<sub>2</sub> is the partial pressure of inspired oxygen (minus water vapor) (partial pressure: 6 kPa at body temperature), P<sub>A</sub>CO<sub>2</sub> is the mean alveolar PCO<sub>2</sub>, R is the respiratory quotient (approximately 0.8 in healthy individuals) and F is a small correction factor which for clinical purposes can be omitted. P<sub>A</sub>CO<sub>2</sub> in most clinical situations is equal to PaCO<sub>2</sub>. Normally with a PaCO<sub>2</sub> of 5 kPa and a barometric pressure of 100 kPa breathing air (O<sub>2</sub> content = 0.21) and a water vapor pressure of 6 kPa, P<sub>A</sub>O<sub>2</sub> = 0.21 (100 – 6) – (5/0.8) = 13.5 kPa.

In a healthy child breathing air the difference between the P<sub>A</sub>O<sub>2</sub> and the PaO<sub>2</sub> is 1–2 kPa. In pure alveolar hypoventilation this difference does not change or become smaller. In the presence of shunt or  $\dot{V}/\dot{Q}$  imbalance the difference rises. Hence the (A–a) DO<sub>2</sub> is an index of severity of mismatching of gas and blood.

**Example 1.** A baby with severe bronchiolitis may have a PaO<sub>2</sub> of 10 kPa in 70% oxygen and a PaCO<sub>2</sub> of 8 kPa. The (A–a) DO<sub>2</sub> = 0.7 (100 – 6) – (8/0.8) – 10 = 46 kPa. He has both  $\dot{V}/\dot{Q}$  mismatching, resulting in a rise in (A–a) DO<sub>2</sub>, and alveolar hypoventilation, resulting in a rise in PaCO<sub>2</sub>.

**Example 2.** A child with infective polyneuritis breathing 30% oxygen has a PaCO<sub>2</sub> of 7 kPa and a PaO<sub>2</sub> of 18 kPa. The (A–a) DO<sub>2</sub> = 0.3 (100 – 6) – (7/0.8) – 18 = 1.5 kPa. This child has pure alveolar hypoventilation as the (A–a) DO<sub>2</sub> is normal and the PaCO<sub>2</sub> is raised.

In rare disorders which affect the alveolar membrane, where clinical disability is mainly reduced exercise tolerance and airway function is

normal, oxygen transport across the membrane may be adequate at rest but not during exercise. The (A–a) DO<sub>2</sub> may become abnormally wide only during exercise.

### Acid–base abnormalities

These relate to disturbed hydrogen ion homeostasis in body fluids. The maintenance of a normal blood pH is a function of lung and kidney which together control the buffering capacity of the blood. The most important physiological buffer is bicarbonate, because of its relationship with CO<sub>2</sub> which is excreted through the lungs. The Henderson–Hasselbalch equation describes the relationship:

From this:

$$H^+ \propto CO_2/HCO_3^-$$

and:

$$pH = -\log H^+ = \log (HCO_3^-/CO_2)$$

Provided the ratio of HCO<sub>3</sub>/CO<sub>2</sub> remains constant, the pH will remain constant.

When the acid–base balance is disturbed and the normal values of pH and PCO<sub>2</sub> are altered it is helpful to know something of the status of the buffering system in the blood in order to unravel the sequence of events. The *base excess* is a useful parameter which reflects the metabolic component of the abnormality under steady state conditions (*not* during rapid changes in acid–base status). When the blood gases are analyzed the pH of the sample is determined. The CO<sub>2</sub> electrode is calibrated with gases of high and low CO<sub>2</sub> concentrations and the PaCO<sub>2</sub> of the sample determined. Blood pH and log PaCO<sub>2</sub> have a linear relationship whose slope varies according to whether there is an excess or deficit of base. The line which describes the relationship when there is neither excess nor deficit is known as the 'normal buffer baseline'. The amount of base which has to be added to or removed from this 'ideal' sample to reach the line which describes the actual sample is referred to as the base excess or deficit (see also Ch. 17).

In *respiratory acidosis* the PaCO<sub>2</sub> rises and the pH falls, and in order to maintain the ratio HCO<sub>3</sub>/CO<sub>2</sub> the kidney conserves bicarbonate.

*Metabolic acidosis* in pulmonary or cardiac disease reflects tissue hypoxia due to poor oxygen delivery, resulting in local lactic acid production. Other important causes include renal failure, severe infection and acute diabetic ketoacidosis. In these settings bicarbonate falls as it buffers the rise in hydrogen ions while a simultaneous increased drive to breathe results in increased CO<sub>2</sub> removal and a return towards a more normal HCO<sub>3</sub>/CO<sub>2</sub> ratio.

*Respiratory alkalosis* occurs when the PaCO<sub>2</sub> falls due to voluntary or artifactual hyperventilation or hyperventilation due to CNS pathology (e.g. meningoencephalitis). The hydrogen ion concentration falls and to conserve the HCO<sub>3</sub>/CO<sub>2</sub> ratio and hence the pH, the kidney sheds bicarbonate.

*Metabolic alkalosis* occurs in children when acid is lost through vomiting, as in pyloric stenosis. Hydrogen ions are lost and the bicarbonate rises. Hypoventilation produces a compensatory rise in  $\text{CO}_2$ .

*Mixed respiratory and metabolic acidosis* is a common situation in pediatric practice. Tissue hypoxia results in metabolic acidosis and inadequate ventilation results in respiratory acidosis. The  $\text{PaCO}_2$  is elevated and the bicarbonate and pH are low. There will be a base deficit.

The administration of bicarbonate in this situation is tempting, particularly when the pH is below 7.2. However, in order for bicarbonate to correct the metabolic component,  $\text{CO}_2$  must be formed and excreted from the lungs and in the presence of respiratory failure with an already elevated  $\text{PaCO}_2$  this may not be possible. Administration of bicarbonate may therefore elevate the  $\text{PaCO}_2$  even further. The blood–brain barrier is much more permeable to  $\text{CO}_2$  than it is to bicarbonate and the effect on the CSF will be to paradoxically reduce pH with serious consequences for the child who is not receiving ventilatory support. Even in pure metabolic acidosis such as occurs in diabetic ketoacidosis, rapid administration of bicarbonate can have this effect (see Ch.15).

The treatment for mixed acidosis is the correction of the respiratory component first of all by increasing ventilation. The metabolic component may respond to better oxygenation, improved circulation or correction of anemia. When the  $\text{PaCO}_2$  has returned to normal, bicarbonate may be given if the metabolic component persists.

### Measurement of gas transfer

Gas transfer at alveolar level can be studied by measuring the diffusing capacity for carbon monoxide ( $D_{\text{co}}$ ). By measuring the FRC by helium dilution simultaneously, the diffusing capacity can be normalized for variation in lung volume ( $K_{\text{co}}$ ). The test has its main use in detecting the response to treatment of interstitial lung diseases (e.g. those associated with connective tissue disorders) in older children.

### Measurement of arterial blood gases and acid–base balance

Oximetry has largely replaced arterial blood gas measurement for most children. Blood gas measurements are indicated for worsening acute lung disease where exhaustion (muscle fatigue) suggests the need for mechanical ventilation and in chronic lung disease as a guide to progress. Sampling of arterialized capillary blood (i.e. after warming or application of histamine cream) may be adequate for pH monitoring, but in general arterial sampling is preferable for postneonatal patients.

Blood should be collected from a radial artery cannula or, if impossible to site, by arterial puncture from the radial artery. This vessel is preferred for three reasons. First, the chance of sampling venous blood in error is small as no major veins lie nearby. Second, there is a good collateral circulation to the hand should circulation be compromised in any way as a result of the procedure. Third, the vessel is accessible. If pulsation is difficult to feel, as in shock, it may be approached blindly. The femoral artery, on the other hand, has a direct medial relation to the femoral vein. Infection may be introduced into the femoral sheath or into the hip joint from the groin. Collaterals will not compensate for femoral artery thrombosis, a particular hazard if the vessel is damaged in the presence of hypovolemia. It is also worth remembering that the femoral vessels may be used for cannulation at cardiac catheterization and it is particularly annoying for the cardiologist if the site has been traumatized.

As the walls of arteries are particularly sensitive and more than one attempt may be necessary to obtain blood, local anesthetic cream should be applied to the site 30 min before starting and local anesthetic should be injected around the site. As well as being a kindness, this should allow the blood to be collected under conditions which are as stable as possible although admittedly anxiety is not always avoided. Hyperventilation will reduce the  $\text{PaCO}_2$  and consequently the pH will rise; crying in a child who has a right-to-left intracardiac shunt may increase the shunt and reduce the  $\text{PaO}_2$ .

Non-invasive methods of measuring oxygenation include the transcutaneous  $\text{PO}_2$  electrode, which is at best a trend indicator in

**Table 20.3** Typical arterial blood gas values for adolescents and young adults in room air at sea level. All values tend towards the lower ranges in younger children and are lower still in infants

pH	7.35–7.45
$\text{PaO}_2$ (kPa)	11.5–13.5
$\text{PaCO}_2$ (kPa)	4.7–6.0
$\text{HCO}_2$ (mEq/L)	22–28

Data adapted from Cassels & Morse<sup>80</sup> and Gaultier et al<sup>81</sup>

postneonatal patients, and the pulse oximeter for monitoring oxygen saturation (e.g. in acute severe asthma and during sleep studies). For  $\text{PCO}_2$ , transcutaneous measurements again provide trends while end-tidal sampling using an infrared  $\text{CO}_2$  meter gives a useful assessment of alveolar breath (and hence arterial)  $\text{CO}_2$  only when lung disease is mild and during mechanical ventilation. 'Normal' values for adolescents and young adults are given in Table 20.3.

## BREATHING

### Physiology

The principal muscle of inspiration is the diaphragm, innervated by the phrenic nerve (C2–5). As with other skeletal muscles, within its usual working range the tension it can generate is proportional to its length. Because the diaphragm adopts a curved shape, when it contracts the pressure difference across it is proportional to the tension developed and inversely proportional to the radius of the curvature. Thus as a pressure generator, the diaphragm works best near its end expiratory position, where its radius of curvature is smallest (more domed). Hyperinflation by flattening the diaphragm, and increasing the radius of curvature, reduces the effective pressure generated for any particular muscle tension, reduces efficiency and may lead to muscle fatigue. The resulting alveolar hypoventilation, whose onset can be quite sudden, is the major contributory factor to respiratory failure in severe bronchiolitis.

Because of its tangential insertion, normal diaphragmatic contraction causes the chest wall to expand laterally ('bucket handle' effect) and anteriorly ('pump handle' effect). Scoliosis, for example, disturbs normal integrated movements of the diaphragm and chest wall and may lead to respiratory failure, presenting initially during sleep, when the diaphragm may be the sole muscle of breathing.

The phasic action of the intercostal muscles plays a part in stabilizing the chest wall, as illustrated by the indrawing (recession) which occurs during inspiration in patients with intercostal weakness (e.g. acute polyneuritis, spinal muscular atrophy) or in normal infants during rapid eye movement sleep (when the intercostal muscles remain passive). The intercostal muscles are particularly important in infancy, as the chest wall is inherently unstable and the expanding action of the diaphragm is less effective because of its less acute, more direct insertion into the rib cage and because of the more horizontal arrangement of the ribs.<sup>83</sup>

Expiration is normally a passive function, dependent on the elastic recoil of the lungs and chest wall. The elastic work normally carried out by the diaphragm during inspiration is almost totally 'recovered' during expiration and the work expended in overcoming frictional forces (the resistance to air flow) is dissipated as heat. However, active expiratory effort, applied mainly by the muscles of the anterior abdominal wall, may be needed if ventilatory demands are great (e.g. during exercise), if there is increased resistance to expiratory airflow (e.g. laryngeal edema) or if the natural recoil of the lungs is reduced (as in emphysema). The diaphragm may be used as a brake during expiration, although when a more effective brake is required (e.g. in neonatal respiratory distress or infantile bronchiolitis), the variable resistance of the glottis may be used, resulting in characteristic expiratory grunting.

From the point of view of the respiratory physician, the brain is part of the respiratory system! Apart from recognized CNS disorders which can affect the respiratory centers (e.g. Leigh disease) and congenital central hypoventilation (see p. 684 – Congenital hypoventilation syndrome),

altered central respiratory drive is especially dependent on sleep state (see p. 683 – Sleep and respiratory disorders). Rapid eye movement (REM) sleep is normally associated with a small drop in  $\text{PaO}_2$ . However, when upper airway obstruction is present (e.g. due to weakness or to tonsillar or adenoidal hypertrophy) or in the presence of severe lung disease (e.g. cystic fibrosis, severe scoliosis), the degree of hypoventilation may be profound, leading to periods of extreme hypoxemia. The consequences may be severe (pulmonary hypertension, hypoxic fits or brain damage) or limited to sleep disturbance as a consequence of repeated waking, leading to excessive somnolence (or paradoxically in children, hyperactivity) the following day.

Control of breathing may become clinically important in chronic respiratory failure with hypercapnia (e.g. terminal lung disease, chronic neuromuscular disorders) when renal compensation for respiratory acidosis leads to an increase in plasma and CSF bicarbonate concentration. This acts as a buffer, blunting the sensitivity of the respiratory center to further rises in  $\text{PCO}_2$ , again leading to severe hypoventilation during REM sleep, when the metabolic control of breathing is paramount.

### Measurement of respiratory muscle strength

The function of the respiratory muscles is best assessed by clinical observations assisted (in the absence of gross lung disease) by comparison of supine and standing vital capacity. Diaphragmatic paralysis will be accompanied by a fall in vital capacity of more than 10% and by paradoxical respiratory movements of the rib cage and abdomen in the supine posture. Direct measurements by mouthpiece and transducer of the maximum pressure which can be generated at the mouth during inspiratory effort from residual volume, and expiratory effort from total lung capacity, allow precise quantitations of respiratory muscle strength. Unfortunately, if weakness affects the facial muscles, children find it impossible to maintain an airtight seal around a mouthpiece.

## SPECIAL INVESTIGATIONS – IMAGING

Despite recent advances in imaging (see also Ch. 8), the plain chest radiograph (CXR) continues to play a fundamental role in the evaluation of the pediatric respiratory system. Many diagnoses are confirmed or excluded by a simple CXR without recourse to other complex imaging modalities. When pleural fluid or a pneumothorax is suspected an additional decubitus film (with the patient positioned on his/her side) or a horizontal shoot through lateral film are also occasionally useful.

Apart from ultrasound (US) examination and magnetic resonance imaging (MRI), all thoracic imaging techniques involve irradiation. Certain images involve exceedingly low radiation doses, e.g. krypton 81m ventilation lung scan ( $^{81\text{m}}\text{Kr V}$ ); others may be more invasive and have significantly high inherent radiation, e.g. cardiac catheterization, computed tomography (CT) or bronchography. It is therefore important to consider the invasiveness, the radiation dose and the potential discomfort to the patient when planning detailed pulmonary investigations.

The importance of the esophagus in particular should not be forgotten when chest disease in young patients is being investigated. Diseases of the upper gastrointestinal tract, e.g. hiatus hernia, gastroesophageal reflux or recurrent aspiration, may all manifest with chest signs or symptoms.

### RADIOGRAPHY OF UPPER AIRWAYS

The lateral neck/postnasal space and sinuses are frequently included on the same lateral radiograph. The palatine tonsils as well as the adenoidal area can be studied on this film. The adenoids may be quite large in normal children, making the diagnosis of adenoidal hypertrophy difficult. The relationship of the trachea to the cervical spine as well as the general tracheal caliber should be well visualized. The lateral view has certain technical limitations and it is important to be sure that the projection is adequate, i.e. the floors of the anterior, middle and posterior fossae of the skull are overlapping, and that the cervical spine is truly lateral. The normal space between the trachea and the cervical spine is

approximately the diameter of one vertebral body. An apparent increase in this space may be pathological but may also be due to the radiograph being taken in expiration – in this latter situation the trachea may show some buckling or the hyoid bone may be elevated.<sup>92</sup>

The frontal projection visualizes the facial sinuses but in children under 5–6 years of age the relatively small size of the facial bones makes it exceedingly difficult to interpret plain sinus views. Although the antra are usually aerated sufficiently by the age of 18–24 months to be seen on a radiograph, diagnosing sinusitis from plain radiographs is notoriously unreliable. In older children the ethmoid and frontal sinuses, the nasal septum and turbinate bones should be seen. There is a wide age range in the normal development of these sinuses such that when sinusitis needs to be diagnosed or excluded with certainty most radiologists recommend CT or MRI.

### CHEST RADIOGRAPHY

For a frontal posteroanterior (PA) chest radiograph [anteroposterior (AP) in younger children], the patient must be straight. This is best evaluated on the film by either the relationship of the medial ends of the clavicles to the pedicle of the vertebral body or by the symmetry of the anterior ribs on each side. Even slight rotation can cause unusual appearances in a normal patient. The medial ends of the clavicles should lie at the level of the fourth vertebral body. Radiographs in inspiration are generally preferred, the degree of inspiration judged by counting either the anterior rib ends in the mid-clavicular line down to the level of the diaphragm (there should be 5–6 ribs present) or counting the posterior aspect of the ribs where down to the tenth rib should be seen on inspiration above the hemidiaphragm. A film in expiration is often regarded as being of little value although it infers that no overinflation or air trapping is present and this film may permit exclusion of lobar consolidation. A film in expiration should not be disregarded but rather carefully reviewed to consider whether it needs to be repeated. Pathological conditions which result in a loss of lung compliance, e.g. opportunistic infection in the immunosuppressed child, cause repeated 'expiration films' to be obtained. It is worth noting that the normal pediatric cardiothoracic ratio of 60% may be exceeded on an expiratory radiograph in a normal child, leading to the erroneous impression of cardiomegaly.

In the infant or sick child, supine AP chest radiographs are commonly carried out. Here the classic signs of well-known pathological conditions alter, e.g. a pleural effusion may only be seen as a 'apical cap'; a pneumothorax may not appear as a peripheral lung edge; and a pneumomediastinum may appear only as a vague translucency in the mediastinum. A lateral chest radiograph with a horizontal beam or a decubitus film may be useful when doubt persists following the AP view.

The normal visualization of the cardiac outline as well as the diaphragm is due to an aerated lung being adjacent to a more solid non-aerated organ. Loss of the normal outlines means that the adjacent lung tissue is no longer aerated; this can occur with consolidation (i.e. fluid in the alveolar spaces due to infection, inflammation, hemorrhage or pulmonary edema). If the airway remains patent throughout, then consolidation without major collapse may occur. If there is collapse in a lobe of lung, i.e. loss of volume, then bronchial pathology, e.g. foreign body, mucus or extrinsic compression, must be borne in mind. When consolidation occurs first it is not possible for this solid pulmonary parenchyma to lose volume to any major extent. The diagnosis of a collapsed lobe is made by either identifying a displaced fissure or displaced hilum.

The lateral chest radiograph requires a greater exposure than the frontal film and because the two lungs are superimposed, interpretation is difficult. This film is no longer part of the 'routine' chest radiograph in pediatrics but is rather reserved for specific clinical situations such as persistent post-pneumonic change (Fig. 20.14). In children with known solid tumors, in whom initial screening with CT and CXR is normal, follow-up may be with repeat CXR, usually including a lateral film also, at intervals determined by protocol. When a suspicious new lesion is seen, CT is required. In a child with recurrent chest pathology undergoing

**Fig. 20.14** A 3-year-old girl with unresolved pneumonia in the left lower lobe. (a) PA chest radiograph at 3 months of age. (b) Following recovery from the acute episode the routine follow-up chest radiograph 6 months later showed persistent shadowing in the left lower lobe. Persisting post-pneumonic lower lobe changes like these raise the possibility of an underlying sequestration, as proven subsequently in this case. An abdominal ultrasound should be performed to search for an anomalous feeding artery from the abdominal aorta to the lesion, in addition to lung CT in this context. (c) A  $^{99m}\text{Tc}$  macroaggregate perfusion scan (Q) and a krypton 81m ventilation scan (V) were obtained 1 year following the acute episode. The left lung shows decreased perfusion compared to the right with the left lung only contributing 25% of overall perfusion. On ventilation the left lung contributes 37% and there is a segment in the left lower zone which is relatively well ventilated but not perfused. The diagnosis of a sequestered segment was suggested. (d) A digital subtraction angiogram was carried out. The arterial phase shows a vessel arising from the abdominal aorta going cranially into the thorax to supply the abnormal area on chest radiograph. (e) The venous phase shows the drainage from the sequestered segment all going cranially. At surgery a sequestered segment in the left lower lobe was resected.

investigation, a lateral film at the time of the first chest radiograph is recommended. In the long term follow-up of chronic chest disease, e.g. cystic fibrosis, many would recommend that a lateral view is carried out whenever the PA film is obtained. The normal lateral chest radiograph should show progressive translucency over the dorsal spine, i.e. the lower vertebral bodies are blacker than the upper ones. The trachea is well seen; displacement and narrowing are easily detected on this projection whereas tracheal compression is seldom visible on the frontal view.<sup>92</sup>

When the patient is too unwell to sit upright, a horizontal beam radiograph can be useful. For this the patient is placed supine or in a decubitus position and the horizontal X-ray beam allows the effect of gravity to be maximized in order to demonstrate air–fluid interfaces or positional shifts of fluid. Thus either a frontal or a lateral film can be obtained. This technique is useful to demonstrate a small pleural effusion, the presence of pneumomediastinum or pneumothorax and, with intrapulmonary pathology, to demonstrate air–fluid interfaces such as in an abscess. Oblique radiographs, done to search for rib fractures, are recommended as part of a skeletal survey in the context of suspected non-accidental injury.

## FLUOROSCOPY

Examination of the esophagus is the major role for fluoroscopy of the chest. Additional information to be gained during an esophagogram includes evaluation for tracheomalacia (when the trachea, viewed from a lateral position, collapses in expiration by > 50%). If present, a pleural effusion or consolidation may also be noted.

Evaluation of the motion of both hemidiaphragms to assess for suspected immobility or paradoxical motion secondary to phrenic nerve injury is easily performed, although particularly in smaller children, the same information can be achieved with US, thereby avoiding irradiation.

A fully distended esophagus is essential for an adequate examination by contrast or barium. An esophagogram can show extrinsic lesions such as a vascular ring – a double aortic arch causes a posterior impression on the esophagus whilst an aberrant left pulmonary artery (so-called pulmonary sling) typically indents the anterior esophagus posterior to the trachea (Fig. 20.15). Intrinsic diseases such as hiatus hernia, gastroesophageal reflux or incoordinate swallowing with aspiration can also be diagnosed.

A dedicated esophagogram is necessary in those patients with a normal barium swallow in whom an H-type tracheoesophageal fistula is suspected. This usually requires an injection of contrast via an esophageal tube which is gradually withdrawn with the child in the prone position. Prone positioning allows the dependent anterior esophagus to be well coated which, with the aid of gravity, helps improve the likelihood of finding a small fistula to the trachea.

## BRONCHOGRAPHY

High-resolution CT (HRCT) is very accurate in defining bronchiectasis, such that the indications for bronchography have reduced considerably. Furthermore, surgical treatment for bronchiectasis is now uncommon. The current major indication for bronchography is for suspected localized bronchomalacia, particularly in ventilator dependent children. However, it is an invasive procedure and should only be undertaken by an experienced pediatric radiologist. Bronchoscopy is also useful in the investigation of localized tracheobronchomalacia (see p. 683 – Bronchoscopy).

## ANGIOGRAPHY

This is the most invasive radiological investigation in the cardiorespiratory system and is therefore reserved for those patients in whom the diagnosis is unconfirmed by any other technique. Digital subtraction angiography allows a small volume of contrast to be used and provides high quality imaging with a lower radiation burden to the child (Fig. 20.16). With the advent of multidetector CT (MDCT) and more recently fast gadolinium-enhanced dynamic MRI sequences, the need for

pulmonary angiography continues to reduce. Increasingly angiography is performed not for diagnostic purposes but for intervention and embolization, e.g. arteriovenous malformation or a sequestered lung segment.

## ULTRASOUND

Aerated lung prevents the propagation of an ultrasound beam. Pathology, e.g. pleural fluid or other collection, must lie adjacent to the pleura to be visualized. In the opaque hemithorax on CXR, i.e. so-called lung white-out, US can easily distinguish between the presence of fluid, a mass or lung collapse and can give a useful guide as to how much fluid is present. When a peripheral lung mass is present, then US can determine if this is predominantly cystic or solid. Occasionally in a child with pneumonia it is difficult both clinically and radiologically to assess how much fluid is present in addition to the consolidation; US is particularly useful if the consolidation is basal in location. Effusion and empyema may require tapping or draining and in this context US is very useful in defining the appropriate site for chest tube insertion. The diaphragm is well visualized by US, especially on the right, and therefore may be useful when defects are suspected. In cases of suspected diaphragmatic palsy subsequent to surgery US can be as accurate as fluoroscopy in assessing diaphragmatic motion and has the advantage that it can be performed in the intensive care setting. Antenatal diagnosis by US of diaphragmatic hernia or an adenomatoid malformation in the chest may alert the pediatrician to the birth of an infant who may require the facilities of a neonatal intensive care unit.

Children with stridor in whom the diagnosis of extrinsic compression is being considered should undergo US (echocardiographic) examination. Ultrasound in experienced hands can detect the site of the aortic arch and may thus pick up a right-sided arch or double aortic arch. The detection of an aberrant left pulmonary artery arising from the right pulmonary artery and swinging back to the left between the esophagus and trachea may be missed, however, on echocardiography.<sup>92</sup>

The normal thymus can have a variety of appearances on CXR, being particularly prominent in children under 3 years of age. A large thymus can be mistaken for a mediastinal mass or upper zone pneumonia. A large normal thymus can be easily identified with US corresponding to the apparent CXR abnormality, ruling out more sinister pathology. In cases of suspected sequestered segment, US may show the feeding vessel arising from the abdominal aorta coursing upwards into the chest.

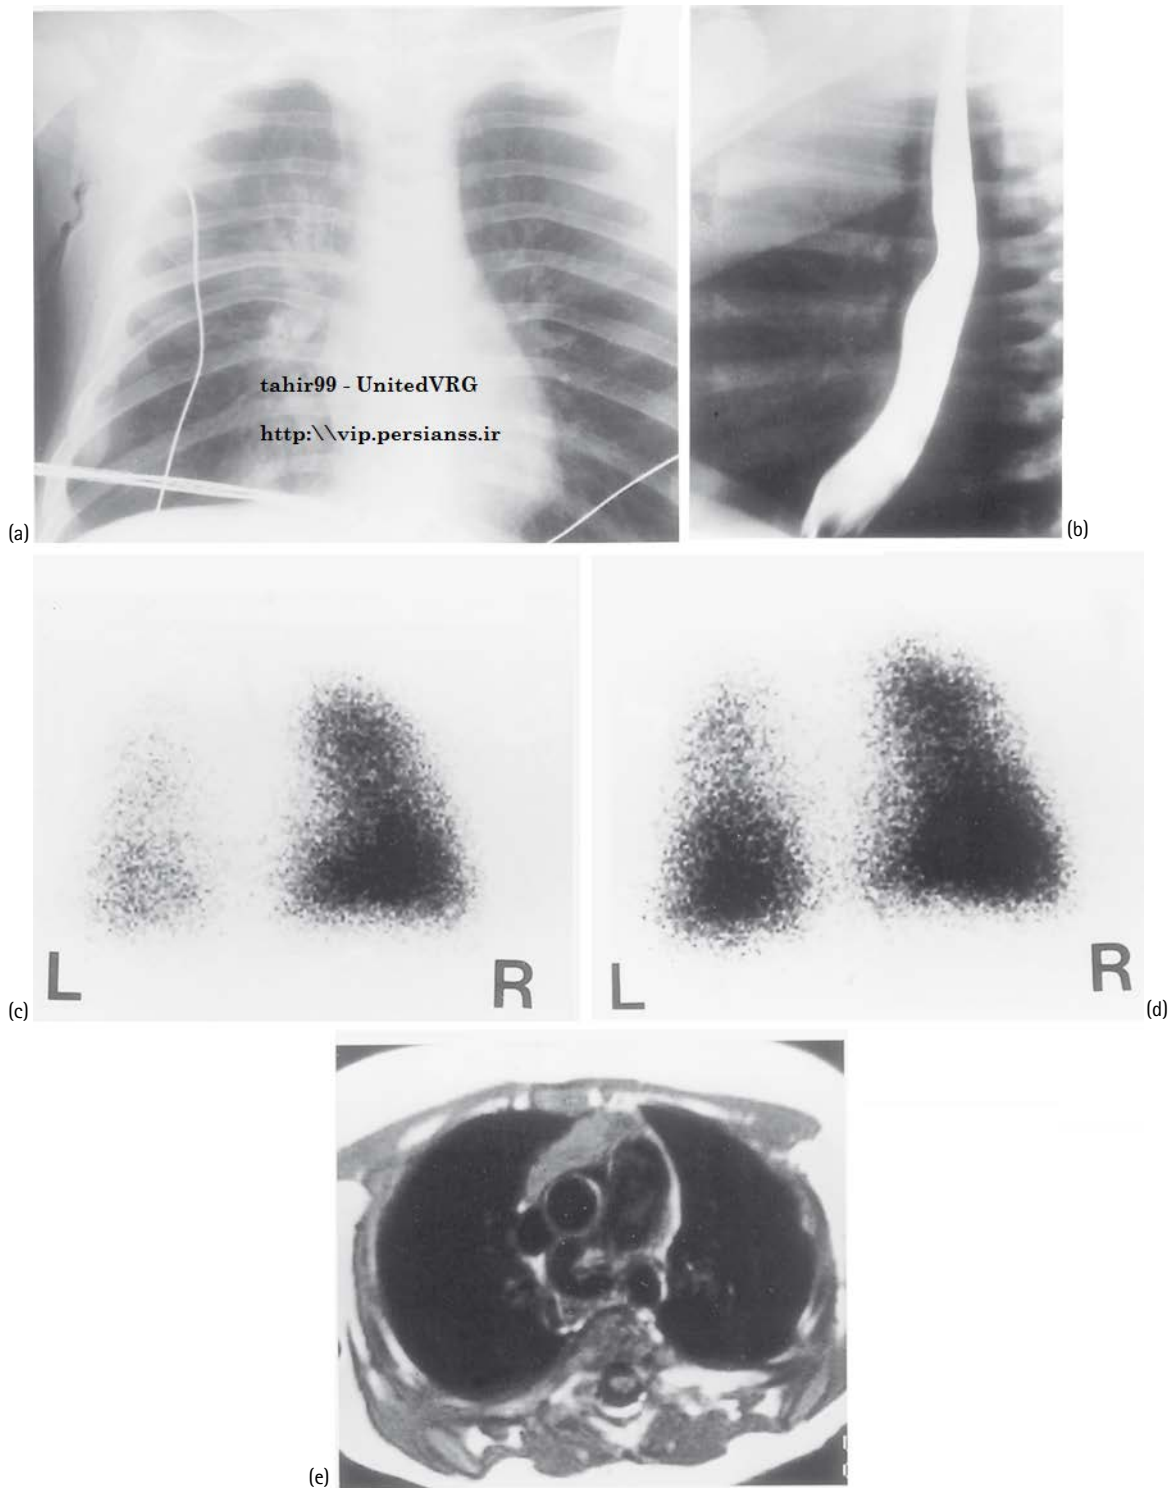

## RADIOISOTOPE INVESTIGATIONS

### Ventilation/perfusion lung scans

Sequential images of both ventilation and perfusion can be obtained in children of any age. V/Q scans even have been carried out in the newborn. Multiple views are obtained so that a three-dimensional image of the lungs is built up. <sup>81m</sup>Kr is an inert radioisotope gas with a half-life of 13 s. The inspired air/<sup>81m</sup>Kr mixture never reaches equilibrium in the alveolar air-spaces. The image is therefore of alveolar ventilation and not lung volume. This holds true for all children over 1–2 years but in an infant the high respiratory rate may invalidate this situation so that the <sup>81m</sup>Kr V scan may reflect a complex lung volume/specific ventilation situation. Xenon-133 (<sup>133</sup>Xe) is used in many institutions where Kr is unavailable. The advantages of this gas are its ready availability and relatively long half-life of 5.3 days; the disadvantages are the relatively high radiation dose. As it requires very good patient cooperation it is used with difficulty in the child under 6 years old. Only a single posterior view can be obtained and therefore it is difficult to compare the <sup>99m</sup>Tc perfusion image with the <sup>133</sup>Xe image.

<sup>99m</sup>Tc MAA Technetium Labeled macroaggregated albumin are injected intravenously and are stopped by the first capillary bed, normally the lungs. This gives images of pulmonary perfusion. In pulmonary hypertension caution should be exercised but a perfusion scan may be undertaken if clinically indicated. In the presence of right-to-left shunts perfusion lung scans should ideally be avoided but have been used without ill effect; the <sup>99m</sup>Tc MAA are then seen in the systemic circulation (mainly kidneys and brain).

**Fig. 20.15** A 6-month-old boy with stridor. (a) The PA chest radiograph shows evidence of overinflation in both lung fields. The left upper zone shows fewer vessels than on the right. There is a deformity of the posterior aspect of the 7th rib but no previous surgery had been undertaken. (b) The lateral project of the barium swallow shows clear indentation on the anterior wall of the esophagus at the level of the carina. This is a typical appearance of an aberrant left pulmonary artery which is only seen in the true lateral projection on barium. (c) Krypton 81 m ventilation lung scan shows normal ventilation of the right lung with decreased ventilation of the left upper lobe. (d)  $^{99m}\text{Tc}$  macroaggregate perfusion scan reveals a normal right lung with decreased perfusion of most of the left lung. The left lung contributed 32% to overall perfusion and 39% to overall ventilation. (e) MRI scan of the mediastinum shows the aberrant left pulmonary artery arising from the right pulmonary artery and curling around behind the trachea but in front of the esophagus. This child underwent resection and anastomosis of the left pulmonary artery to the main pulmonary artery. The postoperative  $\dot{V}/\dot{Q}$  lung scan revealed a normally perfused and ventilated left lung (not illustrated).

(a)

(b)

**Fig. 20.16** Hybrid congenital pulmonary malformation. (a) Coronal CT image at lung window settings showing a cystic lesion in the right lower lobe typical of a congenital cystic adenomatoid malformation (CCAM). (b) Adjacent slices showed more normal lung parenchyma with apparent air trapping. Blacker (lower attenuating) lung with fewer vessels visible in the parenchyma is more characteristic of air trapping as seen with congenital lobar emphysema (CLE) (although this lesion is in a lower lobe which is unusual for CLE).

(Continued)

(c)

(d)

Fig. 20.16 (cont'd) (c) Volume-rendered reformatted CT image, after contrast administration, showing a large vessel arising from the lower thoracic aorta on the right which supplied the lesion in the right lower lobe. Systemic arterial supply to a lung abnormality is characteristic of a pulmonary sequestration. (d) Conventional angiography confirms the large feeding vessel prior to embolization. This congenital pulmonary malformation can thus be regarded as a hybrid lesion containing elements of a CCAM, CLE and sequestration within it.

The  $\dot{V}/\dot{Q}$  images reflect regional lung function. The main indication for  $\dot{V}/\dot{Q}$  scanning now is in suspected pulmonary embolism with  $\dot{V}/\dot{Q}$  studies being occasionally useful in children with established disorders such as obliterative bronchiolitis in whom regional lung function warrants assessment.

### Radioisotope milk scan

This is used for evaluation of gastroesophageal reflux (see Ch 19, p. 605) and pulmonary aspiration.  $^{99m}\text{Tc}$ -sulfur colloid is added to a normal feed (10 MBq/100 ml). Following the feed a small volume of nonradioisotope fluid is given to clear any activity from the esophagus. Infants are cuddled for 5 min; all children are placed supine over the gamma camera. Continuous imaging for 1 h then takes place with delayed images of the lungs 3–5 h after completion of the feed. The Tc-sulfur colloid has a small particle size and is not absorbed by gut mucosa. When aspiration occurs the activity may be seen in the lung. This test is more sensitive than a barium swallow in detecting gastroesophageal reflux since the esophagus is studied for up to 60 min continuously rather than intermittently as with barium studies.

### COMPUTED TOMOGRAPHY

As CT scanning times reduce, particularly with the introduction of fast MDCT scanners, the indications for thoracic CT in children have increased.<sup>93</sup> CT affords excellent anatomical detail, particularly in older children who can suspend respiration. MDCT has the added advantage, when contiguous (adjacent) images are taken, that sagittal and coronal reconstructions are possible with similar resolution to standard axial imaging (see Fig. 20.16). There are essentially two types of chest CT studies generally performed. Standard, contiguous 1–2 mm sections are used when the whole chest or mediastinum is examined in detail. Indications here would include assessment of the pulmonary vasculature,<sup>94</sup> empyema (Fig. 20.17) or suspected adenopathy, typically performed after intravenous contrast enhancement. Standard contiguous slices would also be used in staging for suspected lung metastases in children with known solid tumors. HRCT involves using fine sections, usually 1 mm slices at 10–20 mm intervals through the lungs to assess for diffuse lung disorders such as an interstitial disease or bronchiectasis. The very fine detail of selected areas of the lung that is achievable with HRCT can help characterize unusual processes, define their extent and in certain cases plan an appropriate area for biopsy. The major disad-

Fig. 20.17 Axial CT after intravenous contrast enhancement showing a moderate sized, low attenuating right-sided pleural effusion (curved arrow), proven to be an empyema at drainage. Note the adjacent area of consolidation, some thickening of the parietal pleura (arrowhead) and edema of the extrapleural space. Intravenous contrast administration has resulted in dense opacification of the cardiac chambers and descending aorta.

Fig. 20.18 High resolution chest CT image showing chronic right middle lobe collapse with airways dilatation, i.e. bronchiectasis (curved arrow). In addition, bronchial wall thickening is seen in the right lower lobe with the classic signet ring sign of bronchiectasis, which is due to a dilated airway adjacent to a more normal sized pulmonary artery, also evident (thick arrow). Normal cardiac pulsation has resulted in blurring of the cardiac outline.

vantage of CT is that it carries a large radiation burden and so should be used sparingly in young patients. Most pediatric centers now routinely utilize low dose (low mA) techniques to keep radiation to a minimum. As only selected areas through the lungs are examined, HRCT involves a relatively low radiation dose in comparison to standard CT. HRCT is very accurate in the assessment of bronchiectasis (Fig. 20.18). A normal HRCT essentially excludes this diagnosis assuming the study is of a reasonable quality. Expiratory images in cooperative older children can be very useful in showing air trapping with small airways disease, e.g. obliterative bronchiolitis (Fig. 20.19). Decubitus positioning mimics expiration (in the dependent lung) in sedated younger children. The role of HRCT is controversial in cystic fibrosis, but routine CT assessments are certainly justifiable in the context of clinical trials.

Virtually all solid tumors with the exception of neuroblastoma (which characteristically metastasizes to bone) require a chest CT at presentation. If the initial CT is negative for metastases, most cancers

Fig. 20.19 Axial high resolution CT post single lung transplant in a child who had had a previous right pneumonectomy for cystic fibrosis. Obliterative bronchiolitis is evident in the left lung transplant, manifesting as areas of varying attenuation and curvilinear interstitial septal thickening. The peripheral blacker or low density foci represent areas of air trapping which become more conspicuous in older, cooperative patients who can breath hold for expiratory images.

are followed up thereafter with serial CXRs – except osteosarcoma which has a high propensity for pulmonary relapse and so merits repeated CT studies in the first few years from diagnosis.

In cases of suspected sequestration, CT after contrast enhancement often reveals the feeding vessel arising from the abdominal aorta although the venous drainage is less often seen. Mediastinal pathology is well visualized and tissue characterization allows some differentiation of solid from cystic lesions.

## MAGNETIC RESONANCE IMAGING

The role of MRI in chest pathology is still being established. The mediastinum and airways are well visualized but negative (black) signal from aerated lung precludes good pulmonary imaging for the foreseeable future. MRI is highly accurate in assessing vascular anatomy and so can easily demonstrate a vascular ring or double aortic arch.<sup>92</sup> The increasing availability of fast gadolinium-enhanced angiographic sequences has reduced the indications for arteriography of the lungs and great vessels.<sup>95</sup> A cooperative, still patient is an absolute prerequisite; hence there is a continuing need for sedation or anesthesia in smaller children.

## ENDOSCOPY OF THE AIRWAY

### BACKGROUND

The passage of instruments through the larynx to visualize, sample and manipulate the lower airways is a procedure with many applications in pediatric respiratory medicine.

Bronchoscopy has a long history. It was first developed nearly 100 years ago for the diagnosis and removal of foreign bodies from the trachea or bronchus. Early instruments were rigid and had a low level of illumination and a limited visual field. With better illumination and improved optics wider applications became possible.

The first flexible fiberoptic bronchoscope was developed in Japan in 1966. This instrument made it possible to see easily parts of the airway that were difficult to visualize using the rigid bronchoscope. It also became possible to perform bronchoscopic examinations without the need for general anesthesia, and with a significant reduction in operative morbidity. This led to a dramatic increase in the usefulness of bronchoscopy as a diagnostic and therapeutic tool. The application of fiberoptic bronchoscopy to pediatrics had to await the development of smaller instruments. Wood and Fink first described the use of the flexible bronchoscope in children in 1978.<sup>96</sup> Fiberoptic bronchoscopes small enough for use in children only became widely available in 1981. Technical progress has allowed a greater number of fiberoptic bundles per unit area, increasing the flexibility of the bronchoscope while retaining and even enhancing light transmission. Smaller bronchoscopes with a wider field of vision, providing a sharper, less grainy picture, are now being manufactured. Developments in instrumentation have made bronchoscopy an increasingly useful diagnostic and therapeutic tool in the newborn, infants and children.

While adult physicians are frequently looking for evidence of malignancy, pediatricians are usually looking for anatomical airway abnormalities or inflammatory or infective conditions. In children, upper airway problems are a common reason for endoscopic evaluation and 'bronchoscopy' often involves examination of the upper as well as the lower airway.

## TECHNIQUES USED IN PEDIATRICS

### Endoscopes

In order to perform bronchoscopy in children, the bronchoscope must meet some specific technical requirements. First, the instrument must be sufficiently small that it can safely enter the trachea (in a full-term newborn infant the trachea is approximately 5 mm in diameter). Second, it must have suitable optical characteristics and provide for illumination of the airway.

#### *Rigid bronchoscopes*

Small rigid bronchoscopes meet these criteria and are available in sizes from 2.5 mm (the nominal size of a rigid bronchoscope refers to the smallest internal diameter through which instruments may be passed, not to the outer diameter which may be several millimeters greater because of the thickness of the material). Endoscopes suitable for use in infants are 2.8 or 3.5 mm in external diameter.

Rigid bronchoscopy in children requires a general anesthetic, the bronchoscope functioning as an artificial airway allowing effective ventilation either with positive pressure inflation or with a Venturi jet injection device. With appropriate anesthetic technique, spontaneous respiration through the bronchoscope allows for assessment of laryngo-, tracheo- or broncho-malacia.

The optical properties of the rigid bronchoscope alone are poor but when a Hopkins glass rod telescope is passed through the bronchoscope, the optical resolution is excellent. Rigid bronchoscopy is particularly good at visualizing the posterior wall of the larynx such as when looking for a laryngeal cleft or H-type tracheoesophageal fistula. In children, although angulated telescopes can be used to look into the upper airways, direct access to more distal bronchi and to the upper lobes using a rigid bronchoscope is limited.

The main advantage of the rigid bronchoscope is that it provides complete airway control during the procedure. The excellent view and the extensive range of instruments available mean that a wide variety of therapeutic maneuvers can be carried out. Rigid bronchoscopy remains the procedure of choice for foreign body removal, tissue resection and biopsy where there is a risk of copious hemorrhage.

#### *Flexible bronchoscopes*

In the flexible fiberoptic bronchoscope light to visualize the airway is transmitted via a solid bundle of glass fibers. The child has to breathe around rather than through the endoscope.

There is now a range of endoscopes suitable for use in smaller children and neonates from a number of manufacturers (Table 20.4). The distal tip can be flexed by the operator in a single plane with side to side movement brought about by rotation of the shaft of the instrument made possible when the proximal shaft forms a looped shape. All but the smallest flexible endoscopes incorporate a small suction channel.

The standard pediatric endoscope has an external diameter of 2.8 mm with a 1.2 mm suction channel. The suction channel can be used to perform bronchoalveolar lavage, or to pass small instruments for bronchial brushings or bronchial biopsy. In older children, a small adult endoscope with an external diameter of 4.9 mm can be used. This has a larger working channel, enabling more effective suctioning and the use of larger biopsy forceps for epithelial or transbronchial biopsy (TBB).<sup>97</sup>

In infants less than 3000 g, an endoscope will nearly totally obstruct the airway. Bronchoscopy can be performed by pre-oxygenating the

Table 20.4 Examples of flexible endoscopes commonly used in the examination of the pediatric airways

Model*	Outer diameter (mm)	Angulation	Suction channel (mm)	Comments
BF-XP40	2.8	Up 180°, down 130°	1.2	Can pass through a 3.5 mm ET tube Previous versions were the standard flexible instrument used in children
BF3C40	3.3	Up 180°, down 130°	1.2	
BFP30	4.9	Up 180°, down 140°	2.2	

\* All these instruments are manufactured by the Olympus Optical Company, but other manufacturers make instruments of similar specifications

infant with 100% oxygen and limiting the time below the glottis to 30–40 s. Alternatively, the airways of small neonates can be visualized with the 2.2 mm 'ultra thin' bronchoscope which lacks a suction channel. Endoscopes can be passed through a connector placed between the endotracheal tube and the ventilator, allowing uninterrupted ventilation and oxygen delivery during the procedure.

### Video recording

Video recording is an important part of any endoscopic procedure in children. With a video monitor, the operator's assistants can view the findings and anticipate the operator's needs. The use of video also facilitates training by allowing trainees either to watch the procedure or to be carefully supervised performing the procedure. Recording improves documentation of endoscopic findings and facilitates communication with other members of the clinical team. Reviewing the video with a child's parents can be particularly helpful in explaining the study findings to them.

### Setting and techniques

There are two general approaches to performing bronchoscopy in children: using either conscious sedation in an older child or adolescent, or under general anesthesia. Rigid bronchoscopy invariably requires a general anesthetic.

General anesthesia is not essential for flexible bronchoscopy in children. In many cases, airway endoscopy can be safely performed under conscious sedation and topical anesthesia. Adequate conscious sedation has most frequently been achieved using a combination of a short acting benzodiazepine and an opiate. A topical vasoconstrictor, applied to the nasal passages before the procedure, enlarges the nasal passages and decreases the risk of epistaxis. Lignocaine is applied to the same nostril and then delivered directly via the endoscope's suction channel above the vocal cords and below in the trachea and main bronchi. There is evidence that topical anesthesia in infants and children exaggerates the findings commonly associated with laryngomalacia. Because overestimation of these findings might lead to unnecessary treatment, it is important to examine the larynx and contiguous structures before applying topical anesthesia.<sup>98</sup>

While flexible bronchoscopy under sedation and topical anesthesia can provide excellent airway access, it is often difficult to be precise about the level of sedation achieved and the child is often sedated to a deeper level than is consistent with conscious sedation. The benefits of general anesthesia in terms of child safety and comfort, as well as the ease of examination, have been increasingly recognized and, in most circumstances, are now preferred.

When general anesthetic is employed for flexible endoscopy, or bronchoscopy performed on a ventilated patient, the flexible bronchoscope is passed down an endotracheal tube or through a laryngeal mask airway (LMA). An LMA has the important advantage of allowing the use of a larger diameter bronchoscope with a larger suction channel than could be passed through an endotracheal tube on the same child. This can make direct removal of foreign bodies possible or allow larger biopsies to be obtained through the use of larger instruments or biopsy forceps. Increasingly, the use of general anesthesia via an LMA is becoming the standard approach for children.<sup>99</sup>

### Patient monitoring

It is essential that one person other than the endoscopist is solely responsible for observing and monitoring the child during the procedure. Many centers will have an anesthetist responsible for the sedation and monitoring of the child even in the absence of the need for a general anesthetic. Before the procedure, children undergoing endoscopy should have an i.v. line placed. Monitoring during the procedure should always include continuous pulse oximetry as well heart rate, respiration and color. Access to appropriate resuscitation equipment including suction and supplemental oxygen, and antagonists for any sedative agents used, must be immediately available and staff involved in airway endoscopy must be fully trained in resuscitation.

### Contraindications and complications of airway endoscopy

Contraindications to bronchoscopy are largely relative. When performed by properly trained personnel in carefully controlled conditions, bronchoscopy is a low-risk procedure. Nevertheless, bronchoscopy should only be performed if the relative benefits of the procedure outweigh the risks. Complications are more likely in children with:

1. bleeding diatheses that cannot be corrected;
2. massive hemoptysis;
3. severe airway obstruction;
4. severe hypoxia;
5. pulmonary hypertension;
6. lung abscess where there is a risk of pus spreading throughout the lung if the cavity is ruptured.

Ankylosis of the jaw or neck may preclude rigid bronchoscopy.

The complications of airway endoscopy can generally be divided into those associated with the medications used before and during the endoscopic procedure, and those related to the instrumentation.<sup>100</sup>

Inadequate topical analgesia may lead to laryngospasm or other vagally mediated phenomena. Inadequate sedation may lead to patient discomfort; alternatively, too much sedation may lead to respiratory depression and apnea. Episodes of hypoxemia, bradycardia or apnea are common but usually transient and self-limiting.

Transient high fever is common within 24 h after a bronchoalveolar lavage. Small hemoptyses commonly follow biopsy procedures. The risk of trauma to the oropharynx or airway is greater with the rigid bronchoscope. More serious problems, including laryngospasm and pneumothorax, can occur, but are rare. Airway instrumentation may exacerbate airway narrowing in children with already compromised airways such as those with subglottic stenosis. Nebulized adrenaline (epinephrine) or intravenous corticosteroids may tide the child over but, rarely, intubation may be necessary. The reported incidence of pneumothorax following TBB is up to 8%.<sup>101</sup>

With careful attention to detail, the safety record of airway endoscopy in children is excellent and bronchoscopy can now be performed easily and safely even in small premature neonates, and ventilated children in the pediatric intensive care unit (PICU).

### Infection control

Spread of infection during bronchoscopy has been suggested to be both under-recognized and under-reported.<sup>102</sup> Unless proper infection control procedures are followed, the greater number of procedures now being undertaken is likely to be associated with more frequent episodes of infection attributable to bronchoscopy. Accordingly, clinical staff involved in endoscopic procedures should be educated in infection control procedures. Those who may be exposed to body secretions during bronchoscopy should use universal precautions.

To prevent cross-infection between children or contamination of specimens collected, endoscopes must be scrupulously cleaned and disinfected after each use. Rigid bronchoscopes can be autoclaved. Flexible bronchoscopes must first be cleaned with detergent (including the suction channel) to remove any residue before being placed in a suitable sterilizing solution. Detailed guidelines have been published on the appropriate duration of sterilization, particularly for high-risk infections such as TB or HIV.<sup>103</sup> The instrument used for each procedure should be identified in the case sheet to enable tracking if there is future suspicion of cross-infection.

### USES AND INDICATIONS FOR AIRWAY ENDOSCOPY IN CHILDREN

Clinical use of airway endoscopy in children falls into two broad categories: diagnostic and therapeutic.

#### Diagnostic uses

Nowadays, the flexible bronchoscope is the instrument of choice for most diagnostic purposes.<sup>104</sup>

### **Direct observation of intranasal, laryngeal, intratracheal and intrabronchial abnormalities**

Endoscopy allows direct visualization of the nasal passages, pharynx, larynx and vocal cords, glottis, trachea, carina, lobar bronchus and more peripheral bronchi. Abnormalities of airway structure, size or patency, including congenital anomalies, stenosis or extrinsic airway compression, and endobronchial masses, particularly foreign bodies or mucus plugging, can all be seen. If an obstructing lesion pulsates it may point to the presence of a vascular abnormality such as a vascular ring. In children with TB, evidence of airway compression or granulation tissue may guide the need for steroid therapy or for the resection of granulation tissue.<sup>105</sup> In children with stridor or persistent wheezing, abnormal airway dynamics can be visualized. Areas of inflammation or bleeding may be directly identified.

### **Direct suction and bronchoalveolar lavage**

Samples may be collected by suction either directly or after lung washings with saline. Bronchoalveolar lavage (BAL) is a method of collecting fluid through the suction channel of a wedged fiberscope after saline has been injected. This method is commonly used for collection of material for the analysis of cellular or biochemical components.<sup>106</sup>

Usually, BAL is carried out in the most affected area identified radiologically or by endoscopy. In diffuse lung disease, the right middle lobe is preferred because fluid recovery is better. BAL is carried out using sterile normal saline solution warmed to body temperature. Various protocols for determining the amount of fluid to be lavaged are available but there is limited information on which is optimal. Fluid is instilled in between two and four aliquots. The first aliquot collected is of more bronchial origin; subsequent aliquots, which are usually pooled, sample more distal airspaces. Generally, the initial fraction is used for culture while later fractions are submitted for cytological and biochemical analysis. A BAL can be considered technically satisfactory if fluid recovery is greater than 40% of the volume instilled and the lavage fluid (except for the first sample) contains few epithelial cells.

### **Bronchial biopsy**

Areas in the airway that look abnormal can potentially be biopsied using endoscopic biopsy forceps. This may be useful if there is suspicion of a granulomatous disease (e.g. caseating tuberculosis). In children with poorly controlled asthma, mucosal biopsies have been used to investigate the extent of bronchial inflammation.<sup>107</sup> With infiltrative lung disorders, TBB may provide an alternative to open or percutaneous lung biopsy, although the small samples obtained are not always sufficient to make a diagnosis.

With an endobronchial brush inserted through the suction channel, it is easy to collect ciliated epithelium from the lower airways for assessment of ciliary function and structure.

### **Bronchography**

Although bronchography has largely been superseded by the development of HRCT, it is easy and safe to obtain a precise bronchogram by injection of contrast medium through the suction channel into the desired lobe or segment. This technique can produce very high quality bronchograms while minimizing the volume of contrast material used.

## **Therapeutic uses**

### **Endoscopic removal of material**

Operative procedures such as the extraction of foreign bodies are difficult with flexible instruments and rigid instruments are almost always used for this purpose. Material obstructing the airway, such as a foreign body, mucus plug or tissue mass, can be removed endoscopically. Mucus plugs can usually be aspirated through the suction channel of flexible instruments.

### **Placing of endobronchial stents**

Stents have been widely used in adults for palliation of inoperable tracheobronchial malignancies. In children, tracheobronchial stenoses are

usually congenital. Surgical treatment has been unsatisfactory, largely because of the occurrence of recurrent stenoses.

There is growing experience with the use of balloon-expandable, metal stents and silicone stents placed under combined bronchoscopic and fluoroscopic guidance. Such procedures have been used for the treatment of airway compression in pediatric patients, especially severe tracheal stenosis, either congenital or after tracheoplasty for congenital tracheal stenosis repair, and for severe tracheobronchomalacia in children as young as 2 months.

Complications, especially with metal stents, are not uncommon. A stent may migrate (often distally) or produce reactive granulation tissue formation (leading to subsequent airway stenosis). It may erode the mucosa or cause problems during attempted removal. If left in situ permanently, the stent may well lead to a fixed narrowing in the context of a growing child.<sup>108-110</sup>

## **SPECIFIC CLINICAL INDICATIONS FOR AIRWAY ENDOSCOPY (TABLE 20.5)<sup>111-113</sup>**

### **STRIDOR<sup>114</sup>**

Chronic stridor is the commonest indication for examination of the airway in infants and children. If stridor is mild and/or intermittent then a conservative approach may be appropriate. Even with mild stridor, an endoscopy may be useful if the parents are very anxious. Showing the parents the abnormality may be particularly valuable in helping them to understand their child's problem.

When the stridor is severe, persistent, associated with apnea, failure to thrive or an abnormal cry, or is present in a child who has previously been ventilated, then chances of a structural abnormality are high and endoscopy is indicated.<sup>113</sup>

The flexible bronchoscope is well suited for the evaluation of stridor. Because the instrument is passed through the nose, the entire airway can be examined. More importantly, a transnasal approach in a spontaneously ventilating sedated child leaves the laryngeal structures in their natural state, without any distorting forces being applied. This allows an evaluation of the 'normal' airway dynamics. If the child has stridor at the time of the examination, then the vibrating structures giving rise to the noise can be identified.

**Table 20.5** Indications for bronchoscopy

Stridor
Unexplained or persistent wheeze
Unexplained or persistent cough
Unexplained hemoptysis
Possible tracheobronchial foreign body aspiration
Investigation of chest radiograph abnormalities
Persistent/recurrent lobar consolidation or atelectasis
Recurrent or persistent infiltrates
Lung lesions of unknown etiology
Pulmonary infection – to identify pathogens
In infection unresponsive to antibiotics
In a child with cystic fibrosis to identify pathogens
In an immunosuppressed child
Recurrent infection
Intensive care/anesthetic room
Examine for the position, patency or airway damage due to ET or tracheostomy tube
Facilitate difficult intubations
Airway injury
Assessment of injury from toxic inhalation or aspiration
Other therapeutic and diagnostic indications
Endobronchial stent placement
Sampling and/or removal of airway secretions and mucus plugs
Endobronchial and transbronchial biopsy

## Laryngomalacia

Laryngomalacia is the commonest cause of persistent non-infective stridor, accounting for over 75% of cases, and is easily diagnosed endoscopically.

Stridor is usually evident in the first few days of life but may not be evident until later in the first month. The noise is a fairly characteristic jerky, inspiratory crowing noise which varies in intensity from breath to breath, commonly being loudest when the infant is crying or in the supine position. The noise may disappear when the infant is quiet, asleep or prone. Usually there is no respiratory distress or cyanosis. Stridor may worsen during an upper respiratory tract infection (URTI). Feeding difficulties and failure to thrive are very uncommon except in severe cases. The noise usually lessens gradually as the child becomes older and in the majority of children has disappeared by about 2 years.

The endoscopic findings of laryngomalacia are characteristic. The epiglottis is long and omega-shaped ( $\Omega$ ). The tissues of the larynx are floppy so that the epiglottis, arytenoids and aryepiglottic can be seen collapsing inwards on inspiration, prolapsing into and narrowing the glottic opening. The floppy tissues vibrate during inspiration causing the stridor, while on expiration the positive pressure of air blows them apart. Concomitant lesions below the cord are not uncommon. Accordingly, it is important that bronchoscopy is performed in addition to laryngoscopy.

## Subglottic stenosis

Subglottic stenosis may be congenital or acquired. It is characterized by a narrowing in the subglottic region such that a bronchoscope appropriately sized for the child's age cannot pass through the subglottic area or passes snugly. Clinically, children may present with stridor, cough or recurrent croup.

Congenital subglottic stenosis is secondary to a small cricoid or thick submucosa. The prognosis is good, with fewer than 50% of cases coming to tracheostomy. Acquired subglottic stenosis is most commonly secondary to prolonged endotracheal intubation in the neonatal period. It may coexist with damage to other parts of the larynx and trachea.

## Vocal cord paralysis

Vocal cord paralysis, unilateral or bilateral, is the second most common laryngeal anomaly in neonates and may be either congenital, secondary to central nervous system disorders, or iatrogenic, usually after surgical repair of cardiovascular disorders. In iatrogenic cases, unilateral paralysis is more frequent and the paralysis is temporary, usually recovering within 2–4 weeks. Children with vocal cord paralysis have a weak or absent cry, respiratory obstruction and difficulty in feeding. The diagnosis is made at endoscopy when passive, paradoxical movements of the vocal cord are observed.

## Subglottic hemangioma

Although rare, subglottic hemangioma may be life threatening. Typically, an afebrile infant presents with increasing biphasic inspiratory and expiratory stridor. The voice is typically normal and there is commonly no swallowing difficulty. In most cases, symptoms are present before 16 weeks of age. The initial presentation may mimic croup but rather than resolving, stridor is progressive. Diagnosis may be difficult because of the rarity of the lesion and the overlap in presentation with other commoner illnesses such as croup. The presence of skin hemangioma should alert the clinician. An association between extensive hemangioma present in a cervicofacial 'beard' distribution and subglottic hemangioma has been noted. If present, the early evaluation of the airway may be appropriate.<sup>115</sup> Diagnosis is confirmed by the presence of a characteristic red or blue lesion seen at endoscopy. Regression usually begins by 2 years of age and thus a conservative approach is preferred. Other than this, treatment options include systemic steroids (prednisolone 2–4 mg/kg for 4–6 weeks, tapering the dose with response), direct steroid injection into the lesion or CO<sub>2</sub> laser excision. For steroid resistant lesions and in the presence of life threatening symptoms, interferon alpha-2a may be effective but has substan-

tial side-effects. Another option in steroid-resistant lesions is vincristine. If the airway is compromised, tracheostomy may be necessary until regression occurs.

## Tracheomalacia and bronchomalacia

Congenital malacia of the large airways is one of the few causes of irreversible airway obstruction in children.<sup>116</sup> In children, malacia has been defined as a collapse of at least 50% in the airway lumen during expiration, cough or spontaneous breathing.

As bronchoscopy has been used more often in children, it is clear that malacia of the large airways is not a rare problem with an estimated incidence of primary malacia of at least 1 in 2100.<sup>117</sup>

Expiratory stridor and a cough, often described as barking, are common symptoms in children with malacia.<sup>117</sup> However, symptoms may vary depending on severity and the presence or otherwise of associated conditions. Severe cases will usually present in the neonatal period with ventilator dependency or severe obstructive episodes with cyanosis ('near death episodes'). Those associated with specific syndromes or congenital heart disease (secondary malacia) may be detected early because of selective screening. Children with milder airway malacia without other clinical features ('primary malacia') often present later with more nonspecific respiratory symptoms such as cough, recurrent lower respiratory infections, shortness of breath, wheeze, rattling or stridor. One series noted stridor in only 18% with cough the most common problem, present in 83%. Not infrequently, children with airway malacia are wrongly diagnosed as severe persistent or therapy resistant asthma because of the lack of response to standard asthma therapy or evidence of irreversible airway obstruction. In children with primary airway malacia, the diagnosis was not suspected before bronchoscopy in half of cases.

At bronchoscopy, abnormalities of the tracheal cartilage may be seen, most typically with anterior flattening of the usual horse-shoe shape. Dynamic movement of the airway during the respiratory cycle produces anteroposterior narrowing in expiration, often more pronounced to one side. Extreme cases will demonstrate a touching, or kissing, of the anterior and posterior parts. With associated anomalies such as tracheo-esophageal atresia, the tracheomalacia may be localized, while in other primary cases it can affect most of the trachea and bronchi.

## PERSISTENT OR UNILATERAL WHEEZING

Persistent wheezing unresponsive to bronchodilators or unilateral wheezing is an important indication for bronchoscopic examination. Lower airway problems were found in 79% of one large series. Tracheomalacia, compression of the left main bronchus usually in association with cardiac anomalies and tracheal compression due to vascular structures were the commonest structural findings. However, previously unsuspected foreign bodies were also surprisingly common.<sup>118</sup>

## PERSISTENT COUGH

If persistent cough is unresponsive to treatment, bronchoscopy may be indicated although the diagnostic yield may be low in the absence of other symptoms and signs. It can, however, be reassuring if the airways are normal.

## UNEXPLAINED HEMOPTYSIS

Hemoptysis is an unusual symptom in children. If the bleeding is of significant size or is persistent and a careful history and examination, including a careful examination of the mouth and nose, fails to identify a cause, then bronchoscopy is indicated. The chances of finding a cause are greater if the bleeding is active at the time of the examination. Rigid bronchoscopy with its better suction is safer if hemoptysis is brisk. Heavily blood-stained BAL fluid raises the possibility of pulmonary hemosiderosis. The demonstration of hemosiderin-laden macrophages in the lavage fluid confirms the diagnosis. If hemoptysis persists after a normal bronchoscopy, a pulmonary origin for the blood is unlikely.<sup>113</sup>

## PERSISTENT ATELECTASIS

If atelectasis persists despite adequate treatment, bronchoscopy should be considered to exclude a foreign body, remove mucus plugs and obtain pathological specimens. In one large series, around 60% of children with persistent atelectasis had a diagnostic abnormality.<sup>118</sup> While the causes were diverse, the commonest finding was the presence of a central mucus plug. Removal of large plugs by lavage and suction frequently can lead to complete and immediate resolution, particularly in young children with massive atelectasis.

## RECURRENT/PERSISTENT PULMONARY INFILTRATES

Bronchoscopy combined with BAL can provide valuable information in the assessment and treatment of a child with pulmonary infiltrates and should be considered in every child suspected of interstitial lung disease.

### In an immunocompetent child

When a child with pulmonary infiltrates fails to respond to a broad spectrum antibiotic or where an atypical pneumonia is suspected and other techniques of collecting airways secretions are not practical, bronchoscopy with BAL can be used to collect specimens for microbiological and cytological analysis. However, samples collected by BAL can be contaminated by bacteria normally present in the respiratory tract. Interpretation of cultures, therefore, may need to be based on quantitative cultures with appropriate thresholds and/or identification of intracellular bacteria on direct examination of the sample in conjunction with the clinical picture. Newer molecular techniques are extending the range of organisms that can be detected.

In children with alveolar proteinosis, alveolar hemorrhage and pulmonary histiocytosis, BAL may be diagnostic. In other situations, even if not diagnostic, BAL cell profiles may help orientate further investigations.<sup>106</sup> Once a diagnosis of an alveolar inflammatory process has been reached, inflammatory markers in BAL fluid may help monitor disease activity and progression, although there is as yet no general consensus on the measurement or interpretation of such markers.

Finally, bronchoscopy and BAL may have a therapeutic role in the removal of material present in the airways resulting from lipoid material in alveolar structures. Several reports have shown that whole lung lavage may be an effective treatment in some children with alveolar proteinosis.<sup>119</sup>

### In an immunocompromised child

In the immunocompromised child with pulmonary infiltrates, bronchoscopy and BAL have an important role. In children with primary or secondary immunodeficiency who develop pneumonitis, BAL should ideally be performed soon after clinical and radiological signs develop, before any antibiotic therapy is started. Where antibiotics are started empirically, bronchoscopy and BAL may be informative in those who do not improve despite adequate antibiotic therapy.

The identification of primary pathogens, such as *Mycobacterium tuberculosis*, *Pneumocystis jiroveci* (formerly *P. carinii*), or respiratory syncytial virus (RSV) not usually isolated from BAL fluid, may be diagnostic. Where the organisms may also be present as airway commensals or contaminants (e.g. *Aspergillus*, atypical mycobacteria, cytomegalovirus), interpretation is more difficult.

Children with HIV can develop a range of respiratory presentations ranging from acute pneumonia to interstitial pneumonitis (see Ch. 27, p. 1155). Bronchoscopy and BAL may help differentiate infectious causes such as *P. jiroveci* from non-infectious pulmonary complications such as lymphoid interstitial pneumonitis.

BAL and TBB are frequently used in the monitoring of children after lung transplantation, either routinely or as a result of clinical and/or radiological deterioration.<sup>101,120</sup> TBB is necessary to establish a histological diagnosis of rejection while BAL fluid can be used for microbiological studies to exclude infection.

## INHALATION OF FOREIGN MATERIAL

### Foreign body aspiration

Aspiration of a foreign body in a child is among the most important indications for bronchoscopy. Indeed, the presence of a foreign body cannot be reliably excluded without a bronchoscopy.

The typical history is of the sudden onset of choking, coughing or wheezing. A careful history will identify a choking episode in most cases. After the initial period, a symptom free interval may follow. Some patients with foreign bodies have chronic or subtle clinical features (atelectasis, recurrent or persisting pneumonia, persistent wheezing unresponsive to bronchodilators, diminished local breath sounds) and radiological changes (hyperinflation or atelectasis of an affected segment), but no history of foreign body aspiration. Others may have no physical or radiological signs.

Peanuts (ground nut) and other nuts are the most common objects inhaled in the UK. These materials are highly irritating to bronchial epithelium and can lead to florid local inflammation and necrosis if not rapidly removed. Grass seeds and seed husks are commoner in other parts of the world and may be especially troublesome because their barbed nature prevents expectoration or removal by bronchoscopy. The most common site of impaction of a foreign body is in a segmental bronchus on the right side.

In the many cases where history, physical examination and radiographic studies suggest a diagnosis of foreign body aspiration, the child should have rigid bronchoscopy without delay.

When there is doubt about foreign body aspiration, a flexible bronchoscopy may be diagnostically valuable. In some children, foreign body aspiration may be totally unsuspected. Wood found a previously unsuspected foreign body in nearly 1% of children undergoing flexible bronchoscopy.<sup>118</sup> If a foreign body is identified, then the child should have a rigid bronchoscopy to remove it. Occasionally when removal of a foreign body has been unusually delayed, it may be necessary to resect an irretrievably damaged lung segment.

### Recurrent aspiration

Bronchoscopy and BAL can be useful in the investigation of a child suspected of recurrent aspiration. Chronic pulmonary aspiration of oral and/or gastric contents occurs when normal airway protective mechanisms are impaired, bypassed or overwhelmed. The resulting airway contamination causes lung injury which may lead to bronchospasm, atelectasis, pulmonary edema, pneumonia or bronchiectasis, depending on the frequency and quantity of aspiration, the composition and pH of aspirated material and the efficacy of the lung clearance response. Thus, there may be a range of clinical presentations ranging from wheezing, through recurrent episodes of pneumonia to chronic inflammation with eventual interstitial fibrosis and bronchiectasis. Children with neurodevelopmental problems are particularly susceptible. The predominant site of pathology depends on the patient's habitual posture: upper lobes in infants nursed supine; basal disease for older children propped in a semi-recumbent position.

There are three main groups of pathophysiological processes that interfere with normal airway protective mechanisms and lead to recurrent aspiration (Table 20.6). Anatomical abnormalities such as cleft palate or laryngeal cleft can lead to pooling of food or saliva in the pharynx. Abnormal swallowing coordination occurring in children with neuromuscular disorders such as cerebral palsy or dysautonomia results in aspiration of material with symptoms likely to occur during feeding. Esophageal disorders cause aspiration by a number of mechanisms. Fistulous connections will lead to lower airway soiling, particularly during feeding. There may be soiling of the lower airway from overspill of contents refluxed from the stomach or more rarely from overspill from a dilated esophagus in conditions such as achalasia or with esophageal strictures.

The diagnosis of recurrent aspiration can be surprisingly problematic. Associated disorders, varying clinical presentations and lack of specific diagnostic criteria all contribute to frequent diagnostic difficulties. Diagnosis starts with a careful history and examination (including a careful dental inspection) combined with observation

Table 20.6 Causes of recurrent aspiration

Swallowing disorders
Anatomical disorders
Cleft palate
Macroglossia
Laryngeal cleft
Neuromuscular disorders
Cerebral palsy
CNS degenerative disorders
Congenital neuromuscular disorders
Dysautonomia
Esophageal lesions
Obstruction
Stricture or compression
Systemic sclerosis
Achalasia
Tracheoesophageal fistula
Gastroesophageal reflux
Hyperinflation (severe asthma, cystic fibrosis)

of the child feeding, followed by imaging studies including a CXR, barium swallow and video recording of the child swallowing. If a fistula is suspected, specific lateral X-ray views are taken while injecting contrast rapidly to distend the esophagus through a slowly withdrawn, gastric tube with side holes. The gold standard for demonstrating gastroesophageal reflux has been a 24-h pH probe study. Gastroesophageal scintiscans using radiolabeled milk may provide direct evidence of aspiration (see p. 673 Radioisotope investigations). While positive studies are highly suggestive of chronic aspiration false positives may occur and none of these tests may rule out aspiration.

Bronchoscopy may provide direct evidence of anatomical abnormalities such as the presence of a tracheoesophageal fistula. Dye can be introduced via the endoscope into the airway with simultaneous esophageal observation endoscopically to observe leakage through a fistulous connection. The semi-quantitative estimation of lipid-laden alveolar macrophages (LLMIs) in bronchoalveolar fluid has been used as a marker of chronic aspiration. While more recent studies suggest that LLMIs alone cannot be used to diagnose chronic aspiration, they may be a useful adjunct when taken in combination with other investigations.<sup>121</sup>

## BRONCHOSCOPY IN INTENSIVE CARE AREAS AND ANESTHETIC ROOMS

There are a number of important uses for airway endoscopy in neonatal and pediatric intensive care units and in pediatric anesthesia.<sup>122,123</sup> Documentation of abnormal anatomy and airway injury secondary to intubation and suction is part of the full assessment of each child. Specific indications for endoscopy in neonatal and pediatric intensive care are discussed below.

### Intubation

Endoscopic intubation is a useful method in difficult to intubate children whose larynx is otherwise impossible to visualize. Following a nasal approach and passage of the endoscope into the trachea, an endotracheal tube (ETT) is passed over the endoscope and directly positioned in the airway under direct visualization. Custom-made intubation endoscopes have a small battery light source and are stiffer and more robust than diagnostic endoscopes, but with care the ultra-thin 2.2 mm bronchoscope can aid intubation with ETTs as small as 3.0 mm.

### Problems with ventilation

Abnormal gas exchange may be due to an ETT problem. Bronchoscopy can quickly confirm ETT patency and position. Children in the PICU with congenital abnormalities (e.g. Di George syndrome, myelomeningocele, congenital heart disease) may have a low placed ETT at bronchoscopy despite an apparent satisfactory position on CXR, due to an associated

short trachea.<sup>124,125</sup> Occasionally endoscopy can assist in selective placement of the ETT into a main stem bronchus in the treatment of persistent contralateral air leak.

Unsuspected congenital airway abnormality (malacia, stenosis, compression, tracheal bronchus) or acquired pathology (granulation tissue, mucus or blood plugs) can also cause difficulty with assisted ventilation, and in an unstable newborn infant or child in intensive care the diagnostic procedure of choice will be an endoscopy. Ventilation can be continued during the examination using a bronchoscope swivel adaptor, with the procedure being well tolerated by the majority of patients.

Bronchomalacia, while often causing a ventilation problem, is unlikely to need any specific treatment. Tracheomalacia may require aortopexy, while tracheal stenosis causing significant ventilation problems may require a slide tracheoplasty. Major airway compression most commonly occurs in conjunction with congenital cardiac disease, which may not be treatable or may even be made worse by corrective surgery. Positioning an expandable metallic stent for a short period can be considered in an attempt to enable extubation in a child who remains dependent on positive pressure ventilation due to a discrete narrowing of a main airway.<sup>126</sup>

## Persistent or recurrent atelectasis

In intensive care, persistent atelectasis can be caused by a congenital lung abnormality or an acquired problem such as airway compression or plugging. In the latter case, bronchoscopy with BAL can remove the obstruction allowing re-inflation of the affected lung. On occasions, a foreign body may be the cause of the consolidation secondary to airway inflammation and obstruction, though the more usual clinical scenario would be one of increased airway obstruction on expiration causing a 'ball valve' effect with resulting lung hyperinflation and airleak.

## Sampling of airway secretions

Flexible bronchoscopy can enable collection of lower airway secretions for analysis in different clinical situations. Current technology limits specimen collection to an ETT large enough to enable the passage of a 2.8 mm diameter scope, which is the smallest instrument available with a suction channel.

Even the sickest child will tolerate quickly passing the bronchoscope into the lower airway to lavage either a lobe identified as abnormal on a CXR, one with thick infected secretions seen at the time of the examination, or alternatively the Right middle lobe (RML) or lingula. While ETT secretions have traditionally been used for antibiotic targeting in nosocomial pneumonia, bronchoscopic BAL is more likely to differentiate bacterial colonization from infection.<sup>127</sup>

Staining for lipid- or hemosiderin-laden macrophages can be an important diagnostic investigation in a ventilated child with unexplained respiratory disease. At times a newborn child will become ventilator dependent due to a surfactant protein B deficiency or alveolar proteinosis. BAL will demonstrate large volumes of cloudy lung fluid, which can be analysed for surfactant.

## CONCLUSIONS

Airway endoscopy is firmly established as an important tool in the investigation and management of respiratory disorders in children. New developments and wider use of the technique mean that the full potential of the technique is still being realized.

## SLEEP DISORDERED BREATHING

Humans spend approximately one third of their lives asleep, yet many of the functions of sleep remain poorly understood,<sup>128</sup> but probably include neocortical maintenance, energy conservation, memory consolidation, neurodevelopmental roles and effects on immunoregulation. Despite its essential role in mammalian function (total sleep deprivation can result in the rapid death of small mammals) and ancestral origins, the structure of sleep has been elucidated only in relatively modern times. Prior to the use of EEG to decipher different stages of sleep in 1937,<sup>129</sup> sleep

was believed to represent a homogeneous state of inertia. Rapid eye movement (REM) sleep was first described in 1953<sup>130</sup> and conventional sleep staging as currently applied is based on the work of Rechtschaffen and Kales,<sup>131</sup> which categorizes sleep into REM and four stages of non-REM (nREM) sleep based on electrophysiological criteria. Sleep is organized into a number of 'sleep cycles' with slow wave sleep predominating during the early part of sleep and REM periods becoming more prolonged in the latter half of a night's sleep. Typically, once adult-type sleep patterns are established, there will be four to five nREM/REM cycles during a night and REM will occupy approximately 20% of the total sleep time. In contrast, sleep in the newborn does not have such clearly defined electrophysiological features that distinguish REM from nREM sleep. Instead, a behavioral state that shares many features of adult REM sleep, active sleep (bAS), is distinct from the nREM equivalent, quiet sleep (bQS). These stages are organized as a number of much shorter sleep cycles than in the adult, each of approximately 1 h duration and comprising equivalent periods of bAS and bQS, such that the neonatal equivalent of REM sleep occupies almost 50% of total sleep time. A diurnal pattern of sleep behavior emerges in the infant at around 16 weeks of age and habitual daytime sleep gradually diminishes over the first 2 years of life.

Sleep is a metabolically active process and is associated with the pulsatile release of a number of important hormones, including growth hormone (see Ch. 15, p. 436). Physiological changes in respiration also occur during sleep and in general these are state dependent, varying between REM and nREM sleep. Minute ventilation falls by about 8–15% during sleep compared with wakefulness. In adults, this is largely due to decreased tidal volume. However, in infants and children, the respiratory rate decreases during sleep, possibly in association with a decrease in tidal volume. During REM sleep, breathing becomes irregular with frequent central apneas, intercostal muscle activity decreases and there is an increase in upper airway resistance. These changes are important in early childhood as infants spend a proportionately greater period in REM or REM-equivalent (bAS) sleep compared with adults. Also, as infants have markedly greater chest wall compliance than adults, the loss of postural muscle tone during REM sleep leads to paradoxical inward rib cage motion during inspiration that is typically associated with airway obstruction in older children.<sup>132</sup> In contrast, during quiet sleep, intercostal muscle activity is maintained and thoracic and abdominal movements are coupled and in phase.

Infants and children have greater ventilatory drive relative to body size than adults.<sup>133</sup> Infants also have an exaggerated biphasic response to hypoxia with an initial increase in ventilation followed by a decrease, often in association with apnea. This is coupled with a higher arousal threshold to hypoxia in children compared with adults, resulting in moderate hypoxemia being a poor stimulus to arousal. In contrast, hypercapnea and increased upper airway resistance are potent stimuli for arousal during sleep in all age groups.

Respiration during quiet sleep is largely determined by autonomic control through chemoreceptor inputs. Thus failure of chemoreceptor control mechanisms, e.g. congenital central hypoventilation, results in hypoventilation that is most marked in, but not confined to, quiet sleep. During REM sleep, infants and children have frequent central apneas. In asymptomatic infants, these have been demonstrated to exceed 20 s duration and to be associated with desaturations to below 81%.<sup>134</sup> Therefore, their clinical significance remains uncertain. The physiological changes occurring during REM sleep also contribute to increased upper airway resistance associated with obstructive sleep apnea syndrome, in which loss of genioglossus tone is an important factor, and to hypoventilation in cases of diaphragmatic paresis or palsy, when ventilation during wakefulness and quiet sleep is maintained by intercostal and accessory muscle activity. Thus, investigation of children with damage to or disorders of any component of the respiratory musculature must include measurements of respiration during sleep, particularly during intercurrent illnesses associated with increased work of breathing. Abnormal respiratory muscles that provide adequate alveolar ventilation when a child is well may not be able to cope under conditions of increased load.

## CONGENITAL CENTRAL HYPOVENTILATION SYNDROME

### Prevalence

Congenital central hypoventilation syndrome (CCHS), previously commonly known as 'Ondine's curse' is a rare (between 1 in 50 000 and 1 in 200 000) congenital condition in which there is an abnormality of control of respiration in the absence of any identifiable primary CNS, neuromuscular, lung or cardiac disease. Approximately 800 cases of CCHS have been identified worldwide.

A Strategic Health Authority, with a population of 1–1.5 million and 10 000–15 000 births per year, will have 3–4 children with CCHS. In the past many children with CCHS may have died in early infancy, but increased awareness of the condition in recent years has led to an increased number of children being diagnosed within a few days of birth.<sup>135–138</sup>

Because of the extreme rarity of this condition, virtually all published studies are based upon case reports, case series and expert opinion (i.e. evidence levels 3 or 4).

### Consequences and benefits of identification

Affected children show hypoventilation during sleep, especially non-REM sleep, but some severely affected patients may also hypoventilate while awake. Untreated children with the more severe forms of CCHS are likely to die within the first few weeks after birth. If not recognized in early infancy, children with the milder forms of CCHS may present with cyanosis, edema and right heart failure with pulmonary hypertension as a consequence of recurrent or chronic hypoxemia. Some children may present with apparently life threatening episodes or apneas necessitating resuscitation. Untreated mild to moderate CCHS is compatible with survival for several months, and it is possible for subtle disease to go unnoticed. In the late-onset variant that presents around 2–4 years of age there are commonly associated hypothalamic disorders, particularly endocrine dysfunction. Several cases have now been reported of presentation of CCHS in adult life, commonly with symptoms dating to early childhood, though in others these are only recognized on the diagnosis of CCHS in a child of the affected adult.<sup>135–140</sup>

### Prevention

Although the great majority of children with CCHS will be the first affected person in the family, recent studies have identified heterozygous de novo mutations of the PHOX2B gene in >90% of children with CCHS,<sup>141–143</sup> raising the possibility of prenatal diagnosis. Genetic investigation and counseling should be offered to all newly diagnosed families.

## Identification and diagnosis

### Diagnostic criteria

The clinical and physiological diagnosis of CCHS has been considered to require the following criteria:<sup>144,145</sup>

1. persistent evidence of hypoventilation during sleep [ $\text{PaCO}_2 > 60 \text{ mmHg}$  (8 kPa)];
2. onset of symptoms usually in the first year after birth;
3. absence of primary pulmonary or neuromuscular disease;
4. no evidence of primary heart disease.

However, the clinical presentation of CCHS is variable and may reflect the severity of the underlying disorder. Children typically present in the newborn period with duskeness or cyanosis when falling asleep, but no associated increase in respiratory effort. These infants may not awaken during these episodes. Hypoventilation may be present during waking but is generally worse during sleep. Presentation may be with apparent life threatening events (ALTEs), or it may be delayed until adult life, as noted above.<sup>140</sup>

CCHS is associated with a number of other conditions affecting or derived from the autonomic nervous system. These include neurocristopathies such as Hirschsprung disease, abnormalities of a range of autonomic functions (e.g. temperature control, pupil size, heart rate variability) and tumors, including ganglioneuroma, neuroblastoma and ganglioneuroblastoma.<sup>135–137,141–143</sup>

In the evaluation of children with sleep hypoventilation, it is important to exclude primary neuromuscular, cardiac or pulmonary disease or any identifiable brainstem lesions. Other conditions that may cause sleep hypoventilation include congenital myopathy, myasthenia gravis, abnormalities of the airway or intrathoracic anatomy, diaphragm dysfunction, congenital cardiac disease, structural hindbrain or brainstem abnormalities and metabolic disorders.

### Assessment

The identification of characteristic abnormalities of the PHOX2B gene – either polyalanine insertions, frameshift or mis-sense mutations,<sup>140–143</sup> in > 90% of children with clinically diagnosed CCHS allows the rapid identification of the diagnosis in the great majority of affected individuals. In the UK, investigation of the PHOX2B gene is available through the UK clinical genetics testing network ([www.geneticstestingnetwork.org.uk](http://www.geneticstestingnetwork.org.uk)).

Definitive physiological evaluation of CCHS includes a detailed assessment of spontaneous breathing during sleep and wakefulness in a reference sleep physiology laboratory. Good quality polysomnography, including an adequate period during both REM and non-REM phases of sleep, is essential. The measurements should include at a minimum, tidal volume and flow (pneumotachograph), movement of the chest and abdomen (respiratory inductance plethysmography), pulse oxymetry, end-tidal CO<sub>2</sub> and ECG, together with EEG and electro-oculogram (EOG) for sleep state determination. This may be supplemented by invasive blood gas measurements, preferably obtained from an indwelling arterial line, to objectively quantify hypoxemia and hypercarbia. Careful observation of tidal volume and respiratory rate of infants during endogenous hypercarbia during sleep and wakefulness may be sufficient to assess central chemoreceptor function. Peripheral chemoreceptor sensitivity to hypoxia may be assessed by measurement of the ventilatory depression caused by hyperoxia from the administration of increased inhaled oxygen concentration. More detailed assessment of chemoreceptor ventilatory responses to hypercarbia may be performed using a rebreathing or steady state challenge with 5% CO<sub>2</sub> administered via a head box. Functional MRI has shown abnormalities of CNS responses to both hypoxia and hypercapnia in multiple CNS sites, including the frontal cortex, cerebellar cortex and basal ganglia, as well as the midbrain, pons and ventral and dorsal medulla.<sup>137,144–154</sup>

### Management

Ventilatory support is necessary in almost all children with CCHS. This may be continuous or during sleep only. In contrast to the generally poor prognosis of untreated infants, > 60% of patients receiving ventilatory support will survive to later childhood.<sup>135–138</sup> Most such children with CCHS have an overall high quality of life, though many have persisting hypotonia with varying degree of neurocognitive deficits, and many have multiple autonomic deficits, particularly affecting heart rate variation, blood pressure control and thermal responses.<sup>146–154</sup> Many children with CCHS suffer from seizure disorders and some show evidence of poor growth and delayed puberty. It is difficult to separate the effects of intrinsic CNS abnormalities from the effects of intermittent hypoxemia in determining the neurodevelopmental outcome. Pulmonary hypertension and cor pulmonale occur in some children with CCHS and may be fatal; it is not yet clear whether these can be completely prevented by rigorous ventilatory management, but in order to minimize the risk of cor pulmonale, current recommendations are to aim to maintain normal levels of both CO<sub>2</sub> and O<sub>2</sub> during all periods on ventilatory support.<sup>137,138,145</sup>

Conventional management of infants with CCHS has been to maintain ventilation via a tracheostomy, but recent reports have shown the feasibility of non-invasive ventilatory support from early infancy for selected infants.<sup>135,136,155,156</sup> With adequate education, support and resources provided to the family and the primary health care team almost all children with CCHS can be safely and effectively cared for at home in the longer term.<sup>135–138,155,156</sup> The practicalities of discharging a child home on ventilation in the UK have been dealt with elsewhere.<sup>157,158</sup>

Several ventilatory options are available for these children. With increasing age and as the infant becomes ambulatory, diaphragmatic pacing using phrenic nerve stimulation is an option for children with CCHS who are ventilator dependent for 24 h a day and who have no evidence of ventilator-related lung disease.<sup>159–161</sup> Phrenic nerve electrodes may be bipolar (relatively easier insertion through the neck but somewhat less reliable because of possible displacement) or more recently quadripolar (more difficult transthoracic insertion but more stable position and hence more reliable). The aim is to ensure adequate alveolar ventilation and oxygenation. Because of the more natural breathing pattern, with negative inspiratory intrathoracic pressure, pulmonary ventilation perfusion matching is improved in some patients by the use of phrenic stimulators. Adverse effects of phrenic nerve stimulators include permanent phrenic nerve damage, diaphragmatic fatigue, discomfort associated with surgical implantation, accidental displacements in ambulatory children and the potential need for repeated surgical revisions. The quadripolar electrodes offer greater duration of pacer support, diminished risk of phrenic nerve damage and diaphragmatic fatigue, and allow optimization of the pacing activity during exercise. Despite limitations, parents and children have emphasized the improvements in mobility and quality of life after phrenic nerve stimulator insertion in CCHS.<sup>159</sup> Despite the very high cost of phrenic nerve stimulators and their insertion and maintenance, this option should be explored for all children who require awake as well as asleep ventilatory support. Phrenic nerve stimulators are usually used only during the daytime, with positive pressure ventilation by a ventilator at night, to minimize the risk of phrenic nerve damage from continuous electrical stimulation, although some patients have chosen to use nerve stimulators round the clock for prolonged periods.<sup>159</sup>

Children who require ventilatory support only during sleep and who are able to cooperate may be considered for non-invasive facemask ventilation with bilevel positive pressure ventilation. Non-invasive ventilation is generally not recommended for children younger than 6–7 years of age, partly because of the likely need for continuous ventilatory support with intercurrent illness, and partly because of the risk of mid-facial growth abnormalities as a consequence of a tightly placed face mask. Some authors have reported successful use of such techniques in early infancy, however.<sup>135,136,155</sup> If non-invasive ventilation is successfully instituted, tracheal decannulation may be performed.

Negative pressure ventilation has been used successfully in one center in the UK.<sup>156</sup> However, this is cumbersome and may need significant equipment adjustment over time. In addition negative pressure ventilation may aggravate any coexisting upper airway obstruction in these children.

Other general supportive measures are also important as many children with CCHS suffer from feeding difficulties and severe gastroesophageal reflux necessitating nutritional support, antireflux medications and in extreme cases antireflux surgery.

Well coordinated multidisciplinary care involving members of the primary, secondary and tertiary health care teams, and regular review in a pediatric sleep physiology laboratory, are central to the successful care of children with CCHS. The monitoring required is well described in the American Thoracic Society guidelines.<sup>145</sup>

Unlike other children on home ventilation, children with CCHS do not show ventilatory responses to hypoxemia or hypercarbia, and may hypoventilate more severely when unwell, with increased right-to-left intrapulmonary shunting. They may show minimal or absent increase in ventilation with exercise, and with infection may develop relative hypothermia rather than fever.

Continuous monitoring of blood oxygen saturation is recommended whenever children with CCHS are on the ventilator, and when they are unwell periodic checks of oxygen saturation are required when awake, as well as assessments of CO<sub>2</sub> levels.

Due to their reduced perception of hypoxia and hypercarbia, and the absence of any appreciation of dyspnea, together with depressed ventilatory responses to exercise, children with CCHS may exert themselves beyond physiological limits and come to harm. Children with CCHS

should be allowed to participate in noncontact sports with a moderate level of activity and frequent rest periods. Swimming may be hazardous for these children – the lack of hypoxic response may put them at risk. Underwater swimming is particularly hazardous, but with very careful supervision gentle swimming may be acceptable. Rhythmic activity with the opportunity to develop a learned increase in ventilation may be of value. Dance is particularly helpful in developing appropriate rhythmic increased ventilation with exercise.<sup>135–138,145</sup>

Children and adolescents with CCHS are at particular risk of severe and potentially fatal hypoventilation on ingestion of alcohol or use of cannabis. Affected children and their families must be informed and warned of these potential dangers.<sup>137,162</sup>

## OBSTRUCTIVE SLEEP APNEA SYNDROME AND RELATED PROBLEMS

Upper airway resistance increases during sleep due to a reduction in the tonic activation of pharyngeal dilator muscles, especially during REM sleep when postural muscle activity is inhibited. When this is associated with situations that increase the upstream resistance in the airway, there is a tendency for airway collapse to occur, which results in a spectrum of clinical manifestations from simple snoring through upper airway resistance syndrome (UARS) to obstructive sleep apnea syndrome (OSAS). These in turn are associated with a range of adverse outcomes that are related, at least in part, to the disturbances of gas exchange and sleep structure that occur in response to upper airway obstruction with or without frank apnea.

Snoring is a cardinal symptom of upper airway obstruction during sleep and occurs in approximately 10% of children on a regular and frequent basis,<sup>163</sup> although only a small proportion of children who habitually snore will have obstructive sleep apnea.<sup>164</sup> In contrast to experience in adults, the single commonest association with OSAS in children is adenotonsillar hypertrophy with peak incidence in the preschool years when adenotonsillar size is maximal in relation to airway cross-sectional area. Other groups of children at increased risk from OSAS include those with craniofacial anomalies, e.g. Robin sequence, Treacher–Collins syndrome, Down syndrome, achondroplasia and mucopolysaccharidosis. Increased awareness of the adverse consequences of occult OSAS in such children has led to calls for screening of high-risk groups, such as those with Down syndrome,<sup>165</sup> but this is still not universally practised. Another population of children at risk of OSAS and one that is likely to represent an increasing proportion of children with sleep disordered breathing is those who are obese.<sup>166</sup> Additionally there are interesting associations of sleep disturbance with control of appetite and weight gain,<sup>167</sup> such that OSAS may also be a risk factor for obesity. There have been case reports of an association between the initiation of growth hormone treatment in children with Prader Willi syndrome (see Ch. 15, p. 503) and a risk of apnea and sudden death,<sup>168,169</sup> but systematic polygraphic evaluation of children with Prader Willi syndrome has indicated that sleep-related problems are common and are probably unrelated to growth hormone treatment.<sup>170</sup> However, consideration should be given to regular assessment of this group of patients.

Although OSAS in children is clearly associated with conditions that increase upper airway resistance, this is an oversimplification of the problem and by no means all children with adenotonsillar hypertrophy will develop clinically significant OSAS. This reflects the balance between forces tending to exacerbate airway collapse during inspiration and the distending forces of pharyngeal dilators. Although there appears to be a positive association between pharyngeal size and severity of sleep disordered breathing,<sup>171</sup> variations in airway neuromotor control during wakefulness have been correlated with the presence of sleep disordered breathing in children,<sup>172</sup> familial aggregation of OSAS has been described<sup>173</sup> and a proportion of children with OSAS in association with adenotonsillar hypertrophy fail to improve after adenotonsillectomy.<sup>174</sup>

Presentation of OSAS in children may be with habitual snoring, with or without a parental description of apneic events, restless sleep or sleeping in an unusual posture, nocturnal enuresis, daytime somnolence, although this is less commonly described in children than in adults with

OSAS, and problems with daytime learning and behavior. A link between sleep disordered breathing and attention deficit hyperactivity disorder (ADHD)<sup>175</sup> and autism<sup>176</sup> has been proposed but the causal relationship remains to be established and there are clearly complex reasons for sleep disturbance in these spectra of disorders. Clinical examination during wakefulness in an otherwise healthy child with OSAS due to adenotonsillar hypertrophy may be unremarkable. However, attention should be paid to ENT examination, careful evaluation of growth and assessment of cardiovascular status, including systemic blood pressure and signs of pulmonary hypertension.

The earliest descriptions of OSAS in children reported strong associations with growth failure and cor pulmonale,<sup>177,178</sup> but these are now uncommon outcomes in the majority of otherwise healthy children who present with OSAS in association with adenotonsillar hypertrophy. Recent attention has focused on the neurocognitive, developmental and behavioral consequences of OSAS and the gathering speculation that adverse consequences in these modalities may not be limited to children with frank OSAS but may occur in association with milder states, including UARS and primary snoring.<sup>167</sup> Several studies have reported decrements in IQ and other measures of cognitive performance, including memory and attentiveness in children with OSAS compared with otherwise healthy children.<sup>179</sup> School performance has been shown to be poorer in children with OSAS and the converse, children with low school performance are more likely to have OSAS, has also been reported. Additionally, treatment of OSAS in this group of children has been demonstrated to improve academic performance.<sup>180</sup> However, although the effects of gas exchange abnormalities and sleep fragmentation that occur in association with OSAS may be largely reversible, there is evidence that longer lasting deficits in neurocognitive performance may also occur.<sup>181</sup> The potential for long term neurological sequelae of sleep disordered breathing has been exemplified by the description of neuronal injury on MRI brain scans in association with OSAS in children.<sup>182</sup>

As well as effects on cognition, OSAS in children has also been implicated in behavioral disturbance, but although sleep disordered breathing has been reported to be associated with daytime hyperactivity disorders<sup>183</sup> and parent-reported sleep disturbance is very common in children with ADHD, a relatively small proportion of children with stringent diagnostic criteria of ADHD have polysomnographic evidence of sleep disordered breathing.<sup>184</sup>

## BREATHING DURING SLEEP IN NEUROMUSCULAR AND RESTRICTIVE DISEASES

Conditions associated with restrictive impairment of ventilatory function are relatively uncommon in childhood but contribute substantially to the burden of sleep-related breathing disorders and the provision of long term domiciliary respiratory support (see p. 687 – Long term ventilation) to such children is increasing rapidly in many countries. Examples of disorders in which nocturnal hypoventilation may be a consequence are neuromuscular diseases, including Duchenne muscular dystrophy, spinomuscular atrophy types I and II, and some congenital myopathies, e.g. nemaline myopathy (see Ch. 22, p. 909), traumatic cervical spinal cord injury, severe kyphoscoliosis, which often coexists with severe neuromuscular weakness, and some restrictive lung diseases, including chronic lung disease of prematurity (see p. 727). In some of these conditions, respiratory failure is a progressive and relatively predictable sequel, such as in Duchenne muscular dystrophy, while in others it is a less consistent or predictable feature. The importance of breathing during sleep in these conditions is that, due to the physiological changes in respiration that occur in sleep, dysfunctional breathing usually predates the occurrence of symptomatic hypoventilation during wakefulness.<sup>185</sup> Symptoms might include apneas, restless or disturbed sleep, feeling unrefreshed after sleep, and problems with concentration, fatigue and sleepiness during the day. Morning headaches may be reported as a consequence of CO<sub>2</sub> retention and a loss of appetite for breakfast is a relatively frequent symptom in children who develop nocturnal hypoventilation. Frequent respiratory infections in these patients are

also common, due to a combination of depressed cough and pulmonary atelectasis associated with chest wall weakness or deformity leading to an inability to preserve functional residual capacity.<sup>186</sup> Bulbar dysfunction and gastroesophageal reflux leading to aspiration may exacerbate these problems. It should be borne in mind that many children who are at risk of nocturnal hypoventilation are likely to have comorbidities and the symptoms associated with these may be difficult to distinguish from those associated with sleep-related breathing disturbance.

## INVESTIGATION AND TREATMENT OF SLEEP DISORDERED BREATHING

The frequency and importance of sleep-related breathing disturbances in children for health, neurocognitive development and behavior should prompt a sleep history in all children, but particularly those in the high-risk groups identified above. This should include questions about sleep onset, quantity and quality (restlessness, arousals, awakenings), how the child appears on waking, and daytime symptoms, including excessive daytime sleepiness or somnolence and problems with concentration, learning and behavior. As mentioned above, although excessive daytime somnolence is a characteristic feature of OSAS in adults, it is less commonly described in children.<sup>187</sup> Symptoms of snoring and other respiratory sounds, descriptions by parents of unusual sleeping postures and careful description of any apneic events should be documented. A history of nocturnal enuresis can be associated with sleep fragmentation due to sleep disordered breathing, and morning headaches and loss of appetite may be symptomatic of nocturnal hypoventilation. Sleep questionnaires have been devised as screening tools for sleep disordered breathing in children,<sup>188</sup> particularly in association with OSAS,<sup>189</sup> but the utility of these is limited by the inconsistent relationship between reported symptoms and objective measurements.<sup>190-193</sup>

The recommended investigation for the detection of obstructive sleep apnea is the sleep polysomnogram (PSG). Criteria for diagnosis of sleep disordered breathing based on polysomnography have been published,<sup>194,195</sup> and it is important to note that these vary considerably from their adult equivalents due to the different spectrum of disorders associated with the condition in childhood. As the name implies, a PSG comprises a variable (but large) number of channels of physiological recordings made continuously during sleep. Typically these will include a measure of breathing movement of the chest and abdomen, often using inductance plethysmography, electrocardiogram, body position and limb motion sensors, pulse oximetry with or without capnography measured either transcutaneously or by end-tidal sampling,<sup>196</sup> an indication of nasal and oral gas flow, and neurophysiological measurements, which include a minimum of two channels of EEG, electro-oculogram (EOG) and electromyogram (EMG), usually measured submentally. These last variables are primarily used for sleep staging and, as obstructive events are more abundant in REM sleep, some authorities argue that a diagnosis of OSAS cannot be excluded without demonstration that the child has spent time in REM. This is one argument against so-called nap studies,<sup>197</sup> as REM is more abundant towards the end of a usual night's sleep. Although PSG can be performed unattended and in the patient's home, the majority are carried out in hospitals or designated sleep laboratories to ensure adequate quality of data recording. However, this has the detriment of putting the child in an unfamiliar sleeping environment, which is likely to alter sleep quality and therefore may in some cases lead to problems with interpretation of data.<sup>198,199</sup> Polysomnography is a resource-intensive investigation that requires specialized equipment and substantial staff time. Therefore, there have been numerous investigations of more limited diagnostic techniques that are suitable for home or unattended use and which may at least serve as screening investigations. These include pulse oximetry,<sup>200</sup> abbreviated polysomnography<sup>201</sup> and video/audio<sup>202,203</sup> recordings. In general, these options are relatively specific and, in the context of a suggestive clinical history of OSAS, an abnormal oximetry or abbreviated PSG study can form the basis for management decisions. In practice, many clinicians will base a decision to proceed to adenotonsillectomy on clinical history alone in otherwise uncomplicated cases.<sup>204</sup> When there is doubt and a screening study is negative, or in the

context of more complicated situations, e.g. when parasomnias or seizures are suspected or when there is excessive daytime sleepiness and sleep fragmentation needs to be assessed, consideration should be given to referral for PSG. In control of breathing disorders, such as CCHS, it is important to measure ventilation during different behavioral states, in which case PSG is again the appropriate investigation. The limited availability of facilities for PSG in some countries has led to the use of more limited studies, such as oximetry and capnography, for the assessment of nocturnal hypoventilation in children with neuromuscular and chest wall disorders, but these have not been subjected to formal validation against the gold standard PSG and will inevitably lead to loss of information.

A variety of surgical approaches to the management of OSAS has been devised, mainly in adult practice, although many have not been subjected to formal RCTs and there is a paucity of evidence for surgical management of OSAS in adults.<sup>205</sup> The majority of otherwise healthy children with OSAS have adenotonsillar hypertrophy and adenotonsillectomy is an effective treatment with a reported success rate in normalizing PSG abnormalities of 83%<sup>206</sup> and substantial improvements in quality of life scores post surgery in both mild and severe disease.<sup>207</sup> Intranasal corticosteroids have been reported to improve symptoms of OSAS in children and are likely to be of benefit when the syndrome is exacerbated by seasonal rhinitis.<sup>208</sup> Other surgical procedures include mandibular distraction, which has a place in the management of even very young children with craniofacial abnormalities in association with OSAS.<sup>209,210</sup> For children who have persistent OSAS after adenotonsillectomy and other patient groups in which OSAS is not accompanied by adenotonsillar hypertrophy, such as morbidly obese children, continuous or bilevel positive airway pressure has been shown to be highly efficacious in reducing the number of apneas or hypopneas but adherence may be suboptimal even in children.<sup>211,212</sup> The management of sleep disordered breathing in children with neuromuscular disease and nocturnal hypoventilation includes long term positive pressure ventilation, which is considered below.

## LONG TERM VENTILATION OF CHILDREN

Home mechanical ventilation (HMV) is a treatment option that is becoming increasingly available and one that is being chosen by families with increasing frequency as an alternative to prolonged hospitalization and institutional care. The goals of HMV in children include extending duration of life and enhancing its quality. Additionally, the use of HMV should reduce morbidity, improve the child's physiological function, help to achieve normal growth and development whenever possible, and also reduce overall health care costs.<sup>213</sup> The ethical and moral issues surrounding long term mechanical ventilation are complex. A useful starting point is to have a methodological framework to help analyze specific situations in order to arrive at a morally justifiable endpoint. Such a framework, based upon principles of respect for autonomy (the obligation to respect the decision making capacities of autonomous persons), nonmaleficence (the obligation to avoid causing harm), beneficence (obligations to provide benefits and to balance benefits against risks) and justice (obligations of fairness in the distribution of benefits and risks), has been reviewed.<sup>214</sup> In this context, for many clinicians, the most challenging patients are those with severe neuromuscular weakness such as spinal muscular atrophy and Duchenne muscular dystrophy. In the end, the decision to ventilate or provide positive pressure support for a child at home will depend upon locally available resources, access to appropriate technology and the attitudes of physicians, caregivers, patients and other health staff.

Children requiring home ventilation or positive pressure support are managed best by a multidisciplinary team and an appropriate care plan must be developed with the patient and caregivers before discharge from hospital. The plan should consider availability of working utilities, i.e. power and telephone services, and ease of access to emergency and respite care and technological support.

The prevalence of HMV in Europe in 2001 has been estimated at 6.6 users per 100 000 population,<sup>215</sup> although there are no recent prevalence data for children. However, a number of reports from centers that care

for children ventilated at home indicate the type of patients who are now being managed in this way.<sup>216-221</sup> There are four main diagnostic groups:

- disorders of the respiratory pump (including neuromuscular diseases, diseases of the chest wall and spinal cord injury);
- obstructive diseases of the airways (including those associated with craniofacial anomalies);
- parenchymal lung diseases (particularly cystic fibrosis and bronchopulmonary dysplasia);
- disorders of the control of respiration (notably CCHS).

Neuromuscular diseases are the largest single group, accounting for between 28% and 51% of cases.

Generally, children are commenced on home ventilation by one of two pathways. First, mechanical ventilation may be started as a result of an acute illness and the child is unable to be successfully weaned from ventilation. Alternatively a decision may be made, in a child with chronic respiratory failure, to electively commence ventilation. Patients ventilated via tracheostomy are usually stabilized in the intensive care unit either during an acute episode of respiratory failure or following an elective tracheostomy. In either case, the ventilatory requirements can be relatively easily assessed because of the stable patient interface and the use of versatile ventilators with a range of modes that further facilitate stabilization. However, for patients requiring non-invasive ventilation (NIV) by nasal or oro-nasal mask the situation is more complex. For example, the patient interface is less stable and prone to leaks and the flow generators commonly used for inspiratory and expiratory support ventilation are relatively unsophisticated. A wide variety of machines that support ventilation are available. The type of machine and settings should be tailored to the patient's characteristics, goals of ventilation and the experience of the center managing the child. Flow generators used for non-invasive positive pressure (NIPP) support might not be suitable for home ventilation in some children because of the low maximum back-up ventilation rates, rudimentary trigger algorithms, high flows and inability to accurately set or determine  $\text{FiO}_2$ .

For patients requiring long-term NIV the establishment of ventilation is best done in hospital with careful attention paid to mask fitting and titration of ventilatory variables. Initially a crude titration can be performed at the bedside but a formal titration PSG should be performed at discharge or, alternatively, soon after discharge for stable patients with straightforward ventilation requirements. Recent evidence supports regular 6–12 monthly titration PSGs for most patients requiring long term NIV, and more frequent assessment in patients with evolving conditions, complex respiratory diseases or difficult interface issues. Prior to titration care should have been taken to fit an appropriate and comfortable mask and then a time is chosen for titration when the child is likely to be asleep. The aims of titration are to establish optimal ventilation and sleep (Fig. 20.20).

Other important considerations before discharge are the need for humidification, airway clearance and alarms that indicate power failure and circuit disconnection. The provision of further home monitoring, such as pulse oximetry and capnography, should be considered on a case-by-case basis. While pulse oximetry, particularly in a child with a supplemental oxygen requirement, may be useful for assessment purposes, it is seldom indicated continuously.

Children ventilated at home via tracheostomy have prolonged survival.<sup>117,222-224</sup> Despite some deaths directly related to the intervention,<sup>225</sup> mortality is generally determined by the underlying disease.<sup>226</sup> Although data for children ventilated non-invasively are few, the same effect on survival is likely since NIV improves respiratory function and delays the onset of daytime respiratory failure.<sup>227,228</sup> Furthermore, after commencing home ventilation, children with neuromuscular diseases have reduced hospitalizations, reduced days spent in intensive care units<sup>229</sup> and improved quality of life.<sup>230</sup> However, global quality of life is difficult to assess, particularly in adolescent patients and families of patients ventilated at home. This is due to complex, dynamically changing interactions between developmental, social and disease factors.<sup>231-234</sup> Improvements in technology, in particular that required for successful

Fig. 20.20 A split night sleep study performed in a 16-year-old boy with Duchenne muscular dystrophy. In the first part of the night he is breathing spontaneously in room air; non-invasive ventilation (NIV) via nasal mask is commenced just before 2 a.m. In the first part of the night there is severe sleep fragmentation, oxygen desaturation and hypercarbia. Once NIV is commenced, oxygenation, ventilation and sleep quality improve. There is an increased percentage of time spent in REM sleep once adequate ventilation is restored – 'REM rebound'.

non-invasive ventilation, will inevitably result in more families and children seeking home ventilation as a management option. The extent to which this is viable will depend upon the availability of resources locally and within individual families.

## ASTHMA

Asthma is the most common chronic disease of childhood, with up to 20% of children being affected. The variability in disease prevalence between countries most likely reflects the major role played by the gene–environment interaction in disease expression. Although asthma can be well controlled by highly effective anti-inflammatory therapy [mainly inhaled corticosteroids (ICSs)] in the large majority of children, optimal asthma control is not achieved in about 50% of all asthmatic children in daily practice. Asthma is still a leading cause of emergency department visits, hospital admission, absence from school, limitations in activity and sleep, and hence imposes a huge burden on the individual, the caregiver and the society.

### Definition

There is no universally accepted clinical definition of asthma.<sup>235</sup> The definition can be physiological, pathophysiological or symptom based and can therefore be purely subjective or include some objective measurement. Several descriptive definitions have been devised and used in a variety of studies. Epidemiological studies tend to focus on recurrent wheeze as the most prominent symptom or on *variation of airway caliber* as the major physiological expression of the disorder. On the other hand, guidelines such as the Global Initiative for Asthma (GINA) define asthma in pathophysiological terms as a *chronic inflammatory disorder* of the airways which causes the airways to be *hyperresponsive* to stimuli which, in turn, causes variable airway obstruction ([www.ginasthma.com](http://www.ginasthma.com)). These differences in definitions and hence in outcome measures may explain the controversy around studies on asthma in general and on asthma epidemiology in particular.

It is agreed that asthma is not a homogeneous disease, but a heterogeneous group of wheezing syndromes.<sup>236</sup> This agreement is mainly based on observations from clinical and epidemiological studies,<sup>237</sup> and is increasingly supported by physiological and pathophysiological data. The group of wheezing or asthma syndromes can be distinguished by risk factors, pathophysiology, treatment response and natural history. Therefore, for educational purposes, it is pertinent to distinguish different phenotypes within the asthma syndromes. It should be emphasized, however, that mixed or overlap syndromes are more common than pure phenotypes,<sup>238</sup> and that patients may change from one phenotype to another over time.

Wheezing syndromes in childhood are usually divided into those observed in children under 6 years of age and those in children aged 6 years and older (Table 20.7). Multi-triggered wheezing syndromes (asthma) have been subdivided into separate descriptive phenotypes according to their most prominent trigger, such as exercise-induced asthma. However, because most children with exercise-induced asthma

(and other such descriptive labels) also have wheeze or airway obstruction brought about by other stimuli, a judgement has to be made as to the major disease feature in such cases.

Table 20.7 contains the descriptive definitions of wheezing syndromes used in this section.

## CAUSATIVE FACTORS

All phenotypes of asthma are multifactorial disorders which are the result of a complex interplay between genetic and environmental factors. These factors are thought to lead to inflammatory and structural changes which cause asthma symptoms. The variability in etiology and pathophysiology explains why overlap syndromes are more common than the pure phenotypes.

### Genetic factors

Asthma runs in families. The risk of asthma in children increases if either parent has asthma or atopy. Most studies suggest that maternal asthma confers greater risk than paternal asthma.<sup>239</sup> However, paternal asthma appears to be the most important risk factor in some populations.<sup>240</sup> In addition, the parental type of obstructive airways disease is an important determinant of disease expression in children. Offspring from parents with a history of preschool wheeze have fewer symptoms than those from parents with asthma.<sup>241</sup> No single gene accounts for the familial segregation of asthma. The model that best explains data from family studies is one of oligogenic loci, i.e. a handful of genes are responsible for the large majority of genetic control, all of which are under strong environmental influences.

Genome screens and linkage studies have identified numerous genes involved in different aspects of asthma syndromes in children, including atopic sensitization, serum IgE levels, airway hyperresponsiveness (AHR), level of lung function, and different cytokines and their receptors. There is strong evidence that genes identified as being important in one population may not be as important in other populations. For example, a disintegrin and metalloproteinase 33 gene (ADAM33) was strongly related to the diagnosis of asthma and to bronchial hyperresponsiveness in a British/US population of families.<sup>242</sup> Studies on the functional properties of this gene brought about the speculation that ADAM33 not only determined the responsiveness of airway smooth muscle cells but also the tissue response to injury, thus linking the gene to inflammation.<sup>243</sup> However, in a more recent and larger American study, no association between asthma and ADAM33 was found.<sup>244</sup>

Although the field of asthma genetics is expanding rapidly, the clinical applicability of this research is limited. So far, only the increased risk of asthma in children of asthmatic parents is used for counseling, mainly to recommend preventive measures to be taken in early life (see p. 694 – Nonpharmacological management).

Recent studies have shown that the response to certain medications is genetically determined and this may have therapeutic implications in the future. For example, the response to bronchodilators is influenced by polymorphisms in the beta-2 adrenergic receptor.<sup>245</sup>

## Environmental factors

### The ‘asthma epidemic’

Environmental factors are of major importance in the development of asthma. This concept was already apparent from the complex inheritance patterns of asthma in families. The investigation of environmental risk factors became more important when it was recognized that the steep increase in the prevalence of asthma in children in the last 20 years of the 20th century could not be explained by genetic factors.<sup>246</sup> As with all studies on asthma in general and genetic studies in particular, this research endeavor was hampered by the lack of uniformly accepted definitions of wheezing syndromes, and hence the likelihood of different phenotypes, each with different interactions with differing environmental factors in different populations. In addition, enormous pressure has been put on the scientific community by government agencies and public opinion to identify and eliminate causative factors to turn around the

Table 20.7 Descriptive definitions of clinical wheezing syndromes

Preschool children (<6 years)
<ul style="list-style-type: none"> <li>● <i>Episodic viral wheeze</i>: episodes of wheezing associated with upper respiratory tract infections (URTIs), interspersed with completely symptom-free intervals</li> <li>● <i>Persistent or multi-trigger wheeze</i>: as above, but with occasional or frequent wheezing between acute episodes associated with URTIs</li> <li>● <i>Allergic asthma</i>: multi-trigger wheeze <i>plus</i> evidence of sensitization to one or more inhalant or food allergens (see p. 691)</li> </ul>
School-aged children and adolescents (6–18 years)
<ul style="list-style-type: none"> <li>● <i>Allergic asthma</i>: multi-trigger wheeze <i>plus</i> evidence of sensitization to one or more inhalant or food allergens (see p. 690)</li> <li>● <i>Non-allergic asthma</i>: multi-trigger wheeze without evidence of sensitization to one or more inhalant or food allergens</li> <li>● <i>Episodic viral wheeze</i>: episodes of (mostly mild) wheezing associated with URTIs, with symptom-free intervals</li> </ul>

'asthma epidemic'. This has likely induced publication bias (with positive associations more likely to be published than negative ones), over-interpretation of study findings (risk factors viewed as causes of asthma instead of epidemiological associations with multiple possible explanations) and exaggerated expectations of asthma prevention programs. Despite these shortcomings, research on asthma risk factors has considerably increased the knowledge on the origins of asthma. It is quite clear, however, that no single most important factor which is responsible for the rise in asthma prevalence has so far been identified. As a result, primary prevention of asthma is not an easy task. The only really evidence-based advice that can be given to parents of children at high risk of asthma (because of parental asthma) is to avoid exposure to cigarette smoke as much as possible. Exclusive breast-feeding also confers a certain degree of protection,<sup>247</sup> but it will never be possible to examine breast-feeding in an RCT in order to achieve level 1 evidence. There also seems to be consistent evidence that hypoallergenic formula for the first 4 months of life (when breast-feeding is not possible or when weaning from breast-feeding) reduces the risk of asthma in children,<sup>248</sup> but methodological problems in these studies limit their applicability in routine practice.<sup>249</sup>

Since the turn of the century, the increase in asthma prevalence has been leveling off or declining in many countries,<sup>250</sup> without any clues as to what environmental changes could explain these trends.

### International comparisons

The International Study of Asthma and Allergies in Children (ISAAC) was designed to study prevalence of asthma and other allergic diseases throughout the world with identical epidemiological methods. Large differences in asthma prevalence rates were found between countries, with the highest prevalence rates in resource rich countries, in particular the UK, Australia and New Zealand.<sup>251</sup> Thus, aspects of Western lifestyle were investigated as possible risk factors. Whilst air pollution was more severe in East Germany before the fall of the iron curtain, prevalence of asthma was much higher in West Germany, suggesting that air pollution was not an important risk factor for the development of asthma.<sup>252</sup> After the two countries were united and the East adopted a more Western lifestyle, the prevalence of asthma and allergic rhinitis rose rapidly to 'Western' levels in the East.<sup>253</sup>

### The hygiene hypothesis

By far the most influential theory on the cause of the 'asthma epidemic' has been the hygiene hypothesis. Coined in the late 1980s after finding that asthma and allergy prevalence were inversely related to family size, it states that a lack of immunological stimuli (infections) in early life deviates the immune system into the allergic state. This hypothesis is supported by numerous observations, including lower asthma prevalence rates in children raised on farms, differences in fecal microflora between atopic and non-atopic children, and lower risk of asthma in children attending kindergarten.<sup>254</sup> The hypothesis has, however, been criticized for a number of reasons:

- The most dramatic improvement in hygiene in the 20th century (clean drinking water) occurred at least half a century before the increase in asthma began.<sup>255</sup>
- There is no association between the rise in asthma prevalence and two major infection reduction measures: childhood immunizations and the use of antibiotics.<sup>255,256</sup>
- It has been shown that the 'asthma epidemic' has at least partly been a self-perpetuating process, with increased awareness of asthma leading to increased willingness to make the diagnosis in wheezy children.<sup>250</sup>

The current version of the hygiene hypothesis is that early-life immunological stimuli (including infections and exposure to gut flora) are important in priming and activating antigen-presenting cells and regulatory T lymphocytes. Proper stimulation of these cells is thought to result in a normal balance of immune responses; disturbances of this process by insufficient or improper immunological stimuli could then cause immune deviation to allergy (and allergic asthma),<sup>257</sup> but also to

episodic viral wheeze<sup>258</sup> and to autoimmune diseases such as diabetes and rheumatoid arthritis. The factors that determine which unfavorable turn the immune system is going to take as a result of insufficient stimulation are as yet unknown.

### Risk factors

With the limitations of observational studies and the variability of study results in mind, Table 20.8 summarizes the most extensively studied risk factors for asthma in children.

The most consistent and best modifiable risk factor for all asthmatic phenotypes in children is exposure to cigarette smoke, both in utero and after birth. It is disturbing to observe that so many parents continue to smoke despite the overwhelming evidence of its deleterious effects on their children's health. Although allergic sensitization is a strong risk factor for childhood asthma and allergen exposure is thought to be a prerequisite for sensitization, studies have found no direct relationship between allergen exposure and the development of asthma.<sup>259</sup> Accordingly, although able to delay symptoms of eczema, allergen avoidance studies have been disappointing in preventing asthma.<sup>260</sup>

### PATHOPHYSIOLOGY

As stated above, the GINA guidelines define asthma in pathophysiological terms as a chronic, eosinophilic inflammatory disorder of the airways which causes the airways to be hyperresponsive to stimuli, which, in turn, causes variable reversible airway obstruction and symptoms of wheeze, dyspnea and cough.

### Airway inflammation

#### Asthma in school-aged children and adolescents

Most of the knowledge of inflammation as the key pathophysiological mechanism in asthma comes from studies in young, otherwise healthy, adults with allergic asthma. The limited evidence on inflammation in general and on eosinophilic inflammation in particular in childhood asthma can be summarized as follows:

- Eosinophilic infiltration is not a consistent finding in mucosal biopsies of children with asthma;<sup>261</sup> neutrophilic infiltration and activation are commonly found.<sup>262</sup>
- The only consistent finding in the few children undergoing biopsy studies has been thickening of the reticular basement membrane (RBM) (Fig. 20.21).<sup>263</sup>
- Studies are hampered by the small sample sizes and highly selected nature of cohorts (patients with troublesome disease or other abnormalities where bronchoscopy is clinically indicated).
- Although there are differences in inflammatory cell profiles in bronchoalveolar lavage fluid between children with allergic asthma, Non-atopic asthma (NAA) and episodic viral wheeze, a great deal of overlap exists between these groups.<sup>264</sup>

Table 20.8 Risk factors for childhood asthma

Risk factor	Preschool wheeze	Asthma in children 6 years of age or older
Parental smoking (both prenatally and after birth)	+++	++
Sensitization to allergens	+	++
Exposure to allergens	-	-
Breastfeeding	+ (protective)	+ (protective)
RSV infection	+	-
Family history	+	++
Obesity	+	+
Prematurity	+	-

+ indicates a positive association; ++ and +++ strong positive associations; - indicates absence of association

Fig. 20.21 Bronchial biopsy specimen of a child with asthma showing reticular basement membrane (RBM) thickening. (From Payne et al<sup>263</sup> with permission)

Thus, asthma in school-aged children and adolescents, as in adults, is characterized by airway inflammation and structural changes, in particular RBM thickening. However, the nature of the inflammation differs from that in adults and appears to be of a mixed eosinophilic–neutrophilic origin.

### **Wheeze in preschool children**

Very few studies have examined airway inflammation in preschool wheezy children. Markers of eosinophil activation correlate with wheeze, irrespective of atopy.<sup>265,266</sup> In preschool children with recurrent wheeze, increased levels of eosinophilic cationic protein (ECP) in plasma indicate a higher risk of persistent wheeze.<sup>267</sup> These indirect observations suggest that eosinophils are involved in the pathophysiology of persistent preschool wheeze. The very few bronchial biopsy studies of early childhood wheeze, however, show different findings, with neutrophil dominated inflammation in toddlers,<sup>268</sup> and lack of inflammation and RBM thickening in infants with recurrent wheeze and documented reversible airway obstruction.<sup>269</sup>

Increasingly, the immune response to viral infection is being considered as an important determinant of recurrent wheeze, AHR and asthma.<sup>270</sup> It has been proposed that early childhood recurrent wheeze is an immunodeficiency disorder, with delayed maturation of Th1 function putting the infant at risk for both sensitization to aeroallergens and severe viral airway infections causing inflammation and lung injury.<sup>271,272</sup> This is supported by observations showing that increased levels of tumor necrosis factor (TNF)-alpha and interleukin (IL)-10 are associated with recurrent wheeze after RSV infection,<sup>273,274</sup> and that severe rhinovirus infections in early life predict recurrent wheezing at the age of 3 years.<sup>275</sup>

### **Airway hyperresponsiveness**

AHR, exaggerated airway response to exogenous stimuli, is considered to be one of the hallmarks of asthma. It is thought that this is caused by chronic airway inflammation (see above). The exaggerated response of the airways to stimuli consists of swelling of airway mucosa, mucus hypersecretion and contraction of bronchial smooth muscle, thus causing airway obstruction and symptoms of wheeze, cough and dyspnea.

It has been suggested that the combination of wheeze and AHR best identifies asthma in population studies;<sup>276</sup> however, AHR can be detected in completely asymptomatic individuals, and no test of AHR will perfectly discriminate children with and without asthma.

AHR can be measured directly (with agents that interact with airway smooth muscle, such as histamine or methacholine) or indirectly (with agents that induce airway inflammation, such as hypertonic saline or adenosine). Perhaps the most convenient way to assess AHR in children is the exercise test. Exercise tests can be performed either by free running for 6 min,<sup>277</sup> or by running on a treadmill at submaximal heart rate for 5 min.<sup>278</sup> A 15% fall in PEF or a 10% fall in FEV<sub>1</sub> indicates a positive test.

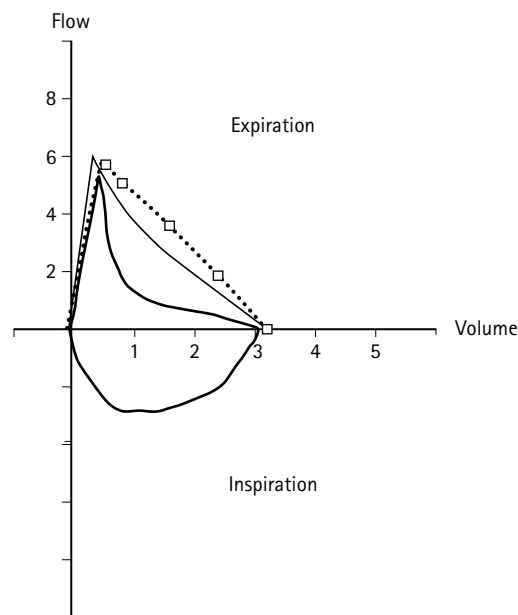

### **Reversible airway obstruction**

The key physiological phenomenon of childhood asthma is airway obstruction, which is reversible, both spontaneously and as a result of treatment. This can be reproducibly measured by spirometry in school-aged children (see p. 692; Fig. 20.22) but is much more difficult to assess in preschool children. The degree of airway obstruction is highly variable: a child with asthma may display perfectly normal lung function at one time and have severe airway obstruction only hours later. Thus, an isolated measurement of airway obstruction is of limited diagnostic value in asthma. On the other hand, normal lung function and absence of response to bronchodilator when a child is symptomatic reasonably excludes asthma. A recent study showed that an improvement of 9% in FEV<sub>1</sub> (as a percentage of the predicted value) after bronchodilator was 50% sensitive and 86% specific for previous wheeze, and increased the odds of subsequent wheeze by a factor of 3.6.<sup>279</sup>

Reduced baseline expiratory flows are assumed to reflect relatively small airway size which is thought to be a key pathophysiological feature of early childhood wheeze.<sup>280</sup> Children with episodic viral wheeze are thought to have smaller airways to nonwheezy children, which are further narrowed when viral infections cause airway mucosal swelling.

### **DIAGNOSTIC APPROACH TO ASTHMA IN CHILDREN**

According to the definition of asthma, the diagnosis can be based on physiological or pathophysiological measures or it can be based on the clinical judgement of the physician (doctor diagnosed asthma). The

**Fig. 20.22** Flow-volume curve of a child with asthma, showing the characteristic concave expiratory pattern with markedly reduced mid-expiratory flow rates (thick line) and the almost complete reversibility to normal values after bronchodilator (thin line). The reference values for peak expiratory flow (PEF), mid-expiratory flows at 25%, 50%, and 75% ( $MEF_{25-75}$ ) of forced vital capacity (FVC), and the FVC itself are represented by squares, and are connected by a dotted line representing a hypothetical 'normal' expiratory flow-volume curve. The  $FEV_1$  can not be read directly from a flow-volume curve because there is no time axis, but the spirometer software will provide it. Note that despite considerable airways obstruction, PEF is normal.

latter is primarily based on asthma history (reported symptoms) and to a lesser extent on physical examination, although according to the GINA guideline ([www.ginasthma.com](http://www.ginasthma.com)) documented wheeze, preferably on chest auscultation, is a requirement for secure diagnosis. Physiological measurements include the assessment of baseline airway function (lung function: spirometry), the reversibility of reduced airflow and the degree of AHR to nonspecific challenges such as histamine, methacholine, cold air or exercise. Pathophysiological measurements include invasive and non-invasive assessments of airway inflammation.

### Asthma history

Children with asthma almost invariably present with recurrent wheeze, dyspnea and cough. A detailed history is the most important diagnostic tool for asthma in children. It helps in differential diagnosis, in classification of the type of asthma (see Table 20.7) and in the assessment of asthma severity. Although taking a good asthma history is time consuming, it is justified because in most cases the diagnosis of asthma can be reliably made or rejected by history alone.

The asthma history focuses on the nature of symptoms, their pattern, triggering factors, influence on daily activities, and response to treatment, environment and family history (Table 20.9).

#### Nature of symptoms

**Wheeze.** Wheeze is the key symptom in asthma. However, patients and parents differ in their description and understanding of wheeze.<sup>281</sup> There is no universally accepted way to circumvent this problem in history taking. Expiratory wheeze should be differentiated from inspiratory noises (see p. 698 – Stridor). Wheeze is caused by turbulent airflow in obstructed intrathoracic airways. Lower airway obstruction can have several causes; hence all that wheezes is not asthma. However, asthma is by far the most common cause of recurrent wheeze in childhood.

**Table 20.9** Items to evaluate in asthma history

Nature of symptoms
Wheeze
Cough
Shortness of breath (dyspnea)
Pattern of symptoms
Episodes (how often, how long)
Only with upper respiratory tract infections (URTIs)?
Symptoms between episodes?
If interval symptoms, evaluate triggering factors
Triggering factors
Specific (allergic): dust, pets, animals, pollen, plants and flowers
Nonspecific: fog, damp weather, cigarette smoke, changes in temperature, 'smells' (perfumes, vapors), stress (emotion)
Exercise
URTIs
Influence on daily activities
Absence from school, parental absence from work
Limitations in sports and play
Nocturnal awakening
Response to treatment
Improvement of symptoms when taking reliever?
Improvement of (pattern of) symptoms when using controller for several weeks?
Environment
Home: pets, cigarette smoke, house dust mite control measures
Local environment: traffic, factories, pollution
Family history
Asthma, allergic rhinitis or eczema in parents and siblings

**Cough.** Although most asthmatic children cough, most children with recurrent cough do not have asthma. The most common cause of recurrent cough is frequently recurring upper respiratory tract infections (URTIs), particularly in toddlers.<sup>282</sup> Parents of children with asthma do not report cough alone as a symptom.<sup>281</sup> Irrespective of its cause, cough tends to be more troublesome at night, consequently, in contrast to popular belief, isolated nocturnal cough is not an indicator for asthma. Children with isolated cough do not benefit from ICSs or from bronchodilators.<sup>283,284</sup>

Chronic wet (productive) cough is unusual in asthma, and should prompt further evaluation for other causes, including bronchiectasis, ciliary dyskinesia and cystic fibrosis.<sup>285</sup> Other history warning signs ('red flags') that should prompt further investigations for other causes are listed below (adapted from British guideline on the management of asthma<sup>235</sup>):

- diagnosis unclear or in doubt;
- symptoms present from birth;
- excessive vomiting or possetting;
- severe URTI;
- persistent wet cough;
- family history of unusual chest disease;
- failure to thrive;
- unexpected clinical findings such as stridor, dysphagia, unusual voice or cry.

**Shortness of breath (dyspnea).** Most children with asthma complain of dyspnea (shortness of breath) when they are wheezy. It is not uncommon, however, that children with obvious wheeze and considerable airway obstruction do not complain of dyspnea. Such poor perception of dyspnea is thought to be caused by adaptation to chronic airway obstruction. This can only be assessed by reviewing the sensation of dyspnea in the presence of wheeze or airway obstruction. Hence, a provocation test to assess AHR may be required to address this issue (see p. 691).

Exercise is a common trigger of symptoms in asthmatic children. However, most complaints of exercise-induced dyspnea are not caused by asthma,<sup>277</sup> but by physiological limitation, dysfunctional breathing

(hyperventilation), vocal cord dysfunction or poor exercise condition.<sup>278</sup> These can sometimes already be distinguished from asthma by the absence of wheeze or the presence of other symptoms such as stridor.

Because shortness of breath is so unspecific for asthma, this symptom should always be assessed in more detail by asking further questions.

### Pattern of symptoms

Evaluating the pattern of symptoms is not only important in distinguishing different wheezing phenotypes (see Table 20.7) but also as an assessment of the effects of treatment. Children with purely episodic wheeze will likely first present during an episode, and will be perfectly normal once the episode has ceased, irrespective of treatment given. Children with infrequent symptoms will be less easily motivated to take daily controller medication than children with daily complaints. It is important to distinguish purely episodic viral wheeze in a child with a negative family history of asthma and atopy, because this particular phenotype is unlikely to benefit from ICS therapy.<sup>286</sup>

### Triggering factors

These are divided into specific (allergic) and non-specific stimuli. Although occasional high dose exposure to allergens such as pets and house dust mite can cause immediate symptoms, the most common pattern of exposure is a chronic one which is usually not recognized as a trigger factor by patients or parents. For example, a child living in a house with a cat will not easily recognize the cat as a trigger factor because he/she is exposed on a daily basis.

### Influence on daily activities

This important feature of asthma can be best evaluated by using validated quality of life questionnaires.<sup>287</sup> If these are not available, the key questions in taking this part of the history are school absence, limitations in play and exercise, and nocturnal awakening with wheeze, dyspnea and cough.

### Response to treatment

Although rapid resolution of symptoms after taking reliever medication is suggestive of asthma, the physician should consider what would have happened if no medication had been taken. For example, the physiological sense of shortness of breath after exercise is commonly perceived as 'dyspnea'. If a bronchodilator is taken, this sensation will subside, as it would have done with rest alone.

### Environment

Home exposure to dust can be assessed by asking about carpeting, upholstered furniture and house dust mite control measures taken. Exposure to pets (including birds) and animals should be recorded. Smoking habits of parents, other caretakers and home visitors must also be assessed.

### Family history

As stated above, asthma is caused by complex gene–environment interactions. Parental asthma and allergy, particularly maternal asthma, determines the risk of asthma in a child and its phenotypic expression. Therefore, in order to take appropriate prevention measures, it is important to know the family history in parents and siblings.

### Physical examination

Physical examination in children with asthma is usually unremarkable. Uncommon findings such as chest hyperinflation and Harrison sulci (Fig. 20.23) indicate chronic airway narrowing.

If the history is insufficient reliably to make or exclude the diagnosis of asthma, a useful approach is to perform a physical examination when the patient is symptomatic. The absence of wheeze in the presence of symptoms reasonably excludes asthma. Conversely, the presence of wheeze on auscultation, preferably supported by a lung function measure of airway obstruction, strongly supports the diagnosis of asthma.

Fig. 20.23 Harrison's sulci in a child with chronic airway narrowing due to severe untreated asthma.

### Investigations

Investigations are usually not needed to make the diagnosis of asthma. Chest films and routine laboratory studies are unhelpful in the diagnostic work-up of asthma. They may be helpful, however, in the differential diagnosis of asthma, either in initial work-up, or when patients respond poorly to treatment (see p. 693). The most common differential diagnoses of asthma are:<sup>288</sup>

- tracheo- or broncho-malacia (particularly in preschool wheeze);
- vocal cord dysfunction or dysfunctional breathing ('hyperventilation');
- recurrent lower respiratory infections (immunodeficiency, cystic fibrosis);
- vascular ring.

### Lung function measurements

Lung function measurements can be useful to demonstrate airway obstruction, response to bronchodilator and AHR (see p. 691), but an isolated measure is of limited usefulness due to the variability of the disease.<sup>289</sup> Although an improvement in FEV<sub>1</sub> of 12% or more after bronchodilator is considered to be highly sensitive for asthma, the scientific basis for this assumption is weak. Most children with persistent symptoms referred for evaluation will nowadays already be using ICSs, and are likely to show normal lung function and absence of bronchodilator response.<sup>290</sup> Although most of these patients have reduced mid-expiratory flow rates, and although increased residual volume levels and air trapping have been demonstrated in children with stable asthma, the usefulness of these measurements in the diagnosis of asthma has never been properly tested.

### Measurement of airway inflammation

Measurement of exhaled nitric oxide (eNO) is a non-invasive way to quantify airway inflammation. The test is easy to perform in children from the age of 4–5 years, is reproducible, and provides a reasonable separation of children with asthma from those without in population studies.<sup>291</sup> During treatment with ICS, however, eNO values tend to return to normal levels (< 10 ppb) rapidly, reducing the usefulness of the test in children using this treatment.

### Tests for allergic sensitization

Although most preschool children with episodic viral wheeze and a considerable proportion of school-aged children with asthma are non-atopic, an assessment of sensitization to aeroallergens is useful, both for diagnostic and therapeutic purposes. Although many clinicians tend to avoid sensitization tests in preschool children because of the low pretest

probability of atopy, this is probably not correct. UK studies have shown general population sensitization rates of 5% in 2 year olds and 20% at 4 years of age.<sup>292</sup>

Total serum IgE levels are of no use in the diagnosis of asthma. Specific IgE tests and skin prick tests are of comparable diagnostic usefulness in determining sensitization. The usual approach is to perform a screening test for the most common aeroallergens in the area. Because food allergy is an unusual trigger factor in asthma, testing for food allergy is not routinely recommended in the diagnostic work-up of asthma.

Based on the results of skin prick or specific IgE tests, asthmatic children are divided into allergic asthma (one or more test positive) or non-allergic asthma. Recent studies show that, in general populations, not only the presence but also the degree of sensitization determines the risk and severity of asthma in children.<sup>293</sup>

## TREATMENT

Comprehensive guidelines for the management of childhood asthma are available in the UK and are updated regularly.<sup>235</sup> Although these guidelines are derived by principles of evidence-based medicine, much less high-quality evidence in many areas is available in children than in adults. Despite this shortcoming, the asthma management guidelines provide an excellent overview of the current treatment options in childhood asthma. The principles of asthma management are given in Table 20.10.

### Nonpharmacological management

Once the diagnosis of asthma has been established, a number of nonpharmacological interventions should be considered. The most important of these is education. In addition, environmental control is important, in particular avoidance of active and passive tobacco smoke exposure. Although increasing evidence suggests that air pollution (in particular from motorvehicle exhaust fumes) may aggravate asthma, no studies aimed at reducing such exposure have been carried out to date.

#### Education of patients and parents

As with any chronic disease, careful and extensive patient and parent education is of key importance in determining the success of asthma management. There is strong and consistent evidence that education is effective in reducing asthma morbidity in children.<sup>294</sup> Education should be aimed at both patients and parents, and should comprise a discussion of disease mechanisms, causative and triggering factors, and explanation of the difference between controller and reliever medication. The treatment plan should be reviewed and a personalized written action plan be provided.<sup>235</sup> The exact content of this written action plan (what to do in what circumstances) seems to be less important than the fact

that the patient has such a plan, and much of the advice given in such written action plans is not evidence based, e.g. the largely ineffective advice to double the dose of ICS during a symptomatic episode.<sup>295</sup>

Correct inhalation technique is critically important in assuring that prescribed medication actually reaches the lower airways.

#### Smoking cessation

The association between passive smoking and respiratory health in children has been extensively reviewed. There is a direct and strong causal relationship between parental smoking and wheeze, asthma, lower lung function, exacerbations of asthma and school absence due to asthma.<sup>296</sup> Parents who smoke should not only be advised to stop smoking because of the dangers to themselves and their children, but also be offered appropriate support to stop smoking. In addition, children should be strongly encouraged and supported not to commence smoking, because this doubles the risk of developing asthma.

If smoking cessation is not feasible, the best advice to parents is to only smoke outdoors.<sup>297</sup>

#### Allergen avoidance

In patients with allergic asthma, reducing exposure to relevant allergens may improve considerably symptoms, lung function and AHR. This has been shown convincingly by transferring patients to low allergen exposure areas, such as hospital rooms or high altitude, for prolonged periods of time. There is no doubt, therefore, that aeroallergen avoidance is useful; the problem is that it is difficult to achieve in practice.

The most common aeroallergen in asthmatic children in Western Europe is the house dust mite. An extensive package of measures is needed to reduce exposure to levels below which symptoms no longer occur, including a mite impermeable mattress, pillow and duvet cover, removing carpets and upholstered furniture, and assuring proper cleaning and ventilation methods.<sup>298</sup> A large US study showed that such an approach in urban children improved asthma outcomes considerably.<sup>299</sup> It has also been shown, however, that applying house dust mite impermeable bed covers alone is not useful.<sup>300</sup> The clinically relevant consideration, therefore, is not whether or not reduction of allergen exposure is effective, but whether or not achieving effective allergen exposure reduction is feasible.

In children allergic to pets, removal of the pet is the only effective way to reduce allergen exposure. Washing the animal or application of high-efficacy vacuum cleaners or air cleaners are not effective.<sup>301</sup>

#### Immunotherapy

Immunotherapy is effective in reducing allergic sensitization and the symptoms associated with it.<sup>302</sup> Although there is strong evidence that immunotherapy is effective in improving symptoms and lung function in asthma,<sup>303</sup> this treatment option is not very popular in Western Europe because of the high efficacy of pharmacological management (see p. 694) in asthma, and the burden of repeated subcutaneous injections in children that may have to be sustained for many years. At present there is insufficient evidence to support sublingual immunotherapy for childhood asthma.

#### Influenza vaccination

A large RCT showed no benefit of influenza vaccination on symptoms and exacerbations of asthma in children.<sup>304</sup> Although influenza vaccination is highly effective in preventing influenza-associated morbidity in children, asthma should no longer be considered an indication for influenza vaccination.

### Pharmacological management

Based on the pathophysiology of asthma with chronic airway inflammation and intermittent bronchial smooth muscle constriction as key features, the pharmacological treatment is based on anti-inflammatory (controller medication) and bronchodilator (reliever medication) therapy. This treatment is preferably administered directly to the airways by inhalation.

Table 20.10 Principles of asthma management

Education and self-management
<ul style="list-style-type: none"> <li>● Explanation of disease mechanisms, triggering factors and pattern of symptoms</li> <li>● Explanation of difference between preventer and controller medication</li> <li>● Inhalation instruction</li> <li>● Regular check-up and correction of inhalation technique</li> </ul>

Determine asthma severity
Choose an age appropriate inhaler device
<ul style="list-style-type: none"> <li>● Inhalation instruction</li> <li>● Regular check-up and correction of inhalation technique</li> </ul>
Prescribe reliever to each patient
Prescribe controller to each patient with persistent asthma

Most children with persistent asthma can be well controlled by treatment with inhaled controller medication alone. The goal of pharmacological management is total control of symptoms (including nocturnal and exercise-induced symptoms), prevention of exacerbations, allowance of normal daily activities including sports and play, and achievement of best possible lung function with minimal side-effects. This goal should be reached and maintained with the lowest effective dose of controller medication.

**Grading asthma severity**

In all recent evidence-based management guidelines, the pharmacological management of asthma is presented in a stepwise fashion, from the mildest cases of intermittent asthma (step 1) through the most therapy-resistant cases of severe asthma (step 5). The first step in pharmacological management, therefore, is to assess asthma severity (Table 20.11). However, because asthma is a variable disease, asthma severity should be re-evaluated on a regular basis and treatment should be adjusted accordingly.

This grading of asthma severity was originally devised for children and adults who did not receive controller medication. Later, when the use of daily ICS therapy became generally accepted, the definitions used for steps 2–4 were generally as follows:

- Step 2: mild persistent asthma: well controlled on ICS therapy alone.
- Step 3: moderate persistent asthma: not well controlled on ICS therapy alone, requires additional treatment for good control.
- Step 4: severe persistent asthma: not well controlled despite ‘step 3’ therapy.
- Step 5: refractory severe asthma: severe symptoms and limitations despite high-dose intensive therapy.

In the American guidelines, levels of lung function abnormality and peak flow variation are given for each severity level; these are based on expert opinion and there is no independent evidence to support them. Most children with persistent asthma and established on ICSs have normal levels of lung function;<sup>290</sup> hence grading of severity based on lung function measurements is not appropriate for children.

**Choosing an appropriate inhaler device**

The majority of medications used to treat childhood asthma are given by inhalation. Children should be prescribed an inhaler device that is suitable for their age (Table 20.12).<sup>305</sup>

After choosing the appropriate inhaler device, children and their parents should be instructed extensively in the correct inhalation technique. This is difficult and time consuming, but extremely important. If inhalation instruction is performed perfunctorily, half of patients will use their inhaler incorrectly.<sup>306</sup> This can be improved by repeated instructions and by having the child demonstrate his/her ability to use the inhaler correctly.<sup>307</sup>

Table 20.11 Grading asthma severity

Severity	Symptoms/day	Symptoms/night
Mild intermittent (step 1)	< 1 time/week Asymptomatic and normal lung function between attacks	<2 times per month
Mild persistent (step 2)	> 1 time/week but < 1/day Attacks may affect activity	> 2 times per month
Moderate persistent (step 3)	Daily Attacks affect activity	> 1 time per week
Severe persistent (step 4)	Continuous Limited physical activity	Frequent
Refractory (step 5)	As in step 4 despite high-dose therapy	

Table 20.12 Inhaler devices for children of different ages<sup>305</sup>

0–2 years	Metered dose inhaler with valved spacer with facemask Second choice: nebulizer
3–6 years	Metered dose inhaler with valved spacer with mouthpiece Second choice: nebulizer
>7 years	Dry powder inhaler Second choice: metered dose inhaler with valved spacer with mouthpiece; metered dose inhaler with breath actuation

**Choosing appropriate medication**

**Reliever therapy (short acting beta-2 agonists)** (Fig. 20.24). Every child with asthma should be given an inhaled short-acting beta-2 agonist (salbutamol, terbutaline) for relief of acute symptoms of wheeze and dyspnea. These should only be used on demand. As their effects subside after approximately 4 h, they may be given up to six times per day. There is good evidence that adding anticholinergic agents such as ipratropium is not needed for relief of symptoms in outpatients,<sup>308</sup> or in preschool children with recurrent wheeze.<sup>309</sup>

**Controller therapy: inhaled corticosteroids.** In patients who experience symptoms or use their reliever agents two or more times per week, daily use of a controller agent is indicated. Inhaled corticosteroids are the drugs of first choice for the treatment of mild persistent asthma in children 5 years of age or older. There is strong evidence that these agents improve symptoms and quality of life, lung function and AHR, and reduce exacerbations and school absence. In most patients with asthma, ICSs alone at dosages of 200 mcg/day (given in two doses) are able to control the disease and normalize lung function, provided that the patient is adherent to medication and inhalation technique is correct.<sup>290,310</sup> Starting with a high dose is not superior to starting with a regular dose.<sup>311</sup>

Different ICSs are available, the oldest ones being beclometasone dipropionate (BDP) and budesonide. Fluticasone and ciclesonide are approximately twice as potent as BDP, hence lower doses of the latter two ICSs should be used.

Side-effects of ICSs are very rare at regular doses, but may occur at doses exceeding 800 mcg/day of BDP equivalent.<sup>312,313</sup> Adrenal suppression is the most threatening side-effect to have been described repeatedly in high-dose treatment, in particular with fluticasone. Although growth of asthmatic children is slightly reduced during the first year of ICS therapy, final adult height is normal, even after treatment with ICSs for many years.<sup>314</sup>

ICSs are more effective than the leukotriene receptor antagonist montelukast in controlling asthma in school children.<sup>315</sup> In preschool children with recurrent wheeze, however, the situation is slightly more complex. Although ICSs are effective in preschool children with multi-trigger wheeze and in allergic asthma,<sup>286,316,317</sup> they are not effective in preschool children with episodic viral wheeze.<sup>286,318,319</sup> As montelukast reduces exacerbation rates and improves lung function and eNO levels in preschool children with episodic viral wheeze,<sup>320,321</sup> this agent may be particularly useful in this clinical setting.

**Step 3 therapy: when ICSs alone are not enough.** In contrast to the situation in adults, limited evidence is available to guide ‘step 3’ therapy in children with asthma who remain symptomatic despite low dose ICS treatment. Although guidelines recommend addition of long-acting beta-2 agonists (LABAs; salmeterol or formoterol) as the treatment option of choice,<sup>235</sup> this has not been substantiated in children.<sup>322</sup> A systematic review and a RCT have shown that addition of LABA to ICS in children has no effect on exacerbation rates.<sup>323,324</sup> Clinical experience suggests that children may, however, respond favorably to the combination of ICS and LABA. A recent study using a combination of budesonide and formoterol, both as maintenance and reliever

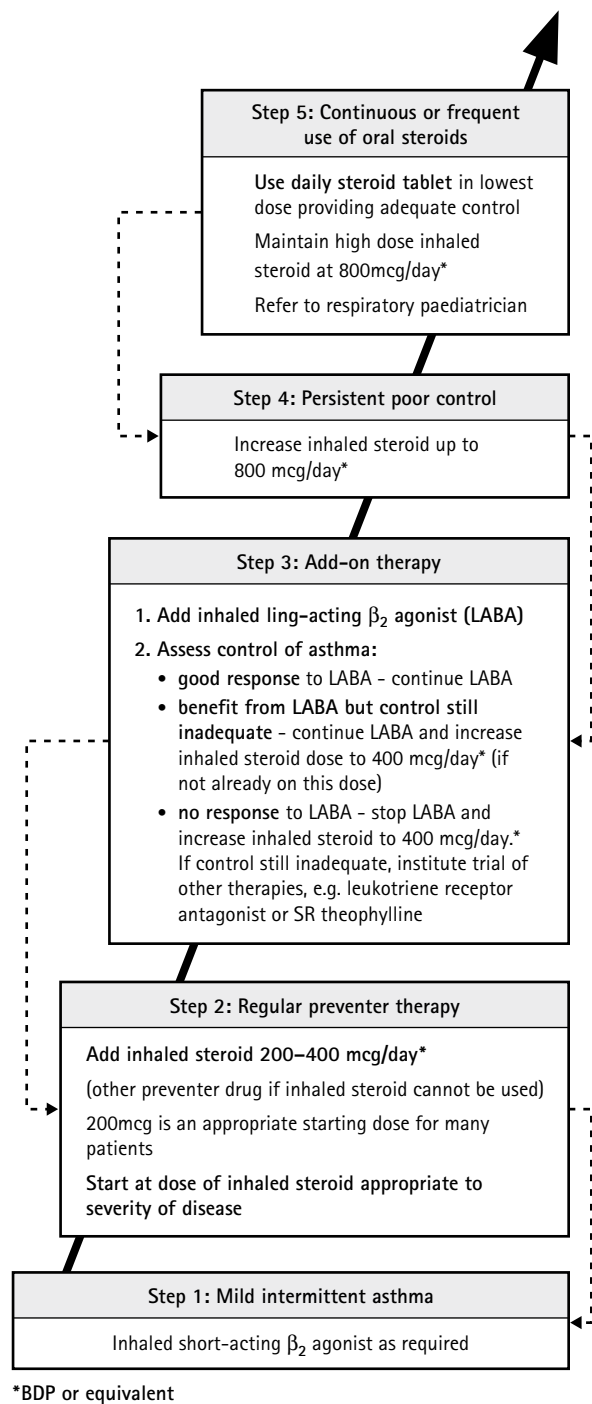

Fig. 20.24 Stepwise management of asthma in school-aged children and adolescents.<sup>295</sup> BDP = beclometasone dipropionate. Doses are given for BDP; same doses apply for budesonide. Use half dosages for fluticasone, ultrafine BDP solution or ciclesonide.

therapy, did show reduction of asthma exacerbations in children.<sup>325</sup> A recent meta-analysis of LABAs in children and adults concluded that LABAs increase severe and life threatening exacerbations, and in adults increase the risk of death.<sup>326</sup> However, these conclusions have been challenged and do not appear to be congruent with falling asthma admission rates and stabilization of asthma deaths in countries with high use of ICSs and LABAs in combination. A LABA should never be used without a concomitant ICS.

Given the observation that the majority of children with asthma can be well controlled on ICSs alone, it is useful to consider possible

explanations for poor treatment response to ICSs before stepping up to add-on 'step 3' therapy:

- ongoing exposure to triggering factors:
  - cigarette smoke;
  - allergens;
  - allergic rhinitis.
- poor adherence to therapy;
- poor inhalation technique;
- other diagnosis than asthma (see p. 693 – Investigations).

If 'step 3' therapy is truly indicated, the British guidelines propose addition of a LABA on a trial basis (see Fig. 20.24). Other treatment options include doubling the dose of ICS or addition of montelukast.<sup>327</sup> Comparative trials between these options in children have not been performed.

There is no good evidence to support decisions regarding the treatment of asthma in cases who remain symptomatic despite 'step 3' therapy; all recommendations in the guidelines are based on Level 3 evidence. Truly severe asthma is a rare but disabling disorder in children, for which referral to tertiary paediatric respiratory care is indicated. Data on the pathophysiology of severe asthma in childhood are slowly emerging.<sup>261</sup> Inflammation is not a consistent feature of severe asthma, neither in bronchial biopsies nor in eNO levels, but thickening of RBM is.<sup>261,328</sup>

Treatment options in severe asthma include combination of high-dose ICS, LABA and montelukast, addition of sustained-release theophylline or subcutaneous terbutaline, and maintenance therapy with systemic anti-inflammatory agents such as prednisolone or ciclosporin. A relatively new and promising treatment option is anti-IgE (omalizumab) which reduces asthma exacerbation rates and improves lung function.<sup>329</sup> Unfortunately, apart from being very expensive, omalizumab requires 2-weekly subcutaneous injections and the effects subside rapidly after discontinuation of therapy.

### Monitoring and follow-up

Although not supported by Level 1 evidence, there is ample circumstantial evidence that close monitoring and follow-up improves asthma outcomes in children. First, it has been shown that poor adherence and poor monitoring is associated with troublesome symptoms, restricted activities and school absence.<sup>330</sup> Perhaps the most convincing data are that once close monitoring and follow-up is instituted, the ICS dose can be reduced by 25% whilst maintaining asthma control.<sup>310</sup> Such follow-up should include re-inforcement of education and inhalation instruction, review of symptoms, exacerbations, school absence and quality of life, and adaptation of maintenance (controller) therapy when needed. Follow-up can be performed safely and (cost)effectively by specialized nurses once the diagnosis and a treatment plan have been established.<sup>310</sup>

Although guidelines recommend close monitoring of lung function in children with asthma, there is no evidence to support this practice.<sup>331</sup> In particular, the recommendation to record peak expiratory flow at home on a regular basis in children with asthma is based on belief and dogma and not on evidence. Written peak flow diaries are very unreliable.<sup>332</sup> In addition, clinical trials show that monitoring peak expiratory flow at home does not improve asthma control, even when the data are recorded electronically.<sup>333</sup> Thus, although it is probably useful to monitor lung function during scheduled follow-up visits to avoid overestimation of asthma control,<sup>334</sup> home monitoring of peak flow can not be recommended.<sup>331</sup>

Monitoring of eNO levels may be useful to predict asthma relapse after discontinuation of ICS, and perhaps in titrating ICS dose.<sup>335</sup>

Although still quite popular, the advice to double the dose of ICS during an (impending) exacerbation of asthma is not proven and should no longer be recommended.<sup>295</sup> Instead, patients should be encouraged to use reliever medication as needed, and to seek medical help when this is insufficient to control symptoms.

### PROGNOSIS

Approximately two thirds of cases of episodic viral wheeze recover completely before the age of 6 years.<sup>280</sup> Because such 'transient wheeze'

can only be recognized in retrospect, and because overlap syndromes between wheezing phenotypes in early childhood are common, the need for maintenance therapy with daily controller agents should be reconsidered from time to time in preschool children. The most common approach to this is to step down and discontinue controller therapy in children in whom asthma control is achieved and maintained for prolonged periods of time. However, as symptoms are frequently worse during the winter, it may not be best practice to withdraw controller therapy after an apparent resolution of symptoms during the summer months.

Although a similar approach to the step down of the maintenance dose of ICS to the lowest effective dose is recommended for school-aged children and adolescents, truly withdrawing such treatment in children aged 5 years or older is not a treatment goal per se. Complete remission of asthma in this age range is possible, although rare. Approximately 50% of children with asthma become symptom-free during their teenage years, but half of these will have a recurrence of asthma symptoms during the third or fourth decade.<sup>336</sup> As it appears that 'growing out of asthma' once established in school-aged children is a relatively rare event, the current perspective is to consider childhood asthma as a life-long chronic disease. It is important to review these data with asthmatic children and their parents when discussing withdrawing ICS therapy, and to strongly discourage them from smoking. As the likelihood of young people taking up smoking is increased if their parents smoke, encouraging parental cessation is a worth while target for prevention.

## ACUTE SEVERE ASTHMA

Although rare in children, fatalities from asthma do occur, and every effort should be made to avoid these. The most important factors associated with fatal asthma are poor asthma education, insufficient or absent use of controller medication, food allergy and the lack of monitoring and follow-up. The most important 'red flags' indicating increased risk of dying from asthma are heavy use of reliever medication, repeated A&E attendance for asthma or a history of a severe attack requiring intensive care or mechanical ventilation.

## Causes and pathophysiology

Although acute exacerbations of asthma can be provoked by multiple triggers (see Table 20.9), viral URTI remains the single most common trigger.<sup>337</sup> More than half of cases of acute severe asthma presenting to hospital are preschool children.

During an asthma attack, smooth muscle constriction causing bronchial narrowing, inflammation leading to airway mucosal edema, and excess mucus secretion contribute to airway obstruction. There is reduced ventilation in some areas and absent ventilation in others, because of airway closure. This results in ventilation/perfusion mismatching and hypoxemia, which in turn stimulates ventilation. Carbon dioxide is extremely diffusible and is rapidly washed out of normally ventilated alveoli. As alveolar minute ventilation rises as a result of hypoxemic drive, PaCO<sub>2</sub> will fall. However, with continued increased work of breathing, exhaustion sets in and minute ventilation falls, leading to a rise in PaCO<sub>2</sub>. The treatment of acute asthma is directed at stopping this happening.

## Assessment

At presentation with an exacerbation, a brief history should include details of usual medication, extra medication and outcomes of previous episodes. Physical examination is often of limited value as it is difficult to categorize severity of wheeze according to physical signs. There is poor correlation between the severity of airway obstruction and physical signs. Nasal flaring, use of accessory muscles and sternal recession all reflect an increased work of breathing. A silent chest, reflecting exhaustion, altered level of consciousness and cyanosis are late signs. Pulsus paradoxus is difficult to measure in children and is not very informative.

Measuring oxygen saturation is useful as an SaO<sub>2</sub> < 92% in air confers increased risk of severe exacerbations requiring hospital admission.<sup>338</sup>

**Table 20.13** Treatment for acute severe asthma in the emergency department

Oxygen: high-flow, humidified, by nasal canula or nonbreathing mask
Bronchodilators: either high-dose $\beta_2$ agonist by metered dose inhaler/spacer
<ul style="list-style-type: none"> <li>• Salbutamol 100 <math>\mu</math>g per puff: 1–5 years 6 puffs <math>\times</math> 3; &gt; 5 years 12 puffs <math>\times</math> 3</li> <li>• Or combination of <math>\beta_2</math> agonist and ipratropium by nebulization</li> </ul>
Prednisolone: initial dose of 1 mg/kg (max 30 mg)

If possible, an FEV<sub>1</sub> or peak expiratory flow should be assessed. Other investigations are not useful in assessing the severity of the attack or predicting outcome.

## Treatment in hospital

Initial treatment in hospital should include supplemental oxygen, inhaled bronchodilators and systemic corticosteroids (Table 20.13).

Supplemental oxygen reduces hypoxemia and improves outcome.<sup>339</sup> Bronchodilators should be given frequently until dyspnea improves. In preschool children, beta-2 agonists by metered dose inhaler/spacer are more effective than by nebulization.<sup>340</sup> It has also been shown, however, that adding anticholinergics to beta-2 agonists improves symptoms and lung function in acute severe asthma.<sup>308</sup> Nebulization can then be a practical way to give oxygen, anticholinergics and beta-2 agonists in a single intervention. Observation for a few hours is recommended to recognize rapid deterioration after initial improvement.

Systemic corticosteroids improve outcome of asthma exacerbations in children.<sup>341,342</sup> Oral prednisolone is the drug of choice; an oral solution or syrup is better tolerated than crushed tablets.<sup>343</sup> There is no evidence to support the use of systemic steroids in acute severe wheeze in children younger than 6 months of age,<sup>344</sup> or to support the home use of prednisolone in episodic viral wheeze in young children.<sup>345</sup>

Most cases of acute severe asthma can be discharged home after this initial treatment, but children who do not improve considerably should be admitted to hospital and followed up closely. This can be done clinically; only if work of breathing and oxygen saturation deteriorate is arterial blood gas analysis indicated.

Refractory cases of acute severe asthma can be treated with intravenous salbutamol,<sup>346</sup> magnesium sulfate,<sup>347</sup> or aminophylline.<sup>348</sup> There is no good evidence to guide the choice between these different treatment strategies.

## CONGENITAL ABNORMALITIES

Congenital lung malformations have assumed increased importance as a result of routine detailed antenatal ultrasound scanning. Pediatricians may be involved in counseling pregnant women about the prognosis for the fetus, as well as in the postnatal management of an apparently normal baby with a small malformation which in past years would have escaped discovery. It is a field in which there is little evidence base, and in which the nomenclature is confusing and used differently ante- and post-natally. There is also increasing interest in the longer term consequences of all congenital lung malformations as greater numbers survive into adult life; follow-up studies have been reviewed.<sup>349</sup>

## GENERAL PRINCIPLES

It is better to describe the abnormality as seen, in simple English, without speculating as to the embryology, since such speculation will almost inevitably be proved wrong in the future.<sup>350</sup> Table 20.14 illustrates this approach. A detailed justification of this nomenclature can be found elsewhere.<sup>350</sup> Two new terms deserve further elaboration. Congenital large hyperlucent lobe (CLHL) is a factual description of an appearance on a CXR or CT scan, whereas congenital lobar emphysema is a frightening and wrong allusion to a condition of elderly smokers, when the

**Table 20.14** Comparison of new nomenclature with old terms, based on the principles of describing what is seen, in clear language, without embryological speculation

New nomenclature	Old terms superseded
Congenital large hyperlucent lobe (CLHL)	Congenital lobar emphysema Polyalveolar lobe
Congenital thoracic malformation (CTM) – described as solid or cystic; if cystic; the cysts are described as single or multiple, thin or thick walled, and the contents described (either from CXR and other imaging, or from pathological examination of excised specimens)	Cystic adenomatoid malformation Congenital pulmonary airway malformation Malinosculation Sequestration (intra- and extra-pulmonary) Bronchogenic cyst Reduplication cyst Foregut cyst
Congenital small lung (CSL)	Pulmonary hypoplasia
Absent lung, absent trachea	Agenesis of lung, tracheal aplasia
Absent bronchus	Bronchial atresia
Narrow bronchus, narrow trachea	Bronchial stenosis, tracheal stenosis
Bilateral right lung, bilateral left lung	Right isomerism, left isomerism

pathology may be too many, not too few alveoli. Congenital thoracic malformation (CTM) is used to describe both sequestration and cystic adenomatoid malformation because they are ends of a spectrum and not discrete entities. Either may have a systemic arterial supply, and pathological features of both may be found in the same lesion.

A further important principle is to describe the lung systematically. For these purposes, the lung is broken into six trees (bronchial, systemic and pulmonary arterial, systemic and pulmonary venous, and lymphatic). Other relevant systems should be described (chest wall, heart and mediastinum, abdomen) and all other systems reviewed, because, as with other congenital abnormalities, there may be coexistent problems elsewhere.

## NASOPHARYNGEAL ABNORMALITIES

Babies are preferential nose breathers, so bilateral choanal stenosis or atresia presents with respiratory distress at birth. Milder forms may present with difficulty feeding. Unilateral disease may present later in childhood, sometimes with a unilateral nasal discharge. Diagnosis is suspected if a nasogastric tube cannot be passed into the pharynx. Management is surgical. Pierre Robin syndrome results in the tongue obstructing breathing secondary to micrognathia. The baby should be nursed prone but if this is unsuccessful a carefully positioned nasopharyngeal tube or tracheostomy may be necessary until the mandible grows sufficiently to accommodate the tongue, usually before the age of 1 year. Babies with congenital syndromes associated with midfacial hypoplasia (e.g. Apert) should also be considered at risk for obstruction to breathing, at least during sleep. Congenital tumors and cysts, such as teratoma, hemangioma, ectopic thyroid and cystic hygroma, are unusual causes of pharyngeal obstruction, all of which require surgical treatment. Crowding of the pharynx occurs in Down syndrome and in disorders associated with a large or abnormally positioned tongue. Sleep-disordered breathing may result from airways obstruction as muscle tone falls during sleep, and polysomnography is indicated for diagnosis. If obstructive sleep apnea is present, adenotonsillectomy may relieve symptoms (for cleft lip and palate, see Ch. 32, p. 1516).

## CONGENITAL STRIDOR

### Laryngomalacia

This accounts for over 75% of stridor in infancy. On endoscopy, the arytenoids, epiglottis and aryepiglottic folds are sucked inwards on inspiration; there may be associated pharyngomalacia and tracheomalacia. Presentation is with isolated stridor in an otherwise well baby in

the first days of life, but usually not at birth, but may be delayed until over 1 month of age. The inspiratory stridor is worse during periods of agitation and upper respiratory tract infection.

If the clinical presentation is characteristic, and the infant is improving, no investigation is needed. If there are any atypical features, including growth failure, bronchoscopy should be performed to exclude other or multiple causes of stridor. This investigation requires skilled anaesthesia and the occasional child may require short term ventilation after the procedure. The stridor usually disappears by the age of 2 years, but sometimes continues into early childhood and rarely beyond 5 years of age.

### Laryngeal stenosis

This is the second commonest cause of congenital stridor and may be caused by supraglottic, glottic or subglottic webs or subglottic stenosis. The most severe form of congenital laryngeal disease is absent larynx. This results in normal appearances from above, but intubation is impossible. The lungs are normal or large. Most laryngeal webs are glottic and present with stridor and a poor cry at or shortly after birth. The severity of the symptoms depends on the size of the web, which may cause complete airways obstruction, a condition incompatible with life unless diagnosed and treated within minutes of delivery. Many of these babies have other severe abnormalities. Treatment is surgical.

Subglottic stenosis is usually the result of soft tissue thickening of the subglottic area, usually acquired following prolonged intubation during the neonatal period. Occasionally laser resection of the granulation tissue or tracheostomy is required but most improve as the larynx grows. Localized tracheo- or broncho-malacia resulting from damage in the neonatal period due to ventilatory assistance may also cause stridor with or without wheeze in the first few years of life. These babies are more likely to require hospital admission if they acquire a respiratory infection as they will almost certainly have associated lower respiratory tract damage.

### Subglottic hemangiomas

These become obvious before 6 months and 50% of babies have hemangiomas elsewhere, usually on the skin. Presentation may be with recurrent croup, improving as the usual prescription for corticosteroids leads to temporary shrinkage of the hemangioma. The diagnosis is confirmed at endoscopy. Most regress during the first 2 years and thus a conservative approach is preferred. If medical treatment is indicated for severe obstruction or complications, prednisolone or interferon may shrink the hemangioma. Severe cases may need laser surgery or even tracheostomy.

### Vocal cord paralysis

This can be unilateral or bilateral. Unilateral is more frequent. Paralysis may be associated with other abnormalities, especially in the cardiovascular and respiratory systems. In most cases the paralysis is temporary with recovery within 4 weeks. Birth trauma with stretching of the neck and the recurrent laryngeal nerve may be a factor. Bilateral paralysis is usually associated with central nervous system disorders, such as hydrocephalus, which may themselves have a poor prognosis. Diagnosis is made at laryngoscopy.

### Laryngeal clefts

Laryngeal clefts are associated with tracheoesophageal fistulae in about 20% and hydramnios in 30%. The infant presents with a toneless cry, choking and cyanosis on feeding, and aspiration pneumonia. Later in childhood a chronic cough or recurrent lower respiratory tract infection may be the only clue. Diagnosis is at laryngoscopy; inexperienced operators may miss a small cleft, particularly if a flexible, rather than a rigid endoscope is used. Surgical repair can be extremely difficult.

### Laryngeal cysts

Laryngeal cysts are very rare and cause stridor and a poor cry in the neonatal period. Endoscopy should be performed cautiously, and no

attempt should be made to approach or go past the cyst if the airway is critically narrowed. Laser de-roofing of the cyst is curative.

### Vascular abnormalities

Vascular abnormalities include abnormalities of the vessels of the aortic arch which cause tracheal compression ('vascular ring'), usually presenting during the first year of life, but not uncommonly later as a prior diagnosis of steroid resistant asthma. Stridor, wheezing and a barking cough are the commonest presenting symptoms. Since the larynx is not involved, the tone of the cry is normal. Excessive secretions, difficulty with feeding and apneic episodes are sometimes associated.

### TRACHEOESOPHAGEAL FISTULA (see also Ch. 37)

The preoperative pulmonary problems associated with tracheoesophageal fistula (TEF) are related either to aspiration of secretions or food through the larynx if, as is usual, the upper end of the esophagus is blind, or to reflux of stomach and duodenal secretions through the distal end of the esophagus into the tracheobronchial tree.

In the rare H-type fistula (4%) aspiration of food may cause recurrent chest infection. The underlying abnormality may even not be diagnosed until adult life. The diagnosis of the H-type TEF is not easy and rests on the demonstration of contrast medium flowing through the fistula. Seventy percent of lesions lie high in the esophagus and since the fistula passes obliquely upwards from the esophagus a tube esophagram (not a barium swallow) should be carried out with the child lying prone. Late presentation may occur with coughing after drinking, hemoptysis, retrosternal pain and recurrent infection.

Prognosis of TEF is related to the gestational maturity of the baby, the presence of pulmonary disease before surgery, the incidence of postoperative pulmonary disease and the presence of associated abnormalities. TEF has a reported association with other congenital abnormalities of 50–70% and 2% of these are associated abnormalities of the respiratory tract.

Long term follow-up of survivors of surgery suggests that airway disease is common. This may be related to disorders of esophageal motility and repeated small aspirations or to the severity of the initial respiratory disease. In addition, at the site of the fistula, tracheal cartilage is inadequately formed or missing and there is an absence of normally ciliated respiratory epithelium. Tracheomalacia accounts for the brassy cough, worse during upper respiratory tract infections. Apneic episodes following feeding are a problem in a small number of babies and the incidence of sudden unexpected death is increased. Whether this is due to aspiration or associated with the tracheomalacia is debated. A mild restrictive pattern of pulmonary physiology is not uncommon in survivors. Some children develop scoliosis, which is a well described complication of thoracotomy,<sup>351</sup> although probably much less frequent with modern surgical techniques.

## LOWER AIRWAY ABNORMALITIES

### Trachea

With total or partial absence of the trachea ('tracheal aplasia'), the main bronchi either communicate only with each other or with the esophagus. The trachea may be smaller than normal in both the sagittal and coronal planes in Down syndrome. Congenital intrinsic tracheal narrowing (stenosis) may take the form of a gradual tapering, an isolated segmental narrowing or a membranous web, or be due to a nodule of ectopic esophageal tissue. Congenital extrinsic compression may be due to a vascular ring or pulmonary artery sling (see p. 701 – Pulmonary arterial abnormalities).

### Bronchial tree

#### *Bronchial arrangement and connections*

Airway morphology is defined by the number of lobes (three for right sided, two for left) and the length of the main bronchus before the first bifurcation (short for right sided, long for left). The commonest abnor-

mal bronchial arrangement is a mirror image, which may be associated with primary ciliary dyskinesia. This must be distinguished from a right-sided congenital small lung (CSL), which may have a systemic arterial supply. In 80% of cases, bilateral right lung is associated with asplenia and hence the risk of overwhelming pneumococcal disease, bilateral left lung (BLL) with polysplenia. Both are associated with abdominal visceral malrotation and complex congenital heart disease.<sup>352,353</sup> A syndrome of BLL, normal atrial arrangement and severe tracheobronchomalacia presenting as steroid resistant wheeze has been described.<sup>354</sup> Other variants are indeterminate morphology; bronchi crossing the mediastinum to supply the contralateral lung (cross-over) and even a tongue of lung crossing the mediastinum (horseshoe lung).<sup>356</sup>

### *Congenital absence of a lobe or lung*

Absent lung ('aplasia') is not uncommon but absence of a lobe or of both lungs is rare. There may be a rudimentary bronchial stump. In bilateral absent lungs the trachea ends blindly and the pulmonary artery arises from the aorta. Unilateral absent lung is often associated with other ipsilateral malformations.

### *Congenital small lungs*

Small ('hypoplastic') lungs may be normal or abnormal in form. Alveoli are reduced in number or size. Normal right and left lung weights at term are 21 and 18 g, respectively; the lungs are small if the lung-to-body weight ratio is <0.012.<sup>357</sup> The reduction in alveoli may be associated with fewer airway generations. Small lungs may be isolated with no underlying cause, but are more usually associated with a variety of other malformations. These include diaphragmatic defects, renal anomalies, extralobar pulmonary parenchymal malformations, and severe neuromuscular and musculoskeletal disorders. Most of these associations have a causal relationship but some, such as that with Down syndrome, are puzzling. Lung growth before birth is dependent upon blood supply, availability of space, respiratory movements taking place in utero and fluid filling the airways. The causes of bilateral small lungs (BSL) are summarized in Table 20.15.

### *Disorders of the bronchial walls*

Airway caliber abnormalities may result in all or part of the bronchial tree being too large or too small. Congenital tracheobronchomegaly (Mounier–Kuhn syndrome) is associated with tracheomalacia and bronchiectasis. There are sacular bulges between the cartilages. An autosomal recessive connective tissue defect has been postulated.<sup>358</sup> This is supported by the occasional association of Mounier–Kuhn syndrome with Ehlers–Danlos syndrome, cutis laxa or Kenny–Caffey syndrome.

Localized narrowing and in particular obstruction due to an absent bronchus often results in cystic degeneration of the lobe distal to the obstruction before birth, as fetal lung liquid continues to be secreted and

Table 20.15 Causes of bilateral congenital small lungs. Occasionally no underlying cause is found

Underlying problem	Example
Abnormal thoracic contents	Diaphragmatic hernia, pleural effusion, large congenital thoracic malformation
Thoracic compression from below	Abdominal tumors, ascites
Thoracic compression from the sides	Amniotic bands, oligohydramnios, asphyxiating thoracic dystrophy, scoliosis
Abnormal vascular supply	Pulmonary valve or artery stenosis, tetralogy of Fallot
Neuromuscular disease	CNS, anterior horn cell, peripheral nerve muscle disease reducing fetal breathing movements

cannot drain into the amniotic cavity. Absent bronchus may be detected radiographically in an asymptomatic individual and presentation may be late. The radiological appearances are virtually diagnostic, consisting of an ovoid hilar opacity, most commonly in the left upper lobe, with branches radiating out into a distal area of hyperlucency. The opacity represents a distended, mucus-filled bronchus that is continuous with the distal airways but has no connection with the more proximal, blind ending airway. The interruption to the airway may take the form of a membrane, a fibrous cord or a gap. The focal opacity seen in absent bronchus is not present in a congenital large hyperlucent lobe (CLHL). The continuity of the cyst with the distal airways and the hyperinflation of the distal lung distinguish absent bronchus from 'bronchogenic cyst'.<sup>359</sup> True congenital bronchiectasis is much rarer than previously thought, but may be found within a CTM.

Congenital bronchomalacia may be isolated, generally with a good prognosis, at least in the short term, and has been described in association with other congenital abnormalities, including connective tissue disorders, and Larsen and Fryn syndrome. Williams and Campbell described a syndrome of generalized bronchomalacia affecting the second to the seventh generations of the bronchial tree. The occurrence in two siblings and the very early onset of symptoms suggests a congenital etiology. Finally, bronchomalacia may be secondary to other congenital abnormalities, such as vascular ring. Fixed bronchial narrowing may be due to defects in the wall (e.g. complete cartilage rings) or extrinsic compression by an abnormal vessel or cyst.

### **Abnormal bronchial connections**

The separation of those parts of the primitive foregut to become esophagus and trachea may be incomplete resulting in TEF (see p. 700). Communication between the trachea and a CTM is also recorded.

### **Alveolar disorders**

Counting alveolar numbers requires an open lung biopsy, and is usually of theoretical importance only. CLHL is an example of a disorder of alveoli. CLHL may be diagnosed antenatally, or presents with tachypnea and respiratory distress in the newborn period, or is a chance finding on a CXR later in life. In some cases it is due to partial obstruction of the lobar bronchus leading to air trapping. The obstruction may be caused by external compression, e.g. by a cyst or abnormal blood vessel; alternatively, intrinsic abnormalities such as mucosal flaps, mucus plugs or twisting of the lobe on its pedicle may be responsible.<sup>360</sup> A deficiency of bronchial cartilage is a diagnosis of exclusion; in practice the cause is frequently not identified. Some patients also have congenital cardiac anomalies. CLHL affects the left upper lobe in about half the cases, the right middle and right upper lobes in most of the remainder and the lower lobes in <10%. Curiously, it almost never becomes infected; if CLHL is the seat of recurrent infection, suspect that the appearances are secondary to bronchial stenosis. Diagnosis should be confirmed on a CT scan, which distinguishes CLHL from a thin walled cystic CTM. If the infant is symptomatic and fails to thrive, then surgical removal is advised. If the child is well, no treatment is needed; even a quite dramatic looking CLHL becomes less prominent over time. Another cause of CLHL is a polyalveolar lobe, which is a pathological, not a clinical, diagnosis. A polyalveolar lobe has a normal number of conductive airways but an increased number of normal sized alveoli in each acinus.

### **Solid and cystic thoracic lesions: clinical approach**

When assessing patients with a suspected congenital lung malformation, it is more logical to describe abnormalities by their appearance, whether on images (CXR, CT or MRI) or pathologically. The use of terms like 'reduplication cyst' and 'bronchogenic cyst' in clinical practice, *prior to the resection of the abnormality*, imply embryology and/or pathology, and should be discarded. A better term to use in clinical practice, which makes no assumptions, is CTM, some forms of which were previously described as a congenital cystic adenomatoid malformation (CCAM) or congenital pulmonary airway malformation (CPAM). CTM encompasses a spectrum of conditions, clinically described as cystic, intermediate or

solid. It will be seen that the clinical definition of CTM includes what the pathologist may previously have described as a CCAM, or a bronchogenic or reduplication cyst, or other more specific term.

### **Solid and cystic lesions: pathological approach**

The same constraints of clarity outlined above should apply to the pathologist. CTM should be used in pathological descriptions, attaching the term cystic, intermediate or solid as above, and describing the tissue in terms of what is seen on microscopy.

Bronchogenic and other foregut cysts are one type of CTM recognizable by cartilage and glands in their wall and a lining of respiratory epithelium. They are usually situated in the mediastinum close to the carina (51%) but may be found in the right paratracheal region (19%), alongside the esophagus (14%), the hilum of the lung (9%) or a variety of other locations (7%) including the substance of the lungs, and even beneath the diaphragm.<sup>361</sup> Cysts may be lined by respiratory-type epithelium but lack cartilage in their walls. Cysts may also have a gastric, intestinal or squamous epithelial lining and a muscle coat. These types of cyst are usually situated in the posterior mediastinum or, as they may be associated with vertebral malformations, even within the spine. They may also be associated with abdominal cysts.

Pathologically, five patterns of 'CPAM' have been recognized, which *clinically* may also be mimicked by other conditions such as pulmonary hamartoma or ectopic tissue (below), which are readily distinguished pathologically. The blood supply may be from either or both of the pulmonary artery and the aorta. Some workers incorporate 'sequestration' into the 'CPAM' spectrum. The fact that 'extralobar sequestrations' may contain tissue identical to CCAM underscores the logic of combining not separating these two conditions and dropping the terms 'sequestration', 'CPAM' and 'CCAM' in favor of the single, catch-all term CTM.<sup>362-364</sup> The five pathological types formerly described as CPAM are overlapping entities. Type 0 ('acinar dysplasia') is incompatible with life. Microscopically, bronchial-type airways that have cartilage, smooth muscle and glands are separated by abundant mesenchymal tissue. Type 1 ('cystic CCAM') is the commonest. The boundary between the lesion and the adjacent normal lobe is sharply delineated but there is no capsule. Radiographically, air-filled cysts that are usually limited to one lobe compress the rest of the lung, depress the diaphragm and cause mediastinal shift. The cysts range in size from 1 to 10 cm. They are lined by pseudostratified ciliated columnar epithelium interspersed with rows of mucus cells of pyloric type. The relevant bronchus is often absent, yet the cysts are usually radiolucent, presumably due to collateral ventilation. Type 2 (intermediate type 'CCAM') is sponge-like, consisting of multiple small cysts as well as solid pale tumor-like tissue. Microscopically the cysts are seen to be dilated bronchioles separated by normal alveoli. Occasional examples contain striated muscle. This type of lesion also may be identified within 'extralobar sequestrations'. Type 3 (solid type 'CCAM') is a large, bulky lesion that typically involves and expands a whole lobe, the others being compressed and the mediastinum displaced. Microscopically, an excess of bronchiolar-like structures are separated by small airspaces which have a cuboidal lining, with no cystic change. Type 4 is characterized by large air-filled cysts which are peripheral and thin walled. They have a simple squamous epithelium composed of alveolar type I cells resting upon loose mesenchymal tissue.

A further type of CTM is 'mesenchymal cystic hamartoma' (MCH). The lesions may be supplied by bronchial, intercostal or phrenic arteries. Pathological examination shows them to consist of multilocular, thin-walled cysts lined by primitive mesenchymal cells that support a ciliated cuboidal epithelium. Muscular hamartomas, which are small focal proliferations of smooth muscle, are occasionally observed incidentally in the lung, sometimes associated with similar lesions in the bowel and liver.

The sequestration spectrum has been used to indicate that a portion of lung exists without appropriate bronchial and vascular connections. Classically, no airway connects the lesion to the tracheobronchial tree and the blood supply is systemic; however, in some there may be a normal airway. Alternatively, an 'airway' may connect the sequestration to

the esophagus or stomach in a complex 'bronchopulmonary-foregut malformation'. Occasionally, 'sequestration' is associated with duplication of the esophagus, stomach or pancreas. There is therefore a spectrum of abnormalities associated with 'pulmonary sequestration'.<sup>365,366</sup> Conventionally, two forms have been recognized: extralobar, which has its own covering of visceral pleura, and intralobar, which is embedded in otherwise normal lung. Both should be considered part of the CTM spectrum. There is often a defect in the diaphragm and about 15% of 'extralobar sequestrations' are abdominal. The veins leaving an 'extralobar sequestration' generally join the azygos or other systemic veins, whereas an 'intralobar sequestration' usually has normal pulmonary venous connections, but as with all CTMs, any combination of arterial supply and venous drainage is possible. The lung tissue in a 'sequestration' is often poorly developed and cystically dilated. The cysts are lined by columnar or cuboidal epithelium, or the 'sequestered' lung may be entirely composed of structures resembling alveolar ducts. Mucus distends the multiple intercommunicating spaces and the lesion appears solid radiographically, unless air enters through a bronchial connection or, in the case of 'intralobar sequestration', by collateral ventilation, when fluid levels are often seen.

### **Management of congenital thoracic malformations**

A CTM most commonly presents as an antenatal ultrasound finding. Antenatal management is beyond the scope of this chapter. It should be noted that the majority of antenatally diagnosed malformations do well, and surgery (if performed) is usually elective.<sup>367,368</sup> The postnatal management of antenatally diagnosed CTM is fraught with difficulty, because of a lack of good information about natural history. If a baby has had a CTM diagnosed antenatally, then a CXR and a thoracic CT scan should be performed. Even quite large malformations may not be apparent on a CXR alone.<sup>368</sup> If the presence of a CTM is confirmed, there is no evidence base on which to offer advice. Reasons for operative removal would be the (currently unquantifiable) risk of infection; risk of malignancy; and (if there is a large systemic arterial supply) risk of high output heart failure. It should be noted that malignancy has been reported even after complete removal of congenital cysts.<sup>369</sup> If operation is contemplated, then it is important to delineate the vascular supply (below) to minimize the risk of severe bleeding. An option for selected malformations with a systemic arterial supply may be coil embolization of the feeding vessels. The author's practice is to offer surgical treatment for all but the smallest CTMs, usually carried out in the second year of life. Others would operate on even the smallest malformation. CTM may also present later in life as a chance finding, with recurrent infection, hemoptysis or steroid unresponsive wheeze due to compression of a large airway. Treatment considerations for the asymptomatic CTM diagnosed later in childhood are largely the same as for antenatally diagnosed ones; symptomatic CTM should be excised. In particular, once a CTM becomes infected, recurrence is inevitable and operation should be advised. Excision may also be needed to confirm the diagnosis and exclude more sinister causes such as a malignancy. Increasingly, excision is performed using video-assisted thoracoscopic surgery (VATS).

### **Abnormally placed pulmonary tissue and abnormal intrapleural tissue**

Abnormal intrapleural tissue of adrenocortical tissue, thyroid (lacking C cells) and liver has been described in the lung and pancreatic tissue has been noted within so-called 'intralobar sequestrations' with gastrointestinal connections. Rarely, a whole kidney may be found above the diaphragm but outside the lung. There may be ectopic lung tissue in the neck, the abdomen or the chest wall, often associated with skeletal or diaphragmatic abnormalities.

### **The arterial trees**

There are two arterial trees (pulmonary and systemic), which are considered separately. Systemic arterial abnormalities of the great vessels of the mediastinum can be subdivided from those of the bronchial

circulation. Finally, the pulmonary capillary bed may be bypassed leading to direct arteriovenous communication; or absent, resulting in minimal pulmonary arteriovenous connections.

### **Pulmonary arterial abnormalities**

In general, the pulmonary arteries and veins follow the bronchial anatomy, and thus pulmonary arterial and venous arrangement mirrors bronchial arrangement. There are important exceptions. The first of these is congenital origin of the left pulmonary artery from the right ('pulmonary artery sling'), sometimes with a cross-over arterial segment, with the right upper lobe supplied by a branch from the left pulmonary artery. Surgical repair of a sling with a cross-over may result in infarction of the right upper lobe if the abnormal vessel has not been discovered. Isolated cross-over pulmonary artery branches in the absence of bronchial cross-over are occasionally seen. They cross the mediastinum to supply lung segments which often are abnormal in other ways.

Lobar and segmental vessels as well as the main pulmonary arteries may be narrowed, and there may be multiple constrictions. Unilateral absence of a pulmonary artery leads to the lung on that side receiving only systemic blood, either through anomalous systemic arteries or enlarged bronchial arteries. The defect may be isolated or associated with other cardiovascular anomalies.

Anomalous systemic arteries supplying the lung may be associated with any CTM, or even be an isolated finding.<sup>370</sup> When operation is contemplated for any CTM, it is important that abnormal vasculature is detected. Inadvertent severance of anomalous systemic arteries has led to fatal hemorrhage, whilst ligation of anomalous veins from adjacent nonsequestered lung has led to infarction of normal tissue. Anomalous systemic arteries are also found if the pulmonary artery is absent and they may also be part of complex arteriovenous malformations. One or both pulmonary arteries may take origin from the aorta. Bilateral origin from the aorta is part of the spectrum of common arterial trunk. Unilateral origin of pulmonary artery from the aorta may be an isolated abnormality.

Congenitally small unilateral pulmonary artery is usually seen in association with an ipsilateral CSL. Normal pulmonary blood flow is needed for normal lung development. Bilateral small or absent pulmonary arteries are usually part of the spectrum of pulmonary valve atresia/tetralogy of Fallot. Very large pulmonary arteries which compress the central airways are seen in absent pulmonary valve syndrome.

### **Abnormalities of the systemic arteries**

Two groups of abnormalities are relevant to the lung. The first group is those producing a vascular ring. There are a number of different variants, which present with stridor, cough, wheeze, and sometimes with recurrent infection or feeding difficulty. Diagnosis is by barium swallow, echocardiogram, bronchoscopy or CT or MRI angiography. Treatment is surgical, but prolonged postoperative symptoms due to the chronic effects of airway compression are common. The second group is the collateral vessels which may arise from the aorta and supply all or part of one or both lungs, or a CTM. These may be hypertrophied bronchial arteries or abnormal nonbronchial vessels; there may be multiple collaterals. This last group may be seen in association with direct pulmonary arteriovenous connections ('pulmonary arteriovenous malformations'). Aneurysm of aortopulmonary collateral vessels has been described.

### **The venous trees**

Anomalous pulmonary veins result in blood from the lungs returning to the right side of the heart. The anomalous veins may join the inferior caval vein or hepatic, portal or splenic veins below the diaphragm, or above the diaphragm they may drain into the superior caval vein or its tributaries, the coronary sinus or the right atrium. The anomaly may be total or partial, unilateral or bilateral, and isolated or associated with other cardiopulmonary developmental defects. Anomalous pulmonary venous connections are often narrow and this may cause relatively mild pulmonary hypertension.

A particular clinical problem is the 'scimitar' syndrome; this is characterized by a small right lung, resulting in the heart being in the right chest (cardiac dextroposition), and an abnormal band shadow representing the abnormal venous drainage to the systemic veins, fancifully compared to a scimitar (which in fact is often absent). Initial treatment which may need consideration is coil occlusion of aortopulmonary collaterals and occasionally of an abnormal vein if venous drainage is double-arched (to both caval vein and left atrium). This intervention may be followed by surgical correction. The results are unlikely to be perfect; some blood supply may be restored, but the ultimate functional result will depend on the normality of the underlying lung. In view of evidence in other contexts that normal intrauterine blood supply is essential for normal lung development, it would be naïve to suppose that a perfect functional result could be achieved whatever treatment is given. Pulmonary venous obstruction is a not infrequent late complication of surgery, particularly if surgery is carried out in infancy. Occasionally lobectomy or pneumonectomy is performed, usually in the context of severe pulmonary hypertension; this operation should only be a last resort.<sup>372,372</sup>

Absence of the pulmonary veins or narrowing of their ostia into the left atrium similarly results in pulmonary venous obstruction. Partial anomalous pulmonary venous drainage may be obstructed or unobstructed. Unilateral anomalous venous drainage may be part of complex lung malformations; it may also be seen in association with what appears to be a simple lung cyst. This underscores the need for accurate delineation of all abnormalities in even straightforward appearing cases. Minor abnormalities of venous connection, such as of a segment direct to the azygos system, are not uncommon and are usually not of practical significance.

No congenital disorders of the systemic (bronchial) venous tree have been described.

### Disorders of connection between the pulmonary and venous trees

An important group of abnormalities which potentially involves systemic and pulmonary arterial and venous trees are the various forms of 'pulmonary arteriovenous fistulae'. They range from the diffuse, microscopic to the single or multiple large abnormality. The large connections may have both a systemic and a pulmonary arterial supply. There may be arteriovenous malformations elsewhere in the body, and they may be part of Osler-Weber-Rendu disease. Presentation is with cyanosis, the chance discovery of an asymptomatic mass on CXR, or with a complication such as systemic embolization or abscess. Confirmation of the diagnosis is with contrast echocardiography. Treatment of discrete lesions is with transcatheter embolization.<sup>373</sup> Medium term follow-up has confirmed that the results are good. Multiple diffuse lesions in both lungs cannot be embolized, and may lead to progressive cyanosis and polycythemia. If symptoms are severe, lung transplantation may need to be considered, but this is a last resort, and is inferior in results to those of multiple embolization, when this is feasible.

Congenital alveolar capillary dysplasia (misalignment of lung vessels) represents a failure of capillaries to extend into the alveolar tissue of the lung, and presents initially as persistent fetal circulation, but which relentlessly progresses to death whatever treatment is given. Histology shows increased septal connective tissue and pulmonary veins accompanying small pulmonary arteries in the centers of the acini rather than occupying their normal position in the interlobular septa (misalignment of lung vessels). The pulmonary arteries are decreased in number and show increased muscularization. Pulmonary lobules are small and radial alveolar counts may be decreased. Alveoli are decreased in complexity, their walls contain few capillaries and there is poor contact of capillaries with alveolar epithelium. The primary fault is poorly understood. The relationship of congenital alveolar capillary dysplasia to a condition previously described as congenital alveolar dysplasia is unclear.

### Lymphatic tree

Congenital lymphangiectasia may be isolated, associated with abdominal lymphangiectasia, or found with congenital heart disease. It usually

presents with relentlessly worsening respiratory distress which does not respond to any treatment; however, it is becoming clear that the prognosis is not uniformly gloomy.<sup>374</sup> Rarely, milder localized cases may present in adolescence.<sup>375</sup> Diagnosis is by HRCT scan appearances, which may be confirmed by open lung biopsy.

Congenital chylothorax may be an isolated abnormality, or associated with congenital abnormality of the main lymphatic duct or pulmonary lymphatics. Associations with Noonan, Ullrich, Turner and Down syndrome, fetal thyrotoxicosis, H-type TEF and mediastinal neuroblastoma have been described; familial cases have been reported.

### RELEVANT CARDIAC ABNORMALITIES

Cardiac malformations may be coincidental, or a fundamental part of the malformation. They are sufficiently common that echocardiography should be a routine part of the work-up of congenital lung disease. Coincidental malformations are seen with, for example, a congenital large hyperlucent lobe ('congenital lobar emphysema'). Lung abnormalities in which heart disease is fundamental include those with the pulmonary atresia spectrum. By definition, lung blood supply is abnormal. These however usually present to the pediatric cardiologists.

### DIAPHRAGM AND CHEST WALL ABNORMALITIES

#### Diaphragmatic anomalies

Diaphragmatic hernia occurs in about 1 in 3600 live births. Classification is according to position – 70–90% occur through the left diaphragm, most commonly posterolaterally between the lumbar and costal muscle fibers (the foramen of Bochdalek).

Usually the diagnosis is made antenatally. Postnatally the infant presents with respiratory distress and physical examination suggests displacement of the heart, and ipsilaterally reduced breath sounds and bowel sounds in the chest. Bowel is seen in the chest on a chest radiograph. Treatment is surgical (see Ch. 37) and it is the degree of pulmonary hypoplasia and iatrogenic ventilator induced lung damage that largely determines outcome. Both lungs exhibit abnormal airway branching and alveolization, although this is more severe in the ipsilateral side.

When the hernia is small presentation may be delayed. These are often anterior and may mimic a cystic CTM on the CXR. The possibility of this diagnosis should be considered in any child presenting with an air-fluid level on a chest radiograph, cystic lesion or where the diaphragm is ill defined. A coexisting pneumonia may further confuse the issue. A barium meal will confirm the diagnosis and operation should proceed immediately diagnosis is made as there is a very real risk of strangulation.

Long term follow-up of successful neonatal surgical repair shows that although lung volumes may be normal, morphologically the lungs probably remain small (with reduced alveolization). Pulmonary perfusion to the ipsilateral lung remains reduced even in adolescence. Long term, most survivors do well, although a few have recurrent respiratory infections and a small minority have severe respiratory disability.<sup>349</sup>

Although most diaphragmatic hernias present antenatally or immediately after birth, a few present in mid-childhood. Whether this is truly a congenital defect, or is in fact an acquired diaphragm rupture, is disputed. In most cases, pulmonary hypoplasia is minimal if present at all, and this suggests that these children in practice have a very different disease.

If the substance of the diaphragm is deficient, usually on one side, the abdominal viscera are elevated (eventration of the diaphragm). Eventration is believed to result from failure of all or a portion of the normal muscularization of the developing diaphragm which remains thin and translucent. It is usually unilateral and isolated, but occasionally other abnormalities are associated. Isolated unilateral eventration rarely needs treatment; occasionally plication of the diaphragm may be indicated if there are recurrent infections in the associated lung. Fluoroscopy will help to distinguish phrenic nerve palsy where there is

paradoxical movement of the diaphragm. In eventration there is little or no movement. Duplication of the diaphragm results in a fibromuscular septum dividing one pleural cavity in two, usually between the right upper and middle lobes.

### Asphyxiating thoracic dystrophy (Jeune syndrome)

This is a rare autosomal recessive disorder of generalized chondrodysplasia in which the costal cartilages in which the ribs are shortened and the rib cage narrowed so that lung development is retarded and the lungs are small. Other manifestations include pelvic and phalangeal anomalies and rarely hepatic, renal and neurological disorders. Those who survive the neonatal period usually succumb to respiratory failure in infancy and early childhood.

### ABDOMINAL DISEASE

Any large abdominal mass or fluid may compress the lungs, thus impairing development. Congenital absence of the kidneys causes oligohydramnios and small lungs (above). Rare CTMs may connect with the stomach and be associated with abdominal visceral malrotation.

### MULTISYSTEM DISEASE

Most congenital lung abnormalities are isolated, but a few are part of a more generalized disorder, e.g. tuberose sclerosis may affect the lung as well as kidneys, heart and brain. Complex abnormalities of lung development may be associated with chromosomal abnormalities.

### RARE LUNG DISEASES

The majority of these conditions are so rare that they will be encountered but once in a lifetime by the general pediatrician. Thus, early referral for specialist review is recommended in suspected cases.

### THE TRUE INTERSTITIAL PNEUMONITIDES

About 50% of children with these conditions present at under 1 year of age. The spectrum includes chronic pneumonitis of infancy (CPI), desquamative interstitial pneumonitis (DIP, the 'usual' pattern of adults, which rarely if ever occurs in children), pulmonary interstitial glycosinosis (PIG), neuroendocrine cell hyperplasia of infancy (NEHI)<sup>376</sup> and nonspecific interstitial pneumonitis (NSIP), the last of which may be subclassified by the presence or absence of a fibrotic component.<sup>377</sup> The cause of many of these conditions is unknown, but mutations of the surfactant proteins (see p. 705) account for some cases; genetic studies should always be considered. Presentation is similar and nonspecific, with cough, tachypnea, respiratory distress, failure to thrive and sometimes cyanosis. The physical signs may include digital clubbing and fine crackles. The CXR appearances are nonspecific, and include generalized ground glass shadowing, reticular nodular infiltrates and honeycombing. HRCT is performed to confirm that an interstitial disease is present; but unlike in adults, it is relatively rare for a specific diagnosis to be made on the scan alone.<sup>378</sup> Diagnosis requires a lung biopsy; transbronchial biopsy gives only small samples, which may be sufficient for the rare diseases with highly specific histological features such as pulmonary alveolar microlithiasis, and is the investigation of choice in the transplant recipient with possible rejection.<sup>379</sup> Some advocate CT guided, percutaneous needle biopsy, but the complication rate is thought by many to be unacceptable.<sup>379</sup> Open lung biopsy (OLB) through a mini-thoracotomy is safe in experienced hands and has a high diagnostic yield.<sup>380</sup> In older children, a VATS procedure may be preferred. However, it has to be said that there seems to be little relationship between biopsy appearances and response to treatment or prognosis. These conditions are so rare that treatment recommendations are scanty. Most pediatricians would treat with hydroxychloroquine alone, or in combination with prednisolone.<sup>381</sup> If there is no response, recommendations are even more anecdotal; pulse methylprednisolone, azathioprine and ciclosporin have all

been tried. Prognosis is variable and unpredictable from either radiology or histological features; in general, the younger the age of onset the poorer the prognosis, but spontaneous and complete resolution of even severe disease is well described. There is a rare autosomal dominant, familial form of DIP for which the gene is currently not identified.

### RARE SINGLE SYSTEM DISORDERS

Interested readers are referred to a comprehensive narrative review.<sup>382</sup>

#### *Extrinsic allergic alveolitis*

The allergen is usually pigeon or budgerigar excreta or moldy hay. Exposure to bird allergen may be indirect via the clothes of a parent. Presentation is with chronic respiratory distress (birds) or acute symptoms within hours of exposure (moldy hay), confirmed by positive serology. Treatment is allergen avoidance; oral steroids are given for severe acute or chronic progressive disease.

#### *Pulmonary alveolar microlithiasis*

This condition, which may be inherited, has a nonspecific presentation but a classical sandstorm appearance on CXR. Calcium carbonate stones are formed within the alveoli; the differential diagnosis is other forms of pulmonary calcification. Pulmonary fibrosis may develop many years later when the patient becomes symptomatic. A narrative review discusses these unusual problems in greater depth.<sup>383</sup>

### THE LUNG AS PART OF A MULTISYSTEM DISORDER

Causes include conditions thought to be autoimmune (scleroderma, systemic lupus erythematosus, rheumatoid disease); inherited conditions (sickle cell disease, Riley–Day syndrome, mucopolysaccharidoses); and those of unknown cause (sarcoidosis, Langerhans' cell histiocytosis, and the disorders of the pulmonary lymphatics).<sup>383</sup> More details on these rare conditions are reviewed elsewhere.<sup>384</sup>

#### *The lung in connective tissue diseases*

The lung may be affected as part of a systemic vasculitis, such as Wegener granulomatosis or Churg–Strauss syndrome. Systemic lupus erythematosus may cause a variety of manifestations, including interstitial pneumonitis, obliterative bronchiolitis, respiratory muscle weakness, pulmonary hemorrhage and pleural effusion. Scleroderma is associated with pulmonary fibrosis, and pulmonary hypertension. All these conditions are so rare that referral to a pediatric respiratory center is advisable if they are suspected.

#### *Histiocytosis*

Lung involvement is usually part of a multisystem disease in children, but in young adults who smoke it may be confined to the lungs. Presentation is with respiratory distress, or sometimes with acute and non-resolving pneumothorax. CXR shows interstitial changes, and HRCT shows characteristic nodules which cavitate, allowing the diagnosis to be made without recourse to further tests. If in doubt, BAL shows increased numbers of Langerhans' cells, and biopsy is definitive. Treatment is smoking cessation, and sometimes prednisolone or a cytotoxic agent. Multisystem disease requires combination chemotherapy usually with inclusion of vinblastine or etoposide (see Ch. 24). The disease may progress to respiratory failure, and recurs in the transplanted lung.

#### *Sarcoidosis*

Pulmonary disease is very rare in children; presentation is more usually with bilateral anterior uveitis, skin rashes and tendon sheath effusions. Diagnosis is on biopsy and is suggested by a high serum level of angiotensin-converting enzyme. Treatment is with steroids, to which may be added hydroxychloroquine and other steroid sparing agents. For refractory cases, a combination of methotrexate and the TNF-alpha blocker etanercept may be considered.

## Pulmonary lymphangiomatosis

Pulmonary lymphangiomatosis is a manifestation of a systemic lymphatic malformation which may also affect the spleen, heart and bone. It is usually fatal over 5–7 years, whatever treatment is tried.<sup>385</sup>

### *Alpha1-antitrypsin deficiency*

The fully expressed disease requires two copies of the protease inhibitor (Pi) Z allele, hence PiZZ, and such individuals usually have serum levels of <2 mg/ml (<20% of normal). The incidence in Caucasian populations is between 1 in 2000 and 1 in 4000 and the pulmonary manifestations usually present in adult life with emphysema or sometimes bronchiectasis. In childhood, however, it presents as a neonatal hepatitis as the site of production is in the liver (see Ch. 19). Pulmonary disease is usually not evident until late in adolescence. Antitrypsin and other proteases help defend the lung from damage associated with the release of proteases such as elastase released from neutrophils which would otherwise cause digestion of lung interstitial tissue and the subsequent development of emphysema. Children who are known to have this disorder should be advised never to smoke, as smoking is a potent stimulus to protease activity in the lung. Many nonsmokers with this condition remain asymptomatic for many years, but prognosis for pulmonary function is poor in smokers. Replacement therapy with alpha1-antitrypsin is now available.

## RARE DISORDERS OF THE BRONCHIOLES

The most distal airways are the physiologically silent areas of the lungs, and are notoriously difficult to investigate. Currently, patchy air trapping in the absence of overt large airways bronchiectasis, best demonstrated with inspiratory and expiratory HRCT, is the best diagnostic pointer.

### *Obliterative bronchiolitis*

Obliterative bronchiolitis (OB) has been described in association with infections caused by adenovirus types 3, 7 and 21; measles, pertussis, influenza A, mycoplasma; after lung transplantation; and secondary to chronic aspiration.<sup>386</sup> Often the cause remains conjectural. The clinical course is one of cough, wheeze and tachypnea in an infant or young child which may be static if the cause is an infection, or progress at a variable rate to respiratory failure and failure to thrive if there is ongoing aspiration. Chest radiography initially shows generalized hyperinflation. HRCT demonstrates patchy air trapping, particularly if the scan is expiratory. Focal hyperlucency involving a lobe or a whole lung represents the radiological appearance of Macleod syndrome, in which the affected lung appears small and hyperlucent. This represents long term damage to lung development, both parenchymal and vascular. HRCT will usually show ipsilateral bronchiectasis, and contralateral, albeit less severe, areas of air trapping. This radiographic appearance should not be confused with other causes of hyperlucency such as hypoplastic pulmonary artery, congenital large hyperlucent lobe (congenital lobar emphysema) or ball valve obstruction to a large airway (see p. 697 – Congenital abnormalities). Radioisotope split lung function studies examining both ventilation and perfusion may help to clarify equivocal radiographic features. In Macleod syndrome the affected lung is small and both poorly perfused and ventilated.

Lung function studies show severe airways obstruction, and, in pure OB, large static lung volumes. Underlying diseases such as cystic fibrosis, immunodeficiency, ciliary dyskinesia and chronic aspiration may need to be ruled out. The main differential diagnosis is fibrosing alveolitis, which should easily be distinguished by HRCT. Management is supportive. Steroids have no proven value. Individuals may find bronchodilators helpful.

The prognosis for OB is most serious after adenoviral disease. Long term oxygen dependency is common.<sup>387</sup> Improvement after 2–3 years may be seen. The condition is usually stable once the initial effects of the devastating infection have burnt out, but some may go on to require lung transplantation. OB developing after lung transplant is eventually fatal, and the results of a second transplantation are very poor.

### *Follicular bronchiolitis*

Follicular bronchiolitis (FB) is part of the spectrum of lymphoid disorders of the lung, which includes lymphoid interstitial pneumonia (LIP). There is a polyclonal expansion of lymphoid tissue, probably part of the bronchus associated lymphoid tissue (BALT), which causes small airways obstruction. Presentation is with chronic respiratory distress, and HRCT demonstrates air trapping, sometimes with associated infiltrates. Such a finding should prompt a full immune work-up, including HIV testing (see Ch. 27). If no immune defect is found, anecdotal evidence suggests that treatment with inhaled steroids and long term macrolide antibiotics (clarithromycin, azithromycin) for their anti-inflammatory effects may be worthwhile.

## SPONTANEOUS AIR LEAKS

Air leaks such as pneumothoraces, subcutaneous emphysema and pericardial and mediastinal air are very unusual outside the neonatal period, and are usually seen as a complication of positive pressure ventilation. Children with airways obstruction such as asthma or cystic fibrosis are at relatively higher risk. A spontaneous pneumothorax in a previously healthy child is extremely rare, and more often is a sign of an underlying lung disease than in adults.<sup>388</sup> Apical bullae or an isolated lung cyst are sometimes identified on a chest radiograph or CT scan. Rare causes include pulmonary Langerhans' cell histiocytosis and lung metastases from a primary sarcoma. Presenting features include sudden chest pain and breathlessness. There are reduced breath sounds over the affected side. In the management of a first episode the options are observation alone, simple aspiration or tube drainage with pleurodesis, depending on the size of the pneumothorax and on risk factors such as distance from hospital or future air travel, as well as any underlying disease. In spontaneously breathing children with acute asthma, an air leak may be identified quite unexpectedly on a chest radiograph; the majority resolves without intervention. Pneumothorax in a patient with cystic fibrosis is usually a sign of severe underlying disease and carries a poor prognosis. Treatment should be discussed with the local transplant center, to avoid prejudicing lung transplantation by too aggressive a pleurodesis.

## PULMONARY HEMORRHAGIC DISORDERS

The spectrum of these disorders has been reviewed.<sup>389</sup> Idiopathic pulmonary hemosiderosis is characterized pathologically by recurrent alveolar bleeding. Presentation is either as an iron deficiency anemia or with respiratory distress. The anemia may respond to oral iron, and the child has frequently been subjected to numerous invasive gastrointestinal investigations before a CXR is inspected. The respiratory presentation is with tachypnea, cough and sometimes but not invariably, hemoptysis. There may be digital clubbing and crackles, and hepatosplenomegaly in up to 20% of children. Gastric aspirates may be positive for hemosiderin-laden macrophages, and the stools positive for occult blood. CXR may show ground glass opacification, or blotchy shadowing. HRCT may strongly suggest the diagnosis, which may also be confirmed by finding hemosiderin-laden macrophages in BAL fluid; open lung biopsy is rarely necessary. An association with IgD milk antibodies (Heiner syndrome) is in fact rarely if ever seen today. Secondary causes of pulmonary hemorrhage, e.g. pulmonary venous hypertension, must be excluded. Treatment is with hydroxychloroquine,<sup>390</sup> to which prednisolone may need to be added. Relapse is common, and death may be from acute massive bleeding or chronic respiratory failure. Treatment should probably be continued for at least 2 years after the last relapse. Cases apparently resistant to therapy should be referred for open lung biopsy, which may not show the expected normal lung architecture with intra-alveolar blood and hemosiderin-laden macrophages, but a neutrophilic vasculitis. This very rare picture is important to identify as it responds to cyclophosphamide.

## PULMONARY VASCULAR DISEASES CHARACTERIZED BY PULMONARY HYPERTENSION

### *Primary pulmonary hypertension*

Primary pulmonary hypertension (PPH) is a diagnosis of exclusion. Presentation is with nonspecific symptoms such as breathlessness and syncope, and the physical signs of pulmonary hypertension (loud pulmonary component of the second heart sound, parasternal heave) may be elicited. Secondary causes such as congenital heart disease are excluded by echocardiography and are discussed in Chapter 21 (p. 765). PPH may be isolated, or inherited as an autosomal dominant disorder, or associated with liver or autoimmune disease, or HIV infection. The gene accounting for some cases of familial PPH has been localized to chromosome 2.<sup>391</sup> Treatment advice is largely based on adult guidelines,<sup>392</sup> which assumes that the adult and pediatric diseases are the same. Possible lines of treatment include oxygen, at least overnight, to maintain normal arterial saturation; anticoagulation; oral pulmonary vasodilators such as the calcium channel antagonists; and, for those rare children who can tolerate it, a continuous intravenous infusion of epoprostenol (prostaglandin, PGI<sub>2</sub>). Alternative modes of delivery are preparations that are active orally, by nebulizer, or by subcutaneous infusion. Recently, these patients have been treated with combinations of the selective phosphodiesterase 5 inhibitor, sildenafil; and the endothelin receptor antagonist, Bosentan. Patients with pulmonary hypertension should be referred to specialist centers for consideration of such therapy. If these fail, lung transplantation is the only other option.

### *Embolic pulmonary hypertension*

This presents in a similar manner to PPH. Spiral CT with contrast or angiography may lead to suspicion of the diagnosis by the demonstration of large pulmonary artery filling defects. OLB may be needed to confirm the presence of microemboli. Thromboembolic disease is the commonest cause. It may be a manifestation of an underlying congenital or acquired coagulopathy. Other predisposing factors include immobility, and a sluggish circulation, as for example after a Fontan procedure or secondary to right atrial stasis in dilated cardiomyopathy. Tumor emboli are another cause, with Wilms tumor or hepatoblastoma the commonest primary sources. Talc microemboli should be considered in adolescents who abuse substances intravenously; crushed up injected tablets result in talc microemboli. Worldwide, schistosomal disease must be the commonest cause of nonthrombotic embolic disease.

### *Pulmonary veno-occlusive disease*

This condition presents as chronic pulmonary venous hypertension, with pulmonary edema resistant to diuretics. Cases are usually isolated, but may rarely be familial, or a complication of cytotoxic chemotherapy. Diagnosis may be confirmed at cardiac catheterization or OLB. There is no known effective treatment, and most cases die of severe pulmonary hypertension unless transplanted.

### *Invasive pulmonary capillary hemangiomatosis*

This is due to proliferating sheets of thin walled capillary channels infiltrating blood vessels and causing secondary vascular occlusion. Familial cases have been described. Diagnosis is by OLB, and the condition is usually fatal.

## PULMONARY VASCULAR DISEASES CHARACTERIZED BY CYANOSIS WITHOUT PULMONARY HYPERTENSION

### *Macroscopic pulmonary arteriovenous malformations*

Pulmonary arteriovenous malformations (PAVMs) are large malformations which typically present with cyanosis, and sometimes a bruit may be heard over the lung field. There may be an associated cerebral AVM with a bruit heard over the cranium. There is an obvious mass on CXR, and contrast echocardiography or peripheral injection of technetium-labeled albumin microspheres confirms a large intrapulmonary right-to-left shunt. Most such PAVMs consist of a direct connection between

the pulmonary arterial and venous circulations, but some also have a systemic arterial supply. Treatment is with transcatheter embolization using a balloon or coil. Untreated, complications include polycythemia, systemic embolization and abscess formation, these last complications being the result of the systemic venous return bypassing the filtration function of the pulmonary capillary bed. Cerebral abscess or embolic stroke are the most feared complications of PAVM.

### *Microscopic pulmonary arteriovenous malformations*

These may be an isolated finding or a manifestation of Osler–Weber–Rendu disease [hereditary hemorrhagic telangiectasia (HHT)], liver disease, or as a complication of some congenital heart diseases. Mutations in two genes leading to Osler–Weber–Rendu disease, ENG (HHT type 1) and ACVRL1 (HHT type 2) have recently been described.<sup>393</sup> Presentation is with cyanosis without respiratory distress, and a clear CXR. There is no treatment other than lung transplantation.

## INHERITED DISORDERS OF SURFACTANT PROTEINS

There are four surfactant proteins, lettered A to D. Surfactant proteins A and D are more properly considered as members of the collectin family, with important functions in host defense but with little surface active function. Inherited disorders of proteins B and C, with a respiratory presentation, have been described. Additionally, abnormalities in the ATP-binding cassette transporter (ABCA3) gene cause a similar picture. The lung histology is very variable, and surfactant genetic studies should be considered part of the work-up of the child with an interstitial lung disease.

### *Congenital surfactant protein B (SpB) deficiency*

This condition presents as relentlessly progressive respiratory distress, usually in a term baby.<sup>394</sup> It is inherited as an autosomal recessive disorder. CXR shows a ground glass appearance. Open lung biopsy shows alveoli filled with lipoproteinaceous material, and special stains confirm the absence of SpB. A few mild cases with prolonged survival have been reported. Successful treatment with granulocyte-colony stimulating factor has been reported. If this fails, lung transplantation is the only other option.

### *Congenital surfactant protein C (SpC) deficiency*

SpC deficiency was first described in a woman with an interstitial lung disease, who gave birth to an infant with respiratory distress.<sup>395</sup> The mother subsequently died. Molecular studies established the diagnosis. Some children previously given the diagnosis of CPI and nonspecific interstitial pneumonitis (NSIP) have subsequently been shown to have inherited defects of surfactant proteins.

### *Congenital ABCA3 deficiency*

The intracellular processing of surfactant proteins is very complex, so it is unsurprising that an alveolar proteinosis-like disease can be produced by mutations in genes encoding processing proteins. This is exemplified by ABCA3 deficiency.<sup>396</sup> This protein is confined to lamellar bodies, implying a role in surfactant protein handling.

### *Pulmonary alveolar proteinosis*

Pulmonary alveolar proteinosis (PAP) is characterized histologically by alveoli which are filled with granular, eosinophilic material staining with periodic-acid Schiff, with preservation of lung architecture. Initially, two forms were recognized; 'idiopathic', responding very well to whole lung, large volume lavage, and secondary to conditions associated with functional impairment of the macrophage (such as hematological cancers and some infections). The possible role of granulocyte-macrophage-colony stimulating factor (GM-CSF) in PAP was highlighted when the GM-CSF knockout mouse was found to have a PAP-like illness with normal surfactant synthesis, and with recovery after GM-CSF replacement. Subsequently, late-onset 'idiopathic' PAP was found to be an autoimmune disease, with autoantibodies targeting GM-CSF, or rarely, with a defect in GM-CSF/IL-3/IL-5 receptor common beta chain. Treatment

with aerosolized or subcutaneous GM-CSF has been successful in some late-onset cases.<sup>397,398</sup>

In some children PAP may be related to a form of immune deficiency such as thymic atrophy, lymphopenia and immunoglobulin deficiency. CXR shows a ground glass appearance and HRCT a typical cobblestone appearance. Unlike adult PAP, whole lung, large volume lavage is usually only of transient benefit, and the prognosis is very poor.

## THORACIC TUMORS

Primary and secondary tumors within the thorax are very rare;<sup>399</sup> even within tertiary specialist pediatric pulmonology practice, thoracic malignancy is usually diagnosed only once or twice a year. Possible presentations include airways compression and stridor; chest wall invasion with either or both of pleuritic chest pain and pleural effusion; systemic symptoms such as fever, malaise and weight loss; or, in the case of a primary tumor, with the effects of secondary systemic disease. The rarity of tumors leads to the very great danger that the possibility is not even considered. Although measurement of catecholamine metabolites, alpha-fetoprotein or beta human gonadotrophin in serum may reveal the diagnosis, surgical biopsy is usually needed. Treatment of all such lesions is the province of the pediatric oncologist (see Ch. 24, p. 1015 for neuroblastoma and p. 1027 for mediastinal tumors).

### Benign tumors

These include true benign lesions such as pulmonary hamartomas and pseudotumors, e.g. plasma cell granuloma. Carcinoid tumors present as an endobronchial mass which may bleed profusely if biopsied. Some behave as true malignancies.

### Primary malignant lung tumors

Less than 2% of childhood cancers are lung primaries. Endobronchial cancer should at least be considered as a possibility in an otherwise unexplained bronchial obstruction. The intrathoracic sarcomas enter the differential diagnosis of large mass lesions within the chest. Whether intrathoracic lymphoma is a true primary pulmonary malignancy is a matter of semantics; suffice it to say that T-cell lymphoma may present as a rapidly progressive upper airway obstruction. Emergency control of the airway may be necessary to prevent asphyxia.

### Metastatic tumors

These usually present in the context of a known primary tumor, most commonly osteo- or other sarcoma, Wilms tumor, germ cell tumors, neuroblastoma or hepatoblastoma. Presentation as pulmonary vascular disease is discussed above. Occasionally metastatic disease is found de novo as multiple round lesions on CXR; the differential diagnosis includes multiple lung abscesses and hydatid disease. Occasionally, pulmonary metastases may be cured surgically; specialist advice should always be sought before recommending such a course.

## Mediastinal tumors

These may be benign or malignant, and there is an extensive differential diagnosis. Presentation is with compression of the central airways leading to stridor; compression of the superior caval vein; and as the chance finding of mediastinal widening on the CXR. Although clues as to the likely histology may be obtained from CT and MRI, most lesions will need a surgical biopsy to establish the exact diagnosis (see Ch. 24, p. 1027).

## CYSTIC FIBROSIS

### EPIDEMIOLOGY

Cystic fibrosis (CF) is the commonest, life-limiting, autosomal recessive disorder of Caucasians. The condition was first described by Dorothy Anderson in 1938. The incidence in the UK is 1 in 2500 live births and approximately 1 in 25 individuals in the general population are carriers for the condition. There are almost 7000 individuals with CF in the UK<sup>400</sup> and an estimated 30 000 in the USA.<sup>401</sup> Survival has improved steadily over the last four decades. Survival curves run nearly parallel after the first year of life, suggesting that much of the increase in life expectancy is due to improvements in care in the first year.<sup>402</sup> Data from the Danish CF clinics (which have some of the best survival figures in the world) show that there is now an 80% chance of a newborn baby with CF reaching his/her 45th birthday.<sup>403</sup> Survival after infancy is consistently worse in girls with CF than it is in boys.<sup>404</sup> The reasons for this are not clear. The incidence of CF is lower in the black population in the USA (1 in 15 000 live births).<sup>405</sup> CF is seen in the Asian community in the UK and there is a more severe clinical phenotype in this group.<sup>406</sup>

### PATHOGENESIS

CF is caused by an abnormality in a protein, known as the cystic fibrosis transmembrane conductance regulator (CFTR). This protein is a cyclic AMP (cAMP)-dependent chloride channel. In the lung, the protein is located on the apical membrane of respiratory epithelial cells. When CFTR function is impaired, chloride ions cannot pass from the cell cytoplasm into the airway surface liquid layer. This defect in the chloride channel is accompanied by overactivity of the epithelial sodium channel (EnaC) with the passage of sodium ions into the cell cytoplasm. These ion transport abnormalities together lead to a reduction in salt levels in the airway surface liquid and the loss of water from this layer by osmosis. This reduces the thickness of the airway surface liquid layer. The cilia can no longer beat freely because they have become entangled in the raft of mucus and particulate matter which forms the mucociliary escalator (Fig. 20.25). Consequently the mucociliary escalator does not function. Mucus plugging of small airways occurs, bacterial organisms in the lower respiratory tract are no longer cleared and secondary bacterial infection occurs. This leads to the release of inflammatory cytokines such as IL-8 and neutrophil driven inflammation. The cycle

Fig. 20.25 (a) The normal mucociliary escalator with normal airway surface liquid volume. (b) In CF the airway surface liquid layer is diminished and the cilia become entrapped in the mucus layer, preventing the cilia from beating in a coordinated fashion.

of infection, inflammation and lung damage eventually leads to permanent dilatation of the subsegmental airways or bronchiectasis. Severe bronchiectasis can ultimately lead to death from respiratory failure. In the upper airway, abnormalities of CFTR, leading to impaired mucociliary clearance, can lead to chronic sinusitis and the formation of nasal polyps.

The effects of abnormal CFTR are not only seen in the respiratory tract. In the normal sweat gland, salt is removed from sweat in the sweat duct, resulting in sweat which is low in salt. In CF this does not occur because of a failure of CFTR function and excessively salty sweat is produced. This is the basis of the sweat test (see below). Abnormalities of CFTR in intestinal epithelial cells result in thick sticky meconium and meconium ileus in the newborn infant with CF. In the pancreas, the pancreatic duct cells are responsible for the production of bicarbonate rich fluid, which dilutes the pancreatic enzymes, produced by the acinar cells. The defect in CFTR impairs water secretion into the pancreatic duct by interfering with chloride–bicarbonate exchange.<sup>407</sup> These thick secretions block the pancreatic ducts, leading to back pressure and destruction of the acinar cells, pancreatic enzyme deficiency and malabsorption. With increasing age, destruction of the pancreatic islet cells also occurs, leading to CF-related diabetes (CFRD). In the liver, CFTR dysfunction in the intra- and extra-hepatic bile ducts leads to bile which has increased viscosity and is depleted in bicarbonate. This leads to obstruction of the ducts and to focal biliary cirrhosis. What is not clear is why the process should be focal, if it affects bile ducts throughout the liver, and why not all patients with CF develop liver disease.<sup>408</sup> In males, CFTR dysfunction leads to absence of the vas deferens and male infertility.

There has been some debate over whether pulmonary inflammation in CF is the result of infection or whether CF itself is a pro-inflammatory condition. Where bronchoscopy and BAL have been performed in infants as young as 3 months with CF, a high proportion (31%) have been found to have lower respiratory tract infection with *Staphylococcus aureus*. In contrast, samples from non-CF control infants did not show significant levels of bacterial pathogens. Levels of IL-8 were high in infants with infection but not in controls or in non-infected CF infants, suggesting that infection is the most important driver of inflammation.<sup>409</sup> The CF airway shows inflammatory dysregulation, with the same amount of bacterial endotoxin leading to significantly more IL-8 release and neutrophil infiltration.<sup>410</sup>

## GENETICS

The gene for CFTR is located on the long arm of chromosome 7. The commonest gene mutation is termed delta F508 and results in the loss of a phenylalanine residue at position 508 in the first nucleotide binding fold of CFTR (Fig. 20.26).<sup>411</sup> Over 50% of individuals with CF are homozygous for the delta F508 and, in the UK, over 90% will have at least one copy of delta F508. However, more than 1000 different

Fig. 20.26 Schematic diagram of the CFTR showing the two nucleotide binding domains. The delta F508 mutation is due to deletion of a phenylalanine residue in the first nucleotide binding domain.

mutations of the CF gene have been identified. Some (termed 'dominant mild mutations') seem to confer a milder phenotype when they occur as compound heterozygotes with delta F508. Mutations of the CF gene can cause a number of distinct defects of CFTR, which are categorized as follows:<sup>412</sup>

- **Class I:** a defect in protein synthesis and no production of CFTR. In the mutation W1282X, the mutant allele has a stop codon which prevents full transcription of mRNA. Some drugs such as gentamicin show promise in preventing this premature termination of translation.
- **Class II:** trafficking defects (includes delta F508). Misfolded CFTR is produced which does not leave the endoplasmic reticulum.
- **Class III:** CFTR is present in the apical membrane but there is a defect of regulation, e.g. G551D where CFTR in the apical membrane does not respond to elevated cAMP.
- **Class IV** (e.g. R117H): CFTR is present in the membrane but does not conduct chloride ions normally.
- **Class V:** Low levels of CFTR are produced or there is a defect of mRNA splicing, e.g. 5T or 7T thymidine tract variant (see below).

The class IV mutation R117H may occur on the same chromosome as either the 5T or 7T thymidine tract variant of intron 8. (The intron represents 'redundant DNA'.) The number of thymidine residues in intron 8 will affect the splicing (removal of bases) of exon 9 (functional DNA) when transcription takes place to form mRNA. Individuals with R117H and 5T on the same chromosome will have a mild CF phenotype whereas 7T is associated with congenital bilateral absence of the vas deferens alone.

The dominant mild mutations are mainly class IV or V. Patients with class IV and V defects have a lower mortality and a milder phenotype than patients who are homozygous for delta F508.<sup>413</sup> Patients with R117H are more likely to be pancreatic sufficient.<sup>414</sup> It is clear that 100% CFTR function is not essential for health as heterozygote carriers do not have clinical manifestations of CF and these individuals express only 50% of normal CFTR. It is thought that CFTR expression of >10% of normal may result in a normal clinical phenotype.<sup>413</sup>

There are great differences in the severity of lung disease, even in individuals who are homozygous for delta F508. This may be due to environmental differences such as viral infection in early life, passive smoking exposure or social deprivation. However, it has been suggested that a number of other genes can act to modify the severity of mutations of the CF gene. A recent study has looked at the effects of polymorphisms in 10 candidate modifier genes in a large sample of CF patients, with a second validation study in a separate large population.<sup>415</sup> This has implicated polymorphisms in the transforming growth factor beta1 (TGF-beta1) gene in more severe lung disease in both delta F508 homozygotes and patients with other genotypes. TGF-beta1 is a signal molecule which influences cell growth and differentiation, inflammation and the immune response. In contrast to its association with more severe disease in CF, it is linked to milder disease in chronic obstructive pulmonary disease.

## MICROBIOLOGY

As mentioned above, pulmonary infection with *S. aureus* occurs in early life in individuals with CF. In older children, other organisms, such as *Haemophilus influenzae*, are found more frequently. By the late teens the majority of CF patients in the UK will have pulmonary infection with *Pseudomonas aeruginosa*.<sup>400</sup> Patients with CF who are homozygous for the delta F508 mutation appear to be hypersusceptible to pulmonary infection with *P. aeruginosa*, due to increased adherence of the organisms to respiratory epithelial cells.<sup>416</sup> Initially the organism is present in the respiratory tract in its free living or planktonic form. However, *P. aeruginosa* has the ability to form bacterial communities or biofilms in the lungs. In the biofilm the organisms are surrounded by an exopolymeric substance, rich in alginate, and can communicate by means of signal molecules, which control the expression of virulence factors. In this form *P. aeruginosa* is protected from neutrophil phagocytosis and from the actions of

antibiotics. The biofilm mode of growth ensures that some organisms will always persist after antibiotic treatment and hence there is selective pressure, favoring the emergence of antibiotic resistance. Furthermore, resistant organisms can be transmitted between patients.<sup>417</sup> A much less common, but clinically important, group of pathogens in CF patients is the *Burkholderia cepacia* complex – a group of environmental organisms which have found a niche in the CF lung. They are highly antibiotic resistant and are transmissible between patients. Acquisition of *B. cepacia* complex is associated with a more rapid deterioration in lung function and increased mortality.<sup>418</sup>

## DIAGNOSIS

The diagnosis of CF is based on the presence of phenotypic features of CF, a history of CF in a sibling or a positive screening test plus evidence of CFTR abnormality, as shown by an abnormal sweat chloride, two mutations in the CFTR gene known to cause CF or abnormal nasal potential difference.<sup>419</sup> The sweat test is the most commonly used test of CFTR function and detailed guidelines are available, describing the correct procedure for the test.<sup>420</sup> The sweat test should not be performed on infants who are < 7 days old; who weigh < 3 kg; in children who are systemically unwell or who have eczema or edema. Sweat production is stimulated by means of pilocarpine iontophoresis and sweat is collected on a piece of sodium-free filter paper, under an occlusive dressing. The amount of sweat collected should equate to 1 g/m<sup>2</sup>/min and the usual collection period is 30 min. This is then analyzed for seat chloride and sodium concentration. A sweat chloride of > 60 mmol/L supports the diagnosis of CF and a chloride of < 40 mmol/L is normal. Values of 40–60 mmol/L are suggestive of CF but are not diagnostic. There are variations on this technique, such as capillary duct systems, which also produce reliable results.

## Newborn screening

There has been controversy over whether CF meets the criteria for a screening program, particularly over whether early intervention affects the natural history of the disease. In a pivotal study, Farrell et al described a controlled trial, conducted over 9 years and involving over 650 000 newborn infants.<sup>421</sup> Infants with an abnormal screening test (initially trypsinogen and subsequently trypsinogen and DNA) were recalled for sweat testing only if their specimen number ended in an odd digit. When children in the control group reached the age of 4 years, a sweat test was performed on those who had not been diagnosed clinically beforehand. The outcomes in children in the early screening group and the control group were compared. A significantly greater proportion of children in the screened group were homozygous for delta F508 and were pancreatic insufficient. However, the children in the early screening group had better nutrition at diagnosis and this was maintained over a 10 year follow-up period, as measured by weight and height centiles. Screening is also associated with an improvement in cognitive function, thought to be related to earlier treatment of vitamin E deficiency.<sup>422</sup> However, screened children acquired chronic pulmonary infection with *P. aeruginosa* significantly earlier than the control group.<sup>423</sup> The investigators attributed this to inadequate precautions against cross-infection. From 10 years onward, the CXR scores were significantly worse in the early screening group and this was partly explained by *P. aeruginosa* status.

Newborn screening has been practiced in parts of the UK for many years. However since 2007, the screening program has been extended to all of the UK.<sup>424</sup> The protocol, which will be used throughout the UK, initially uses an immune reactive trypsin (IRT) measurement on a dried blood spot collected on day 5. Trypsin is raised in blood of newborn infants with CF as a result of pancreatic exocrine failure. Where the IRT test is positive (> 99.5 centile) the sample is tested against a panel of CF gene mutations. This may identify two genes, in which case the child is referred with a presumptive diagnosis of CF. If one gene is identified or none but the initial IRT is very high (i.e. > 99.9 centile), then a repeat IRT is performed at between 21 and 28 days. The cut-off for this sample

is set lower than those used earlier in the process and infants are referred with a 'high likelihood of CF' if their IRT value is above the cut-off.

## Genetic counseling

When an infant is diagnosed as having CF, the parents should be offered genetic counseling. The timing of this may be difficult. When their baby is first diagnosed, parents will have to cope with the demands of a new baby and the therapeutic burden of CF care, and they may not want to see the genetics team right away. However, some couples will wish to have another child after a short interval and it is important to offer the opportunity of genetic counseling before the next pregnancy. In contrast to carriers identified by antenatal screening (see below), parents who already have a child with CF are less likely to have antenatal testing in a subsequent pregnancy.<sup>425</sup> Of those who do, fewer opt for a termination. There may be other family members who may be CF carriers and are also contemplating pregnancy, and antenatal screening can be offered to these couples ('cascade screening').

## Antenatal screening

Although newborn screening is now offered throughout the UK, there has been no population-based implementation of antenatal screening. There are two possible approaches to screening in pregnancy, where there is no family history of CF: 'stepwise' and 'couple' screening. With stepwise screening a genetic test for CF is offered to women attending the antenatal booking clinic (usually before 17 weeks' gestation). If she is shown to be a carrier, then her partner is offered testing. With couple screening, samples are taken from both partners at the same time. The stepwise approach has the disadvantage that a woman will experience unnecessary anxiety, while awaiting the result of her partner's test, if she has been found to be a carrier and her partner subsequently is shown not to be a carrier.<sup>426</sup> However, if couple screening is offered, either the man must attend with his partner or a DNA sample must be provided by post. The uptake for antenatal screening is between 70 and 90%. If both partners are identified as carriers the risk of CF in the fetus is 1 in 4. In the first trimester the diagnosis can be made in the fetus by chorion villus biopsy or, after 12 weeks, by amniocentesis or placental biopsy. Each of these procedures carries a risk of miscarriage. Where an antenatal screening program is in place, the uptake of a diagnostic test on the fetus by high risk couples is high (> 90%). Where CF is diagnosed in the fetus, most couples opt for termination.<sup>427</sup> Where antenatal screening has been practiced, there has been a 65% reduction in the birth incidence of CF.<sup>428</sup> Antenatal diagnosis may also be made following abnormal appearances on fetal ultrasound (see below).

## CLINICAL FEATURES

### Meconium ileus

Meconium ileus is acute small bowel obstruction in a newborn infant due to sticky meconium. It occurs in about 15% of infants with CF. Increasingly the diagnosis is suspected antenatally, because of the finding of echogenic bowel on detailed ultrasound, which confers a risk of CF in the fetus of around 3%.<sup>429</sup> Where bowel dilation is also present, the risk increases to 17%. Genotyping of the parents and the fetus (following amniocentesis) may allow the diagnosis of CF to be made antenatally (where two CF genes are identified in the fetus) or a more precise estimate of the risk of CF in the fetus (where only one gene is found). In some cases meconium ileus will progress to perforation in utero, with abdominal calcification on the plain abdominal radiograph at birth. Where the diagnosis is not made antenatally, the infant may fail to pass meconium in the first 24 h and develops progressive signs of small bowel obstruction. Appropriate supportive care is essential. A nasogastric tube should be passed, hypovolemia should be managed with appropriate fluid replacement and any electrolyte imbalance corrected. In some cases, a hydrostatic reduction of meconium ileus can be achieved by means of a contrast enema. This may reveal an associated microcolon (Fig. 20.27). However, in most cases surgical reduction is unavoidable, with either an ileostomy or a primary anastomosis. Prolonged periods of total parenteral nutrition should be avoided because of the associated cholestasis.

**Fig. 20.27** A contrast enema in an infant with meconium ileus showing microcolon. Contrast would not pass beyond the ascending colon and the terminal ileum is not visible. The diagnosis was suspected antenatally due to bowel dilatation. Placental biopsy at 22 weeks showed that the fetus was homozygous for delta F508.

Infants who present with meconium ileus are at greater risk of subsequent CF-related liver disease, poor nutrition (at 13 years)<sup>430</sup> and worse lung function (at 8–10 years).<sup>431</sup>

### Gastrointestinal features outside the neonatal period

In many parts of the world, the diagnosis of CF is made through newborn screening programs and so it is now uncommon to see infants with CF presenting with severe failure to thrive as a result of pancreatic malabsorption. Similarly, complications such as rectal prolapse are uncommon in a screened population. Infants with CF have a lower birth weight and, in early infancy, the mean weight is more than one standard deviation below normal.<sup>432</sup> Catch-up growth is seen in the first year, although the mean weight remains below the population mean. Infants diagnosed by newborn screening are in a better nutritional state at diagnosis and remain so over a 10 year follow-up period.<sup>421</sup> Much of this benefit is attributed to instituting pancreatic enzyme supplementation, a high calorie diet and supplements of fat soluble vitamins early in life. Vitamin E deficiency causes hemolytic anemia in around 4% of infants with CF.<sup>433</sup> There are reports of both vitamin A deficiency (with xerophthalmia or poor dark adaptation) and hypervitaminosis (as a result of vitamin A supplementation) in CF.

Nutrition in children with CF depends on the balance between energy expenditure and energy intake. Resting energy expenditure in CF can be up to 150% of that seen in unaffected individuals.<sup>434</sup> Much of this increased energy requirement is due to the chronic inflammatory response and energy requirements are increased further during pulmonary exacerbations. Energy intake may be compromised by vomiting, related to coughing or swallowed sputum; gastroesophageal reflux, anorexia or abnormal eating behavior. Malabsorption due to failure of pancreatic exocrine function can be exacerbated by loss of bile salts in the gut, previous small bowel resection (related to meconium ileus), lack

of pancreatic bicarbonate secretion and decreased small bowel pH, liver disease and CFRD.

Distal intestinal obstruction syndrome occurs when the terminal ileum and ascending colon become blocked with fecal material, high in fat. The condition may be brought on by inadequate dosing or poor adherence to pancreatic enzyme supplements and reduced fluid intake or hot weather. Clinically there is intermittent abdominal pain which may progress to intestinal obstruction with abdominal distention and constipation. Vomiting is a late feature and it is important to intervene before this occurs. A mass may be palpable in the right iliac fossa. Mild symptoms may be treated with a simple laxative such as lactulose. For more severe obstruction, treatment with the oral radiological contrast medium gastrograffin may result in the passage of stool and the relief of symptoms. Where this fails, surgical management may be necessary, but this should be avoided where possible.

In the early 1990s, a group of CF patients, presenting with intestinal obstruction, was found to have a histologically distinct form of bowel disease, characterized by mucosal and submucosal fibrosis. This new entity was termed fibrosing colonopathy. A subsequent case control study demonstrated a relationship between the dosage of high strength pancreatic enzyme supplements and the risk of colonopathy.<sup>435</sup> This led to a recommendation by the UK Committee on Safety of Medicines that the dose of any enzyme preparation should be restricted to no more than 10 000 lipase units/kg/d.<sup>436</sup>

### Respiratory features

Cough is an unusual symptom in infants under 4 weeks old and its presence should alert the clinician to the possibility of underlying disease such as CF, primary ciliary dyskinesia or immune deficiency. Wheezing (which is usually persistent rather than intermittent) may be a presenting symptom of CF in the young infant or toddler. In areas where there is newborn screening, it is unusual for children to present with features of advanced chest disease such as chronic productive cough, chest deformity or finger clubbing.

In children with an established diagnosis of CF, the objective is to minimize respiratory symptoms and allow full attendance at school and participation in physical activity. Many children will be symptom free when well. Pulmonary exacerbations (see below) are periods when respiratory symptoms appear in a previously well patient or worsen in children who already have chronic symptoms. These exacerbations are associated with a deterioration in quality of life<sup>437</sup> and reduced life expectancy.<sup>438</sup>

Children who have a productive cough frequently have blood stained sputum or small hemoptyses. These are thought to be due to a localized area of infection eroding a small bronchial vessel. They are managed by treating the underlying infection. Rarely, there may be severe, uncontrolled bleeding into the airway, with life threatening airways obstruction and hypovolemia. A major hemoptysis is defined as bleeding of more than 240 ml in 24 h or 100 ml/d over several days.<sup>439</sup> This complication affects around 1% of patients per year with the vast majority occurring in patients over 16 years. Children who have a major hemoptysis will need high flow face mask oxygen and may require intubation and ventilation. Where there are signs of hypovolemic shock, vigorous fluid resuscitation and blood transfusion are essential. Blood should be sent urgently for hemoglobin, platelets, clotting and group and save. Where the child is shocked, type specific uncross-matched blood can be given to avoid delay. Clotting abnormalities should be corrected. Rigid bronchoscopy may allow the bleeding point to be identified. Definitive treatment through bronchial artery embolization is usually successful, though resection of the segment of lung containing the bleeding vessel may be necessary in some cases.

Similarly, spontaneous pneumothorax occurs in around 1% of CF patients per year, with the incidence increasing with age and severity of lung disease.<sup>440</sup> Pneumothorax may be asymptomatic, being detected on a routine CXR, or may cause chest pain and respiratory distress. If the pneumothorax is <20% of the volume of the affected hemithorax, or if the patient is asymptomatic, then conservative treatment with

Fig. 20.28 Chest radiograph of an 18 year old with CF showing a right-sided pneumothorax and a chest drain in situ. There is underlying severe bronchiectasis and an indwelling intravenous access device.

face mask oxygen is appropriate. If not, a chest drain should be inserted (Fig. 20.28). A small diameter drain will be more comfortable for the child, may cause fewer adhesions and can be inserted using the less invasive Seldinger technique. Adhesions are commonly seen in patients who have had chest drainage for pneumothorax but do not preclude the possibility of lung transplantation.<sup>441</sup> Underwater drainage is maintained until the drain has stopped bubbling and a CXR has shown the lung to be re-inflated, whereupon the drain is removed. Pneumothorax which persists in spite of adequate chest drainage or recurs may require pleurodesis.

### Liver disease (see also Ch. 19)

The hallmark of CF-related liver disease is focal biliary fibrosis. This may progress to multilobular biliary cirrhosis and portal hypertension. Cirrhosis or advanced fibrosis is seen in about 10% of patients who undergo liver biopsy.<sup>441</sup> The peak incidence is before or at puberty, and it is uncommon for previously unaffected adults with CF to develop liver disease. Meconium ileus and pancreatic insufficiency are risk factors for the later development of liver disease. There is no genotype–phenotype correlation with CF liver disease.

In the neonatal period, cholestatic jaundice may be seen in CF, though this is rare. Gall stones or biliary sludge are usually an incidental finding on routine ultrasound. The diagnosis of CF liver disease is frequently made late. Liver function as measured by transaminase levels are an insensitive test for CF liver disease. Children with liver disease usually develop hepatomegaly but this may be confused with a liver which is palpable as a result of air trapping in the chest and downward displacement of the diaphragm. Parenchymal changes on liver ultrasound are often noted when the diagnosis of CF is first made. Liver disease may progress to portal hypertension and splenomegaly, with thrombocytopenia. Esophageal varices can occur, leading to life threatening upper gastrointestinal bleeding. The enlarged liver and spleen can lead to pressure on the diaphragm, in turn leading to retention of secretions and mucus plugging in the lower lobes.

Some clinicians would start treatment in the presence of mild liver abnormalities on ultrasound or persistently raised transaminase levels. Ursodeoxycholic acid is a soluble bile acid which improves the flow of bile. One study has demonstrated that it improves biliary excretion in CF<sup>441a</sup>. However, although lifelong therapy is recommended, once significant liver disease has been shown, there is no evidence that ursodeoxycholic acid improves long term outcomes such as nutrition, death or the need for liver transplantation.<sup>442</sup> Patients with liver disease are usually given vitamin K supplements in an effort to reverse clotting abnormalities. Banding of esophageal varices and transjugular intrahepatic portosystemic shunting (TIPS procedure) are temporizing measures in patients with portal hypertension, which may prevent upper gastrointestinal bleeding. Patients who do bleed should be managed with high flow oxygen, correction of hypovolemia, transfusion and correction of clotting abnormalities. In addition to these general resuscitative measures, an intravenous infusion of octreotide is indicated. Octreotide is a somatostatin analog which reduces variceal bleeding by reducing the pressure in the portal vein. Liver transplantation is the only definitive treatment for cirrhosis and portal hypertension associated with CF liver disease.

### Diabetes

In the USA, 16% of patients with CF have CFRD.<sup>401</sup> The prevalence increases with age, rising to almost 30% of adults with CF. In the UK, the figure is 1% for the under 5s rising to 12% by the late teens.<sup>400</sup> Girls are affected more frequently as are patients with pancreatic insufficiency.<sup>443</sup> Patients with CFRD also have more severe lung disease, more frequent pulmonary exacerbations and poorer nutritional status.

As there is often residual islet cell function, the onset may be insidious and frank polyuria and polydipsia may be absent. CFRD should be suspected in any patient with an unexplained decline in pulmonary function or weight loss not responding to nutritional support. An annual oral glucose tolerance test is recommended as part of the annual assessment in patients over the age of 12 years.<sup>444</sup> CFRD is characterized by post-prandial hyperglycemia more frequently than by fasting hyperglycemia.

Most patients benefit from treatment with insulin, though often a once daily, long acting insulin analog such as glargine can be used alone, to aid adherence. In patients who cannot or will not take insulin, then the oral hypoglycemic agent repaglinide (which stimulates the release of insulin from the remaining islet cells) can be used but is less effective than insulin.<sup>445</sup>

### Low bone mineral density

Over half of young patients with CF have reduced bone mineral density.<sup>446</sup> This is associated with poor lung function, treatment with oral corticosteroids and CF liver disease. In CF the increase which normally takes place in bone mass in adolescence is inadequate and puberty may be delayed, leading to reduced bone mineral density in adulthood.<sup>447</sup> This can in turn lead to an increased incidence of fractures, particularly vertebral compression fractures and rib fractures.

Good nutritional care is essential to allow the physiological increase in bone mass to take place in adolescence. (A quarter of adult bone mass is acquired during the pubertal growth spurt.) Thorough dietary assessment should be undertaken to ensure good intake of energy and calcium. Vitamin D levels should be measured annually (preferably in the autumn) and vitamin D supplemented if levels are low. Adolescents should have regular pubertal assessment as part of their annual assessment. Dual energy X-ray absorptiometry (DEXA) scanning should be considered for adolescents at risk of bone disease. DEXA scanning measures bone mineral content/unit bone area and so must be corrected for height and age. Although a recent trial has demonstrated the effectiveness of the antiresorptive agent alendronate in adults with reduced bone mineral density,<sup>448</sup> this indication is not licensed in children and adolescents.

### Salt depletion

Salt depletion in young children with CF was first reported by Di Sant'Agnes in 1953 following a New York heat wave.<sup>449</sup> Di Sant'Agnes

attributed this to loss of salt in sweat and described abnormal sweat electrolyte concentrations. Salt depletion may be associated with other biochemical abnormalities which constitute pseudo-Bartter syndrome (a combination of hypochloremic, hyponatremic dehydration, with metabolic alkalosis and hypokalaemia) (see Ch. 18, p. 554). Salt supplements should be prescribed for children with CF during periods of prolonged hot weather. In young children oral rehydration solution is a suitable salt supplement.

**Other complications**

Children with CF may have transient flitting joint pain. This is caused by a nondestructive arthritis, thought to be related to immune complex formation. It usually responds to simple analgesic or anti-inflammatory treatment. It should be distinguished from hypertrophic pulmonary osteoarthropathy in patients with severe supportive lung disease and marked finger clubbing.

**TREATMENT**

Parents of a baby diagnosed as having CF will have to cope with the anxiety for their child’s future wellbeing, the practical demands of caring for an infant with CF (such as achieving good nutrition and giving chest physiotherapy), and the ‘ordinary’ stresses of coping with a young infant (sleep deprivation and social isolation). Where the diagnosis has been made by newborn screening, the parents may have had no prior inkling that their baby had a medical problem. It is therefore important to introduce CF therapy in a stepwise fashion to avoid imposing an excessive initial burden of care.

**Nutritional management**

Nutrition must be the first priority. Approximately 83% of infants identified by newborn screening will be pancreatic insufficient.<sup>421</sup> At the first visit, a test for pancreatic insufficiency should be performed, such as stool pancreatic elastase. Even where the genotype is almost invariably associated with pancreatic insufficiency (such as infants homozygous for delta F508) there are exceptions. In spite of early diagnosis through screening, infants may have signs of nutritional deficiency. A mean weight Z score of -0.5 was found at the time of diagnosis in the screened group in one study, with around two thirds of screened infants having vitamin E deficiency and one third vitamin A deficiency.<sup>421</sup>

The use of pancreatic enzyme replacement therapy (PERT) in an enteric coated microsphere formulation has revolutionized the nutritional management of children with CF. These formulations are resistant to gastric acid and therefore much more effective in reducing pancreatic malabsorption. Capsules may be opened and the granules administered to infants, mixed with a small amount of apple puree or fromage frais. Approximately 2500 U of lipase/100 ml of milk is a suitable starting dose. Mothers should be encouraged to breast-feed if they wish to do so and breast-feeding infants with CF has nutritional, immunological and psychological advantages. The dosage of PERT in breast-fed infants is as above, given with each breast-feed. Initially, infants should be reviewed very 1–2 weeks to ensure good weight gain and to troubleshoot any problems with enzyme replacement. Once steady weight gain has been achieved the interval between appointments is gradually extended, to

approximately every 8 weeks. The dose of PERT is gradually increased as the infants grows, with the weight gain and stool appearance used as a guide as to whether an effective dose is being given.

Supplements of the fat soluble vitamins A and E should be introduced early on. Vitamin A can be administered as a liquid multivitamin formulation such as Abidec®. A suitable dose for a preschool child is 0.6 ml once daily. For vitamin E supplementation, alpha tocopheryl in a 100 mg/ml suspension is suitable and 50 mg (0.5 ml) should be administered once daily.

Specific dietary advice will be needed at the time of weaning and parents may need support when the child reaches the toddler age group, when difficult eating behavior is common. Parents of young children with CF may feel very guilty when their child refuses to eat. Giving in to ‘toddler blackmail’ may lead to more difficult behavioral problems later on and sometimes a period of indifferent weight gain must be accepted at this age. Most school-aged children will be able to swallow pancreatic enzymes as capsules and this will increase their effectiveness in overcoming pancreatic malabsorption. Maximal doses of lipase should not exceed 10 000 U/kg (see p. 709 – Gastrointestinal features outside the neonatal period).

There is controversy regarding the best way of monitoring growth in children, with some units using body mass index (BMI) and others percentage weight for height. Although the absolute value for BMI is useful in adults, normal values in children change with age and the results should be recorded on a centile chart. Percentage weight for height has the disadvantage that children whose height is restricted by poor nutrition (nutritional stunting) may appear to have a near normal percentage weight for height. Current recommendations for nutritional intervention in CF are based on percentage weight for height<sup>451</sup> and are summarized in Table 20.16.

Where children with CF are failing to grow there should be a thorough re-evaluation of the child’s condition, looking specifically for the following factors:

- *Non-adherence to diet or enzyme supplements.* In the parents of young children (who adhere to treatment plans on behalf of their child) this may be due to a lack of a full understanding of CF or due to difficult social circumstances. Make sure that explanations have been given with the help of an interpreter where the parents’ first language is not English, and that illiteracy is not the reason for poor understanding. Social support and welfare advice should be followed and, where there is clearly neglect, local child protection procedures should be followed (see Ch 5). School-aged children may not take their enzymes with their school lunch because of teasing or because they do not wish other pupils to know about their CF. Teenagers may be non-adherent because they are asserting their independence – support the young person (and their parents) through the process of transition. Consider the possibility of an eating disorder in this age group.
- *Comorbidity.* Poor weight gain may be the first sign of evolving CFRD. Children may lose weight acutely during a pulmonary exacerbation. Gastroesophageal reflux is more frequent in children with CF.
- *Inadequate enzyme dosage or action.* The dose of enzyme supplements prescribed should be carefully reviewed. An upper dosage limit of

**Table 20.16** Levels of nutritional deficiency with appropriate nutritional support

Percentage weight for height (0–18 years)	Body mass index (> 18 years)	Action
90–110%	19–25	Routine support and advice
85–89%	< 19	Refer to dietician and consider supplements
or weight loss for 4 months (< 5 years)	or 5% weight loss over > 2 months	
or 6 months (5–18 years)		
or weight static for 6 months		
< 85%	< 19	Vigorous nutritional support
or falling two centiles	or 5% weight loss over > 2 months	
and no response to supplements	and no response to supplements	

10 000 U/kg has been recommended by the Committee on Safety of Medicines to reduce the risk of fibrosing colonopathy.<sup>436</sup> Fat-based dosing may give better control of malabsorption.<sup>450</sup> Enzymes work most effectively when taken before and during meals. Enzyme supplements may be inactivated in children with CF because the duodenum is relatively acid, due to the lack of bicarbonate in pancreatic secretions. This can be overcome by prescribing a proton pump inhibitor such as omeprazole.

Where each of these factors has been considered and addressed, nutritional supplements should be considered if appropriate. A recent study of oral calorie supplements has shown that the use of supplements over a 1 year period does not improve nutrition (as measured by BMI centile).<sup>451</sup> However, supplements may have a role in short term supplementation.

Where there is severe nutritional failure, then nasogastric tube or gastrostomy feeding is indicated. Nasogastric tubes are unsightly for older children. They may be passed in the evening for an overnight feed and removed in the morning but this approach suits relatively few children. 'Button type' gastrostomies are more popular than the traditional gastrostomy tube as they cannot be seen under clothing. A gastrostomy can be inserted endoscopically, in which case a tube is inserted initially and a second procedure under anesthetic is usually needed to change to a button. A gastrostomy button can be inserted as a single procedure using a laparoscopic technique. In most cases a polymeric rather than an elemental feed is appropriate. Overnight feeds are often most convenient, though smaller boluses can be given during the day. For overnight feeds, enzyme doses should be divided with half given before the feed starts and the remainder given in the morning. Care must be taken to ensure the gastrostomy is a good fit to avoid leakage of gastric juice and irritation of the surrounding skin. Conversely, children who put on weight rapidly may find that the gastrostomy becomes 'buried' in subcutaneous fat. With any form of overnight feeding, vomiting due to sputum swallowed overnight can be a problem during pulmonary exacerbations. In these circumstances the feed volume should be reduced or the feed temporarily stopped. The volume is then gradually increased once antibiotics and physiotherapy have begun to take effect.

### Chest physiotherapy

Chest physiotherapy, aimed at the clearance of airway secretions, is recommended for all children with CF from diagnosis. For young infants twice daily chest physiotherapy, using percussion and postural drainage, has previously been recommended. Recently, practice has changed, as newborn screening has become more widespread, and babies rarely have chest symptoms at diagnosis. Currently once daily physiotherapy is recommended for young children who are asymptomatic, with therapy given more frequently if the child develops a cough or appears chesty. Parents are taught to perform chest physiotherapy on their children shortly after diagnosis. There is an urgent need for a large, well designed RCT of chest physiotherapy for infants with CF diagnosed by newborn screening. A systematic review which looked at cross-over studies of physiotherapy techniques, has shown that physiotherapy increases clearance of secretions from the airway in CF.<sup>452</sup> There is evidence that percussion and postural drainage is associated with gastroesophageal reflux in infants and some authorities recommend modified chest physiotherapy for infants with CF where the child is not 'tipped'.<sup>453</sup>

As children mature and become more independent, they should be encouraged to use physiotherapy techniques which do not need to be administered by an adult. There are a number of approaches and the technique selected should be tailored to the individual. Techniques include: active cycle of breathing, autogenic drainage, positive end expiratory pressure and oscillatory techniques. There appears to be no difference in outcome when conventional physiotherapy is compared to these contemporary techniques and patients often prefer the more independent approach. Both conventional chest physiotherapy and airway clearance techniques are associated with improved lung function

during exacerbations.<sup>454</sup> It is sensible to combine physiotherapy with physical exercise as this introduces a fun element for younger children (trampolines and dance mats) and improves wellbeing in young people.

### Treatment of pulmonary infection

As noted above (see p. 707 – Microbiology), pulmonary infection occurs in young infants with CF, initially with *S. aureus*. In order to interrupt the cycle of infection, inflammation and lung damage which leads to bronchiectasis, some CF centers recommend prophylactic antistaphylococcal antibiotics from first diagnosis. There are marked international variations in the use of prophylactic antibiotics. In the UK prophylaxis is recommended in national guidelines<sup>455</sup> whereas, in contrast, in the USA prophylaxis has been discouraged because a RCT found an association with acquisition of *P. aeruginosa*.<sup>456</sup> A subsequent Cochrane review has found that prophylaxis is associated with fewer isolates of *S. aureus* from respiratory secretions when given continuously for the first 3 years of life<sup>457</sup> and with no significant association with *P. aeruginosa*. However, there are few data on the use of prophylaxis beyond 3 years of age and longer term data are required in order to resolve this issue. In children over the age of 3 years, intermittent infection with *S. aureus* or with other organisms such as *H. influenzae* should be treated with an appropriate course of oral antibiotics. Similarly, children with a persistent cough and negative cough swab or sputum samples should receive empiric antibiotic treatment based on the last positive respiratory culture.

Where *P. aeruginosa* is found either for the first time or in patients not chronically infected with *P. aeruginosa*, then vigorous attempts should be made to eradicate the organism. Treatment with nebulized tobramycin has been shown to be effective, though the duration of treatment has varied from 1 to 12 months.<sup>458</sup> Treatment with a 3-week course of oral ciprofloxacin and nebulized colistin is also effective, with benefit seen up to 2 years after treatment.<sup>458</sup> The Danish center, where this combination eradication treatment was developed, recommends 3 months of treatment for isolates of *P. aeruginosa* in patients not chronically infected.<sup>459</sup>

Chronic pulmonary infection with *P. aeruginosa* will eventually occur in most CF patients and when it does, patients should receive vigorous early treatment for respiratory exacerbations. It has been difficult to find a consensus over what should be considered the most important features of such an exacerbation. However, in a prospective study the following clinical features were found to be important predictors, when compared with a 'gold standard' of physician diagnosis:<sup>460</sup>

- decreased exercise tolerance;
- increased cough;
- increased sputum;
- decreased appetite;
- absence from school or work;
- increased adventitious sounds.

Strenuous efforts should be made to prevent pulmonary exacerbations in children with CF and a number of preventative strategies are supported by good evidence. Much of the viscosity of sputum is attributable to DNA, mostly derived from neutrophils. The recombinant enzyme dornase alfa ('DNase'), given in nebulized form, will break down DNA and produce less viscous sputum, which is easier for children to expectorate. When given once daily to young children over a 2 year period, this reduced the number of exacerbations significantly (by approximately one third).<sup>461</sup> Nebulized tobramycin, given as a maintenance therapy on a '4 weeks on/4 weeks off' basis has been shown to reduce hospitalizations by a quarter.<sup>462</sup> Although there is better evidence for the use of nebulized tobramycin in CF, many children with chronic *P. aeruginosa* infection receive maintenance treatment with nebulized colistin. An advantage of this approach is that resistance of *P. aeruginosa* to colistin is very uncommon. Azithromycin, although not active against *P. aeruginosa* in a conventional sense, also significantly reduces the number of exacerbations over a 6 month period.<sup>463</sup> Azithromycin is thought to have an anti-inflammatory action and to inhibit *P. aeruginosa* within the

biofilm. It can be taken in a single dose three times per week and so does not add greatly to the therapeutic burden. Nebulized hypertonic saline helps restore the airway surface liquid layer and encourages patients to cough. Over a 1 year period, it has been shown to reduce the number of pulmonary exacerbations,<sup>464</sup> although there is more experience with its use in adults than in children.

As well as these maintenance therapies, annual immunization against influenza is recommended in CF, though properly designed studies are lacking. There is no consensus on passive immunization against RSV in infants with CF and this is expensive. A vaccine against infection with *P. aeruginosa* is currently in phase III clinical trials.

There has been much debate as to when patients with chronic *P. aeruginosa* infection should receive intravenous antibiotics, with some centers favoring regular treatment every 3 months. This policy is not supported by evidence from RCTs,<sup>465</sup> although when regular treatment and symptomatic treatment have been compared the number of courses which patients receive is very similar, suggesting a convergence of these clinical approaches.<sup>466</sup> When intravenous antibiotics are administered, it is recommended that two antipseudomonal antibiotics are used to prevent the emergence of antibiotic resistance.<sup>455</sup> In patients with strains of *P. aeruginosa*, which show some antibiotic resistance, the choice of which antipseudomonal antibiotic to use is not easy. Laboratory sensitivities do not predict clinical response.<sup>467</sup> Commonly, two antibiotics with different and synergistic mechanisms of action are recommended, e.g. a beta-lactam (such as ceftazidime) and an aminoglycoside (such as tobramycin).<sup>455</sup> It is known that pulmonary exacerbations in patients with chronic pseudomonas infection are usually caused by the 'resident' strains of *P. aeruginosa* rather than a new strain and so initial treatment can be based on previous microbiology results, while current microbiology is awaited.<sup>468</sup> Conventionally, antibiotics are administered for between 10 d and 2 weeks. For patients who are well enough, intravenous antibiotics can be administered at home, with less disruption to schooling and reduced costs.<sup>469</sup> In recent years efforts have been made to simplify antibiotic regimens. Once daily aminoglycoside dosing is more convenient to administer than conventional three times daily dosing (particularly for patients receiving intravenous antibiotics at home) and has been shown to be equally effective with less renal toxicity in children.<sup>470</sup> Whichever antibiotic regimen is chosen, good supportive therapy must be ensured, with chest physiotherapy targeted at areas of consolidation and mucus plugging, and good nutritional support. Children who are admitted for treatment of pulmonary exacerbations of CF spend a long time in hospital compared to children admitted for other reasons. A pleasant and appropriate ward environment, with the opportunity to continue schooling (or for preschool children to take part in play activities), are crucial to a good recovery. Young people with CF benefit from peer support in these circumstances. Where this cannot be from other young people with CF (because of the risk of cross-infection), then support from young people with other chronic illness can be just as helpful.

When the response to conventional antibiotic therapy for a pulmonary exacerbation is poor, a thorough review of clinical status and treatment is required. Mucus plugging can lead to lobar collapse and a CXR is indicated. Initial treatment of mucus plugging is with continuing antibiotics and physiotherapy with the addition of oral steroids and dornase alfa. Bronchoscopy and suction of mucus plugs under direct vision may be needed.

Clinical review should include the search for other organisms. Children with pulmonary infiltrates on the CXR and a poor response to antibiotics should be investigated for allergic bronchopulmonary aspergillosis. This is likely where there has been a four-fold rise in total IgE (particularly to above 500 IU/ml) and there are positive aspergillus precipitins.<sup>471</sup> Treatment is with prednisolone 0.5–1 mg/kg once daily for 2–3 weeks, combined with itraconazole (3–5 mg/kg once daily or 200–400 mg for children over 12 years), changing to the same dose of prednisolone alternate daily for 2–3 months. A good response to treatment is indicated by improved symptoms, resolution of CXR changes and a fall in the total IgE level.

Nontuberculous mycobacterial lung infection can occur in children with CF (primarily with *Mycobacterium avium* and *M. abscessus*). These infections become more common as patients get older, with an estimated prevalence of 13% in CF patients who are over the age of 10.<sup>472</sup> Prolonged treatment is required with a combination of agents determined by the organism identified.

Effective antibiotic therapy of *B. cepacia* complex is difficult. Meropenem has some activity and should be combined with a second antibiotic.<sup>473</sup>

## MONITORING PROGRESS

### Annual assessment

The annual assessment is an opportunity to step back and take an overview of the progress that a child or young person has made in the last year. This is a multidisciplinary process, with assessments (where appropriate) made by the clinician, CF dietician, physiotherapist, specialist nurse, pharmacist, social worker and clinical psychologist. It is also a two-way process with the child and his/her family given the chance to discuss the results of investigations and any concerns.

The following investigations are recommended at annual assessment:

- weight, height and BMI. These should be plotted on the appropriate centile chart and progress over the last year reviewed;
- CXR, scored using a recognized scoring system;
- Shwachman Kulczycki score;<sup>474</sup>
- spirometry with more detailed pulmonary function (e.g. bronchodilator test) if indicated;
- blood tests including: full blood count; prothrombin time; liver and renal function; vitamin A, D and E levels; total IgE and aspergillus-specific IgE;
- glucose tolerance test in patients over 12 years;
- sputum for routine pathogens and atypical mycobacteria.

Conventional liver function tests are relatively insensitive for detecting CF liver disease and clinicians should have a low threshold for requesting a liver ultrasound.

It has been suggested that an annual HRCT scan may allow early diagnosis of mucus plugging and bronchial thickening in CF, which may be missed on a conventional CXR. Scans may be limited to six slices to reduce radiation exposure. However, limited CT scans still involve a higher radiation burden than a conventional CXR and an annual CT scan would only be justified if there were evidence that this approach will change management and improve outcome.<sup>475</sup>

### Monitoring response to treatment during a pulmonary exacerbation

As well as the overview provided by the annual assessment, it is helpful to monitor the short term response to treatment, particularly for pulmonary exacerbations. All CF centers will measure pulmonary function and weight before and during intravenous antibiotic treatment. New inflammatory markers such as serum calprotectin and human neutrophil lipocalin (both of which measure neutrophil driven inflammation) are being evaluated in CF. Sputum markers such as arginase may also be useful.

## MANAGEMENT OF ADVANCED DISEASE

### Artificial ventilation

While ventilation cannot be recommended for end-stage lung disease it may be considered during severe pulmonary exacerbations, when recovery is considered likely or as a bridge to transplantation. Non-invasive ventilation is preferable to endotracheal intubation, as children receiving non-invasive ventilation can talk, can perform chest physiotherapy and the ventilatory support can be given intermittently, with rest periods. If non-invasive ventilation is likely to be necessary, it is essential to prepare for this possibility in advance, in order to identify a correctly fitting mask and allow the child to become familiar with the technique. The outcome of any form of ventilation in children is better than in adults.<sup>476</sup>

## Lung transplantation

Lung transplantation is the only definitive treatment for end-stage CF lung disease. Many clinical and psychosocial factors should be considered when referring for transplant assessment. However, patients with a FEV<sub>1</sub> of less than 30% predicted have a 50% risk of dying within 2 years<sup>477</sup> and when lung function deteriorates to this level, transplantation should be discussed with the family. Sequential double lung transplantation is currently the procedure performed most frequently. Figure 20.29 shows the CXR appearance in a child before and after transplantation. Figures from the International Society for Heart and Lung Transplantation ([www.ishlt.org](http://www.ishlt.org)) give a 5 year survival after lung transplantation of around 40%, but 5 year survival of up to 57% is reported by some centers.<sup>478</sup>

Although CF causes generalized bronchiectasis, in some patients one lobe or one lung is more severely affected. This area of the lung can act as a reservoir of infection, which can spread to other, less severely affected lobes. The disproportionate inflammatory response, due to uncontrolled infection in this area, may lead to anorexia, malaise and cachexia, attributable to inflammatory cytokine production. In selected cases, lobectomy or pneumonectomy may be an acceptable alternative to transplantation (Fig. 20.30).<sup>479</sup>

## Palliative care

After a full discussion of treatment options for advanced disease, some children or young people and their families may not wish to be evaluated for lung transplantation or other interventions such as non-invasive ventilation or major lung surgery. In these cases comprehensive and well planned palliative care is essential. This will usually be delivered by the CF team alone or in collaboration with a generic palliative care team. The aim of treatment is no longer to arrest the decline in pulmonary function but to provide good symptom relief. Many of the treatment options will be the same as those used during the active phase of treatment – antibiotics and physiotherapy are an excellent way of relieving symptoms of cough and dyspnea. However, the setting for treatment (hospital vs home) and its duration will be determined by the wishes of

the patient and family. Opiates may be helpful for the management of chest pain and dyspnea and, if the child or young person is in hospital, clear advanced directives describing the resuscitation plan to be followed in the event of a sudden deterioration or respiratory arrest need to be agreed with the patient, his/her family and the caring team. Local practice guidelines should be followed.

## THE FUTURE

There are undoubtedly many reasons for the improvements in survival in CF seen over the last four decades. These include: the establishment of CF centers<sup>480</sup> (including shared care with local hospitals); improved formulations of pancreatic enzyme supplements; vigorous antibiotic therapy to eradicate or treat *P. aeruginosa*; and the establishment of dedicated adult CF centers. However, these improvements in survival have been achieved at a price. Center care is associated with improved nutrition but patients may acquire chronic infection with *P. aeruginosa* earlier in life.<sup>480</sup> Some units which practice regular intravenous antibiotic treatment have better survival<sup>403</sup> but antibiotic treatment exerts selective pressure and produces resistant organisms which may be transmissible between patients. Adverse effects of intravenous antibiotic treatment include allergy, renal failure and deafness. Diabetes and reduced bone mineral density cause substantial morbidity in adults with CF.

Although the CF gene was identified in 1989, there is still no practical therapy based on this discovery which can be used in the clinic. However, a phase II clinical trial of liposome based gene therapy is now ongoing, and the Therapeutic Development Network, of the US CF Foundation is undertaking high throughput screening for novel compounds which may modify CFTR function. Whether or not these developments deliver practical therapies for people with CF, the quality of life and life expectancy for CF patients will still depend on ensuring that current best practice is followed. Accreditation or peer review of CF units will help ensure a uniform high standard of care for patients, irrespective of where they live, and will help the CF team make the case

Fig. 20.29 Chest radiographs of a 13-year-old patient with CF. (a) Before transplantation, showing widespread nodular-cystic shadowing and complete collapse of the left lower lobe due to mucus plugging. (b) After transplantation.

Fig. 20.30 Chest radiographs of a CF patient who had a right pneumonectomy at the age of 7 years. (a) Before pneumonectomy (aged 6 years) showing complete collapse of the right lung due to mucus plugging. (b) After pneumonectomy (aged 12 years) showing mediastinal shift to the right and scoliosis.

for adequate funding of their services. Newborn screening allows therapy to be started early and it would be hoped that this can be linked to a program of RCTs and cohort studies so that therapies where evidence is inadequate can be fully assessed. This should reduce the burden of care by discarding ineffective or harmful interventions whilst concentrating on effective therapies.

## RESPIRATORY INFECTIONS

Although mortality from respiratory infections in previously healthy children is now rare in the UK, respiratory infections continue to account for a large number of hospital admissions, one half of all illnesses in preschool children and one third of GP attendances. A preschool child has, on average, six to eight respiratory infections per year, ranging in severity from mild colds to severe lower respiratory infections, such as bronchiolitis. Lower respiratory tract infections (LRTIs) are commonest in the first year of life and then decline in incidence during subsequent years.

### UPPER RESPIRATORY TRACT INFECTIONS

Upper respiratory tract infections (URTIs) are common and, although rarely fatal, are a source of considerable morbidity, especially in young children. URTIs account for 95% of all respiratory infections and include colds, pharyngitis, tonsillitis, otitis media, sinusitis, croup and epiglottitis.

#### The common cold

The common cold is a short, mild and usually self-limiting illness. However, it has a substantial impact in terms of school absence and complications, including secondary bacterial infection and exacerbation of underlying respiratory conditions such as asthma and CF. Children may have up to 12 colds per year, usually acquired from day care or from siblings. The causative organisms of the common cold are viruses of which there are more than 200 types, the most common being rhinovirus, responsible for up to 40% of cases.

#### Clinical features

The common cold is characterized by rhinorrhea, sore throat, cough, fever and malaise lasting up to 7 d and often a lingering mucopurulent nasal discharge. Otitis media may be a complicating feature, often with secondary bacterial infection. In infants colds may manifest as irritability, snuffles and difficulty with feeding. Infants under 3 months of age are particularly susceptible to rapidly evolving secondary bacterial LRTI, and other infections such as septicemia, meningitis and pneumonia should be considered in infants with poor feeding. Allergic rhinitis is sometimes difficult to distinguish from the apparent permanent colds of toddlers, but is characterized by a clear watery nasal discharge with a pale nasal mucosa. The discharge associated with a foreign body is unilateral, purulent, foul-smelling and blood-stained. Other diseases may present with a nasal discharge, including primary ciliary dyskinesia and immune deficiencies.

#### Treatment

Many interventions for the treatment and prevention of colds have been studied since the 1940s. There is no evidence to support treatment with antibiotics to hasten clinical improvement or to reduce the number of days missed from school or work.<sup>481</sup> Some antiviral agents have been shown to be useful in prevention of colds and further assessment of these agents, focusing on non-virus-specific compounds, is necessary. Evaluations of nonspecific measures such as Echinacea, humidified air, nasal decongestants, vitamin C and zinc have reported some positive results but there is insufficient evidence to recommend any of these for the treatment or prevention of colds.

#### Acute otitis media (see also Ch. 32)

Acute otitis media is one of the most frequent diseases in early infancy and childhood. The peak incidence is between 6 and 15 months. Although for most children acute otitis media is a disease which resolves spontaneously, it represents a large health burden and a substantial amount of money is spent on antibiotics to treat this disease. Secondary bacterial infection is common following a viral URTI. *H. influenzae*, *Streptococcus*

*pneumoniae*, *Moraxella catarrhalis*, *M. pneumoniae* and occasionally Gram negative bacteria, particularly in the neonatal period, are the most likely bacterial pathogens.

### Symptoms and signs

Non-specific symptoms such as fever, poor feeding, irritability, diarrhea and vomiting are presenting features of an infant with otitis media. An older child will complain of earache. On examination, a red, dull, bulging tympanic membrane suggests acute suppurative otitis media. Hemorrhagic bullae on the surface of the eardrum suggest *M. pneumoniae* infection. Rupture of the membrane may follow, often with dramatic relief of pain.

### Complications

Meningitis and mastoiditis are rare but important complications. Chronic suppurative otitis media has in the past been attributed to inadequate treatment of the acute infection but this relationship remains unclear. Temporary hearing loss at all sound frequencies is common.

### Treatment

Analgesia and antipyretics should be used for symptomatic relief. Topical analgesia may be useful.<sup>482</sup> Although there is limited evidence to support this intervention, one RCT reported a 25% reduction in pain 30 min after instillation of anesthetic ear drops compared with placebo.<sup>483</sup>

Despite a large number of published clinical trials, there is no consensus on the use of antibiotic therapy for acute otitis media. The primary considerations are whether treatment with antibiotics is justified and, if so, what is the optimal duration of treatment. As most cases will resolve spontaneously, any benefit must be weighed against possible adverse reactions and the emergence of bacterial resistance.

The decline in suppurative complications of otitis media in North America and Europe during the 1940s and 1950s was attributed to antibiotic therapy. However, evidence since then suggests that long term outcomes are similar in antibiotic treated and untreated children with acute otitis media living in resource rich countries.<sup>484</sup>

A recent meta-analysis that pooled the results of 10 studies suggested that, in comparison with placebo, antibiotic treatment of acute otitis media in children is associated with a small benefit in reduction of pain at 2–7 d into the illness.<sup>485</sup> A semi-randomized trial in Sweden in 1954<sup>486</sup> reported a rate of mastoiditis of 17% in an untreated group compared with none in the penicillin treated group. However, this was excluded from the above meta-analysis because of significant methodological flaws. Another systematic review concluded that 60% of children will improve spontaneously after 24 h without any treatment and 80% of cases will resolve within 3 d.<sup>487</sup> A further review has reported that a short course of antibiotics (< 7 d) is as effective as a longer course (7 d or longer) for the treatment of uncomplicated acute otitis media in children.<sup>489</sup>

In cases where the child is not toxic and the parents are in agreement, it may be reasonable to delay antibiotic prescribing unless pain and/or fever persist for 2 d. This practice has resulted in a decreased use of antibiotics in children without significant adverse effects.<sup>489,490</sup> The American Academy of Pediatrics and the American Academy of Family Physicians have recently published a clinical practice guideline recommending this approach in selected children over 6 months old.<sup>491</sup>

Current evidence does not support the use of decongestants or antihistamines for otitis media. No additional benefit has been demonstrated in terms of symptom relief or prevention of complications and an increased risk of adverse effects has been reported.<sup>492</sup>

### Pharyngitis and tonsillitis

Sore throat is a common complaint and is usually associated with URTIs. Although it is usually a self-limiting problem, it causes significant morbidity, school absence and high consultation rate in general practice, resulting in a large number of antibiotic prescriptions.

### Etiology and diagnosis

Most sore throats have a viral etiology, especially in children under the age of 3 years. Viral pathogens include adenovirus, influenza and parainfluenza, Coxsackie A and Epstein–Barr virus (EBV), which are the causes of herpangina and glandular fever respectively. The primary bacterial etiology is Group A beta-hemolytic streptococcus. It is difficult to distinguish clinically between viral and bacterial sore throat and results of throat swab culture correlate poorly with symptoms. A purulent exudate over the tonsils does not signify a bacterial etiology, but a membrane may be suggestive of EBV or diphtheria. Petechial hemorrhages on the palate and cervical lymphadenopathy are nonspecific signs which often accompany pharyngitis. Interpretation of throat swabs is complicated by the 40% asymptomatic carriage rate in the general population. Rapid antigen tests may be used but these tests have low sensitivity and have not changed practice in primary care.<sup>493</sup>

### Treatment

The majority of children with sore throats require only symptomatic treatment with simple analgesia. A recent meta-analysis concluded that antibiotic treatment of sore throats reduced the number of complications, including glomerulonephritis, rheumatic fever, acute otitis media, acute sinusitis and quinsy.<sup>494</sup> However, the incidence of these complications in the UK is low and the evidence does not support the routine use of antibiotics to prevent complications. Penicillin has been shown to have a small benefit in providing symptomatic improvement in children with severe symptoms of sore throat, but is not recommended for routine use.<sup>495</sup> If Group A beta-hemolytic streptococcus has been isolated, a 10 d course of penicillin or a shorter course of a cephalosporin or macrolide may be effective. The convenience of once or twice daily dose regimens of cephalosporins should be balanced against the potential for the emergence of resistant strains of streptococcus.

The effectiveness of tonsillectomy for the treatment of recurrent tonsillitis has not been formally evaluated.<sup>496</sup> Tonsillectomy has a significant perioperative complication rate of around 1–2%, but there are suggested benefits for children, not only in reducing the number of sore throats, but for general health including growth. Tonsillectomy is generally considered if a child has had more than six to seven significant recurrences over 1–2 years despite antibiotic treatment, has significant obstructive sleep apnea, or has had two or more peritonsillar abscesses.

### Diphtheria (see also Ch 28, p. 1213)

Diphtheria is an acute, communicable disease caused by *Corynebacterium diphtheriae*. Despite the success of mass immunization in many countries, diphtheria remains an important cause of mortality. Early, accurate microbiological diagnosis and identification of contacts and carriers are imperative since delay in specific treatment may result in death. Recent developments have focused on methods of detection of the potent exotoxin produced by *C. diphtheriae*, the definitive test for the diagnosis of diphtheria.

### Symptoms and signs

The possibility of diphtheria should be considered in the differential diagnosis of sore throat, especially in patients traveling from Eastern Europe, the Indian subcontinent and South East Asia. The incubation period is 1–6 d and it is possible that travelers may arrive in the early stages of the disease. Diphtheria is characterized by local growth of the bacterium in the pharynx with pseudomembrane formation. The membrane becomes greenish–black and firmly adherent and can involve the tonsillar zones, larynx, soft palate, uvula and nasal cavities. Less commonly, bacterial growth can occur in the stomach or lungs; systemic dissemination of toxin then invokes lesions in distant organs. When the membrane involves only the nasal septum the disease is relatively minor. However, extension to the larynx causes stridor and upper airway obstruction. Prior to immunization, laryngeal diphtheria was the commonest indication for tracheostomy in Britain. The patient presents with a sore throat, stridor, fever and general malaise. The clinical features may be indistinguishable from epiglottitis.

### Treatment

Infected children should be isolated and urgent attention should be given to protecting the airway, with a team on standby for tracheostomy if necessary. Treatment is with antitoxin 5000–30 000 U intravenously and systemic penicillin 4 hourly. Erythromycin can be used to treat carriers. More details are given in Chapter 28.

### Whooping cough (see also Ch. 28)

Whooping cough, or pertussis, is a respiratory infection caused predominantly by the bacterium *Bordetella pertussis*. A wide range of other respiratory pathogens can cause a similar illness, including *Bordetella parapertussis*, RSV, adenovirus, *M. pneumoniae* and *Chlamydia trachomatis*. *B. pertussis* is transmitted by respiratory droplets and causes disease only in humans. The incubation period is around 7–10 d.

Whooping cough is underdiagnosed by pediatricians and family doctors. Early diagnosis and prompt public health notification allows review of vaccination programs and can lead to more effective treatment and control measures, such as prophylaxis for contacts at risk, thus preventing further cases and avoiding inappropriate investigations.

### Symptoms and signs

The onset of cough is preceded by a catarrhal stage of fever and coryza, which can be easily missed. The catarrhal prodrome is the most infectious stage of the illness. The onset of a hacking cough is often nocturnal before becoming constant and occurring in paroxysms, classically rising in pitch and terminating with a whoop and/or vomiting. Between coughing spasms, the child may look well, but the cough can be forceful enough to precipitate petechiae, subconjunctival hemorrhages, pneumothorax and subcutaneous emphysema, rib fractures or rectal prolapse. After the acute phase of the disease, many patients continue to cough for prolonged periods, sometimes for several months. Adolescents and adults may present with typical disease but more frequently with isolated prolonged cough. Complications include pneumonia, failure to thrive from post-tussive vomiting, seizures, encephalopathy, secondary bacterial infection and pulmonary hypertension.

Infants are a particularly vulnerable group. There is little placental transfer of passive immunity to pertussis and, until primary vaccination is completed at 4 months, this age group is at risk if exposed. There is often a household contact with pertussis, often the mother, which may be proven by culture, or detailed enquiry may reveal a history of concurrent paroxysmal cough. Presenting features in infants include nonspecific cough, poor feeding, vomiting, cyanosis, apnea and bradycardia, usually without the characteristic paroxysmal cough or whoop. This can make the diagnosis difficult and it is often confused with bronchiolitis. Despite intensive care treatment, there is still significant mortality, particularly in infants requiring mechanical ventilation. There is a high rate of major complications such as bacterial pneumonia, pulmonary hypertension, air leaks, seizures and encephalopathy. Pertussis can occasionally be the cause of sudden infant death.

### Diagnosis

The gold standard for the diagnosis of *B. pertussis* is culture of the organism from pernasal swab or nasopharyngeal aspirate. The sensitivity of this technique decreases the later the sample is taken after the onset of the illness, but can be increased by using the PCR technique. If more than 2 weeks after disease onset, serology for pertussis toxin IgG may be more useful. There is a characteristic peripheral blood lymphocytosis and extreme leukocytosis may be an independent predictor of mortality in the neonatal age group.<sup>497</sup> Chest X-rays may demonstrate pulmonary infiltrates, particularly in the perihilar region. These may represent excess secretions, which can lead to areas of atelectasis and compensatory hyperinflation of other lung regions.

### Treatment

Pertussis is highly infectious and barrier nursing of hospitalized patients must be enforced. Assisted ventilation may be needed for respiratory failure or prolonged apnea.

A macrolide is the antibiotic of choice for clearance of *B. pertussis* infection on culture; however, it is most effective during the catarrhal stage of the disease. There is probably no effect on outcome if started more than a week after onset of the illness. A 14 d course of erythromycin has been the treatment of choice but shorter-course macrolide antibiotics (e.g. azithromycin, clarithromycin) may be as effective with fewer adverse effects and improved adherence to therapy.

Early phase I clinical trials of an intravenous pertussis immunoglobulin have indicated that this preparation is safe and achieves high levels of pertussis toxin antibody titers in infants.<sup>498</sup> There is no RCT evidence to support the use of salbutamol (albuterol) for the treatment of pertussis.<sup>499</sup>

In view of the high rate of secondary transmission of the organism to household members, macrolide antibiotics have been used as chemoprophylaxis for close contacts of the primary case to protect non-immunized or partially immunized infant contacts, who are at risk of severe disease. A review of the evidence for the use of erythromycin in preventing secondary transmission showed very little benefit, compared with the protection conferred by the vaccine.<sup>500</sup> Therefore, it should probably be reserved for vulnerable contacts only. Further blinded RCTs of erythromycin prophylaxis should consider shorter courses of erythromycin as well as the newer macrolide antibiotics, which have fewer adverse effects. For prevention see Chapter 28, p. 1197.

## INFECTIONS CAUSING UPPER AIRWAY OBSTRUCTION

The major infective causes of upper airway obstruction are croup, epiglottitis and bacterial tracheitis (Table 20.17). Rarer causes include retropharyngeal abscess, cellulitis or severe tonsillitis. Other causes of stridor include foreign body aspiration, angioneurotic edema, vallecular cyst or abscess, inhalational burns, diphtheria, epiglottic hemangiomas or other congenital abnormalities.

### Croup

Croup (laryngotracheobronchitis) is a common cause of airways obstruction in children. The term croup refers to a clinical syndrome characterized by a barking cough, inspiratory stridor and hoarseness of the voice. These symptoms are thought to be due to edema of the larynx, trachea and bronchi as a result of a viral infection, hence the term laryngotracheobronchitis. Parainfluenza types 1 and 2 are the most common infecting organisms, but rhinovirus and RSV can also cause croup. Although croup is a self-limiting illness, it causes frequent visits to GPs and hospital emergency departments and often results in hospitalization. Although severe croup occurs infrequently, early recognition of the signs of severe airways obstruction is important.

### Symptoms and signs

Coryzal symptoms are followed over 12–24 h by a harsh, barking cough. Stridor is most evident when the child is upset and the parents often report that the onset of symptoms is at night, when the child is woken in the early hours of the morning by cough and stridor. The symptoms may reach a peak on the second or third night. Usually, croup resolves spontaneously over a 3–4 d period. Certain groups of children such as those with pre-existing subglottic stenosis following prolonged neonatal ventilation or those with Down syndrome may be at greater risk of severe croup. In patients with atypical features, e.g. those aged over 6 years or with a high fever, alternative diagnoses such as epiglottitis, bacterial tracheitis, retropharyngeal abscess or inhaled foreign body should be considered.

### Assessment of severity

Laboratory and radiological investigations are unhelpful. The decision to treat or admit to hospital is based on clinical features and an assessment of the severity of the croup. Signs of a severe episode of croup include evidence of hypoxemia such as restlessness and cyanosis, and signs of airways obstruction such as subcostal and intercostal recession. The intensity of the stridor itself is a poor indicator of severity. A child with a low oxygen saturation in air is likely to have severe upper airway

Table 20.17 Clinical presentations of upper airway obstruction due to infections

	Croup	Epiglottitis	Bacterial tracheitis
Age	1–2 years	2–6 years	Throughout childhood
Causative organism	Parainfluenza	<i>Haemophilus influenzae</i>	<i>Staphylococcus aureus</i> <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i>
History	Onset 1–2 d Coryza Barking cough	Onset < 24 h Sore throat Dysphagia	Onset < 24 h Rattling cough Sore throat
Signs	Fever < 38.5 °C Nontoxic Harsh stridor Hoarse voice	Fever 38–40 °C Toxic Upright position Open mouth, drooling Muffled stridor	Fever 38–40 °C Toxic Mucopurulent secretions Absent or soft stridor
Course	Resolves 4–10 d Intubation < 3%	All need intubation	Intubation in > 80%, often > 1 week
Treatment	Steroids Adrenaline (epinephrine)	Cephalosporin	Cephalosporin

obstruction. Some units use croup scores to grade the severity and to guide treatment and the decision to admit to hospital.<sup>501</sup>

## Management

The most important aspect in the management of children with croup is airway maintenance.

Children with mild croup, i.e. barking cough with no clinical signs of obstruction, require reassurance. There is no evidence that steroids have a place in the management of this group. Recent trials have shown that mist/humidified air provides no additional symptom improvement, nor does it alter the overall course of the disease process.<sup>502,503</sup>

**Steroids.** The results of meta-analysis have shown that treatment with steroids is effective in improving the symptoms of croup in children, with improvement in croup severity scores, shorter hospital stay, fewer admissions to intensive care units (ICUs) and decreased use of adrenaline (epinephrine).<sup>504</sup> The evidence supports all children with croup and increased effort of breathing, i.e. accessory muscle use and/or stridor at rest, being treated with corticosteroids.<sup>505</sup>

The most frequently studied classes of steroids in croup have been dexamethasone and budesonide. Dexamethasone is a potent steroid with an anti-inflammatory ratio of 5:1 compared with prednisolone. It can be administered either by mouth or intramuscular injection. Budesonide is a synthetic glucocorticoid with a lower bioavailability than beclomethasone because of its hepatic first-pass clearance. Most of the nebulized dose is deposited in the upper airway, the point of maximal inflammation in croup. No significant difference in efficacy has been demonstrated comparing oral or intramuscular dexamethasone with nebulized budesonide<sup>506</sup> and both treatments are effective as early as 6 h and for up to at least 12 h after administration. Oral dexamethasone (0.6 mg/kg) may be the best treatment option because of its ease of administration, widespread availability and lower cost. In a child who is vomiting, nebulized budesonide (2 mg) or i.m. dexamethasone may be preferable.

**Adrenaline (epinephrine).** Adrenaline is a potent stimulator of alpha and beta-adrenergic receptors. In patients with croup, it is believed to provide short term benefit due to its ability to reduce bronchial and tracheal secretions and mucosal edema. It is not a definitive treatment but may allow time for the underlying pathology to resolve. Nebulized adrenaline (5 ml of 1:1000 solution) should be considered for children with croup who have moderate to severe respiratory distress, i.e. accessory muscle use, stridor at rest and/or signs of hypoxemia. The onset of action has been observed as early as 30 min after treatment and its duration is around 2 h.<sup>507</sup> Because of the relatively short duration of action, patients may have rebound symptoms as the effects of the drug wane, although this may also indicate progressive worsening of the croup.

Glucocorticosteroids should therefore be given contemporaneously with adrenaline to attenuate rebound and patients given adrenaline should be observed carefully for at least 2 h. There is some evidence that it is safe to discharge improved patients after a period of observation.<sup>508</sup>

## Epiglottitis

Epiglottitis is an airway emergency with a high risk of acute complete obstruction of the upper airway. Its primary cause is *H. influenzae* type b (Hib). The epiglottitis is characteristically swollen, edematous and cherry red. The introduction of the conjugate Hib vaccine to the UK primary immunization schedule in October 1992 has substantially reduced the incidence of epiglottitis. However, there continue to be sporadic cases due to vaccine failure<sup>509</sup> and clinicians should continue to have a high index of suspicion, even in a fully vaccinated child. Other pathogens include *Streptococcus*, *Staphylococcus* and *Klebsiella*.

Hib has been shown to be an important cause of life threatening childhood infections worldwide. Epiglottitis is the second most common of these in industrialized countries and accounts for 10% of Hib infections worldwide with meningitis being the most common (52%). Epidemiological data from 19 countries before implementation of routine immunization showed average incidences of epiglottitis of 13 per 100 000 in children aged 0–4 years and 5 per 100 000 in those aged 0–14 years, with higher rates in Sweden and parts of Australia and lower rates in resource rich countries. Worldwide there were 12 000 cases per year and 400 deaths, i.e. a 2.5% mortality.

## Prevention

Conjugate vaccines against Hib were introduced in the late 1980s and have been shown to have an efficacy exceeding 90% from the first months of life.<sup>510</sup>

Introduction of the vaccine has been associated with a dramatic decline in the incidence of Hib over a short period. This is partly due to the ability of the vaccine to prevent nasopharyngeal Hib colonization and thus confer herd immunity. From September 2006, children in the UK receive a dose at 2, 3 and 4 months of age and a booster at 12 months as part of the standard vaccination program. Ninety percent coverage has been achieved and the incidence of all Hib infections is now 2 per 100 000 or less in children aged 0–4 years, which represents a decline of over 97%.

## Clinical features

Differences between the presentation of croup and epiglottitis are presented in Table 20.18. Epiglottitis generally affects slightly older children, usually aged 2–6 years, although it has been reported in infants and is being increasingly recognized in adults. It may occur at any time

Table 20.18 Features of bacterial and viral pneumonias

	Bacterial	Viral
Fever	>38.5 °C	<38.5 °C
Respiratory rate	>50/min	Normal or raised
Recession	Present	Marked
Wheeze	Not usually an early sign	Often present
CXR	Consolidation	Hyperinflation Segmental collapse in 25%
Coexisting disease	Consider influenza, measles, other viruses; cystic fibrosis, immune problem if recurrent	Consider bacterial infection; aspiration if recurrent

of year, but more often in spring and winter. Children usually lack a viral prodrome and complain of a sore throat which progresses within hours to a toxic illness in which the child appears irritable, pyrexial and dyspneic. The child has dysphagia and prefers to sit forward with the neck extended and the arms forward for support to optimize the patency of the airway. There is marked intercostal and subcostal recession and use of the accessory muscles of respiration. A soft inspiratory stridor results from edema of the supraglottic mucosa and physical obstruction of the airway results in drooling and muffled voice. Fatigue develops if the obstruction is not relieved. Cyanosis and deteriorating conscious level are precursors of impending complete obstruction and respiratory arrest.

### Diagnosis

The diagnosis is made on clinical grounds and ensuring an adequate airway takes precedence over all investigations. Airway radiology should never delay definitive diagnosis and management of the airway. The full blood count shows a characteristic immature polymorphonuclear leukocytosis and blood cultures are positive for *H. influenzae* in around 50% of cases.<sup>511</sup> The yield of positive culture results from pharyngeal swab is lower than that of blood.

### Treatment

As soon as epiglottitis is suspected, preparations should be made to protect the airway and the child should be given 100% humidified oxygen. Any procedure that may cause distress to the child, such as examination of the throat, should be avoided as this may precipitate sudden occlusion of the airway due to intense vagal discharge and laryngeal spasm. Attempts should be made to provide a comfortable environment for the child with the parent present. Observation of the child or radiological confirmation of the diagnosis are not appropriate and can be dangerous, due to rapid progression of the airway occlusion. Intravenous access should be obtained only after stabilization of the airway and fluid resuscitation may be required for the toxic child.

**Airway management.** Direct examination of the larynx is indicated to exclude other causes of laryngeal obstruction such as abscesses or foreign bodies. This should be carried out under inhalational anaesthesia, with a team on standby prepared for immediate airway intervention with either an endotracheal tube or tracheostomy. This team should include a pediatrician, anesthetist and ENT surgeon and preferably the examination is carried out in the anesthetic room with the child breathing spontaneously. Nebulized adrenaline (epinephrine) may provide temporary relief, but should not be used unless measures for protecting the airway are already available and should be abandoned if it causes distress to the child. Inhalation of sevoflurane has been reported to be a safe and effective anesthetic induction agent and is better tolerated than the traditional agent halothane.<sup>512</sup>

**Antimicrobial therapy.** In addition to airway management, antibiotics are the definitive treatment for epiglottitis. Third generation cephalosporins such as cefotaxime and ceftriaxone are usually recommended to cover the increasing emergence of beta-lactamase producing strains of *H. influenzae* that are resistant to treatment with ampicillin or chlor-

amphenicol. Rifampicin prophylaxis (20 mg/kg daily for 4 d in children aged 3 months–12 years) may be recommended for non-immunized contacts and to the index case to eradicate carriage of the organism.

### Complications

Pulmonary edema following relief of the upper airway obstruction is a recognized complication and is probably due to alterations in capillary wall permeability. This can be managed by using a moderate level of continuous positive airway pressure (CPAP) or positive pressure ventilation with positive end expiratory pressure (PEEP). Other manifestations of Hib infection such as exudative tonsillitis, otitis media, pneumonia, meningitis, pericarditis and septic arthritis have been observed to coexist with epiglottitis.

### Bacterial tracheitis

Bacterial tracheitis is a severe condition characterized by acute upper airway obstruction and purulent secretions within the trachea. Affected children can present at any age with a fever, sore throat, hoarse voice and soft stridor. The onset of symptoms is often acute. Prolonged endotracheal intubation is often required and severe septicemia may follow with associated high mortality and morbidity. *S. aureus* is the commonest organism involved, with Group A *Streptococcus* and *H. influenzae* also identified. There is a suggestion of an epidemiological change in recent years towards a less morbid condition in which children are less toxic and require intubation less frequently, with *M. catarrhalis* and viral causes becoming more common.<sup>513</sup> Diagnosis is usually made at laryngoscopy by visualization of the inflamed trachea and the presence of purulent secretions and a pseudomembrane. Secretions can be collected for culture. Treatment is with supportive airway management with intensive care if necessary and a broad spectrum, intravenous antibiotic.

## LOWER RESPIRATORY TRACT INFECTIONS

Lower respiratory tract infections (LRTIs) are a common cause of mortality in developing countries and represent a major cause of morbidity among children worldwide. LRTIs account for 5% of all respiratory infections and include bronchiolitis, pneumonias and exacerbations of respiratory exacerbations in bronchiectasis. One in four children has a LRTI in the first year of life. Differential diagnoses include CF, aspiration associated with gastroesophageal reflux or H-type tracheoesophageal fistula.

### Bronchiolitis

Bronchiolitis is the commonest cause of lower respiratory tract illness in infants and is an important cause of acute and long term morbidity. The infecting organism in around 75% of cases is RSV; others include adenovirus and rhinovirus. RSV causes annual winter epidemics of respiratory disease and can also manifest as pneumonia, otitis media, croup or mild URTIs. During a single epidemic, over 70% of infants become infected with the virus and almost all infants are infected by the end of their second winter. Thirty percent of these develop lower respiratory tract symptoms and between 0.5 and 1.5% are admitted to hospital with RSV bronchiolitis.

Infants at high risk of severe RSV bronchiolitis include those born prematurely, and those with cardiovascular disease, chronic respiratory disease including bronchopulmonary dysplasia (BPD) and CF or immunosuppression.

### Clinical features

**Acute.** The peak age of infants hospitalized with RSV bronchiolitis is around 3 months. The clinical features of the illness reflect the plugging of small airways with inflammatory exudates leading to a large increase in airway resistance and a corresponding increase in work of breathing, leading to fatigue of the respiratory muscles. Characteristically there is a short prodromal upper respiratory tract illness with coryzal symptoms and low-grade pyrexia, followed by rapid onset of tachypnea, hypoxia, moist cough and difficulty feeding. Increased work of breathing is reflected by

suprasternal, subcostal and intercostal recession with head bobbing and nasal flaring. The predominant feature on auscultation is crackles with or without the presence of wheeze. As the chest becomes hyperinflated, the liver is displaced and is often easily palpable in the abdomen.

Signs of more severe illness include apnea, especially in young and preterm infants, irritability, listlessness, cyanosis and reduced conscious level. Approximately 2% of infants who are hospitalized with RSV bronchiolitis require assisted ventilation because of either an obstructive bronchiolitis or, more unusually, a restrictive pneumonia or acute respiratory distress syndrome (ARDS).

**Chronic.** Lower respiratory tract RSV infections are associated with increased respiratory morbidity in the early years of life. At 9–10 years of age, those who had RSV infection as babies have an increase in respiratory symptoms<sup>514</sup> but the mechanisms contributing to this chronic respiratory morbidity are unclear. RSV does not itself appear to lead to atopic asthma. The long term outcome can in part be predicted by the presence of wheeze during the acute illness, with those in whom wheeze is the dominant symptom having a much greater likelihood of having asthma later in life than those with classical bronchiolitis. Factors such as a family and personal history of atopy and eosinophilia appear to be the best guide to predicating who will exhibit asthmatic symptoms. In the group with acute bronchiolitis (i.e. predominantly crackles) there is an excess of symptoms generally associated with intercurrent viral infections compared with controls, but these appear to have a much better prognosis with prevalence falling rapidly through early childhood.<sup>515</sup>

### Diagnosis

Rapid identification of RSV infection can be confirmed by immunofluorescence on nasopharyngeal aspirate samples, which gives a result within hours, or by viral culture.

### Radiology

Chest radiology is unhelpful in typical cases of bronchiolitis and should be avoided unless there is an underlying illness or deterioration in clinical status suggesting the need for intensive care. Chest X-rays show hyperinflation with multiple areas of interstitial infiltration. Signs of segmental or subsegmental collapse occur in 25% and this often leads to the inappropriate use of antibiotics.

### Treatment

Current therapy for RSV bronchiolitis is primarily supportive, involving maintenance of hydration and oxygen status. Nasogastric or intravenous feeding is required if the baby is unable to suck. Oxygen saturation monitoring is necessary and oxygen should be administered via nasal prongs or headbox if the oxygen saturation falls below 92%. An increasing oxygen requirement indicates worsening disease with increasing ventilation/perfusion imbalance. Hypercapnia is a sign of exhaustion and alveolar hypoventilation and if this develops the baby should be moved to a high-dependency area or intensive care for ventilatory support.

Overall, evidence from RCTs does not support the use of additional therapies. Bronchodilators, including adrenaline (epinephrine), have not been shown to be helpful, except perhaps in reducing a clinical severity score,<sup>516,517</sup> and desaturations have been reported after salbutamol (albuterol) nebulization.<sup>518</sup> The majority of studies have demonstrated no benefit from inhaled or oral corticosteroid therapy either in the acute phase or in the prevention of post-bronchiolitic wheezing.<sup>519,521</sup> Antibiotics are not indicated except in the case of secondary bacterial infection which is rare in babies who do not need ventilatory support.

Ribavirin inhibits viral replication and is the only available antiviral agent active against RSV. Although early studies of the effect of ribavirin found some benefit, a systematic review of 10 trials showed no reliable evidence of efficacy.<sup>521,522</sup> For infants who require respiratory assistance, there is a paucity of evidence to support modes of non-invasive ventilation such as CPAP or continuous negative extrathoracic pressure (CNEP).<sup>523</sup> In severe cases, particularly infants with chronic lung disease, conventional ventilation alone may be insufficient. Extracorporeal

membrane oxygenation (ECMO) has been shown to be associated with a survival of over 50%.<sup>524</sup> Nitric oxide may improve the respiratory status of those infants with restrictive lung disease or pre-existing pulmonary hypertension by improving gas exchange, although its long term influences remain unproven. DNase may be efficacious and exogenous surfactant can improve oxygenation and may lead to a shorter duration of ventilatory support and ICU care,<sup>525</sup> although further RCTs to confirm these findings are awaited.

### Prevention

RSV is spread by direct contact with infected secretions and contaminated objects and this may be reduced by effective and appropriate hand-washing and cohort nursing. The importance of these measures in the prevention of RSV transmission should not be underestimated. There is as yet no safe and effective vaccine for use in infants. A formalin-inactivated vaccine was introduced in the 1960s but this led to more severe respiratory disease in vaccinated infants during the following season. Until an effective vaccine is developed, alternative prophylactic measures must be optimized.

Palivizumab is a humanized monoclonal antibody that provides immunoprophylaxis against serious LRTIs caused by RSV. In a double-blind, placebo-controlled trial,<sup>526,527</sup> intramuscular palivizumab 15 mg/kg every 30 d for 5 months significantly reduced RSV-related hospitalizations by 55% in infants with prematurity and/or BPD/chronic lung disease (CLD) and by 45% in infants with hemodynamically significant congenital heart disease, and was most effective in infants under 6 months born at or before 35 weeks' gestation. The number needed to treat was 17, i.e. 17 patients would need to be given monthly injections to prevent one RSV-related hospital admission. There were also fewer admissions to ICU, fewer total hospital days and fewer days with supplementary oxygen. The administration of the product appears to be safe and is easy to administer but it is costly and should therefore be reserved for infants at highest risk of severe RSV infection. Other high-risk infants in whom palivizumab has not been formally assessed, such as those with immunodeficiency and CF, might potentially benefit from palivizumab.

### Pneumonia

LRTIs are a common cause of morbidity among children in resource rich countries and a major cause of mortality in resource poor countries. Of these infections, pneumonia is the most serious and can still be difficult to diagnose because of lack of reliable diagnostic methods. The epidemiological pattern of pneumonia is constantly altering because of changes in patient characteristics, altered immune status and changes in medical practice. There is an increasing level of resistance to antibiotics by the more common pathogens such as *S. pneumoniae*. For these reasons, accurate identification and treatment of the individual etiological organisms causing pneumonia is important.

### Community acquired pneumonia

Community acquired pneumonia is defined clinically as the presence of symptoms and signs of pneumonia in a previously healthy child due to an infection that has been acquired outside of hospital.<sup>528</sup> The diagnosis can be verified radiologically by demonstrating consolidation on CXR if available.

### Etiology

Identification of the responsible organism is a challenge because of difficulty in obtaining adequate samples, lack of reliable diagnostic methods and difficulty in differentiating infection from colonization. In 20–60% of cases a pathogen is not identified and in those that are, around 14–35% appear to be caused by viruses alone and a substantial proportion (8–40%) represent a mixed infection. Age is a good predictor of likely pathogens with viruses being the most frequently identified cause in younger children. In older children, when a bacterial cause is found, it is most commonly *S. pneumoniae* (pneumococcus), followed by *Mycoplasma* and chlamydial pneumonia.

Overall, *S. pneumoniae* is the most common bacterial cause of pneumonia in childhood. The commonest viral cause is RSV with others including influenza A, influenza B, parainfluenza and adenovirus. Respiratory syncytial virus and influenza viral infections typically peak in late autumn and winter, whereas bacterial pneumonias exhibit less marked seasonal fluctuations. *Chlamydia pneumoniae* and *M. pneumoniae* occur commonly in children older than 4–5 years and increase in incidence over the age of 10 years. Nonserotypable *Haemophilus* and *M. catarrhalis* were previously considered nonpathogenic for the respiratory tract but do occasionally cause pneumonia. Enterobacteriaceae, Group A *Streptococcus* and *S. aureus* are uncommon in the immunocompetent host, but when they occur can cause severe disease including lung abscesses, empyema and pneumatoceles. Atypical organisms such as *Chlamydia* and *Legionella* species can cause disease of the lower respiratory tract in children, although these organisms are seen more commonly in adults.

### Clinical features

Pneumonia is classically characterized by rapid onset of fever, tachypnea, cough and difficulty with feeding or difficulty in breathing in the older child. These symptoms are frequently preceded by a relatively minor upper respiratory tract illness with coryza and low-grade fever. It is often difficult to distinguish those children with viral pneumonia from those with bacterial disease (see Table 20.18) and there is considerable overlap in the clinical findings in young children and infants with pneumonia and other LRT illnesses such as bronchiolitis. Bacterial pneumonia should be considered in children under 3 years of age when there is a fever of  $> 38.5^{\circ}\text{C}$  with chest recession and a respiratory rate of  $> 50/\text{min}$ . On examination, crackles on auscultation are classical, and bronchial breathing is a late sign indicating consolidation. Wheeze may also be present in viral or mycoplasma pneumonia but the presence of wheeze in the preschool child makes bacterial pneumonia unlikely. Symptoms of lower lobe pneumonia in older children may include abdominal pain, reflecting referred pain from the diaphragmatic pleura, and can occasionally lead to a paralytic ileus with abdominal distention. Upper lobe consolidation may be associated with neck pain and apparent neck stiffness. Chest pain is common and is due to accompanying pleuritis. Pulse oximetry should be performed on every child admitted to hospital with pneumonia.

### Laboratory investigations

Blood cultures should be collected on all children suspected of having bacterial pneumonia but yield an organism in only around 10–15% of cases. Only a small number of bacterial pneumonias are accompanied by bacteremia and many children receive antibiotics before reaching hospital.

Culture of respiratory specimens is the best method for identifying organisms causing pneumonia on culture. However, small children are unable to expectorate sputum and procedures such as BAL are generally regarded as too invasive to be used routinely, other than on an ICU.

*Nasopharyngeal specimens* for viral antigen detection (such as immunofluorescence) and/or viral culture should be collected from all children under the age 18 months as soon as possible, as viral shedding is maximal at the time of onset of symptoms. The presence of a virus in the upper respiratory tract does not necessarily imply that this is the cause of the pneumonia.

*Serology* can be useful in cases where no microbiological diagnosis was reached during the acute illness. Acute serum samples should be saved and a specimen for convalescent titers at 2–4 weeks is necessary, leading to a delay, and can be complex due to multiple serotypes. This method is useful for the detection of atypical species such as mycoplasma and chlamydia.

*PCR* is a technique used to amplify deoxyribonucleic acid (DNA) from microorganisms in either blood or respiratory secretions. This technique offers the possibility of a rapid bacteriological diagnosis and may be more sensitive than bacterial culture, especially if antibiotics have already been given.

Other laboratory investigations include full blood count and C-reactive protein (CRP). A high white cell count and CRP may be more suggestive of bacterial pneumonia, although there is considerable overlap so that confident prediction of the microbiological diagnosis is not possible on these variables alone and they should not be measured routinely.

### Radiology

Because the clinical features of pneumonia may be nonspecific, CXRs are often used to confirm the presence and determine the location of a pulmonary infiltrate. CXRs do not reliably distinguish between bacterial and viral pneumonias, although interstitial shadowing or peribronchial infiltrates are said to be more characteristic of a viral infection and lobar consolidation of pneumococcal disease. The radiological features of segmental consolidation are difficult to distinguish from those of segmental collapse seen in around 25% of viral LRTIs. Complete resolution of radiographic changes may take several weeks. CXRs are also used to identify associated air leaks, effusions and abscesses. Follow-up CXRs should only be performed after lobar collapse, an apparent round pneumonia, or for continuing symptoms.

### Treatment

For the management of pneumonia in children, it is important first to assess the severity of the illness and second to direct treatment against the identified or likely pathogen. These factors are important in deciding whether to withhold or to prescribe antibiotic therapy, whether the child requires admission to hospital and whether therapy should be given via the oral or intravenous route. As outlined above, definitive information about the causative organism is rarely available, and therefore empirical treatment is often necessary.

The majority of children with community acquired pneumonia can be managed in primary care. In the mildly unwell, ambulatory child, infection is most likely to be viral and therefore antibiotics can be withheld. Children with difficulty breathing, poor feeding or vomiting, intermittent apnea or grunting or who are in need of supplementary oxygen require hospital admission. Supportive measures include adequate hydration and nutrition. Antipyretics and analgesia may also be required.

Because of concerns about antimicrobial resistance, it is preferable that effective narrow spectrum agents are used wherever possible. Penicillin remains the treatment of choice for *S. pneumoniae*, and amoxicillin is the first choice oral antibiotic for children under the age of 5 years or if *S. pneumoniae* is suspected because it is effective, well tolerated and cheap. Both mycoplasma and chlamydia are susceptible to macrolide antibiotics such as erythromycin, azithromycin and clarithromycin<sup>529</sup> and these are the drugs of choice if either of these infections is suspected and in cases of penicillin-resistant strains of *S. pneumoniae*. Because mycoplasma pneumonia is more prevalent in older children, macrolide antibiotics may be used as first line empirical treatment in children aged 5 years and older. RCT evidence has also shown that an early switch to oral therapy after a short (2 d) course of intravenous therapy has comparable efficacy to a full week's course of intravenous therapy, and can reduce hospital stay and costs, with no increased adverse patient outcome.<sup>530</sup> If the child remains pyrexial or unwell 48 h after admission with pneumonia, re-evaluation is necessary with consideration given to possible complications such as a parapneumonic effusion or lung abscess.

### Prevention

The improvement in uptake of routine vaccines against Hib, *Bordetella pertussis* and influenza has had an impact on both prevention of cases of these infections in children and helping to reduce spread of cases in the community. Pneumococcus is known to be the most common bacterium isolated from children with pneumonia. The existing capsular polysaccharide vaccine (Pneumovax) is ineffective in younger children but the new conjugate vaccine (Prevenar) is immunogenic in children from 2 months of age (see Ch. 4, p. 35). This vaccine was licensed for use in infants and young children in the USA in 2000. The subsequent

introduction of the vaccine into the childhood immunization schedule led to a significant decrease in pneumococcal disease.<sup>531</sup> The vaccine is effective against invasive and non-invasive pneumococcal infection and, like all conjugate vaccines, provides long-lasting immunity. On 8 February 2006, the Departments of Health in England, Scotland and Wales announced the inclusion of Prevenar in the childhood immunization schedule. This has important implications for the future prevention of pneumococcal infection in the UK.

### ***Staphylococcus aureus* pneumonia**

*S. aureus* is an organism that is causing increasing concern as a cause of both hospital- and community-acquired pneumonia. Carriage rates in adults are around 10–40%, although this figure is lower in children. The organism produces coagulase and is also capable of producing toxins which cause different clinical presentations with varying degrees of severity.

A new pattern of severe disease due to the Pantone–Valentine leukocidin (PVL) toxin is emerging in the UK, Europe and the USA.<sup>532,533</sup> PVL is a toxin which destroys white blood cells and is rare but can be found in both methicillin sensitive and resistant strains of *S. aureus*. PVL-positive *S. aureus* can be associated with necrotizing skin lesions, cellulitis or septic arthritis but can also cause a highly lethal form of community-acquired necrotizing pneumonia carrying a mortality rate of around 40%.

PVL-associated *S. aureus* infection should be considered in cases of community acquired pneumonia in young immunocompetent, previously well adults or children presenting with fever, hemoptysis, severe sepsis and often a preceding flu-like illness. There is typically a marked leukopenia, high CRP, multilobar infiltrates on CXR and rapid clinical progression to ARDS.

Clinical management is supportive, usually requiring intensive care, in addition to early aggressive antibiotic therapy with combinations including vancomycin, clindamycin, linezolid, rifampicin and co-trimoxazole in high doses. The combination used will reflect susceptibility of individual isolates. Linezolid and clindamycin have the added advantage of suppressing toxin production. Other therapies such as intravenous immunoglobulin and activated protein C may be appropriate because of the high mortality rate. The care of the patient should include strict infection control measures.

### **Atypical pneumonia**

#### ***Mycoplasma***

*Mycoplasma* is a common cause of pneumonia in schoolchildren and young adults. Epidemics tend to occur in 4–7 year cycles with a peak incidence in autumn, thought to correspond with children returning to school. In early school years it is responsible for about 12% of pneumonia, rising to 20% in older schoolchildren and over 30% in young adults. The incubation period is 2–3 weeks. The symptoms associated with pneumonia are often much worse than the physical signs would suggest. Classically, a dry cough develops over 1–2 d with a low-grade fever. The cough can be debilitating and may be confused with pertussis. Often severe, systemic complaints such as weakness, headache, sore throat, arthralgia and chest or abdominal pain predominate. Signs in the chest are often subtle but auscultation may reveal fine crackles, either localized or multifocal, and wheeze may be present in up to 30%. Rashes are common in association with *M. pneumoniae* and Stevens–Johnson syndrome, hemolytic anemia, polyarthritides, pericarditis, hepatitis, pancreatitis, myocarditis and encephalitis have all been described as rare complicating features. CXR changes are nonspecific and variable. Interstitial infiltrates, multifocal or lobar shadowing, hilar adenopathy and effusions have all been described. A rise in paired specific antibody titer is regarded as the gold standard for the diagnosis of *M. pneumoniae*. Cold agglutinins are often used as an acute test but their value is limited as they are neither fully sensitive nor specific for mycoplasma infection and may also occur in cytomegalovirus (CMV) and EBV infection. Culture of the organism takes about 3 weeks and is therefore not of clinical use. PCR can be applied to blood or nasal secretions and may increase diagnostic yield in combination

with serology. Macrolide antibiotics such as erythromycin, azithromycin or clarithromycin are effective treatments for mycoplasma.<sup>529</sup>

#### ***Chlamydia***

Chlamydia is an obligate intracellular parasite. Three species of chlamydia are pathogenic in man.

*Chlamydia trachomatis* is a cause of pneumonia in the newborn and can be recovered from 25% of infants of mothers who have been identified positive for chlamydial antigen. It can be acquired across intact amniotic membranes and so babies delivered by Cesarean section can be infected as well as those delivered vaginally. About 15% of infected infants develop signs of pneumonia, from 4–6 weeks of age, a dry, 'staccato' cough being a classical feature. Crackles are described more frequently than wheeze. There is a history of sticky eye in 50%. Chlamydia is isolated by cell culture from respiratory secretions or conjunctival scrapings. Chlamydia may also be isolated from high vaginal swab from the mother in whom carriage may be asymptomatic. The respiratory disease is generally mild and responds poorly to erythromycin. Respiratory symptoms can persist for at least 7 years afterwards but it is difficult to know whether this is because chlamydial infection identifies a host susceptibility or because it leads to permanent damage.

*Chlamydia pneumoniae*, identified in 1986, is a common cause of community acquired pneumonia in school-aged children. Symptoms are initially upper respiratory followed by a prolonged hoarse cough which may persist for months after treatment. Treatment is with erythromycin or another macrolide antibiotic.

*Chlamydia psittaci* is the cause of psittacosis, a rare and potentially fatal zoonosis acquired from birds. Most wild urban birds are infected but the infectivity of birds to man is variable: pigeons are poorly infective but parakeets and budgerigars are highly infective. The symptoms and signs range from a mild 'flu-like' illness to pulmonary involvement with a mild to moderately severe pneumonia. The diagnosis rests on a history of contact with infected birds in the presence of respiratory infection and with rising titers to chlamydial antigen. Treatment is with a macrolide antibiotic, or a tetracycline in children over 12 years. Extrapulmonary manifestations include myocarditis, nephritis, thrombophlebitis and meningoencephalitis.

#### ***Legionnaires' disease***

Legionnaires' disease is an unusual disorder in childhood. It occurs either sporadically or in epidemics in communities. *Legionella pneumophila* is a Gram negative, aerobic organism. It survives in warm water and is harbored in water supplies and water-cooled air-conditioning systems and transmission is either by inhalation or by ingestion of contaminated water. Infected infants and children suffer from widespread and sometimes life threatening pneumonia. Serological studies demonstrate raised titers to *L. pneumophila* and the organism can be identified at lung biopsy. Treatment is with macrolides, quinolones or co-trimoxazole.

#### ***Q fever***

This is caused by infection with the rickettsial organism *Coxiella burnetii* acquired from livestock such as cattle and sheep. Animal to animal transmission is via ticks; however, infection to humans is airborne from contaminated feces, urine and birth products such as placenta. It is a frequent cause of 'flu-like' symptoms and when the organism causes pneumonia, fever is universal and is accompanied by a dry cough. Diagnosis is serological and if erythromycin is ineffective it usually responds to treatment with quinolones or rifampicin.

#### ***Fungal infections***

Despite the prevalence of fungi in the environment fungal disease is rare. Fungi cause both pathogenic and opportunistic infections and in the UK the latter, affecting children with altered host defense mechanisms, are by far the most prevalent.

*Histoplasmosis*, *blastomycosis* and *coccidioidomycosis* are exceptionally rare in children outside the US and South America. All cause

illnesses which range from asymptomatic infection to disseminated disease and all have clinical features which are very similar to tuberculosis. In the lung, granulomas associated with hilar lymphadenopathy can progress to pneumonia, cavitating pulmonary lesions and pleural disease. Diagnosis rests on appropriate skin testing and sputum culture. Amphotericin B is used to treat severe blastomycosis and coccidioidomycosis but the treatment of histoplasmosis is extremely difficult.

*Aspergillus* causes two forms of respiratory disease in childhood: allergic bronchopulmonary aspergillosis (see p. 712 – Treatment of pulmonary infection) caused by hypersensitivity in children with underlying lung conditions such as asthma, CF and invasive pneumonitis, usually in immunocompromised hosts.

*Actinomyces* is due to species of *Actinomyces* which live in the mouth, in dental plaque and calculus. As mouth hygiene has become better actinomycosis, in which organisms reach the chest by inhalation, has become rare.

### Parasites

Pulmonary eosinophilia or Loeffler syndrome is believed to be caused by *Ascaris*, *Toxocara*, hookworms or *Strongyloides*, although drugs such as aspirin, penicillin and the sulfonamides have been implicated. Pulmonary involvement includes cough, wheezing, shortness of breath, hemoptysis, fever and weight loss. Diagnosis is suggested by migratory pulmonary infiltrations and a high eosinophil count in the peripheral blood. Identification of the offending parasite can be made by stool examination and by serological methods.

### Persistent bacterial bronchitis

Persistent bacterial bronchitis (PBB), sometimes termed persistent endobronchial infection or chronic suppurative lung disease, is a condition characterized by a persistent, wet cough present for longer than 1 month that resolves with appropriate antibiotic therapy. The majority have onset of symptoms in the first year of life and the commonest precipitating event is probably a viral LRTI which leads to disruption of the normal mucociliary clearance mechanism, making the airways more susceptible to bacterial infection. The commonest organisms to be isolated are *H. influenzae* and *S. pneumoniae*.

Recent reports have emphasized the importance of making a specific diagnosis in children with a chronic cough and in particular have highlighted the important prognostic implications of an ongoing wet cough and the importance of PBB as the commonest cause of a chronic cough.<sup>534,535</sup> If untreated, the condition is likely to lead to damaged airways, and may be a precursor to bronchiectasis. The condition is often misdiagnosed as 'difficult asthma', although the two can coexist causing significant challenges in diagnosis and management.

Currently there is no consensus regarding treatment. Appropriate and aggressive medical treatment has been reported to lead to a dramatic reduction in morbidity and complete resolution of symptoms in the vast majority of patients. However, a small number have a more protracted course and underlying causes such as CF, primary ciliary dyskinesia or significant immunodeficiency should be excluded. A suggested approach is the use of an appropriate high-dose antibiotic and review of the response at 2 weeks. Typically the cough takes 10–14 d to resolve. If there has been a clear response to this intervention the treatment is continued for a further 4–6 weeks or up to 6 months in some centers in order to keep the airways free from colonization and permit repair of the affected airways. For those with persistent symptoms, physiotherapy is an important part of the treatment regimen. Intravenous or nebulized antibiotics may be needed for those with more troublesome symptoms. The accurate identification and development of RCTs of management of children with PBB and 'pre-bronchiectasis' remain challenges for the future.

### Parapneumonic effusion and empyema

Parapneumonic effusion and empyema are parts of a continuum of pleural complications of bacterial pneumonia. In the initial stages of

development of parapneumonic effusion there is pleural inflammation with leakage of fluid and protein into the pleural space. Bacterial invasion ensues, followed by leukocytes and then activation of fibroblasts with the formation of loculations. If the inflammatory process continues, a thick peel is formed on both pleural surfaces with pleural fluid becoming a gelatinous mass. The visceral peel can contract and entrap the underlying lung. There may be fever, cough, chest or abdominal pain and dyspnea. The usual clinical signs are reduced breath sounds and dullness to percussion on the affected side, and children with empyema usually look unwell. There is often anemia, leukocytosis, thrombocytosis and raised inflammatory markers such as CRP.

The bacteria most frequently responsible are *S. pneumoniae*, *S. aureus*, and Group A *Streptococcus*. Recently, PCR on pleural fluid has identified the responsible organism in culture negative cases.<sup>536</sup> After CXR, ultrasound is very useful and can identify fibrinous septation, rind formation and also lung mobility. Computed tomography (CT) can be used as an additional mode of imaging.

Blood cultures should be taken and appropriate intravenous antibiotics started. Guidelines for the management of pleural infection in children have been published.<sup>537</sup> Small uncomplicated effusions may be managed with antibiotic therapy alone, but larger effusions are best managed with closed chest tube drainage. The place of intrapleural fibrinolytic therapy in childhood empyema has become clearer in recent years. A randomized placebo controlled trial showed that 3 d of urokinase therapy was associated with a significantly shorter hospital stay, which was further reduced if a small percutaneous drain was used.<sup>538</sup> The use of video-assisted thoracoscopic surgery (VATS) as an alternative method of debridement of the pleural space has been increasingly used in some centers. However, a randomized trial of urokinase versus VATS as a primary procedure showed no difference in outcomes between the two therapies.<sup>539</sup>

Imaging can be used to assess response to treatment but should not dictate therapy alone. Multiloculated effusions and organizing empyemas may not resolve with chest tube placement and fibrinolysis and may need operative intervention. Thoracotomy with removal of fibrinopurulent debris and if necessary decortication of thickened parietal pleura to release entrapped lung can however produce rapid recovery with a short hospital stay.<sup>540</sup>

Intravenous antibiotics should be continued until there is clinical improvement with defervescence, guided by change in inflammatory markers. Oral antibiotics should be given for at least another 2 weeks. Chest radiography may show pleural thickening for several months. With appropriate management most children make a good recovery.

## RESPIRATORY DEFENSES AND INFECTION IN THE COMPROMISED HOST

The lungs are continuously exposed through respiration to a multitude of airborne particles and microorganisms. A complex system of host defense exists for protection against this repeated challenge, but when this breaks down significant and recurrent infection can occur.

### PULMONARY HOST DEFENSE

There are both physical and immune defenses. Immune defense mechanisms are either innate or specific, although there is considerable interaction between the two.<sup>541</sup>

#### Physical and innate immune defense

The upper airway and branching airways in the lung are the first line of defense with airborne particle deposition dependent on particle size, flow rates during inspiration, and age. Large particles (>10 microns) are usually trapped in the upper airway whereas smaller particles may be able to penetrate beyond the terminal bronchioles. Particulate or chemical stimulation may trigger the neurally mediated protective

reflexes of sneeze, cough and bronchoconstriction. Cough is also an adjunct to the normal mechanism of mucociliary clearance and is particularly important when the latter is defective. Laryngeal integrity and competence of airway protective reflexes are important further defense mechanisms.

The bronchial tree down to the 16th bronchial division at the terminal bronchioles is lined by ciliated columnar epithelium. This is covered by a layer of mucus which is propelled by ciliary movement to the oropharynx where it is swallowed or expectorated. Small particles and organisms are thereby cleared from the airways. Each epithelial cell has around 200 cilia composed of nine interconnected doublet microtubules surrounding and joined to two centrally positioned microtubules. Cilia start beating with a slow recovery stroke by bending sideways and backwards, followed by an effective stroke which propels mucus in a cephalad direction.<sup>543</sup> Ciliary beating results from ATP driven sliding of microtubules via dynein arms, and is coordinated locally in metachronal waves. Normal ciliary beat frequency is 11–16 Hz.

Tracheobronchial mucus is produced by the submucosal glands, goblet cells and Clara cells, and through transudation from the vascular space and alveolar fluid. It consists of glycoproteins (mucins), proteoglycans, lipid and water. The airway surface liquid consists of two layers: an inner periciliary liquid layer in which the cilia beat, and an outer mucus layer, which is viscous and into which the tips of the cilia just penetrate.<sup>542</sup>

The lungs however provide an additional chemical defense. Airway surface fluid contains a variety of antimicrobial molecules, including lysozyme, complement, fibronectin, transferrin, lactoferrin, lipopolysaccharide binding protein, defensins, cathelicidins and collectins. There has been much recent interest in the role of these substances in health and disease states.<sup>543</sup> The collectins include surfactant proteins A and D and mannose-binding lectin, synthesized by the distal airways and alveolar type II cells. The epithelium appears to be able to respond to the presence of pathogens by induction of these antimicrobial factors, as well as by secretion of cytokines for recruitment of inflammatory cells.<sup>544</sup>

Macrophages are present in large numbers throughout the lung, in alveoli, airways and in the interstitium. They play an important role in defense against agents that have escaped clearance by the above mechanisms, through phagocytosis but also by activating other inflammatory cells. Mast cells and polymorphonuclear leukocytes can also be activated through non-immunological mechanisms. Neutrophils can be recruited and activated in the lung, and kill pathogens by phagocytosis and mechanisms including the respiratory burst. This is more effective if they are opsonized with specific antibody.<sup>545</sup> Some encapsulated organisms are not susceptible unless opsonization occurs.

### Specific immune defense

The predominant antibody in respiratory secretions in the upper airway is secretory IgA, which is synthesized locally in the submucosa and is dimeric in structure. IgA can activate the alternative complement pathway and can inhibit viral binding to epithelial cells and neutralize toxins. Conversely IgG relies on transudation from the bloodstream with an increased concentration in the lower airway where it exceeds IgA concentration in bronchoalveolar fluid. IgG activates complement via the formation of immune complexes and acts as an opsonin facilitating phagocytosis. IgM and IgE are also present in respiratory secretions.

Lymphocytes are the main effector cells in the specific immune response, comprising approximately 10% of the cells in bronchoalveolar fluid.<sup>542</sup> Pulmonary macrophages, dendritic cells and B cells act as antigen presenting cells, interacting with CD4+ T cells, leading to secretion of IL-1. This activates CD4+ cells further to produce IL-2 which induces proliferation of both CD4+ and CD8+ cells. CD4+ cells can stimulate B cells to produce immunoglobulin and also produce lymphokines such as interferon-gamma which activates macrophages and natural killer cells in delayed-type hypersensitivity.<sup>545</sup> CD8+ cells effect cell-mediated cytotoxicity which destroys virus-infected cells.

### IMPAIRED HOST DEFENSE

Impairment of any of the above mechanisms can lead to infection. This applies to innate physical defenses as well as to the specific immune pathways. Compromise of the upper airway defenses, such as bypassing the upper airway by tracheostomy or in children with neurological disability associated with impaired cough or laryngeal reflexes, leads to recurrent respiratory infections. Mucociliary clearance is affected by a variety of environmental pollutants as well as by disease states. It is also impaired in CF, mainly due to abnormal amounts of viscous mucus, asthma and respiratory infection.<sup>542</sup> Recent viral and bacterial infections can induce temporary ciliary dysfunction.

#### Primary ciliary dyskinesia

Cilia line the nasal cavity, paranasal sinuses, middle ear, eustachian tube and parts of the male and female genital tracts. The term primary ciliary dyskinesia (PCD) refers to all congenital abnormalities of ciliary function. If ciliary beating is slow or uncoordinated then mucociliary clearance will be impaired. The incidence of PCD is at least 1 in 20 000, but there is probably considerable underdiagnosis.<sup>546</sup> The clinical features are variable but the main feature is chronic sinopulmonary infections. It can present in the neonatal period with unexplained tachypnea or pneumonia, particularly when there are no other risk factors, or rhinitis. In the older child there may be apparent asthma that responds poorly to treatment, or chronic wet cough with sputum production. There may be a history of chronic secretory otitis media with continuous discharge after grommet insertion. Purulent rhinitis and sinusitis are common. Adult males are usually infertile due to defective sperm motility or dyskinetic cilia in the vas deferens and there is associated female subfertility. Repeated respiratory infection can lead to bronchiectasis.

Fifty percent of patients with PCD have malrotation of the internal viscera with dextrocardia or complete mirror image arrangement. The absence of normal ciliary activity is thought to allow random rotation of the thoracic and abdominal viscera early in development. Kartagener syndrome refers to a triad of situs inversus, sinusitis and bronchiectasis, but this term is no longer used. Inheritance of PCD is generally autosomal recessive through a number of gene mutations that are reflected in the range of structural defects observed. There has been significant recent progress in the elucidation of the molecular basis of PCD, with mutations identified in DNAI1 and DNAH5.<sup>547</sup>

Guidelines for diagnosis and standards of care have been published.<sup>548</sup> The clinician should have a high index of suspicion and a child should be investigated if there is any combination of the above clinical problems. However, it may be appropriate to investigate for other disorders first. Nasal nitric oxide is abnormally low in PCD and, where available, this can be used as a screening test.<sup>549</sup> Ciliated cells can be obtained from the nasal mucosa using a cytology brush. These should be examined in a center with appropriate equipment and expertise by direct inspection and quantification of ciliary beat frequency (CBF). If CBF is low or the beat pattern is abnormal, ciliary ultrastructure should be assessed using electron microscopy.

Ciliary abnormalities in PCD include defects in the dynein arms, radial spokes, microtubules, nexin links between microtubules and ciliary disorientation.<sup>550</sup> Secondary ciliary abnormalities can occur, mostly with microtubular defects. Unless the ultrastructure is completely diagnostic of PCD, a repeat sample should be taken.

Daily physiotherapy is recommended with increased frequency during exacerbations of respiratory infection. Exercise should be encouraged and bronchodilator therapy may be useful. There should be regular monitoring of pulmonary function and sputum surveillance. Prolonged oral and, if necessary, intravenous antibiotics should be given early in any respiratory infection. Children should be referred to an otolaryngologist and for hearing assessment. Nasal steroids, or novel therapies such as DNase, hypertonic saline, beta-adrenergic agonists, uridine-5'-triphosphate or arginine, may prove to be useful.<sup>551</sup> Generally the prognosis is good with appropriate management.

## Bronchiectasis

Bronchiectasis has been defined as permanent dilatation of the subsegmental airways. Its incidence in developed countries has decreased over recent decades with the decline in incidence of infections associated with the development of bronchiectasis, including measles, pertussis and pulmonary tuberculosis. It is now mostly associated with an underlying condition. Recognized causes of bronchiectasis are listed in Table 20.19. There has been recent recognition of an increase in the identification of non-CF bronchiectasis using CT imaging.<sup>552</sup>

The underlying pathophysiology appears to be accumulation of purulent secretions and obstruction of the airway leading to dilatation. There is loss of the ciliated epithelium and the airway elastic tissue together with edema and chronic inflammation. Classification into cylindrical, varicose and saccular types has been described but this does not generally correlate with the underlying etiology. There is a rare congenital form (Williams–Campbell syndrome) in which the airway cartilage is abnormal. Bronchiectasis may follow the right middle lobe syndrome, in which there is chronic atelectasis. Young syndrome comprises bronchiectasis, sinusitis and obstructive azoospermia, but with normal ciliary function.

Symptoms are chronic cough, purulent sputum and recurrent respiratory infections. There may be crackles over affected lobes, wheeze and digital clubbing. Chest radiography may show nonspecific changes such as peribronchial thickening, atelectasis and persistent infiltrates. High resolution CT is the investigation of choice to identify bronchiectasis. This can show thick walled and dilated bronchi that are larger than their accompanying pulmonary artery (the ‘signet ring’ sign), and associated lobar or segmental collapse. Pulmonary function tests usually show an obstructive defect with combined obstructive and restrictive patterns in advanced disease.

Underlying conditions should be identified and have been found in up to 70% of series.<sup>552</sup> Appropriate investigations are directed towards the conditions listed in Table 20.19, and include sweat test, immune function studies, ciliary brushing and esophageal pH monitoring. Flexible bronchoscopy can be used to look for bronchial stenosis, compression or foreign body, as well as directing antibiotic therapy on the basis of culture of BAL fluid.

Sputum cultures commonly yield *S. aureus*, *S. pneumoniae*, *H. influenzae* and possibly *P. aeruginosa* or *E. coli*. Oral and occasionally intravenous antibiotics should be given during exacerbations guided by sputum surveillance. Regular physiotherapy is an important aid to mucus clearance. Treatment should be given for the underlying cause if identified.

**Table 20.19** Causes of bronchiectasis

Cystic fibrosis
Immunodeficiency
Primary ciliary dyskinesia
Bacterial pneumonia
Foreign body aspiration
Allergic bronchopulmonary aspergillosis
HIV infection
Gastroesophageal reflux
<i>Mycobacterium tuberculosis</i> endobronchitis
<i>Bordetella pertussis</i>
Adenovirus pneumonia
Measles pneumonitis
$\alpha$ 1-Antitrypsin deficiency
Marfan syndrome
Ehlers–Danlos syndrome
Autoimmune disorders
Asthma
Young syndrome
Bronchogenic carcinoma
Williams–Campbell syndrome
Mounier–Kuhn syndrome

Bronchodilators may be of benefit, as directed by spirometry. Surgical resection may be helpful, particularly if the bronchiectasis is limited to one lobe. Repeated CT imaging has recently shown that some changes of bronchiectasis can resolve over time.<sup>552,553</sup>

## Immunodeficiency (see also Ch. 27)

Respiratory tract infections are common in childhood and most children do not have an immunodeficiency. However, if there is a defect in immune defense then respiratory infection can be one of the first and most serious clinical manifestations. This may either be a primary immunodeficiency, an acquired disorder or from immunosuppressant therapy for another condition. Any of the following presentations may be an indicator that there is a problem in the immune system and that investigation may be warranted:

- recurrent bacterial respiratory infections;
- persistent respiratory infection not responding to appropriate therapy;
- severe infection with an organism of low pathogenicity;
- presence of an opportunistic pathogen;
- unexplained bronchiectasis;
- family history of primary immunodeficiency or unexplained infant deaths;
- features of a syndrome associated with immunodeficiency.

It is important to be aware of and to look for other features that are associated with immunodeficiency disorders, e.g. growth failure, chronic diarrhea, skin infections and rashes, and hepatosplenomegaly. The possibility of more common conditions should be entertained first. Immune function investigations should be conducted in a stepwise fashion, starting with a full blood count and differential, and serum concentrations of IgG, IgM, IgE and IgA. Depending on these results, the persistence of symptoms and the degree of suspicion, further investigations may include the following: serum concentrations of IgG subclasses, HIV status, quantification of specific antibody responses, e.g. to tetanus toxoid or pneumococcal vaccination, complement studies, lymphocyte phenotype and function, and neutrophil function. The clinical presentation and the organisms involved can be a guide to the most appropriate investigations.

## Primary immunodeficiencies

These have been recently classified into broad categories including:<sup>554</sup>

- predominantly antibody defects;
- combined B- and T-cell immunodeficiencies;
- congenital defects of phagocyte number and/or function;
- complement deficiencies;
- other well-defined immunodeficiency syndromes (e.g. Wiskott–Aldrich syndrome, Di George syndrome, ataxia-telangiectasia).

There has been significant recent progress in the identification of the molecular basis of many of the primary immunodeficiency diseases.<sup>555,556</sup>

## Predominantly antibody defects

X-linked agammaglobulinemia usually presents in early childhood with recurrent respiratory infections, with a particular susceptibility to encapsulated bacteria such as *S. pneumoniae* and *H. influenzae*. Serum concentrations of IgG, IgA and IgM are absent or very low and there is a decrease in circulating B lymphocytes.

Common variable immunodeficiency (CVID) usually presents later in childhood or adulthood, usually with recurrent pyogenic respiratory infection. There is a progressive decline in levels of IgG, IgA and often IgM. Both conditions should be treated with immunoglobulin replacement. Bronchiectasis can result from recurrent infection.

Selective IgA deficiency is present in 1 in 700 Caucasians but in many individuals it is asymptomatic. However, in some it may be related to recurrent sinopulmonary infections and autoimmune disease. Replacement therapy is not usually required.

It is also sometimes difficult to establish the clinical significance of selective IgG subclass deficiency. IgG2 antibodies are primarily directed against polysaccharide-encapsulated bacteria and this response is poor

under the age of 2 years, predisposing this group to infection with these organisms. Some children with IgG subclass deficiency may have recurrent infections, particularly if there is associated IgA deficiency, but others are asymptomatic. Specific antibody response may be of greater clinical importance.

### Combined B- and T-cell immunodeficiencies

Severe combined immunodeficiencies (SCIDs) often present in the first 6 months of life with persistent respiratory infections, particularly with viruses, fungi or intracellular bacteria.<sup>555</sup> *Pneumocystis jirovecii* (formerly *carinii*) is the most common respiratory pathogen. Other important features are failure to thrive, recurrent oral candidiasis and persistent diarrhea. The absolute lymphocyte count is usually low. Early diagnosis is extremely important with bone marrow transplantation a potentially curative procedure. Successful gene therapy has been reported in some patients.

In X-linked hyper-IgM syndrome B lymphocytes are unable to switch immunoglobulin production from IgM to IgG, IgA or IgE, due to a deficiency of the CD40 ligand normally found on activated T cells. There is also neutropenia and infants are prone to opportunistic infection.

### Congenital defects of phagocyte number and/or function

These give particular susceptibility to *S. aureus*, *P. aeruginosa*, enteric Gram negative bacteria and fungi. Neutropenia may be isolated or part of a wider disorder. Respiratory infection often occurs in association with involvement of the skin and gastrointestinal tract. Chronic granulomatous disease (CGD) results from a deficiency in intracellular killing of ingested microorganisms through a failure of production of superoxide. Chronic infected granulomas may form in the lungs, lymph nodes, liver, urogenital and gastrointestinal tracts. There are X-linked and autosomal recessive forms, with onset of symptoms usually before 1 year of age.<sup>555</sup> Diagnosis is by demonstration of failure of phagocytes to produce a normal respiratory burst, e.g. with the nitroblue tetrazolium (NBT) test, or by assessment of superoxide production with flow cytometry. Treatment includes prophylaxis with cotrimoxazole and itraconazole, prompt empirical therapy for acute infections, interferon-gamma and potentially bone marrow transplantation.

### Secondary immunodeficiency (see also Ch. 27)

Acute respiratory infections are a leading cause of death worldwide, with many due to immunodeficiency from malnutrition. All aspects of immune defense may be compromised by malnutrition leading to infection from both common and opportunistic organisms. Infections themselves may cause immunosuppression, e.g. pneumonia following measles. Many chronic conditions can also lead to a secondary immunodeficiency. Immunoglobulins can be lost in nephrotic syndrome or protein losing enteropathy. Children who have had a splenectomy or who have functional hyposplenism from sickle cell disease are at increased risk of infection with encapsulated organisms.

Respiratory tract infection is one of the main manifestations of HIV infection. Upper and lower respiratory tract infections are common, not only with usual bacteria and viruses such as *S. pneumoniae*, *H. influenzae* and RSV, but also opportunistic organisms. *Pneumocystis jirovecii* pneumonia (PCP) is a common first AIDS indicator illness. The pattern of PCP in HIV infection has changed with prophylactic therapy and highly active antiretroviral therapy, but considerable associated mortality remains.<sup>557</sup> *Mycobacterium tuberculosis* is an extremely important pathogen worldwide. Lymphocytic interstitial pneumonitis (LIP) is a non-infectious complication of HIV, with characteristic diffuse reticulonodular infiltrates on CXR. It can present with a gradual onset of cough, tachypnea and hypoxemia, and may respond to systemic corticosteroids.

Cytotoxic therapy in the treatment of malignancy or immunosuppressant therapy for bone marrow or solid organ transplantation is the commonest cause of secondary immunodeficiency. Although its incidence has decreased, infection is a major reason for treatment-related death in childhood leukemia, particularly with bacterial sepsis.<sup>558</sup> The

main risk factor is chemotherapy-induced neutropenia, underlying the need for prompt antibiotic treatment in febrile neutropenia, with the use of empirical antifungal therapy if it is prolonged. The causative organisms in respiratory infection following bone marrow transplantation vary with time after transplantation. An initial period of neutropenia induced by the conditioning regimen predisposes towards bacterial and fungal pneumonias. With engraftment there is the risk of acute graft versus host disease, with the need for immunosuppressive therapy with corticosteroids and ciclosporin A, associated with viral (particularly CMV), fungal and *P. jirovecii* infection. Late pneumonias (>4 months post transplant) are related to humoral defects to encapsulated organisms. Bronchiolitis obliterans can occur during this period. CMV is the major organism causing pulmonary infection in recipients of solid organ transplants.

### GENERAL APPROACH TO PNEUMONIA IN THE IMMUNOCOMPROMISED

It is important to have a low threshold for investigation and treatment in immunocompromised children. Similarly a respiratory tract infection that is unusually prolonged or has atypical features should raise the suspicion of an immunodeficiency. Children with significant immunocompromise will often present for the first time with respiratory disease, and common respiratory pathogens can be devastating. Likely organisms can be predicted in a known defect but any infection is potentially possible and microbiological investigation should be conducted carefully in order to obtain a diagnosis. In addition mixed infection is not uncommon. There are also non-infectious processes that may either simulate or complicate infection, including pulmonary edema, atelectasis, hemorrhage, drug- or radiation-induced pneumonitis, and tumor infiltration.

Fever is a sensitive sign of infection, but clinical and other features may vary due to the abnormal host response. An interstitial pneumonitis may present with a dry cough, tachypnea and dyspnea, but there may be few findings on auscultation. Chest radiography can show variable abnormalities and is not specific but there are some recognizable patterns. Diffuse interstitial changes are associated with infection with *P. jirovecii*, and viral infections such as CMV and adenovirus. Lobar consolidation can be caused by common bacteria, but can also be seen in some fungal infections. A nodular appearance, cavitation or abscess formation occurs in bacterial infection with *S. aureus* and anaerobes, and fungal infections. Computed tomography, particularly high resolution, can provide extra information, and is a more sensitive investigation for other complications, e.g. bronchiectasis or bronchiolitis obliterans.

Blood cultures should be obtained before empirical treatment is started. Treatment protocols will vary between centers and with the clinical setting, but usually include broad-spectrum antibiotic cover of Gram negative and Gram positive organisms. A macrolide may be added to cover *M. pneumoniae*, high-dose cotrimoxazole for *P. jirovecii*, and potentially antifungal therapy. Urine or blood can be sent for bacterial antigen detection but serology is rarely helpful due to limited antibody response. Nasopharyngeal aspirates are useful in the younger child with urgent immunofluorescence for respiratory viruses, CMV and *P. jirovecii*. Sputum collection is often difficult, but in the older child sputum can be induced by the nebulization of hypertonic saline. Gastric aspirates are helpful in the diagnosis of *M. tuberculosis*.

Further investigation is necessary when there is failure to respond to empirical therapy and when the causative organism is not identified. Flexible bronchoscopy with BAL is a safe procedure that is often used in immunocompromised children.<sup>559</sup> However, even this technique has limitations in identifying pathogens, particularly after empirical treatment or with the use of prophylactic therapy. If children are intubated, an alternative is nonbronchoscopic BAL. Transbronchial biopsy is useful following lung transplantation. Open lung biopsy is generally reserved for both treatment and diagnostic failure despite BAL, and can identify both infection and non-infectious conditions.<sup>560</sup>

## PNEUMOCYSTIS PNEUMONIA

*P. jirovecii* is now regarded as an atypical fungus and is the leading opportunistic pathogen, particularly in those with impaired cell mediated immunity. It can cause a severe interstitial pneumonitis presenting with nonspecific features including cough, tachypnea, fever, hypoxia and often no added sounds on auscultation. It is common in HIV infection when its presentation may be more insidious and it is often the first AIDS indicator disease.<sup>561</sup> Chest radiography typically shows diffuse bilateral infiltrates that spread outwards from the perihilar areas (Fig. 20.31). Several morphological forms of *P. jirovecii* are recognized.<sup>562</sup> Cysts contain sporozoites and are identified with most of the traditional staining techniques, whereas the smaller trophozoite forms are more abundant and attach themselves to type I pneumocytes. The host inflammatory response plays a significant part in the lung damage in infection. The organism cannot be cultured but can be identified in sputum, nasopharyngeal aspirate, BAL fluid or lung biopsy using immunofluorescent techniques or PCR.

Treatment is high dose co-trimoxazole. Intravenous pentamidine is an alternative if there is treatment failure or if co-trimoxazole is not tolerated. Respiratory support may be necessary. Corticosteroids have reduced the need for mechanical ventilation and mortality in randomized studies.<sup>563</sup> Children at risk of *Pneumocystis* infection should have prophylaxis with co-trimoxazole; other options are dapsone or inhaled pentamidine.

## VIRAL PNEUMONIAS

### Cytomegalovirus

Like other herpes viruses, CMV can become latent following primary infection. Pneumonitis can occur following reactivation in CMV positive patients with secondary immunodeficiency or with primary infection. It is a particular problem in HIV infection and in bone marrow, renal and lung transplantation. The clinical features of CMV pneumonitis are similar to PCP with a diffuse reticulonodular pattern on CXR. There may be extrapulmonary involvement, such as hepatitis, colitis or retinitis. CMV can be identified in urine, blood, nasopharyngeal aspirates and BAL fluid by using immunofluorescence and PCR techniques. However, these results may need to be interpreted with caution. A definitive diagnosis of

Fig. 20.31 Bilateral interstitial pneumonitis due to *Pneumocystis jejunii* in an infant with vertically acquired HIV infection.

CMV pneumonitis is made with lung biopsy, with characteristic intranuclear and intracytoplasmic inclusions and positive immunohistochemistry. Significant recent progress has been made with quantitative PCR for CMV plasma viral load, as well as RNA and antigen detection, in guiding treatment and prophylaxis.<sup>564</sup> Treatment includes intravenous ganciclovir and foscarnet, but mortality is significant. Those at high risk can receive prophylaxis with ganciclovir or aciclovir.

### Varicella zoster

Primary varicella infection in the immunocompromised, particularly lymphopenic, patient can produce overwhelming disease with visceral dissemination and pneumonitis. There may be cough, dyspnea and chest pain, with bilateral nodular infiltrates on chest radiography that may coalesce. Varicella in the immunocompromised child should be treated promptly with intravenous aciclovir. Varicella-zoster immunoglobulin (VZIG) should be given within 72 h to at risk patients who have had exposure to varicella.

### Herpes simplex

Mucocutaneous herpes simplex infection is common in severe immunodeficiency. More severe infection can progress to involve the upper airway, including the trachea, and can cause a pneumonitis. Prophylaxis and treatment is with aciclovir.

### Adenovirus

Adenoviruses commonly cause respiratory infections in immunocompetent children, but can result in a severe pneumonia in the immunocompromised. There may be associated renal or hepatic involvement. There is no specific antiviral therapy but ribavirin may be used.

### Measles

Bacterial pneumonia can complicate measles infection and this is a major cause of death of children in resource poor countries. There is insufficient evidence to support the use of antibiotics in all children with measles to prevent pneumonia.<sup>565</sup> With immunocompromise, measles can cause a progressive giant cell pneumonia that may be fatal. There may be an atypical rash, and coarse nodular infiltrates on CXR. Prior exposure to measles or vaccination is usually protective and with good uptake of immunization it is fortunately rare.

## FUNGAL INFECTIONS

### Aspergillus

Invasive pulmonary aspergillosis, usually due to *Aspergillus fumigatus*, can occur in prolonged neutropenia, bone marrow transplantation and HIV infection. Clinical features include fever, cough, chest pain, tachypnea and rapid deterioration. A chronic necrotizing form also exists. Chest radiography can show nodular changes and cavitation, but CT imaging is more sensitive at detecting suggestive abnormalities. BAL may be useful but definitive diagnosis is with lung biopsy. Treatment includes amphotericin, voriconazole or caspofungin. Further therapy may include the use of granulocyte colony stimulating factor and surgery on focal lung lesions.<sup>566</sup>

### Candida spp

Prolonged neutropenia, HIV infection, combined immunodeficiencies and prolonged presence of a central venous catheter are the major risk factors for deeply invasive *Candida* infection. Pulmonary infection can result from hematogenous spread or aspiration from the oropharynx. Treatment is with amphotericin B or fluconazole.

## CHRONIC LUNG DISEASE OF PREMATURITY

Although chronic lung disease (CLD) is usually ascribed to preterm infants, hence CLD of prematurity, it may also affect older more mature infants (Table 20.20). The early course of CLD whilst the infant is in the neonatal intensive care unit is described in Chapter 12. This section

**Table 20.20** Diseases which may lead to a prolonged requirement for oxygen. By far the commonest is oxygen dependency due to prematurity

Preterm	Chronic lung disease of prematurity Wilson–Mikity syndrome Chronic pulmonary insufficiency of prematurity
Term	Meconium aspiration Respiratory infections Pulmonary hyperplasia Muscular disorders
Surgical	Tracheoesophageal fistula Congenital diaphragmatic hernia
Congenital abnormalities	Cystic adenomatoid malformations Congenital lobar emphysema Sequestration of the lung Chylothorax

considers the features associated with CLD after discharge from hospital. Since CLD predominantly affects the preterm child, most definitions have focused on this group of infants. The earliest definitions described the different stages through which the infant progressed during development of his/her disease and the extreme stage (IV on Northway's original classification<sup>567</sup>) with large cystic changes interspersed with areas of collapse was termed bronchopulmonary dysplasia (BPD). Although the term BPD or new-BPD is widely used, the preferred term remains chronic lung disease of prematurity or CLD, since it embraces a wide range of diseases which may lead to the development of oxygen dependency. Many definitions have been proposed (see Ch. 12) but the most commonly used are oxygen dependency beyond 28 d of age with chest radiological changes or oxygen dependency at 36 weeks' post-conceptual age.<sup>568</sup> A more recent report from a meeting sponsored by the NICHD has proposed yet another definition in the face of extremely preterm infants surviving the early neonatal period, to facilitate comparisons between units.<sup>569</sup> This definition is based on whether the infant is greater or less than 32 weeks' gestation at birth and also attempts to classify the severity based on respiratory support including oxygen and ventilation requirements. Regardless of the definitions of CLD, it is clearly important to determine why the definition is required in the first instance.<sup>570</sup> For mechanistic studies, the definition is likely to be oxygen dependency at 28 d but for epidemiological studies oxygen dependency at 36 weeks' corrected gestation is more likely to be more relevant.

## INCIDENCE

Estimating the incidence of CLD is problematical because of inconsistencies in case definition between different studies. Furthermore, incidence is often quoted for individual units which is subject to referral bias and to local practices. Varying approaches between individual units, for example the approach to extremely preterm infants, will markedly influence the local incidence. There are few comprehensive population-based studies which are essential to precisely estimate the incidence of CLD. In the Trent region of the UK, systematic data have been collected since 1987 for infants born at less than 32 weeks' gestation. Analysis of these data suggested that, despite falling birth rates, the number of babies of < 32 weeks' gestation admitted to neonatal units increased significantly.<sup>571</sup> For the two consecutive 5-year periods 1987–1992 and 1992–1997, during which a number of therapeutic modalities, including regular use of antenatal corticosteroids, exogenous surfactant therapy, high frequency ventilation and postnatal corticosteroids, were introduced, the survival improved for both time periods (Fig. 20.32). [Odds ratios adjusted for gestation and birth weight for survival at 28 d of age: 1.69 (1.23–2.33) between 1987 and 1992 and 1.90 (1.36–2.64) between 1992 and 1997.] During the first of these periods, the odds ratio for

**Fig. 20.32** Odds ratios for survival and CLD at 28 d of age between 1987–1992 and 1992–1997. Note improvement in survival between both time periods but with increased incidence of CLD during the first period. \*Odds ratios corrected for gestation and birth weight. (Adapted from Manktelow 2001).

CLD, defined as oxygen dependency at 28 d of age, increased [2.20 (1.47–3.30) adjusted for gestation and birth weight]. However, during the second period the odds ratio was 0.72 (0.5–1.03), suggesting no further increase despite a further improvement in survival. Taken together these data suggest that the survival of increasingly preterm infants in recent years has not resulted in an increased incidence of CLD.

The reported incidence of CLD (whether defined as oxygen dependency at 28 d or 36 weeks' postconceptional age) varies from 18% to 36% between centers.<sup>572–574</sup> In Trent, the unadjusted incidence has remained remarkably stable at 40–45% for infants born at < 32 weeks' gestation and who required mechanical ventilation.<sup>575</sup> This is despite interunit differences in practices and approaches to care of extremely preterm infants. Factors which may affect the reporting of the prevalence and incidence of CLD from different units are given in Table 20.21.

## PATHOPHYSIOLOGY

The risk factors which lead to the development of CLD are described below. However, it is worth re-iterating that although the risk factors associated with the development of CLD have been accurately described, the mechanisms which lead to the development of CLD remain largely unknown. Antenatal and postnatal factors contribute to the development

**Table 20.21** Factors that may affect the reported incidence and prevalence of chronic lung disease

Population base of community	<ul style="list-style-type: none"> <li>• Social factors</li> <li>• Environmental factors</li> <li>• Age and health structure of community</li> <li>• Ethnic mix of population</li> </ul>

From Kotecha & Silverman<sup>571</sup>

of lung injury in infants destined to develop CLD.<sup>576</sup> Mechanical ventilation and oxygen therapy have received much attention in the past. More recently, antenatal factors, especially infection, have assumed more prominence, particularly as antenatal infection is also associated with preterm labour.<sup>577</sup> It is now thought that antenatal infection may trigger pulmonary inflammation in the fetus and that the resulting lung injury can be exacerbated by oxygen therapy and mechanical ventilation.

With the survival of extremely preterm infants, the pathological changes observed in infants who do not survive the neonatal course have altered over the years. When CLD affected more mature infants, both lung fibrosis and atelectatic areas were regularly seen.<sup>578</sup> With CLD now largely confined to the smallest immature infants, the picture has changed to one of decreased alveolization rather than lung fibrosis. The final number of alveoli is decreased markedly and associated with rudimentary air sacs of increased diameter and decreased gas exchanging surface area.<sup>579,580</sup> Whether dysregulated lung growth is due to arrest of normal lung growth<sup>581</sup> or due to accelerated lung growth resulting in reduced final numbers of alveoli<sup>576</sup> is unknown. The decrease in alveolar number is associated with abnormal deposition of extracellular matrix components, including elastin.<sup>582</sup> Abnormalities are also seen in the larger airways with smooth muscle extending more distally in infants with CLD compared with normal lung development.<sup>583</sup> It is likely that this last observation is responsible for the airways obstruction that is described in infants with CLD. Initially the airways may respond to bronchodilators but with subsequent remodeling and fixed airways obstruction, the response to such treatment becomes less predictable. Whether similar changes of smooth muscle hypertrophy occur in the airways of infants with 'new' CLD is currently unknown.

### CLINICAL FEATURES

The clinical features of infants developing CLD in the neonatal intensive care unit are discussed in detail elsewhere (see Ch. 12). A typical infant with CLD will have been born prematurely and may have received mechanical ventilation and oxygen therapy either from birth or at some stage during the neonatal course.<sup>571</sup> Prolonged oxygen requirement is the most consistent feature and clinical signs of respiratory distress,

including an increased respiratory rate, inter- and sub-costal recession, may be evident even at rest. At the more severe end of the spectrum, the infant may develop chest deformities, including a barrel chest reflecting air trapping and Harrison's sulci indicating increased diaphragmatic workload. Some of these infants may be discharged home on oxygen. Associated problems include poor appetite and reduced weight gain despite increased energy intake. Vomiting and feeding difficulties may be present due to gastroesophageal reflux. Other features of being born too early include poor sucking, retinopathy of prematurity and early evidence of neurodevelopmental delay.

On examination, besides an increased respiratory rate and the features mentioned above, widespread wheezing and/or crackles may be present throughout the lung fields on auscultation especially in those at the extreme end of severity. In most infants, however, tachypnea without added breath sounds is the norm. Pulmonary hypertension when present may manifest with signs of right ventricular hypertrophy and tricuspid regurgitation. If prolonged endotracheal intubation has been necessary, signs of upper airway obstruction due to subglottic stenosis may also be present.

Chest radiographs are likely to show abnormalities ranging from mild haziness of type I disease (Fig. 20.33a)<sup>584</sup> to large cystic areas interspersed with areas of atelectasis of type 2 or Northway Stage IV BPD (Fig. 20.33b). Lung function testing in infancy (which remains largely a research tool) may demonstrate evidence of gas trapping. In addition, decreased dynamic and static lung compliance and increased airway resistance are commonly reported. Response to bronchodilators is variable but may provide a guide to future treatment of the child. Electrocardiography and echocardiography (discussed below) are indicated, particularly when pulmonary hypertension is suspected.

Causes of oxygen dependency other than prematurity are likely to have been excluded by the time the child is discharged from the neonatal unit. Nevertheless, there are a number of associated differential diagnoses that should be sought and treated as appropriate (Table 20.22). Obstructive disorders are discussed in pp. 689–697 (Asthma) but other disorders including laryngo-, tracheo- and broncho-malacia, subglottic stenosis, laryngeal webs and granulomas, vascular rings and enlarged

Fig. 20.33 Chest radiograph showing (a) haziness of both lung field with oxygen dependency typical of type I CLD (Hyde 1989), and (b) more cystic changes associated with CLD typical of Type II (Hyde 1989) or Stage 4 CLD (Northway 1967). Note also presence of pH probe for assessing presence of gastroesophageal reflux.

**Table 20.22** Conditions which may be associated with chronic lung disease

System	Clinical manifestation
Respiratory	Oxygen dependency for hypoxia Airways obstructive disease Laryngo-, tracheo- or broncho-malacia Subglottic stenosis Acquired bronchial stenosis Respiratory viral infections Aspiration pneumonitis
Cardiovascular	Pulmonary hypertension Cor pulmonale Arterial hypertension
Gastrointestinal system and growth	Gastroesophageal reflux Malabsorption Poor growth
Renal	Renal calculi
Central nervous system	Developmental abnormalities Behavioral abnormalities
Ophthalmology	Retinopathy of prematurity
Metabolism	Rickets Electrolyte imbalance

tonsils should be sought and treated. In one study, 30% of low birth weight infants underwent surgery for upper airway abnormalities.<sup>585</sup>

Exacerbations of respiratory disease may occur as a result of respiratory infections, gastroesophageal reflux with or without pulmonary aspiration, airways obstruction and heart failure. Of particular importance are viral respiratory infections which remain a common cause of morbidity in children with CLD. Because of decreased respiratory reserve, many infants with CLD present with severe exacerbations of their respiratory status during viral respiratory infection. Of particular note is RSV. In one retrospective study of hospitalizations for RSV in Tennessee, USA, there were 40.8 hospitalizations for RSV per 1000 infants under 1 year of age.<sup>586</sup> For infants with medical factors the estimated number of hospitalizations per 1000 infants under 12 months of age were: 388.4 for infants with CLD and 92.2 for infants with congenital heart disease. The rates also increased with decreasing gestation: 57.2 per 1000 children if born between 33 and 36 weeks' gestation, 65.9 if born between 29 and 32 weeks' and increasing to 70.0 if born at <28 weeks' gestation. Clearly, respiratory viruses, particularly RSV, place a great burden on both human and economic resources. Therefore considerable effort has been directed to both prevention and treatment of this infection. Ribavirin has not been as efficacious as initial expectations predicted and intravenous pooled immunoglobulins have had variable success reported. The IMPACT study, an RCT of the monoclonal antibody palivizumab in infants <35 weeks' gestation, showed a 55% reduction of the proportion of preterm infants admitted to hospital from 10.6% in the placebo group to 4.8% in the treated group. In infants with CLD the reduction was 39%, from 12.8% in the placebo group to 7.9% in the treated group.<sup>587</sup> On this evidence, the American Academy of Pediatrics recommends this drug for infants at risk of acquiring RSV. In Europe, cost and case-mix considerations restrict the use of palivizumab to infants at risk of severe exacerbations of respiratory status. A recent statement from the Joint Committee of Vaccination and Immunisation (JCVI) in the UK recommended palivizumab prophylaxis for: (a) children under 2 years of age with CLD, on home oxygen or who have had prolonged use of oxygen; (b) infants under 6 months of age who have left-to-right shunt, hemodynamically significant congenital heart disease and/or pulmonary hypertension; (c) children under 2 years of age with severe congenital immunodeficiency.<sup>588</sup> However, it was interesting that the definition of CLD suggested by the JCVI was oxygen dependency at 28 d, which substantially increases the number of infants recommended for palivizumab treatment. Reassuringly, data from the PICNIC study in Canada demonstrated that infants with CLD who acquired RSV

and required mechanical ventilation did not fare worse than children with other respiratory disorders (CF, congenital lung malformations, respiratory disease associated with CNS disorders).<sup>589</sup>

## EXTRAPULMONARY COMPLICATIONS

### Growth and nutrition

Many other systems may be affected in children with CLD either directly as a result of developing CLD or indirectly due to being born prematurely (see Table 20.22). Gastroesophageal reflux is common. It may exacerbate respiratory disease if recurrent aspiration occurs or can provoke airways obstruction via reflex neural pathways. Gastroesophageal reflux may present with vomiting, failure to thrive, cough, poor feeding and in the worst cases recurrent lower respiratory tract infections or aspiration pneumonitis. Twenty-four hour esophageal pH monitoring and an upper gastrointestinal tract contrast study are the investigations of choice to confirm gastroesophageal reflux (see Ch. 19, p. 605). Medical treatment with a prokinetic agent together with a feed thickener or alginate are the drugs most often used and in the worst cases reduction of gastric acid by H<sub>2</sub> blockers or proton pump inhibitors is useful. Erythromycin has been used in low doses for its prokinetic action. Fundoplication is required in some children in whom medical treatment fails, as evidenced by failure to thrive, continuing respiratory exacerbations or rare complications of gastroesophageal reflux including hematemesis, anemia or strictures. The diagnosis and management of gastroesophageal reflux in infants has been extensively reviewed by Vandenplas et al.<sup>590</sup>

Growth failure is common in infants with CLD due to a number of reasons that may include increased work of breathing, hypoxemia, gastroesophageal reflux, neurodevelopmental abnormalities resulting in poor feeding, heart failure and other complications of prematurity including necrotizing enterocolitis. Groothuis et al reported that oxygen therapy appeared to improve growth as its discontinuation was associated with poor growth which did not improve to previous levels with the re-introduction of oxygen treatment.<sup>591</sup> However, more recent data from the BOOST trial suggest that oxygen saturations of between 91% and 94% did not affect growth when compared with oxygen saturations of between 95 and 98%.<sup>592</sup> Nevertheless, increased energy intake is indicated in these children to promote growth and high calorie supplements are often necessary. In some cases enteral feeds may have to be given or supplemented via a nasogastric or gastrostomy tube.

### Cardiovascular system

Cardiac abnormalities are often seen in children with CLD. These include increased pulmonary vascular resistance due to respiratory disease, right-to-left shunting, left ventricular hypertrophy most likely due to corticosteroid treatment during the neonatal period, patent ductus arteriosus (which will have been treated in the neonatal period) and fluid overload. One or a combination of these features may result in heart failure manifested as poor feeding and failure to thrive, tachypnea, hypoxemia and worsening respiratory disease, and inappropriate weight gain.

Pulmonary hypertension remains the commonest association with CLD and markedly improves with oxygen treatment.<sup>593,594</sup> Cor pulmonale is now uncommon especially since the introduction of home oxygen programs. Electrocardiographs may demonstrate right heart strain or hypertrophy and echocardiography may be used to estimate the degree of pulmonary hypertension in the presence of tricuspid regurgitant flow. Indirect methods of assessing pulmonary arterial pressures by echocardiography and Doppler have also been used (e.g. the ratio of pulmonary arterial acceleration-to-right ventricular ejection time).<sup>594</sup> Such measurements may be used to determine the fixed and reversible components of pulmonary hypertension with the child on and off oxygen. The data may be useful in determining when to wean an infant from supplemental oxygen.

### Neurodevelopmental complications

It is almost impossible to attribute the risk of developing neurodevelopmental abnormalities exclusively to CLD as sick extremely preterm

infants are at risk of developing both conditions. Of particular note is that systemic corticosteroid administration in the early neonatal period has been associated with neurodevelopmental delay.<sup>595</sup> Majnemer et al reported the results of a case control study of 27 children with CLD and a similar number of preterm controls matched for gestational age, birth weight and year of birth.<sup>596</sup> Neurological abnormalities were more prevalent in the CLD group (71%) compared with the controls (19%). A variety of disorders were described including cerebral palsy, subtle neurological disorders, microcephaly and behavioral difficulties. Feeding disorders including dysphagia and sleep disorders are also more prevalent in these children. Retinopathy of prematurity leading to visual impairment, in some cases blindness, and hearing abnormalities are more common in infants with CLD. Respiratory responses to hypoxia may be blunted in infants with CLD when compared with non-oxygen-dependent preterm infants, at least in the early stages after weaning from oxygen.

## MANAGEMENT

### General aspects

The management of the oxygen-dependent child with CLD can be divided into pulmonary and nonpulmonary aspects. The latter should focus on maximizing the growth of the child and on treating conditions such as gastroesophageal reflux which may exacerbate existing respiratory disease. Cardiovascular abnormalities should be sought and treated as necessary. Pulmonary hypertension is likely to respond to oxygen therapy and is discussed below. Full immunization of these infants is essential and live vaccines should be avoided if there has been prolonged corticosteroid treatment. Multivalent pneumococcal vaccination is now included in UK routine immunization for all infants.<sup>597</sup> Influenza vaccination is recommended but not licensed for infants below 6 months of age.<sup>598</sup> Input from relevant agencies, including community pediatricians, health visitors, dieticians, physiotherapists, speech and occupational therapists, and educational psychologists, is often necessary, especially if neurodevelopmental abnormalities are evident.

For established CLD, the mainstays of therapeutic treatment remain:

- domiciliary oxygen;
- corticosteroids;
- bronchodilators;
- diuretics.

Due to the small numbers of infants with established CLD in any one center, there have been very few adequately powered, controlled evaluations of the above treatments in this group of children. Most studies have been uncontrolled observational studies or have included only small numbers of patients. Almost all studies of these treatments have been confined to the neonatal period and are discussed in Chapter 12. Many of these studies have evaluated only short term outcomes and their relevance to longer term outcomes is unknown. The variations of treatment, particularly the use of corticosteroids, diuretics and bronchodilators between the continents was recently described in a series of articles describing the treatment of CLD.<sup>599-602</sup> As a result most treatment which is described below is empirical and founded on 'best practice' rather than evidence.

### Domiciliary oxygen

By definition children with CLD are hypoxemic in room air and their wellbeing, particularly with regard to growth, development, work of breathing and pulmonary hypertension, may depend on achieving normoxemia using oxygen therapy. The criteria for prescribing domiciliary oxygen vary between units but, generally speaking, an infant with an oxygen requirement, i.e. supplemental oxygen is required to achieve arterial PaO<sub>2</sub> of >8 kPa or arterial oxygen saturation (SaO<sub>2</sub>) of 94%, should be considered for domiciliary oxygen if attempts to wean the child from oxygen have failed. Particular attention should be paid to hypoxemia during periods of feeding orally by bottle or breast.

More recent data have challenged the optimal target oxygen saturations: the BOOST and STOP-ROP trials suggest that oxygen saturations of lower than 94% may not result in poor growth, neurodevelopmental outcomes or increased pulmonary hypertension.<sup>602,603</sup> Nasogastric feeding may not preclude the child from going home on oxygen but may place a greater burden and stress on the family. Clearly the family should be willing and capable of looking after the child on oxygen. A stable oxygen requirement and a thriving child are ideal but changes to respiratory treatment, particularly the recent cessation of corticosteroids, may result in a rebound increase in oxygen requirements.

Oxygen is most often given by nasal cannulae<sup>604</sup> and is most commonly delivered by an oxygen concentrator.<sup>605</sup> Portable cylinders, especially the lighter versions, allow greater mobility and are helpful for emergency use. Liquid oxygen is sometimes necessary if flow rates higher than 1 L/min are required. Oxygen is now prescribed by the attending pediatrician and provided regionally by a limited number of commercial companies which provide a 24 h service.<sup>606</sup> The oxygen provider will install and provide initial training for the parents. It is usual to provide two outlets – one in the living room and one for the child's sleeping area.

Monitoring of oxygenation is essential. Pulse oximeters have transformed the monitoring of these children. A small number of units have used *continuous* monitoring with transcutaneous monitors but few have used pulse oximeters in this way, partly due to movement artefacts and partly due to the poor quality probes of portable machines for small infants. Therefore, most units have relied on intermittent oxygen saturation measurements on a regular basis. Monitoring should be frequent early after discharge, during intercurrent infections and during weaning of oxygen. Specialist respiratory nurses provide a vital link between the hospital environment (to which the family should have 'open' access) and the community. Infants should also be evaluated regularly within the hospital environment in the presence of all relevant agencies. Weaning from oxygen can commence once the child is stable and thriving.<sup>606</sup> Usually by this stage the oxygen saturations are ≥94% and only insignificant drops occur during feeding and sleep (≤4%). Where available, echocardiography can be used to determine the reversible component of pulmonary hypertension by assessing the pulmonary arterial pressures on and off oxygen. Rates of weaning vary greatly, from increasing time off oxygen gradually, e.g. 15–60 min every week, to completely stopping the oxygen abruptly. Regardless of rates of weaning, it is essential to monitor the child's oxygen saturations once off oxygen and at times of intercurrent infections. The duration of oxygen dependency varies widely but in one study of infants with CLD discharged at a mean age of 3.7 months, mean duration of oxygen therapy was 97 d (range 15–320 d), and the mean age of discontinuation of oxygen was 6.9 months (range 3–14.7 months).<sup>607</sup> It is necessary to continue to monitor after weaning, especially at times of viral URIs.

The challenge over the next few years is to assess and identify the optimal oxygen saturations for preterm infants at which adverse events such as poor growth, increased pulmonary arterial hypertension and neurodevelopmental delay are avoided.

### Corticosteroids

The only clear evidence for the use of corticosteroids for CLD remains the ability of these drugs to facilitate extubation of ventilator dependent infants. Most clinicians are much more cautious than previously due to the association of these drugs with adverse neurodevelopment.<sup>595,608,609</sup> In contrast to ventilated preterm infants, adequate studies of the use of both systemic and inhaled corticosteroids in established CLD are lacking. Caution with the use of dexamethasone, the most frequently used corticosteroid for CLD, was reported by Noble-Jamieson et al in 1989.<sup>610</sup> They treated 18 non-ventilated infants with CLD with either dexamethasone or placebo, and reported that, although there was an initial decrease in oxygenation requirements with steroid treatment, the overall duration of oxygen dependency was similar in both groups. Of particular note was the observation that the treated group had an apparent increase in periventricular abnormalities. In the most recent Cochrane review of the

use of inhaled corticosteroids in established CLD by Lister et al,<sup>611</sup> only one study published as an abstract was included in their analysis. In that study,<sup>612</sup> nonventilated infants of at least 36 weeks' corrected gestation and who were oxygen dependent were included. Budesonide (1 mg) was administered by an Airlife Misty-Neb jet nebulizer three times a day for 7 d. A significant reduction in oxygen requirements was observed by the authors. In another study of 18 preterm infants at a mean postnatal age of 10.5 months, the use of inhaled beclomethasone for 6 weeks was associated with an improvement in respiratory tract symptoms and functional residual capacity.<sup>613</sup> Since this study did not specify the number of infants with oxygen dependency, it is difficult to extrapolate the results to infants with established CLD.

In practice, the approach adopted by most is to consider the clinical need (e.g. wheezing) and clinical response to the use of inhaled corticosteroids in infants with CLD and to continue treatment in those who respond, but to actively cease treatment when an adequate response is not observed. Pulmonary function tests may be useful but remain largely a research tool for this group of infants. As this set of children form a large group in the community, there is a clear need for adequately powered RCTs to examine the role of both systemic and inhaled corticosteroids in infants with established CLD.

### Bronchodilators

Several studies have shown that preterm infants who are mechanically ventilated have an improvement in lung compliance and resistance following the administration of bronchodilators.<sup>614</sup> Whether these agents have a beneficial effect on longer term outcomes, including symptoms or oxygen dependency, is unknown. In established CLD, marked airway smooth muscle hypertrophy is seen.<sup>583,615</sup> It is likely that this increased smooth muscle stabilizes the compliant infant airway but whether relaxation of airway smooth muscle by bronchodilators leads to increased airway resistance by increasing dynamic airway compression is speculative. Few studies have investigated bronchodilators in infants with CLD beyond the neonatal period. A Cochrane review could identify only one study of prevention by salbutamol (albuterol).<sup>616</sup> Most studies have examined a small number of children in short term, observational studies. In one study of 1-year-old infants with CLD treated with inhaled salbutamol, decreased airway resistance was reported in half the group with no improvement in the remainder.<sup>617</sup> Similarly in older children, functional small airways abnormalities remain and a favorable response to salbutamol is seen in some but not all children.<sup>618</sup> Taken together, these data suggest that there is a subgroup of children who had CLD in infancy who have reversible airways obstruction. However, routine use of salbutamol in all children with CLD is not recommended but should be assessed clinically. If no response is observed, the treatment should be stopped.<sup>618</sup>

Similarly, few studies have evaluated the benefits of inhaled ipratropium bromide in infants with CLD, especially beyond the neonatal period. Benefit from ipratropium has been noted in small studies of ventilated neonates and during early infancy with improvement observed in some children.<sup>619</sup> As with salbutamol, not all children with CLD respond to ipratropium. Another poorly studied area is the optimal method of administering bronchodilators. A metered-dosed inhaler is most frequently used with a spacer device such as the Aerochamber. Questions remain regarding the optimal dose, timing and assessment of clinical response when bronchodilators are used in children with established CLD.

### Diuretics

There have been few studies investigating the role of diuretics in CLD beyond the neonatal period. Even those in the neonatal unit have investigated only short term pulmonary outcomes such as decreased pulmonary resistance, improved compliance and reduced oxygen requirements. Cochrane reviews of the use of diuretics have concluded that studies of longer term outcomes are necessary.<sup>620–622</sup> Clearly diuretics are indicated for cardiac failure diagnosed by excessive weight gain, tachypnea, tachycardia, hepatomegaly and peripheral edema. The short-term benefits on respiratory mechanics from diuretics are likely to result from a direct action on pulmonary vascular resistance and on extracellular pulmonary water. Whether there are longer term benefits, e.g. decreased numbers of days of oxygen dependency, is currently unknown. In addition, adverse effects of long term diuretic treatment may be clinically important. The use of diuretics, especially loop diuretics such as furosemide, can result in renal calcification and calculi which often but not always resolve on cessation of therapy. It is usual practice to use loop diuretics in the short term and to change over to a combination of a thiazide and spironolactone to decrease the risks of adverse effects, although electrolyte imbalance with hyponatremia and hypokalemia may still be troublesome.

### PROGNOSIS

There has been great improvement in survival of preterm infants and, with home oxygen programs, the outlook for children with CLD has also improved vastly. However, although there is improvement in the respiratory status of preschool children following CLD as infants, as they reach adolescence there remains a degree of respiratory morbidity as evidenced by increased cough, wheezing and decreased exercise tolerance. Lung function improves with time but, compared with healthy controls or preterm controls without CLD, persisting abnormalities, particularly of FEV<sub>1</sub>, more peripheral airway function (FEF<sub>25–75</sub>) and gas trapping have been reported.<sup>623–625</sup> The decreased alveolar numbers described in infants with CLD is of concern.<sup>580</sup> Whether these children are candidates for chronic pulmonary dysfunction in later life remains to be seen.

### THE FUTURE

Despite improvements in prognosis for infants with CLD, there are a number of areas which need to be refined over the next few years. The optimal oxygen saturation range clearly needs to be identified. The role of therapeutic agents such as systemic and inhaled corticosteroids, bronchodilators and diuretics in children with established CLD clearly needs clarification. Further information regarding efficacy, doses and their timing and routes of administration is required urgently. The role of supportive therapies, such as the effects of nutrition on lung growth, need to be clarified further. Since candidates for developing CLD are preterm and at an early stage of lung development, we need a better understanding of both normal lung development in the fetus and also after the infant is delivered. Only by understanding the underlying mechanisms, including the role of antenatal factors such as infection in the development of CLD, are we likely to develop specific targeted therapies for developing or established CLD which do not have adverse effects, including poor neurodevelopment.

## CLINICAL ASSESSMENT OF HEART DISEASE

Detailed clinical evaluation is essential in the assessment of a child suspected of having a cardiac lesion. A comprehensive history provides information on the nature and severity of the condition. It also helps to establish a rapport with the child and family. A thorough physical examination is also necessary. If suspicion of a cardiac lesion exists, an electrocardiogram may give additional information. Chest radiography is seldom helpful in the diagnosis of a specific cardiac lesion. It remains useful in differentiating heart disease from other conditions and in assessing the severity of some lesions. Echocardiography has revolutionized the diagnosis and management of children with heart disease. It must be carried out and interpreted in conjunction with the clinical findings, if errors in diagnosis are to be avoided.<sup>1</sup> Cardiac catheterization is less frequently used in diagnosis, but transcatheter intervention is performed for a range of conditions. Other investigations are helpful in evaluating some children.

## HISTORY

Symptoms can give important clues to the diagnosis and severity of heart disease. The history can also help to differentiate cardiac lesions from other conditions.

*Infants* with heart failure present with feeding difficulties and symptoms of respiratory distress. The infant takes frequent small feeds, rapidly becoming exhausted. This results in poor weight gain, which in some children is also due to increased energy expenditure.<sup>2</sup> It is important to assess the volume of feed, or the time taken if breast-feeding. Infants may perspire profusely, particularly with feeds. Parents may notice that their baby breathes rapidly and suffers from recurrent chest infections. Cyanosis may not be recognized until it is quite severe.

*Children* often present with an asymptomatic murmur. Heart failure manifests as breathlessness and reduced exercise tolerance. Orthopnea and nocturnal dyspnea indicate severe heart failure. Cyanosis rarely

presents in children over a year of age. A history of 'blueness around the lips' is most likely to be due to cold, crying or breath-holding episodes.

A detailed history is also essential when assessing a child with palpitations, dizziness or syncope. In childhood, chest pain is rarely cardiac in origin and is more likely to be musculoskeletal, pulmonary or due to anxiety. Angina occurs during intense physical activity and is relieved by rest. It is a crushing central chest pain, not related to breathing.<sup>3</sup> It lasts some minutes, unlike muscular pain, which is often fleeting and sharp. Symptoms associated with acquired heart disease such as rheumatic fever, Kawasaki disease and myocarditis are discussed later.

Children may also have symptoms that are unrelated to a cardiac lesion. Nonspecific symptoms, such as tiredness, can cause concern in a child with a cardiac lesion. Reassurance may be necessary if this is not due to the heart condition. A history of prematurity, fetal distress or other congenital anomalies may have a bearing on diagnosis. A maternal history of diabetes, systemic lupus erythematosus, phenylketonuria or drug ingestion (p. 765) results in a higher incidence of congenital heart disease. A family history of heart disease, arrhythmias or sudden death, particularly in first-degree relatives<sup>4</sup> or parental consanguinity, results in an increased risk.<sup>5</sup>

## CLINICAL EXAMINATION

A detailed examination provides essential information for diagnosis, assessment of severity and monitoring of children with heart disease. Systematic examination is preferable but may be adjusted to obtain the maximum information in young children. It is sensible to listen to the heart with a toddler seated on the parent's lap before attempting to feel the femoral pulses or measuring the blood pressure.

## GENERAL FEATURES

Children with some congenital abnormalities have a 20–40% incidence of heart disease and 20% of children with a cardiac lesion will have

Table 21.1 Normal values of respiratory and heart rates in infants and children<sup>17</sup>

	Birth–6 weeks	6 weeks–2 years	2–6 years	6–10 years	Over 10 years
Respiratory rate/min	45–60	30–40	20–30	15–25	12–20
Heart rate/min	125 ± 30	115 ± 25	100 ± 20	85 ± 20	75 ± 20

an extracardiac anomaly.<sup>6</sup> Chromosomal abnormalities are the most common, occurring in 10% of children with congenital heart disease and this will increase as more are identified. Down, 22q11 deletion, Williams, Noonan and Turner syndromes are most commonly associated with congenital heart disease, but many other associations have been reported.<sup>1</sup>

Weight and height should be plotted on a growth chart together with birth weight, to assess growth. Poor growth is associated with heart failure and cyanosis. It may also be unrelated to the cardiac lesion, particularly in children with dysmorphic features. The respiratory rate should be recorded. Normal values are shown in Table 21.1.<sup>17</sup> Tachypnea may be cardiac or respiratory. Upper airway obstruction with stridor can occur in association with a vascular ring. Chronic upper airway obstruction can cause pulmonary hypertension. Estimation of the jugular venous pressure is difficult in young children, and hepatomegaly is a more reliable indicator of systemic venous congestion.

## CARDIOVASCULAR EXAMINATION

### Heart failure

Signs of heart failure should be sought in any child suspected of having a cardiac lesion (p. 762). Particular attention should be paid to peripheral perfusion, edema and respiratory distress.

### Cyanosis and clubbing

Mild central cyanosis may be difficult to detect. It must be distinguished from peripheral cyanosis (acrocyanosis) that does not involve well-perfused areas such as the tongue and mucous membranes. Central cyanosis requires the presence of more than 5 g/dl of reduced hemoglobin in the arterial circulation, so anemia will affect the recognition of cyanosis. With the advent of pulse oximetry it has become clear that cyanosis with an oxygen saturation in the region of 85% can be detected clinically in children in good light. Clubbing of the digits takes months to develop, and is not seen in young infants.

### Pulses

Pulses should be evaluated for rate, rhythm, volume and character. Rate varies with age, and ranges are shown in Table 21.1. Faster rates are normal during crying or activity, but persistent tachycardia (> 200 beats/min in neonates, 150/min in infants or 120/min in older children), bradycardia (< 70 in under young children, < 50 in older children) and irregular rhythms should be evaluated with an electrocardiogram. Sinus tachycardia is usually present with heart failure. The volume of both arms and femoral pulses should be assessed to exclude coarctation and other arterial anomalies. Radiofemoral delay is difficult to appreciate in children with a rapid pulse, but a difference between the volume of the right axillary and femoral pulse is significant. Femoral pulses should be checked at the postnatal examination, but if the arterial duct is still patent, the pulse may be palpable in the presence of coarctation. The femoral pulses should be checked again at routine assessments, and if there is a suspicion of heart disease. Poor volume of all pulses reflects a reduced cardiac output indicating hypoplastic left heart syndrome, critical aortic stenosis, severe heart failure, shock or cardiac tamponade. A wide pulse pressure (the difference between systolic and diastolic pressure) produces a collapsing (bounding) pulse in children with a large arterial duct, arteriovenous malformation, severe anemia and severe aortic regurgitation. A slow rising (plateau) pulse is found in severe aortic stenosis.

## Blood pressure

Blood pressure should always be recorded in *the right arm*, as the measurement in the left may be lower if coarctation is present.<sup>8</sup> Blood pressure should be measured with the child lying or sitting comfortably with the sphygmomanometer at heart level. The inflatable cuff should cover two thirds of the upper arm from shoulder tip to elbow and completely encircle the arm. A smaller cuff will give a falsely high reading. If there is any suspicion of aortic coarctation, both arm and leg pressures should be measured. The blood pressure in the leg is normally higher than the arm. A measurement in the leg that is 10 mmHg or more lower than in the arms is abnormal.

Blood pressure in children is labile, and measurements above the 95th percentile on at least three different occasions are necessary to diagnose hypertension.<sup>8</sup> Taller children have higher blood pressures than smaller ones. Charts of the 50th, 90th, 95th and 99th percentile for blood pressure, related to sex, age and height, are shown in Tables 21.2 and 21.3.<sup>8</sup> Twenty-four hour ambulatory blood pressure monitoring can be performed on older children. It is useful in those whose readings are affected by anxiety.

Automated oscillometric methods with digital readout of systolic, diastolic and mean pressure are increasingly used. These are reasonably reliable, but inaccuracies occur with movement. Measurement done in this way is approximately 10 mmHg higher than that obtained by auscultation.<sup>9</sup> Comparisons are not available for infants and young children. Measurements obtained by oscillometric devices that exceed the 90th percentile should be repeated by auscultation.<sup>8</sup>

## Precordial examination

This may reveal a bulge indicating chronic cardiac enlargement. Scars from previous surgery should also be noted. The apex beat is felt at the fourth left intercostal space within the midclavicular line. It is produced by the left ventricle and is displaced laterally and inferiorly with cardiomegaly. It is palpable on the right in dextrocardia. Left ventricular hypertrophy produces a forceful impulse that is usually not displaced. Right ventricular enlargement produces a diffuse impulse at the lower half of the sternum and in the epigastrium. A poorly felt apex beat suggests a pericardial effusion or severe heart failure. Dextrocardia should be excluded by palpating the right precordium. Thrills are palpable over the site of maximum intensity of loud murmurs, but the thrill of aortic stenosis is felt in the suprasternal notch. Thrills are usually systolic. Rarely diastolic thrills occur in severe mitral or tricuspid stenosis. The loud second heart sound of severe pulmonary hypertension is sometimes palpable.

## Auscultation

Auscultation of all phases of the cardiac cycle should be systematic and include the whole precordium, axilla and the back. Note changes during inspiration and expiration, and with the child sitting and lying. The heart sounds and high-pitched murmurs are best heard with the diaphragm of the stethoscope, and low-pitched ones with the bell.

The *first heart sound* is caused by mitral and tricuspid valve closure and is best heard at the apex. It is louder with tachycardia, as the valve leaflets are further apart in early systole. It is usually single, reflecting mitral closure but split if tricuspid closure is delayed. The *second heart sound* is caused by aortic and pulmonary valve closure and is best heard at the upper left and right sternal borders. During inspiration, pulmonary valve closure is delayed because of the increased volume

Table 21.2 Blood pressure levels for boys by age and height percentiles (adapted from Falkner et al<sup>6</sup>)

of blood returning to the right heart, causing audible splitting. On expiration the valves close simultaneously, and the sound is normally single. Delayed closure of the pulmonary valve in expiration results in ‘fixed’ splitting. It occurs in children with atrial septal defect or right bundle branch block. A single second heart sound occurs when one of the components is inaudible. The pulmonary component of the second heart sound is loud in pulmonary hypertension. A *third heart sound* occurs early in diastole and is caused by rapid ventricular filling. It is low-pitched and heard at the apex in normal children. A *fourth heart sound* occurs late in diastole and is due to atrial contraction. A *gallop rhythm* is caused by diastolic filling of a poorly compliant ventricle and occurs in heart failure. *Ejection clicks* are heard just after the first heart sound. They are due to abnormal but mobile valves, or proximal arterial dilatation. Pulmonary ejection clicks are maximal over the pulmonary area, but aortic ejection clicks are best heard at the lower left sternal edge. *Midsystolic clicks* are due to mitral valve prolapse (at the apex) or an Ebstein anomaly of the tricuspid valve (at the fourth left intercostal space).

*Murmurs* are described in terms of loudness, quality, timing, duration, site of maximum intensity and radiation.<sup>10</sup> Murmurs are graded from 1 to 6: 1 barely audible, 2 faint but heard immediately, 3 easily audible but no thrill, 4 easily audible with a thrill, 5 very loud, 6 heard without stethoscope. There is no relationship between loudness and severity of a lesion. The *quality* of a murmur can be distinctive. Innocent murmurs are often vibratory. A high-pitched blowing murmur is heard with aortic or mitral regurgitation, or a small muscular ventricular septal defect. A lower-pitched harsh murmur occurs with outflow stenosis or a perimembranous ventricular septal defect. A very low-pitched diastolic rumble occurs with mitral stenosis. Timing of murmurs is crucial in diagnosis.

*Systolic murmurs:*

- Early: due to a small muscular ventricular septal defect.
- Ejection (crescendo–decrescendo): due to aortic or pulmonary stenosis, atrial septal defect, innocent murmur.
- Pansystolic: due to a ventricular septal defect, mitral or tricuspid regurgitation.
- Late systolic: due to mitral valve prolapse.

In infants with fast heart rates, it can be difficult to distinguish between ejection and pansystolic murmurs. If a distinct first heart sound is audible, it is more likely to be ejection.

*Diastolic murmurs* are usually pathological and occur with a systolic murmur.

- Early (decrescendo): due to aortic or pulmonary regurgitation, and best heard with the diaphragm of the stethoscope.
- Mid-diastolic: due to increased flow or stenosis of the mitral or tricuspid valve and best heard with the bell of the stethoscope.

Presystolic accentuation indicates significant narrowing.

*Continuous murmurs* are heard during systole and through the second heart sound into diastole. They occur when an artery communicates with vessel or heart chamber at lower pressure in systole and diastole. They are caused by an arterial duct, systemic to pulmonary (Blalock–Taussig) shunt or arteriovenous fistula. They may be confused with ejection systolic murmurs closely followed by an early diastolic murmur, or a venous hum.

The *site of maximal intensity and radiation* of a murmur is very helpful in diagnosis. A murmur results from turbulent blood flow and is usually loudest at this site. The typical sites of maximal intensity of the common systolic murmurs are summarized in [Figure 21.1](#). A loud murmur will be conducted widely over the precordium, but most radiate to specific areas. The typical features of individual lesions are

Fig. 21.1 Diagrammatic representation of the precordium showing the usual sites at which the murmur of the most common acyanotic lesions is heard. AoSt, aortic stenosis; ASD, atrial septal defect; DA, ductus arteriosus; MR, mitral regurgitation; PSt, pulmonary stenosis; VSD, ventricular septal defect.

discussed separately. Table 21.4 summarizes the typical findings in common types of congenital heart disease.

## ELECTROCARDIOGRAPHY

Cardiac muscle, like all muscle, requires an electrical impulse to initiate depolarization. The heart generates and conducts its own electricity and electrocardiography records the cardiac electrical activity, usually from the body's surface. Electrocardiography is a fundamental part of assessment of children with known or suspected congenital or acquired cardiac disease. It provides the main method of evaluation of children with cardiac arrhythmias (p. 790).

Interpretation of the electrocardiogram is a skill acquired only with practice. Whilst the expert can evaluate an electrocardiogram (ECG) almost at a glance, the newcomer should adopt a systematic approach.<sup>11</sup>

Knowledge of the patient's age, cardiac (or other) diagnosis, and medications will enhance interpretation. One of the most important influences on interpretation of pediatric ECGs is the change in the normal ECG that occurs with growth and age. Familiarity with the variation in the normal pattern is required before distinction between normality and abnormality can be made with confidence.<sup>12-14</sup>

The ECG is conventionally recorded at a speed of 25 mm/s and at a calibration of 1 cm = 1 mV. Accurate positioning of the leads on the surface of the skin (especially the chest leads) is important. A standard 12 lead ECG includes three standard (bipolar) limb leads I, II, and III, three augmented unipolar limb leads aVR, aVL, and aVF, and six unipolar chest leads, V1–V6. Recordings from children sometimes include additional right chest leads V4R and/or V3R but these are generally less helpful now that echocardiography is widely available.

Routine evaluation of an ECG involves assessment of the heart rate, heart rhythm, QRS axis, then the P waves, QRS complexes, T waves and measurement of the PR, QRS and QT intervals. Many modern ECG machines automatically measure and display many of these variables. The measurements are usually accurate and reliable but a machine-derived interpretation of the ECG should always be treated with caution, even if it is produced by a pediatric algorithm. The machine often distinguishes between normality and abnormality fairly accurately (assuming the age of the child is entered into the algorithm) but analysis of the type of abnormality may be less reliable.

## THE NORMAL ELECTROCARDIOGRAM

Normal sinus rhythm produces a P wave with a normal axis originating from the high right atrium, normal 1:1 atrioventricular conduction with a normal PR interval, a QRS of normal duration, axis and morphology, and a T wave of normal axis and duration. The rapid evolution in the normal ECG in early infancy mainly reflects the change in ventricular dominance resulting from adaptation to postnatal hemodynamic changes. The changes in the normal pattern with age<sup>15</sup> and many

Table 21.4 Typical clinical findings in the most common forms of congenital heart disease

Lesion	Pulses	Ventricular activity	Heart sounds	Systolic murmur	Diastolic murmur	Radiation of murmur
Large ventricular septal defect (VSD)	Normal	Biventricular	Increased P2 if pulmonary hypertension	Pansystolic Lower left sternal edge	Mid-diastolic at apex	Apex and back
Small perimembranous VSD	Normal	Normal	Normal	Loud pansystolic Lower left sternal edge	Nil	To apex and back
Small muscular VSD	Normal	Normal	Normal	Soft early systolic Lower left sternal edge	Nil	Nil
Atrial septal defect	Normal	Right ventricle	Second sound widely split and 'fixed'	Ejection Upper left sternal edge	Mid-diastolic at left sternal edge	Back
Large arterial duct	Collapsing	Biventricular	Increased P2 if pulmonary hypertension	Continuous Upper left sternal edge	Mid-diastolic at apex	Back
Small arterial duct	Normal	Normal	Normal	Continuous Upper left sternal edge	Continuous	Nil
Pulmonary stenosis	Normal	Right ventricle (if severe)	Ejection click at pulmonary area	Ejection Upper left sternal edge	Nil	Back
Aortic stenosis	Normal	Left ventricle (if severe)	Ejection click at left sternal edge	Ejection Upper right sternal edge	Nil	Neck
Coarctation of the aorta	Reduced or delayed femoral pulse	Left ventricle (if severe)	Ejection click at left sternal edge (if bicuspid aortic valve)	Ejection Upper left sternal edge	Continuous if collaterals present	Back
Fallot's tetralogy	Normal	Right ventricle	Single second heart sound ± Ejection click	Long ejection Upper left sternal edge	Nil	Back
Transposition of the great arteries	Normal	Right ventricle	Single second heart sound	Nil	Nil	Nil

normal values for ECG measurements at different ages<sup>12,13</sup> have been well described.

U waves are commonly seen in children and may be prominent in chest leads. Peaked U waves (especially in lead V2) may occasionally give a notched appearance to the T wave and may simulate atrial tachycardia with 2:1 atrioventricular conduction. Check by examining other leads to confirm the presence of sinus rhythm with 1:1 conduction. One common normal variation is the presence of an RSR' pattern in lead V1. This does not amount to right bundle branch block, as the QRS duration is normal. T waves in lead V1 also vary considerably with age. They should be inverted between the ages of 7 days and 7 years and precordial T wave inversion may persist into adolescence. A rhythmic variation in sinus rate, related to respiration (respiratory sinus arrhythmia), is very common at all ages and should be regarded as normal. Minor variations in heart rhythm are also common at all ages and should be borne in mind when interpreting 24 h ECG recordings.<sup>16</sup>

In addition to the standard surface electrocardiogram, the exercise ECG may be used for dynamic assessment of children with structural heart disease. Signal averaging of the ECG is occasionally used for detection of underlying abnormalities not visible on a standard 12 lead ECG.<sup>17</sup> Heart rate variability analysis is a subtle form of autonomic evaluation that is still mostly used as a research tool.<sup>18</sup> Ambulatory recording of the ECG, patient-activated event recorders, and implantable loop ECG recorders are available for evaluation of patients with known or suspected cardiac arrhythmias.

## THE ABNORMAL ELECTROCARDIOGRAM

The sensitivity and specificity of the ECG in differentiation of normality from abnormality is very variable. The ECG is almost always abnormal in cardiac abnormalities such as atrioventricular septal defect, tricuspid atresia, anomalous origin of the left coronary artery from the pulmonary artery, Wolff–Parkinson–White syndrome and long QT syndrome but these are relatively rare conditions. However, other than in diagnosis of arrhythmias, there are few situations in which the ECG is diagnostic without being considered alongside the results of other investigations.

### The PR interval

The PR interval increases with age and decreases with heart rate. It is shortened in Pompe disease and in Wolff–Parkinson–White syndrome and is prolonged in conditions such as atrioventricular septal defect or Ebstein's anomaly of the tricuspid valve, by some drugs and in rheumatic fever.

### Ventricular hypertrophy

Unfortunately, the ECG performs poorly in evaluation of ventricular hypertrophy, particularly when this is mild, and echocardiography is often a more appropriate investigation.<sup>19</sup> Right ventricular hypertrophy is suspected when there is an upright T wave in lead V1 between the age

of 1 week and 7 years or when the height of the R wave in lead V1 is above the 98th centile for age. Other signs include a QR pattern in right chest leads, a deep S wave in lead V6, an RSR' pattern in V1 (as in atrial septal defect) and right axis deviation. Left ventricular hypertrophy is suspected when the R wave in V5 or V6 or the S wave in V1 exceeds the 98th centile, especially if there is associated lateral T wave inversion. Simply adding the R wave in V5 to the S wave in V2 or the R and S waves in V2 in the hope of detecting significant left ventricular hypertrophy has disappointing sensitivity and specificity.<sup>19</sup> Biventricular hypertrophy may be difficult to recognize. It is suggested when criteria for left and right ventricular hypertrophy are both satisfied, or by a combined R wave and S wave in lead V4 exceeding the 98th centile for age.

### Bundle branch block

Right bundle branch block (RBBB) results from a delay in activation of the right ventricle. Early activation of the left ventricle (as in Wolff–Parkinson–White syndrome with a left-sided pathway) gives a similar appearance. RBBB is recognized when the QRS duration is prolonged in association with a broad secondary R wave in V1 and a wide S wave in V6 (Fig. 21.2). It is a common finding after surgery for repair of a variety of congenital heart defects. 'Incomplete' RBBB (with a similar QRS morphology but a normal QRS duration) is a fairly common normal variant and is a characteristic, but not universal, feature of atrial septal defect.

Left bundle branch block (LBBB) is caused by delay in left ventricular activation. It produces a deep S wave or QS complex in lead V1 and a notched R wave in lead V6 (Fig. 21.3). The QRS duration is prolonged. A similar appearance is produced by early right ventricular activation (as in Wolff–Parkinson–White syndrome with a right-sided pathway or in right ventricular paced rhythm). LBBB is rare in children and is always abnormal. It may be seen in advanced aortic valve disease, cardiomyopathy, myocarditis, or after endocarditis but is perhaps most often found after cardiac surgery.

### Other abnormalities of the QRS complex and ST segment

Wolff–Parkinson–White syndrome is the association of an accessory atrioventricular conduction bundle with the propensity to cardiac arrhythmias. It produces a short PR interval and a slurred upstroke to the QRS – the delta wave (Figs 21.2 and 21.3). There is often an abnormal mean frontal QRS axis and T wave inversion but the exact pattern depends on the position of the accessory pathway.

Signs of ventricular ischemia or infarction are rare in children but they may be present in congenital abnormalities of the coronary arteries, Kawasaki disease, cardiomyopathy and myocarditis. They include reduction in the height of R waves, abnormal Q waves, abnormalities of the ST segment and T wave inversion. Pericarditis characteristically produces ST segment elevation without T wave inversion. ST shift is also seen in ischemia, metabolic disturbances, and head injury and is sometimes a normal variant in right precordial leads.

Fig. 21.2 A comparison of the ECG appearances of right bundle branch block (RBBB), Wolff–Parkinson–White syndrome with a left-sided accessory pathway (L WPW), and pacing from the left ventricle (LV Pace) in leads V1 and V6. The similarities are due to the fact that in each case the left ventricle is activated before the right ventricle.

Fig. 21.3 A comparison of the ECG appearances of left bundle branch block (LBBB), Wolff-Parkinson-White syndrome with a right-sided accessory pathway (R WPW), and pacing from the right ventricle (RV Pace) in leads V1 and V6. The similarities are due to the fact that in each case the right ventricle is activated before the left ventricle.

### Abnormalities of the QT interval

The QT interval is measured from the onset of the QRS complex to the end of the T wave (which is sometimes difficult to define) and is conventionally measured in lead II. It is shortened by hypercalcemia, hypoxia and digoxin and is prolonged by many factors including hypocalcemia, head injury, antiarrhythmic drugs such as amiodarone and sotalol, and sometimes by other drugs. Perhaps the most important cause of QT prolongation is the long QT syndrome. The QT interval, in common with all other intervals measured on the ECG, varies with the heart rate. It is usually normalized to a heart rate of 60 per minute to produce a corrected value (QTc) by dividing the measured QT interval (in seconds or milliseconds) by the square root of the RR interval (measured in seconds). Thus  $QTc = QT/\sqrt{RR}$ . The 'upper limit' of QTc is often said to be around 440 ms or 0.44 s but values up to 460 ms or 0.46 s may not be abnormal.

### CHEST RADIOGRAPHY

This provides some diagnostic information regarding significant cardiac lesions but is of no value in trivial defects or in distinguishing these from innocent murmurs.<sup>20</sup> Its role in diagnosis has largely been superseded by echocardiography. Chest radiography should be examined for the cardiac size and configuration, pulmonary vascularity and lung disease. Skeletal abnormalities, the thoracic and abdominal situs, and other abnormalities should also be identified. Repeated chest radiographs are of little value in assessing progress of a cardiac lesion.

**Cardiac size.** A semiquantitative assessment of the heart size can be calculated from the cardiothoracic ratio. This is the ratio of the cardiac diameter (measured as the sum of the distance from the midline to the right and left margins of the cardiac shadow) to the maximal internal thoracic diameter (Fig. 21.4). In normal children the ratio is less than 0.5 but can be up to 0.55 in the first two years of life. It is not possible to detect individual chamber enlargement without an additional lateral film, which is seldom justified. Cardiomegaly is almost always present with a significant cardiac defect, apart from obstructive lesions such as pulmonary or aortic stenosis. It is caused by:

- Ventricular enlargement due to volume overload associated with a left to right shunt, valve regurgitation or ventricular dysfunction.
- Atrial enlargement due to tricuspid or mitral regurgitation, or rarely stenosis.
- Pericardial effusion.

Isolated cardiomegaly, found when a chest radiograph is taken for another reason, is usually spurious. Reasons include a film that is not taken in full inspiration or one taken from the front (anteroposterior). Pectus excavatum and other skeletal abnormalities will also give the appearance of cardiomegaly. The thymic shadow in infants overlies the upper mediastinum and can suggest cardiomegaly.

**Configuration of the heart.** A characteristic appearance may be found with certain congenital cyanotic lesions but these are variable and are only suggestive of the diagnosis. The upper right cardiac border may have a bulge from anomalous pulmonary venous connection, or an azygous continuation of the inferior caval vein. A dilated ascending aorta or right aortic arch will give a similar appearance. A left superior caval vein or other abnormal systemic or pulmonary venous connection can cause an abnormal appearance of the upper left heart border. Post-stenotic dilatation of the pulmonary artery also causes a prominent shadow at the upper left heart border.

**Pulmonary vascularity.** Increased pulmonary blood flow from a left to right shunt is manifest as large vessels passing outwards from the hilum. With pulmonary edema the hilar vessels are less well defined but the bronchi become more easily seen. If pulmonary edema is severe, linear septal shadows appear in the lower lateral aspects of the lung fields. Pulmonary hypertension produces large proximal and small distal vessels. Underperfused (oligemic) lung fields are seen in cyanotic heart disease with reduced pulmonary blood flow.

**Pulmonary disease.** Chest radiology is important in distinguishing cardiac from respiratory disease in a symptomatic child.

**Other abnormalities.** A penetrated film demonstrating the bronchi can help to establish the thoracic situs. The left main bronchus arises from the trachea at a less acute angle and its first branch arises more distally. Congenital skeletal abnormalities occurring with certain syndromes such as VATERL will be apparent. Rib notching may be seen with coarctation of the aorta in older children.

### ECHOCARDIOGRAPHY

Echocardiography (the use of ultrasound to examine the heart) is the most important diagnostic technique in congenital heart disease.<sup>21-23</sup> Pediatric cardiologists rely on it to diagnose structural heart disease by creating moving images with cross-sectional (or '2D') echocardiography. Cardiac hemodynamics, including assessment of pressure gradients across stenoses and septal defects, are assessed with Doppler echocardiography. Precise timing of cardiac events and assessment of left ventricular function can be done with the older technique of single beam ultrasound ('M-mode' or movement-mode echocardiography).

Fig. 21.4 Diagrammatic representation of the measurement of the cardiothoracic ratio:

$$CTR = \frac{A + B}{C} \times 100 \text{ where}$$

A + B = maximum transverse diameter of the heart

C = maximum transverse diameter of the chest.

Since it is now such a crucial aspect of pediatric cardiology, it is important to know of its indications, strengths and limitations. A knowledge of cardiac anatomy is also necessary.

**CROSS-SECTIONAL (2D) ECHOCARDIOGRAPHY**

Echocardiographers usually use a sector scan; the image that results is shaped like a section of a pie. This sector is built up of many individual lines of ultrasound, sweeping across the sector. Since the heart rate is high in pediatrics, the frame rate (the number of completed sectors per minute) must be high to avoid a jerky appearance to the heart movement. The best definition is achieved by using ultrasound with higher frequencies, but the higher the frequency, the poorer the tissue penetration. The best compromise between these two factors means a frequency of 8–12 MHz can be used for preterm infants with often extremely good

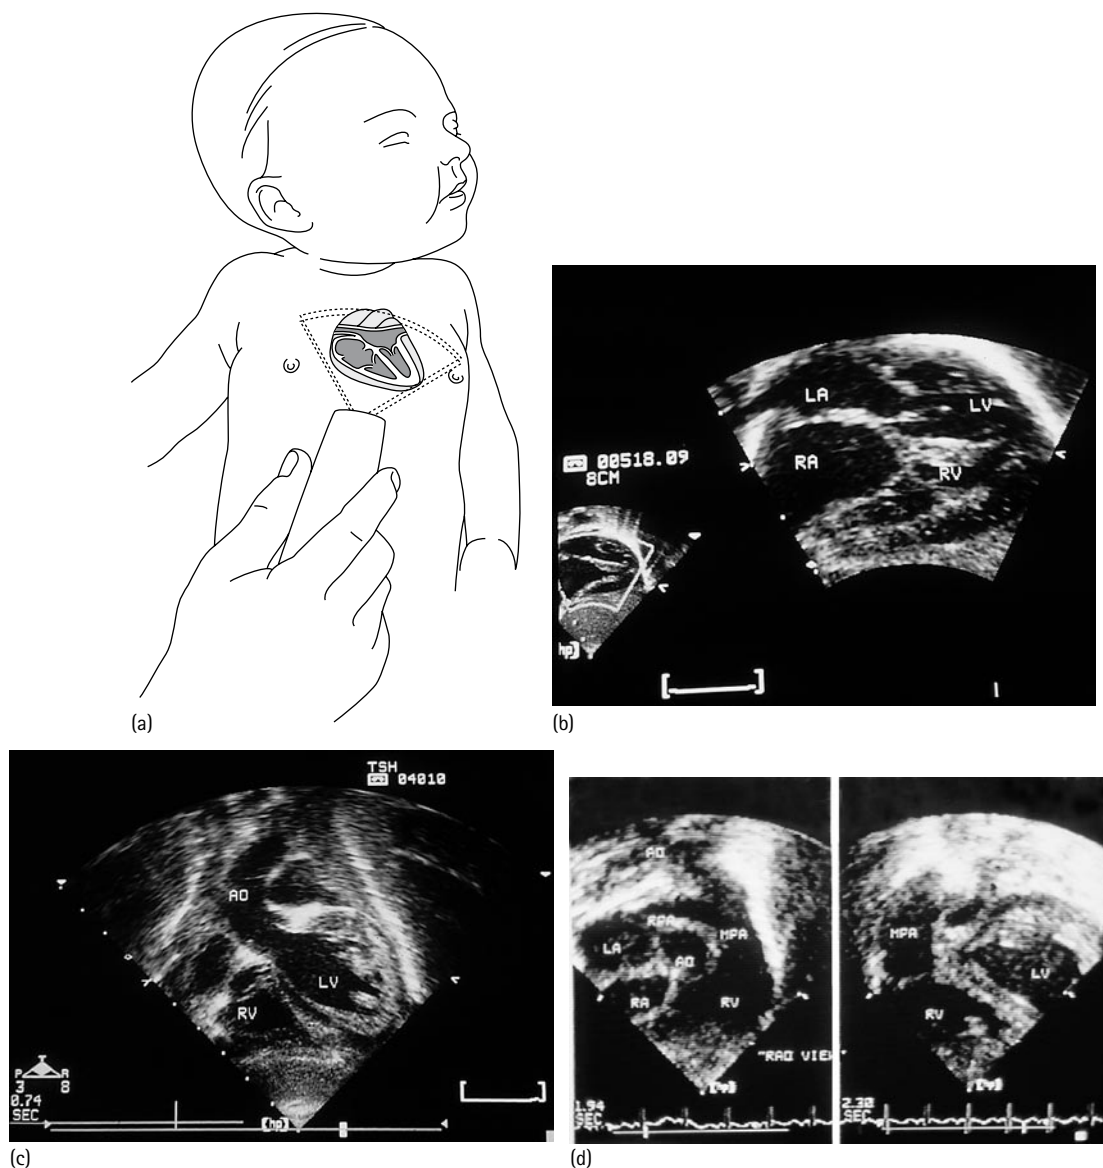

image quality, but a frequency of 2–3 MHz is needed for larger children and adults.

**Echocardiographic windows**

Since ultrasound cannot pass through the air within the lungs, the ultrasonic approach to the heart is through echocardiographic ‘windows’ where there is little or no air between the transducer and heart. These are subcostal, apical, parasternal and suprasternal (see Figs 21.5–21.9). In the newborn there are large echo windows making imaging easier than in older children and adults, and it is often possible to do most of the scan subcostally.

**Imaging axes**

Since the heart lies at an angle within the chest, the apex pointing caudal and leftward, the ‘standard’ anatomical cuts (coronal, sagittal, etc.)

**Fig. 21.5** (a) Diagram showing the position of the transducer and orientation of the scanning plane to provide a subcostal four chamber image of the heart. (b) Subcostal four chamber image demonstrating the four chambers. This is an ideal view to see atrial septal defects. (c) Tilting the probe anteriorly brings the ascending aorta into view. (d) Left: rotating anticlockwise brings the right ventricular outflow tract and pulmonary arteries into view [subcostal short-axis or ‘RAO’ (right anterior oblique) view]. MPA, main pulmonary artery; RPA, right pulmonary artery. Right: rotating clockwise shows the interventricular septum and another view of the right ventricular outflow tract. These views are especially useful in tetralogy of Fallot to assess obstruction of the right ventricular outflow tract. (From Skinner et al 2000<sup>23</sup>.)

**Fig. 21.6** (a) Diagram showing the position of the transducer and orientation of scanning plane to provide an apical four chamber view of the heart. (b) Apical four chamber echocardiogram. Note that the screen has been inverted. The arrow indicates the lower position of the tricuspid valve as it arises from the septum. This region between the two atrioventricular valves is known as the atrioventricular septum, dividing the left ventricle from the right atrium. (c) Apical view of the heart with the probe angled posteriorly to bring the coronary sinus (CS) into view (not to be confused with a low atrial septal defect!). (d) Apical view of the heart with the probe angled anteriorly and rotated to the right bringing the left ventricular outflow tract and aortic valve into view – this is an apical long-axis image. (From Skinner et al 2000<sup>22</sup>.)

are not used. Instead the scanning planes are related to the axis of the heart. There are three axes that form the majority of standard views. They correspond to the mathematical x, y and z axes and are at right angles to each other. They create the long axis, short axis and four chamber views. Examples from the normal infant's heart are shown in Figures 21.5–21.8.

## Relating normal cardiac anatomy to the standard echocardiographic views

### The four chamber views

The plane of this cut through the heart is parallel to the bed upon which the patient is lying. These views, from the apex or subcostal regions (Fig. 21.5b and 21.6b), show that the ventricles are caudal and leftward of their corresponding atria. The most caudal valve in the heart is the tricuspid, which is attached to the septum closer to the cardiac apex than the mitral valve. This offsetting of the tricuspid valve (Fig. 21.6b) means that there is an atrioventricular septum dividing the left ventricle from the right atrium; this part of the septum is absent in atrioventricular septal defects. Since a tricuspid valve is always associated with a right ventricle and a mitral valve with the left, this offsetting is used to identify left and right ventricles.

The atrial septum lies obliquely at 45° to the sagittal plane of the body and is best examined from the subcostal approach (Fig. 21.5). However, the ventricular septum curves in a complex way from a plane which is nearly sagittal to one which is nearly coronal, separating respectively the inlet and outlet portions of the two ventricles. Because of this complex shape, the search for ventricular septal defects needs to include all available views. There is also a tiny component of the septal wall which is not muscular and is known as the membranous septum, closely related to the tricuspid and aortic valves. It has atrioventricular and interventricular portions separated by the attachment of the septal leaflet of the tricuspid valve.

With posterior tilt of the probe in the four chamber plane, the entry of the pulmonary veins into the back of the left atrium can be seen, as can the coronary sinus running in the atrioventricular groove behind the left atrium and opening into the right atrium.

### Short axis views

These cut through the heart like transverse slices through a green pepper, and can be obtained from the left parasternal (Fig. 21.7) or subcostally (Fig. 21.5d – left). They show that the right heart 'wraps' around the left heart. The right heart chambers are anterior to the left

**Fig. 21.7** (a) Diagram showing the position of the transducer and orientation of the scanning plane to provide a parasternal short-axis image of the heart at the aortic valve level. (b) Parasternal short-axis echocardiograph at the level of the papillary muscles (towards the apex of the left ventricle). This image is used to obtain an M-mode cut through the left ventricle to assess left ventricular function (see text). (c) Tilting away from the apex (towards the right shoulder) brings this view of the mitral valve. AML, anterior mitral valve leaflet; PML, posterior mitral valve leaflet. (d) Further tilt shows this cut at the aortic valve [as in (a)]. Note here how three aortic valve leaflets are seen, and how the right heart wraps around the aorta. Tilting the probe further still away from the apex demonstrates the pulmonary artery bifurcation. (From Skinner et al 2000<sup>22</sup>.)

heart chambers. The left atrium is the most posterior cardiac chamber directly anterior to the esophagus at the bifurcation of the trachea, and has the pulmonary veins draining into the back of it. The right atrium is rightward and anterior, and the tricuspid valve is in a nearly vertical plane.

The aortic valve is seen to lie in a central position (Fig. 21.7d). The pulmonary valve lies anterior and cranially and the atrioventricular valves flank the posterior and caudal margins of the aortic valve. The pulmonary trunk comes from the anterior aspect of the heart, swings to the left side of the ascending aorta, heading posteriorly, bifurcating into the left and right pulmonary arteries. This posterior course of the main pulmonary artery explains why pulmonary valve stenotic murmurs are transmitted to the back.

Angling the short axis cut down towards the apex of the left ventricle brings first the mitral valve structures into view, gaping like a 'fish mouth' as the leaflets open and close (Fig. 21.7c). The cut nearer the apex shows that the mitral valve is tethered and supported by two groups of papillary muscles: the anterolateral and posteromedial groups (Fig. 21.7b).

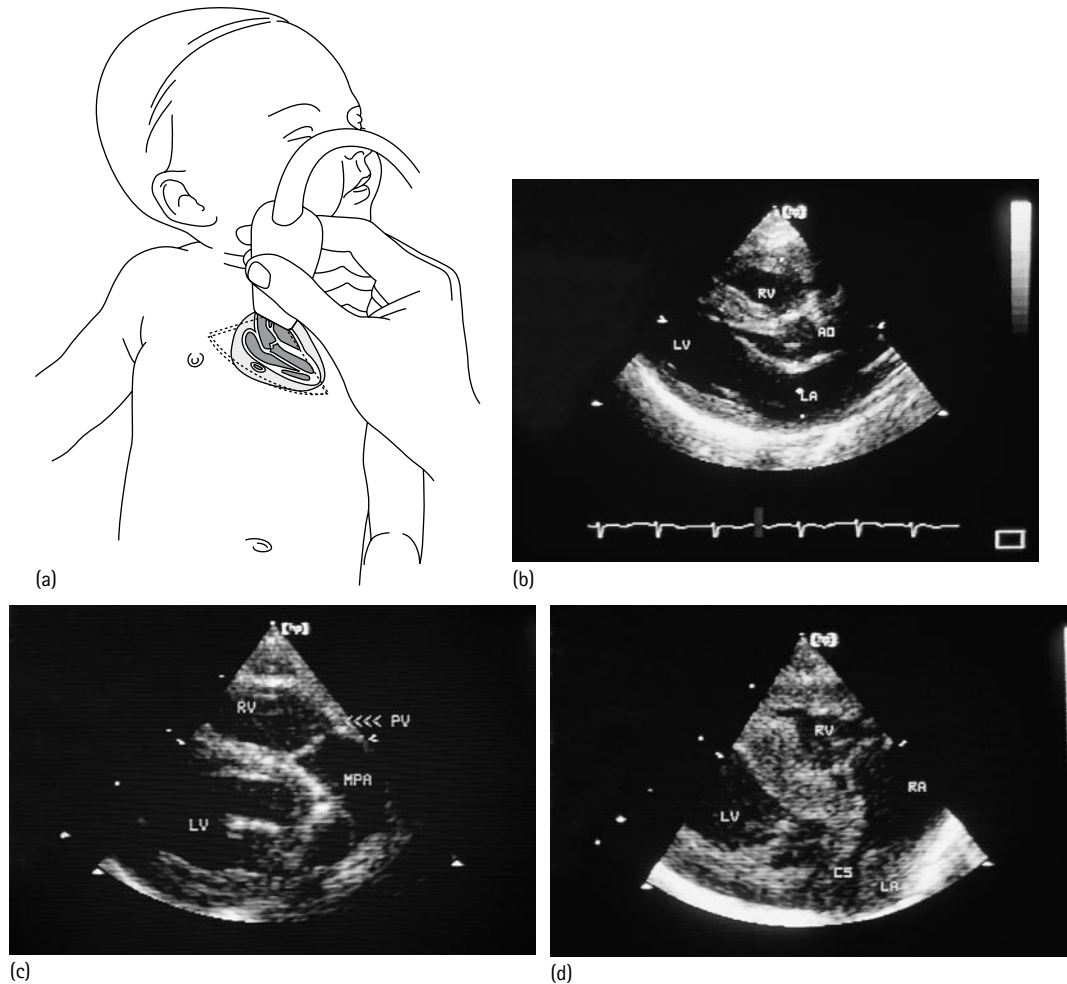

### Long axis views

These views (imagine a cut through the stalk and extending into a green pepper) can be obtained from the left parasternum (Fig. 21.8) or the apex (Fig. 21.6c). They show the relatively straight outflow from the left ventricle to the aorta (compare this to the angled outflow of the right ventricle seen in the short axis view). The anterior leaflet of the mitral valve is in fibrous continuity with the aortic valve, whereas there is a muscular infundibulum between the tricuspid valve and the pulmonary valve. The ascending aorta passes superiorly, obliquely to the right and slightly forwards towards the sternum.

### Suprasternal views

These views (Fig. 21.9) demonstrate the arch of the aorta which supplies origins to the brachiocephalic (innominate) artery and the left common carotid artery as it runs superiorly for a short distance before passing backwards and to the left. The arch finishes on the lateral aspect of the vertebral column after the origin of the left subclavian artery. Aortic coarctation most commonly appears just after this point.

**Fig. 21.8** (a) Diagram showing the position of the transducer and orientation of scanning plane to provide a parasternal long-axis image of the heart. (b) Echocardiogram showing a standard parasternal long-axis image of the heart, ideal for demonstrating the left heart. The mitral valve is widely open in this diastolic frame. Ao, aorta; LV, left ventricle; RV, right ventricle. (c) Tilting towards the left shoulder reveals a long-axis view of the main pulmonary artery (MPA) and pulmonary valve (PV). (d) Tilting to the right, away from the left shoulder, reveals the tricuspid valve between the right atrium (RA) and right ventricle (RV). The coronary sinus (CS) is seen draining into the right atrium. LA, left atrium. (From Skinner et al 2000<sup>23</sup>.)

### THREE-DIMENSIONAL ECHOCARDIOGRAPHY

Increased computer power means that freehand real-time three-dimensional echocardiography will begin to move from the research laboratory into clinical practice. Early signs are that this will improve diagnostic accuracy in congenital heart disease.<sup>24</sup>

### NOMENCLATURE IN CONGENITAL HEART DISEASE

There is a trend to avoid eponyms and Latin terms in congenital heart disease because they may mislead and are confusing to nonspecialists; 'solitus' doesn't mean solitary for instance, but 'usual'. 'Inversus' doesn't mean mirror imaged, it actually means 'upside down'. Another essential and helpful part of new cardiac anatomical nomenclature is 'sequential chamber localization' or 'sequential segmental analysis'<sup>25</sup> where congenital heart disease is characterized descriptively using anatomical and physiological terms in a sequential fashion.

### SEQUENTIAL CHAMBER LOCALIZATION

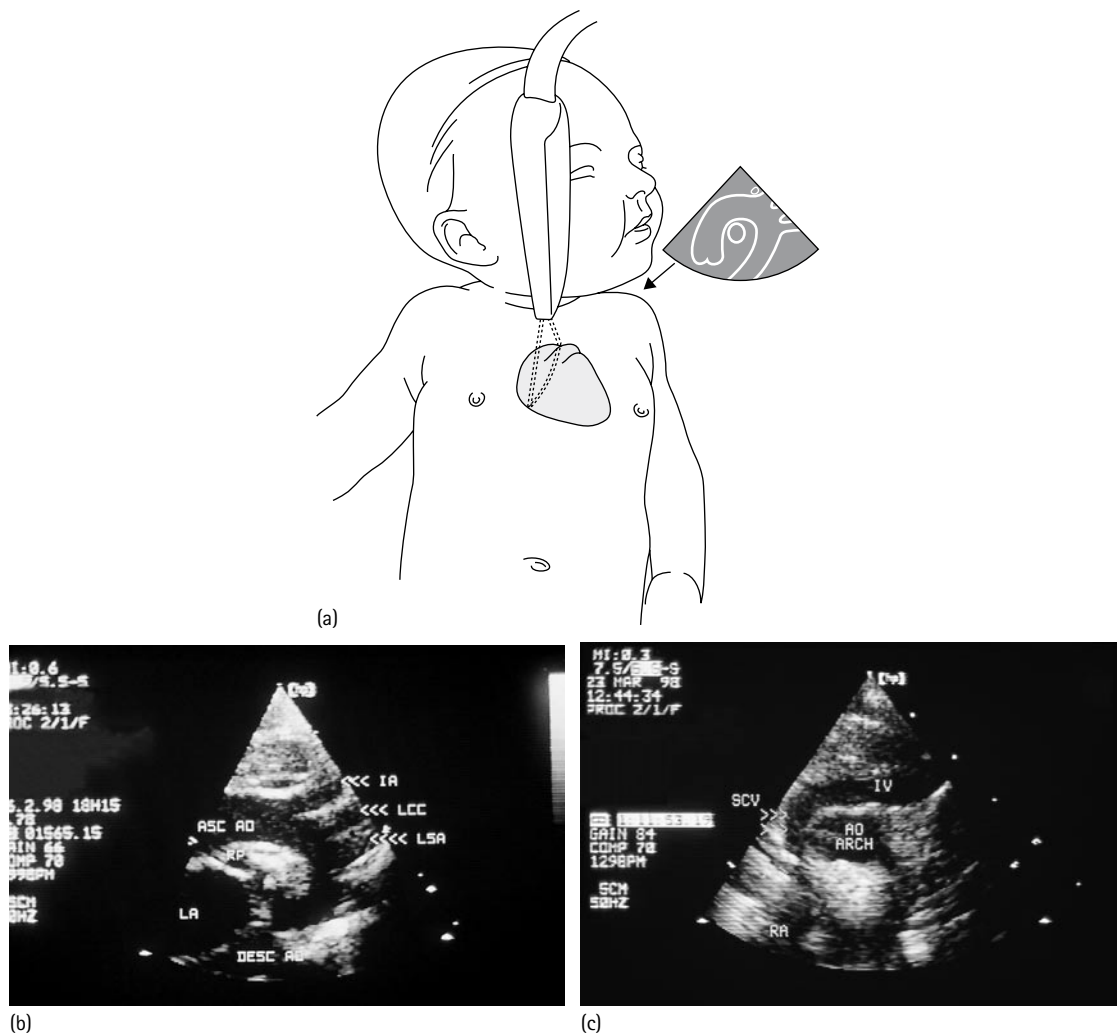

If you wish to build a safe house, you first consolidate the foundation before proceeding to the subsequent floors. Taking the same approach to help understand and describe complex heart diseases,

the floors, or segments, of the heart are the atria, the ventricular mass and the great arteries. The type of connection between each segment is also described. The possibilities for each segment are shown in [Table 21.5](#).

Thus a normal heart has the usual atrial arrangement, atrioventricular concordance and ventriculo-arterial concordance. A cyanosed newborn with transposed great arteries has isolated ventriculo-arterial discordance. The condition formally known as 'congenital corrected transposition' is now described as atrioventricular discordance with ventriculo-arterial discordance. The infant is not cyanosed, but the morphological right ventricle is the systemic ventricle. Most pediatric cardiologists start scanning from venous inflow and end with arterial outflow, noting abnormalities along the way. This means starting with subcostal views and ending with the suprasternal views.

### Venous inflow and the atria

In the transverse abdominal cut, the inferior caval vein is normally to the right and the aorta to the left. This is reversed when there is abdominal situs inversus (mirror image position). If the thoracic contents are also mirror-imaged, the apex of the heart is seen pointing to the right. The incidence of congenital heart disease is not increased in such cases. It is, though, if the heart and the stomach are not on the same side.

**Fig. 21.9** (a) Diagram showing the position of the transducer and orientation of the scanning plane required to obtain views of the aortic arch with a conventional left-sided aorta. Note that a roll has been placed behind the shoulders to extend the neck. (b) Image of the aortic arch and branches obtained from the suprasternal window. IA, innominate artery (or right brachiocephalic artery); LCC, left common carotid artery; LSA, left subclavian artery. Arch interruptions and coarctations are best viewed like this. (c) With a transverse scanning plane, the innominate vein (IV) drains to the superior caval vein (SCV). (From Skinner et al 2000<sup>23</sup>.)

**Table 21.5** Possible sequential segmental arrangements in congenital heart disease

Segment	Possibilities	Examples/comments
Great veins	Describe abnormalities of position and connection	e.g. Anomalous pulmonary venous drainage, left superior caval vein connecting to coronary sinus
Atria	Usual arrangement Mirror image (left atrium on the right side) Two right atria (right atrial isomerism) Two left atria (left atrial isomerism)	'Situs inversus' Asplenia is common, pulmonary veins connect abnormally Often no inferior caval vein present
Atrioventricular connection	Concordant (RA–RV, LA–LV) Discordant (RA–LV, LA–RV) Ambiguous (if the two atria are the same morphology) Absent right connection Absent left connection Double inlet	e.g. Tricuspid atresia e.g. Mitral atresia
Ventricular mass	Two ventricles (biventricular connection) 'Single' ventricle (univentricular connection) LV with a rudimentary RV RV with rudimentary LV Solitary indeterminate ventricle	This is the most common form
Ventriculo–arterial connection	Concordant (RV–PA, LV–Aorta) Discordant (RV–Aorta, LV–PA) Double outlet Single outlet	Most common is double outlet RV e.g. Common arterial trunk, pulmonary atresia
Great arteries	Describe abnormalities	e.g. Patent arterial duct, aortic coarctation, branch pulmonary artery stenosis

Totally anomalous pulmonary venous drainage is seen as failure of the pulmonary veins to connect to the back of the left atrium (Fig. 21.10a).

The echocardiogram is not reliable in deciding on the atrial arrangement. The appearances of the atrial appendages are the only reliable way of differentiating the atria, and they are often not well seen. Fortunately the plain chest X-ray can help. The atria and lung always go together. On chest radiography, a short bronchus on the right suggests a three-lobed right lung on that side with early branching, and a right atrium on the right. On the left, the bronchus is normally longer and bifurcates to supply a two lobed lung indicating that the morphological left atrium lies on the left. Mirror imaging of the lungs will give a long bronchus on the right and a short one on the left. Two long bronchi means two left lungs and two short bronchi means two right lungs – left atrial isomerism and right atrial isomerism respectively. Atrial septal defects are best defined from the subcostal position.

### Atrioventricular connection

The connection may be 'concordant' when right atrium leads to right ventricle and left atrium to left ventricle (Fig. 21.6b), or 'discordant'

when right atrium leads to left ventricle and left atrium to right ventricle. A 'univentricular connection' occurs when both atria drain to one ventricle, either a double inlet left or right ventricle (Fig. 21.10c). There is another form of univentricular connection where either the right or left connection is absent, either mitral or tricuspid atresia (Fig. 21.10b) ('absent left' or 'absent right AV connection' respectively). In the presence of atrial isomerism, the atrioventricular connection is of necessity 'ambiguous', as it cannot be either truly concordant or discordant.

### Ventricles

To define atrioventricular concordance the ventricles need to be positively identified, not by position (since a morphological right ventricle can be on the left for example), but by morphology. If there are two ventricles in the heart, the tricuspid valve is always in the right ventricle and the mitral always in the left ventricle. The atrioventricular valve anatomy is, therefore, the most reliable way of identifying the ventricle.

The right ventricle is identified by its heavy trabeculation, a muscular 'moderator band' across its apex, an infundibulum (muscular section

Fig. 21.10 Echocardiographic images in children with abnormal connections. LA, left atrium; RA right atrium. (a) Totally anomalous pulmonary venous drainage. The pulmonary veins drain into a pulmonary venous chamber (PVC) which does not communicate with the left atrium. (b) Absent right atrioventricular connection (tricuspid atresia). The diminutive right ventricle is hardly visible. The interatrial septum bows across to the left, since in this case the atrial septal defect was restrictive. MV, mitral valve. (c) Double inlet ventricle. Both atrioventricular valves enter into a single large ventricle (V). (d) Ventriculo-arterial discordance. The left ventricle connects with an artery that bifurcates early and is hence the pulmonary artery (PA). This infant was cyanosed due to transposition of the great arteries. (From Skinner et al 2000<sup>23</sup>.)

dividing inlet from outlet) and a tricuspid valve which attaches directly to the septum and inserts more apically than the mitral valve. The left ventricle has finer trabeculations, no infundibulum and the mitral valve attached to (usually) two papillary muscles but never attached to the septum.

One or other of the ventricles may be small or even absent. Patients with double inlet left ventricle usually have a small anterior right ventricle connected to the main chamber by a ventricular septal defect and leading to a great artery, frequently the aorta. Double inlet right ventricles with smaller posterior left ventricles are excessively rare. Very occasionally there are truly single ventricle hearts.

### Practical point

Features that help to differentiate the right from the left ventricle in complex congenital heart disease:

#### The tricuspid valve

- Is always associated with the morphological right ventricle.
- Is supported in part from the septum.
- Is not in fibrous continuity with the outlet valve.
- Arises from further down the septum than the mitral valve.

#### The mitral valve

- Is always associated with the morphological left ventricle.
- Is in fibrous continuity with the outlet valve.
- Has no support from the septum.

### Ventriculo-arterial connections

The aorta is identified by not branching early, and having coronary arteries arising from it. The pulmonary artery bifurcates early into two branches. The connection can be 'concordant' when the right ventricle leads to the pulmonary artery and left ventricle to the aorta, or 'discordant' when the right ventricle leads to aorta and left ventricle to pulmonary artery (complete transposition) (Fig. 21.10d). 'Double outlet' can be present from either right or left ventricle and 'single outlets' of the heart describe pulmonary atresia, aortic atresia and common arterial trunk.

Associated lesions such as ventricular and atrial septal defects, valve stenosis or regurgitation, and great arteries abnormalities such as patent arterial duct or aortic coarctation must be identified.

### DOPPLER ECHOCARDIOGRAPHY

The speed of blood flow is determined by the Doppler shift created by moving red cells reflecting back ultrasound waves at a different frequency from that which was transmitted by the transducer/receiver. If our brains were programmed like an echocardiography machine, we would be able to determine the speed of an ambulance, with siren blaring, by the increase in pitch as it raced towards us.

The speed of blood flow calculated is relative to the transducer/receiver. Blood flowing at ninety degrees will cause no frequency shift. It is therefore essential to align with flow in order to determine the true speed. From blood flow velocity it is possible to derive volume of blood flow (cardiac output) and pressure gradients (see below). There are three modes of Doppler ultrasound: pulsed wave, continuous wave and color Doppler.

#### Pulsed wave Doppler ultrasound

Low velocities can be sampled in discrete positions around the heart using pulsed-wave Doppler ultrasound. A small sampling gate is superimposed on the imaging screen. The receiver only listens for its transmitted pulse when it expects the sound waves to have returned (according to the speed of sound and the distance away).

High velocities cannot be measured reliably with pulsed wave Doppler due to a problem relating to the sampling frequency needing to be at least half the wavelength of the frequency shift (the Nyquist limit). Instead, high velocities are measured with continuous wave Doppler ultrasound.

#### Continuous wave Doppler ultrasound

This form of Doppler ultrasound continuously sends and receives its signals. It is not subject to the Nyquist limit and can measure very high velocities accurately. However, since it receives signals back from all along its course, and not at one particular depth, care has to be taken not to be confused by high velocities coming from a valve or vessel further away or closer than that being imaged. An example of a high velocity is shown in Figure 21.11.

#### Colour Doppler ultrasound

This is created by the computerized ultrasound machine placing hundreds of pulsed wave Doppler sample gates all over the cardiac chamber, and color coding the speed and direction at that point. For example, red and yellow are slow and fast towards the probe respectively, and blue and green are slow and fast away from the probe. Areas of turbulence and high velocity are shown by a mosaic of mixed colors. This technique is especially useful in detecting ventricular septal defects, valvar or arterial stenosis, and regurgitation (Fig. 21.11).

#### Determination of pressure gradient

The simplified Bernoulli equation can be used to estimate pressure drop across a stenosis, across a shunt lesion such as a ventricular septal defect, or across a regurgitant valve. The peak velocity is measured with continuous wave Doppler:

$$P_1 - P_2 = 4V^2$$

$P_1 - P_2$  is the pressure drop across the obstruction (mm Hg) and  $V$  is the peak velocity (m/s). It is imperative that the Doppler beam is aligned with flow, to avoid underestimation of the peak velocity.

#### Valvar stenosis

This technique means that cardiac catheterization is no longer needed to determine pressure gradients across valves. However, the Doppler gradient is consistently higher than that measured at catheterization. This is because the Doppler gradient is the maximal instantaneous pressure gradient (the largest difference before and after the stenosis at any time in the cardiac cycle), whereas catheter gradients are expressed as the peak to peak gradient (the difference between the highest pressure before and the highest pressure after the stenosis).

#### Pulmonary arterial (PA) pressure

Pulmonary arterial pressure can be estimated by determining the pressure drop between the right ventricle (RV) and the right atrium (RA) by measuring peak velocity of tricuspid regurgitation (TR). Thus:

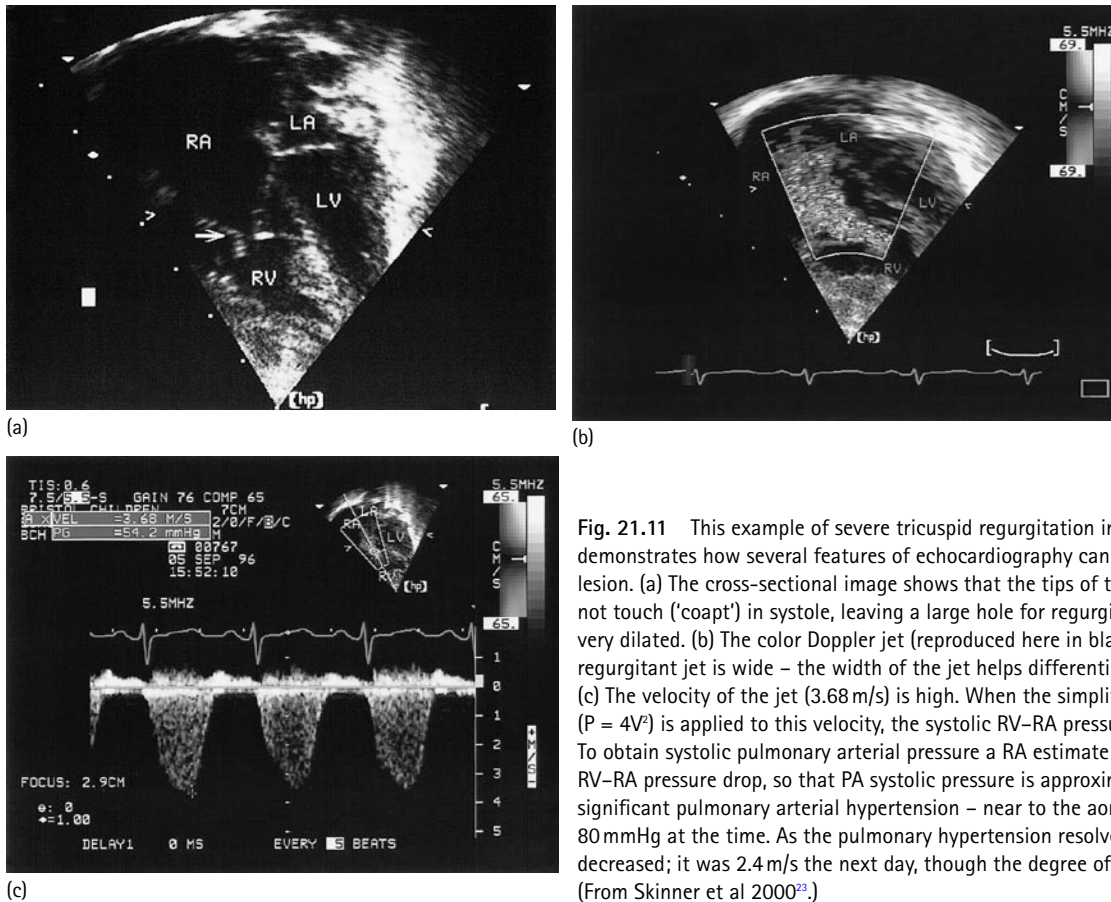

$$\text{RV systolic pressure} = 4 \times \text{TR jet velocity}^2 + \text{RA pressure}$$

Right ventricular systolic pressure approximates to pulmonary arterial systolic pressure (if the pulmonary valve is not stenotic), and right atrial pressure varies little and can in most circumstances be assumed to be 5 or 10 mmHg. The technique is remarkably accurate at all ages and is valuable because of the high incidence of trivial or mild tricuspid regurgitation in the normal population and in many congenital heart diseases. Pulmonary artery pressure can also be estimated by measuring the peak velocity across a ventricular septal defect or arterial duct.

#### Determination of cardiac output

It is possible to determine left and right ventricular output reasonably reliably in the absence of turbulence in either outflow tract. Cardiac output is equal to stroke volume  $\times$  heart rate. Left ventricular stroke volume (LVO) is determined by multiplying the flow velocity integral at the aortic valve (measured with Doppler) and the cross-sectional area of the aortic valve (AoCSA) (determined from the valve diameter measured with cross-sectional echocardiography). The flow velocity integral is the area under the velocity curve, and is often known as the 'stroke distance'

**Fig. 21.11** This example of severe tricuspid regurgitation in a newborn infant demonstrates how several features of echocardiography can be put together in assessing a lesion. (a) The cross-sectional image shows that the tips of the tricuspid valve leaflets do not touch ('coapt') in systole, leaving a large hole for regurgitation. The right atrium (RA) is very dilated. (b) The color Doppler jet (reproduced here in black and white) shows that the regurgitant jet is wide – the width of the jet helps differentiate grades of severity. (c) The velocity of the jet (3.68 m/s) is high. When the simplified Bernoulli equation ( $P = 4V^2$ ) is applied to this velocity, the systolic RV–RA pressure drop is 54.2 mmHg. To obtain systolic pulmonary arterial pressure a RA estimate of 10 mmHg is added to the RV–RA pressure drop, so that PA systolic pressure is approximately 64 mmHg. There was significant pulmonary arterial hypertension – near to the aortic pressure in this infant of 80 mmHg at the time. As the pulmonary hypertension resolved the regurgitant jet velocity decreased; it was 2.4 m/s the next day, though the degree of regurgitation remained severe. (From Skinner et al 2000<sup>23</sup>.)

(AoSD), since it represents the distance the column of blood ascends the aorta in systole.

$$\text{LV stroke volume(cc)} = \text{AoSD(cm)} \times \text{AoCSA(cm}^2\text{)}$$

$$\text{LV cardiac output(cc/min)} = \text{AoSD(cm)} \times \text{AoCSA(cm}^2\text{)} \times \text{heart rate}$$

It is usual to represent ventricular output indexed to body surface area (litres/min/m<sup>2</sup>). The technique is of research interest, especially in intensive care, but is not widely used due to concerns of repeatability error in measurements.

### Assessment of valvar regurgitation

Color Doppler is of immense value in identifying valve regurgitation, but the assessment is not precisely quantifiable. Other semiquantitative measurements are added to a visual assessment of the color jet. The more severe the regurgitation, the wider the color jet at the valve. The method is more sensitive than auscultation. Trivial valvar regurgitation is a normal finding in all except the aortic valve. Severe atrioventricular valve regurgitation is associated with dilatation of the respective atrium, and reverse flow in the caval or pulmonary veins. Severe aortic or pulmonary valve regurgitation leads to dilatation of the corresponding ventricle, and reverse flow in the distal pulmonary arteries or descending aorta, respectively.

### Assessment of ventricular function

**Right ventricle.** Visual assessment of ventricular function from cross-sectional images (normal, hyperdynamic, mild, moderate or severe depression) is still the best method of evaluating right ventricular function. This is because the complex shape of the right ventricle makes it difficult to obtain repeatable measurements and accurate mathematical algorithms.

**Left ventricle.** The left ventricle is more amenable to mathematical algorithms to determine ejection fraction. However, the single most useful

and repeatable technique avoids such complex formulae and employs M-mode echocardiography to measure the *fractional shortening* (FS) or percentage reduction of the left ventricular diameter in systole. Thus:

$$\text{FS(\%)} = \frac{\text{LV diastolic dimension} - \text{LV systolic dimension} \times 100}{\text{LV diastolic dimension}}$$

The normal value lies between 28% and 44% and is reduced with poor myocardial function and increased with volume overload, such as with a left to right shunt through a ventricular septal defect or arterial duct. The measurements are made just beyond the tips of the mitral valve, from the parasternal position, and accurate measurements of septal and posterior wall thickness can be made in assessing ventricular hypertrophy (Fig. 21.12).

## CARDIAC CATHETERIZATION

Diagnostic cardiac catheterization and angiocardiology are undertaken to obtain detailed information on the anatomical abnormality and its hemodynamic effects. The indications for diagnostic catheterization have changed with the widespread availability of high resolution echocardiography. With hemodynamic information from spectral Doppler studies and color Doppler mapping to assist in shunt detection, most congenital heart disease can be diagnosed and managed using echocardiography alone.<sup>26</sup> Cardiac catheterization is necessary to obtain accurate assessment of pulmonary vascular disease and for accurate shunt calculations.<sup>27</sup> Angiography is useful for coronary and distal pulmonary artery imaging and clarification of more complex arterial or venous abnormalities. However, computerized tomography and magnetic resonance imaging provide excellent images of vascular structures.

Cardiac catheterization is usually performed under general anesthesia, although occasionally procedures in infants and adolescents may be

Fig. 21.12 The M-mode images across the short axis of the left ventricle (a) with the cross-sectional image (b) showing the position from which the M-mode image is derived. Fractional shortening is calculated as end diastolic diameter (EDD) – end systolic diameter (ESD) divided by end diastolic diameter  $\times 100$ .

undertaken with local anesthesia and sedation. The approach is generally percutaneous through the femoral vessels, although the brachial, axillary or internal jugular routes are occasionally used. Arterial catheterization may be avoided if the venous catheter can be passed into the left side of the heart through an atrial or ventricular septal defect. An atrial septostomy can be performed through the umbilical vein in the first few days of life.

### Calculating the left to right shunt

The oxygen saturation is measured in the large veins, atria, ventricles and great arteries. A significant left to right shunt is suggested by a rise in oxygen saturation of 5% or more in the right atrium (atrial septal defect), right ventricle (ventricular septal defect) or pulmonary artery (persistent arterial duct). Systemic and pulmonary output can be calculated from the Fick principle<sup>37</sup> and the pulmonary to systemic flow ratio (Qp:Qs) is calculated from the oxygen saturation values in the aorta (Ao), pulmonary artery (PA), pulmonary vein (PV) and the mixed venous saturation (MV) from the formula:

$$Qp : Qs = \frac{Ao - MV}{PV - PA}$$

While these figures give results sufficiently accurate for clinical management, they are not absolute values and will vary with time and hemodynamic status. A shunt ratio of more than 1.8:1 is likely to require intervention, whereas one of less than 1.5:1 is insignificant.

### Pressure gradients

Pressures are measured in the atria, ventricles, great arteries and occasionally veins. Peak pressures in the ventricles and arteries measure transvalvar or arterial gradients. In children, the gradient rather than valve area is generally used in deciding on the need for intervention. Pressure gradients show considerable variation with time or sedation. Consideration must be given to whether the need for intervention should be based on a Doppler measurement with the patient awake, rather than a lower one obtained at catheterization with the child sedated or anesthetized.

### Pulmonary vascular resistance

The mean pressure in the atria and great arteries is required for estimation of pulmonary and systemic vascular resistance, which is indexed for body surface area.<sup>37</sup> The pulmonary vascular resistance, rather than the pulmonary artery pressure, is the main determinant of the prognosis and the operability of a child with a left to right shunt. When it is elevated, it is appropriate to assess whether it is fixed or can be reduced by the administration of a pulmonary vasodilator such as 100% oxygen or nitric oxide<sup>27</sup> at the time of the catheter procedure.

### Angiography

This is performed by the injection of radiological contrast into the chamber or vessel immediately proximal to the abnormality, e.g. left ventricle for ventricular septal defect, right ventricle for pulmonary stenosis, and ascending aorta for coarctation. Angiography is now less important for the definition of cardiac and vascular abnormalities as echocardiography, computerized axial tomography and magnetic resonance imaging provide similar information less invasively.

### Complications

Although cardiac catheterization is a relatively safe procedure, death can occur, most commonly in patients with severe pulmonary hypertension. Complications include femoral artery occlusion, hemorrhage (from cardiac structures or traversed vessels), arrhythmias, cardiac or vessel damage, and cerebral embolism.

## INTERVENTIONAL CARDIAC CATHETERIZATION

More than half of all pediatric cardiac catheterization is now related to interventional procedures and is a crucial part of the management of heart disease in children. Balloon atrial septostomy (Fig. 21.13) was the first pediatric interventional catheter procedure and it remains life saving for infants with inadequate intracardiac mixing, as in transposition of the great arteries. It can be performed using ultrasound or radiographic imaging.<sup>28</sup>

### Opening procedures

Balloon Valvuloplasty (Fig. 21.14) is now the accepted treatment for pulmonary valve stenosis.<sup>29</sup> It is safe and effective (unless there is severe valve dysplasia) and seldom requires reintervention.<sup>30,31</sup> It can be performed in the neonatal period.<sup>32</sup> Aortic balloon valvuloplasty is an alternative to surgery for aortic stenosis<sup>33</sup> unless there is additional significant regurgitation. The results are comparable<sup>34–36</sup> but both are palliative, and progression of aortic stenosis always occurs.

Balloon dilatation, with or without stenting, is used for a wide variety of arterial and venous narrowing.<sup>28</sup> Balloon dilatation is the treatment of choice for residual or recurrent coarctation following surgery.<sup>37,38</sup> However, there is a higher risk of aneurysm and residual hypertension in young children who have not had previous surgery.<sup>39</sup> Balloon dilatation does not appear to be effective in the treatment of

(a)

(b)

(c)

**Fig. 21.13** Balloon atrial septostomy using echocardiographic imaging. (a) A balloon septostomy catheter is advanced from the umbilical or femoral vein into the right atrium and across into the left atrium. (b) The balloon is inflated in the left atrium and pulled across the atrial septum. (c) The atrial septal defect created is identified with the asterisk. LA, left atrium; RA, right atrium.

neonatal coarctation.<sup>40</sup> Balloon dilatation is also used to improve narrowing of pulmonary arteries.<sup>41</sup> In smaller children, balloon dilatation alone is usually performed, but in older children and adolescents, stent placement, although technically challenging, may provide more effective and longer lasting relief of stenoses. Balloon expandable metallic stents are used for treatment of both recurrent and native

(a)

(b)

**Fig. 21.14** (a) Right ventricular (RV) angiogram of a child with pulmonary valve stenosis showing a thickened pulmonary valve (PV) and post-stenotic dilatation of the main pulmonary artery (MPA). (b) The balloon catheter is inflated across the valve resulting in relief of the stenosis.

coarctation in an attempt to produce more 'permanent' results and reduce the risk of aortic rupture or aneurysm formation. Similar stents have also been used to improve narrowing in pulmonary arteries. There are concerns regarding the use of stents in young children, because growth will not occur.<sup>40</sup>

Radiofrequency energy can be applied to intravascular tissues, using specially designed catheters, to perforate occluded valves or vessels to allow subsequent balloon dilatation. This is most commonly performed for relief of valvar pulmonary atresia.<sup>42</sup>

### Closing procedures

Closure of the persistent arterial duct with a coil or device is now the procedure of choice for children over a year of age.<sup>28,43,44</sup> Closure of more than 50% of atrial septal defects<sup>45</sup> is possible with one of a variety of devices, and results are comparable with surgery.<sup>46-48</sup> The surgical approach is still required for some anatomical variants and large defects. Although the vast majority of hemodynamically significant ventricular septal defects still require surgical closure, transcatheter devices are available for defects that are difficult to close surgically.<sup>28,43,49</sup> A wide variety of devices are used to occlude venous collaterals, residual surgical shunts, coronary artery and arteriovenous fistulae. Transcatheter replacement of pulmonic and aortic valves has been achieved in selected patients.<sup>50</sup>

## OTHER CARDIAC INVESTIGATIONS

### MAGNETIC RESONANCE IMAGING (MRI)

Improvements in imaging quality and acquisition times have resulted in its increased use for the imaging and assessment of congenital heart disease, particularly in complex cases.<sup>51</sup> It provides three-dimensional, dynamic images of cardiac structures and is particularly suitable for visualizing the aortic arch (Fig. 21.15), peripheral pulmonary vasculature, and in the assessment of ventricular volumes. All images must be gated to the cardiac cycle and performed during 'breath holding' to minimize respiratory artifact. To obtain optimal image quality, the child must either be old enough to cooperate fully with the examination or ventilated under general anesthesia.<sup>51</sup> Children with pacemakers and some intravascular devices cannot undergo magnetic resonance imaging.

### COMPUTERIZED AXIAL TOMOGRAPHY (CT)

CT scan with injection of contrast provides excellent imaging of cardiac and vascular structures. The anesthetic time is shorter than for MRI, but this must be balanced against the radiation dose for CT.

(a)

(b)

Fig. 21.15 Lateral projection of an aortogram (a) and magnetic resonance image (b) of coarctation of the aorta. The arrow indicates the coarctation. Asc Ao, ascending aorta; Desc Ao, descending aorta.

### RADIONUCLIDE ANGIOGRAPHY

Radionuclide scanning is less frequently performed in children than in adults. However, there are occasions when it may be required (e.g. following Kawasaki coronary arteritis) and it is performed in the same way as in adults. Lung perfusion scanning can assess pulmonary blood flow in children with complex pulmonary vascular abnormalities.

### AMBULATORY ELECTROCARDIOGRAPHIC MONITORING

Continuous ambulatory 24 hour electrocardiographic (Holter) monitoring assists in the evaluation of transient events, bradycardia, certain incessant or paroxysmal tachycardias and those associated with symptoms such as syncope. The electrocardiogram is usually recorded continuously for 24–72 hours and provides a printout of any irregularity. Two channel recordings are better than one, and an event marker can be used to correlate symptoms with electrocardiographic events. This technique has clarified the variations in heart rate and rhythm that

occur in normal children. The heart rate varies from 45 to 180/min, and may be as low as 30 beats/min during sleep.

Many rhythm disturbances occur infrequently, and the chance of detection from a single 24 hour electrocardiographic recording will be small. An event recorder is activated by the child or parent when the symptom occurs. There are many different types, but most record a short strip in solid state memory. The record is printed and analyzed by transmitting it by telephone or returning it to the cardiac center. Another method of detecting infrequent but potentially serious arrhythmias is with an event or loop recorder implanted under the skin in the left upper chest.<sup>52</sup> This can be programmed to record significant pauses, bradycardia and tachycardia.

### ELECTROPHYSIOLOGICAL STUDIES

Arrhythmias may be further evaluated by intracardiac electrophysiological studies in which several electrode catheters are passed transvenously to the right side of the heart and intracardiac potentials are recorded from multiple sites, including the bundle of His. Simultaneous recordings of surface and intracardiac electrocardiograms help to determine more precisely the exact site of origin, delay, and direction of impulse conduction in complex arrhythmias. These techniques have their greatest value in defining the exact mechanism of tachycardia and may result in more appropriate therapy, particularly in children who have drug resistant tachyarrhythmias and who may be candidates for radiofrequency catheter ablation therapy of their arrhythmias.

### EXERCISE TESTING

Exercise testing is increasingly used in pediatric cardiac practice. The techniques are similar to those used in adults, although end points and levels of exercise achieved must be adjusted for age. Documentation of peak heart rate, level of exercise achieved and electrocardiographic changes can influence the timing of intervention or evaluate the efficacy of a procedure on effort tolerance. In cyanosed children, saturation monitoring during exercise provides additional information in these situations. Exercise testing can identify and evaluate exercise-related arrhythmias, clarify symptoms in more complex situations and is helpful in long QT syndrome. Measurement of blood pressure response to exercise is important in children following repair of coarctation. Even quite small children can exercise on either the treadmill or a bicycle ergometer, but exercise telemetry or Holter monitoring can also provide useful information.

### HEAD-UP TILT TESTING

Syncope is a common problem in childhood, occurring in one in five adolescents.<sup>52,53</sup> Most have 'neurally mediated' syncope related to a disturbance of autonomic control of blood pressure and heart rate. This can sometimes usefully be differentiated from other causes of syncope by head-up tilt testing. Various protocols all involve head-up tilting on a table with foot support to an angle of 60°, for up to 45 minutes after an initial horizontal stabilization period. Continuous electrocardiogram and blood pressure monitoring (usually non-invasive) is performed. A positive response usually consists of hypotension and bradycardia before syncope. This provides an explanation for a child's symptoms and paves the way for more successful management.<sup>52</sup>

### THE ASYMPTOMATIC CHILD WITH A MURMUR

The incidental finding of a murmur in an asymptomatic child is common. The clinician must decide whether the murmur is innocent, or if further investigation is required. If the murmur is pathological, the child will need regular follow-up, antibiotic prophylaxis for dental and other surgical procedures, and possibly specialized treatment. A careful history is essential, but children with an innocent murmur may have unrelated symptoms. Innocent murmurs can be diagnosed accurately

by their distinctive features. A thorough examination identifies clinical features that are likely to be associated with heart disease. It is much more common to diagnose an innocent murmur as pathological than to call a cardiac lesion innocent.<sup>20</sup>

## INNOCENT MURMURS

Innocent murmurs are the most common murmurs in pediatric practice. They occur in the majority of children, usually between 6 weeks and 7 years of age, but they can occur throughout childhood and adolescence.<sup>54</sup> There is a variety of innocent murmurs. A small number of children have more than one, for example a vibratory systolic murmur and venous hum.

### Vibratory (Still's) murmur

This accounts for the majority of innocent murmurs.<sup>54</sup> It is characterized by a short vibratory ejection systolic murmur, maximal at the lower left sternal edge and radiating towards the base. It changes in intensity on sitting, and on extending the neck. The exact cause is unknown, but is likely to be due to vibration of structures within the ventricles. The differential diagnosis includes small muscular ventricular septal defect and mitral valve prolapse. If the site of maximal intensity is not accurately defined, it may be confused with mild pulmonary or aortic stenosis or an atrial septal defect.

### Pulmonary and aortic flow murmurs

These are soft ejection systolic murmurs maximal in the pulmonary or aortic areas, produced by increased flow across the outlet valves. The common causes are pyrexia, anemia and pregnancy. Review after the fever has subsided prevents referral of a child who no longer has a murmur. The differential diagnosis includes mild aortic or pulmonary stenosis or an atrial septal defect.

### Venous hum

This is a continuous murmur maximal in the lower part of the neck and subclavicular area, usually on the right. It is due to turbulence in large veins. It is loudest on sitting up and disappears on lying down, turning or lightly compressing the jugular vein in the neck. The differential diagnosis is a persistent arterial duct or arteriovenous fistula.

### Features associated with heart disease in the asymptomatic child

A number of specific clinical features are associated with heart disease.<sup>55</sup> These include a murmur that is:

- pansystolic;
- grade 3 or more in intensity;
- harsh in quality;
- maximal at the left upper sternal border.

The presence of an abnormal second heart sound or a click is also an indication that the murmur is not innocent. Outside the neonatal period, a murmur heard in the back is usually pathological, and diastolic murmurs are always abnormal. Palpation of the femoral pulses is essential. Other clinical features that are more likely to indicate a cardiac lesion are feeding difficulties or failure to thrive in infants, dysmorphic features and noncardiac lesions.

### Investigation and management

A complete examination with careful auscultation by a trained clinician is the most useful method of diagnosing an innocent murmur. Chest radiography is likely to be misleading, invasive and unhelpful.<sup>20</sup> An electrocardiogram may be useful in alerting the clinician to the possibility of an atrial septal defect, but may also be misleading. If the murmur is innocent, firm reassurance should be given and the child discharged. Parents should be told that the murmur might be heard intermittently for many years. They should also be reassured that the heart is normal.

If the murmur is not typical of an innocent murmur, or if other features suggest a cardiac lesion, the child should be referred to a pedi-

atric cardiologist. Echocardiographic examination without assessment by a cardiologist or pediatrician competent in echocardiography is not appropriate, as it can be misleading.<sup>1</sup> When a child is referred to a pediatric cardiologist, there is often an expectation that an echocardiogram will be carried out. Although it has been shown that this is usually unnecessary,<sup>54</sup> it may be done to allay fears and prevent further reviews.

## HEART FAILURE

Heart failure occurs when the heart:

- Fails to supply sufficient blood for the body's needs.
- Does not allow adequate pulmonary or systemic venous return.

This results in physiological compensatory mechanisms. These include salt and water retention by the kidneys to increase preload, vasoconstriction through the renin-angiotensin axis to increase afterload, and increased catecholamines to improve cardiac output. If the underlying insult continues, these mechanisms overcompensate and heart failure develops. It is most frequently associated with congenital heart disease, usually occurring in the first few months of life. Closure of the arterial duct or fall in pulmonary vascular resistance causes increased pulmonary blood flow, which explains the timing of presentation. Other causes include valvar or myocardial disease, or persistent tachy- or bradyarrhythmia. Noncardiac causes include shock, profound anemia and a large arteriovenous malformation.

## CLINICAL FEATURES

The commonest signs are tachycardia, tachypnea and hepatomegaly, the liver size providing an indication of severity. The child appears restless, fretful and pale. Peripheral perfusion may be poor with a capillary refill time of greater than 3 seconds. Measurement of four-limb blood pressure is essential.

*In infants* combined ventricular failure occurs, with pulmonary and systemic venous congestion. Respiratory symptoms are more marked on feeding. The association of stiff lung parenchyma with soft, flexible ribs causes chest deformity with a deep anteroposterior diameter and flaring of the lower part of the rib cage. This combination produces the 'Harrison's sulcus', the trough created just above the lower ribs anteriorly. There may also be intercostal or subcostal recession during inspiration. With marked respiratory distress there is an audible grunt and flaring of the ala nasi. Pulmonary edema must be differentiated from respiratory infection. Crepitations are not often heard in the chest and marked edema is rare, although some facial puffiness or pitting of the dorsal surfaces of the hands or feet may develop. Pedal edema in newborns is usually lymphedema associated with Turner or Noonan syndrome. Sweating occurs at rest, during feeding or on exertion, and hepatomegaly is common. Chronic heart failure causes feeding difficulties. Initially, weight gain may result from fluid retention, but failure to thrive is seen later. Specific auscultatory signs of the cardiac abnormality causing failure may be detected. Sometimes a gallop rhythm is audible.

*In older children*, heart failure is relatively uncommon. It usually results from acquired heart disease or arrhythmia and exhibits the clinical features of left or right heart failure as in the adult. These include effort intolerance, dyspnea, cough, ankle edema and abdominal pain.

## INVESTIGATIONS

Investigations should be directed at accurately determining the cause, as this is essential for treatment. Electrocardiographic changes may reflect the underlying diagnosis. Sinus tachycardia must be differentiated from an arrhythmia. Chest radiography shows cardiomegaly and prominent vascular markings, due to increased flow or venous obstruction. Echocardiography provides information regarding the cardiac lesion and allows assessment of left ventricular function (Fig. 21.12). If there is a primary myocardial problem, this should be investigated (p. 802).

## MANAGEMENT

The primary aim is correction or improvement of the underlying cardiac or noncardiac condition. Supportive therapy is directed at improving myocardial function, reducing preload and afterload, and controlling heart rate. There are no evidence-based guidelines for the management of heart failure in children.<sup>56</sup> Treatment is extrapolated from adult data, despite the difference in causes.

*Diuretics* remain the initial treatment, most commonly the loop diuretics furosemide or a thiazide. Concomitant use of spironolactone has been shown to be beneficial both for its potassium sparing effect, and the aldosterone receptor blocking action.

*Angiotensin converting enzyme (ACE) inhibitors* (captopril or enalapril) are widely used<sup>56</sup> and are usually introduced if diuretics are insufficient to control heart failure. They decrease the formation of angiotensin II, resulting in vasodilatation. This reduces left ventricular afterload and facilitates left ventricular function. They have been shown to improve survival in adults. In ventricular septal defect, they reduce the left to right shunt by reducing the systemic, and thus left ventricular pressure. The initial dose should be small and gradually increased to the maintenance dose over a period of time. Observation is required for possible hypotension immediately after the initial dose and each increment. Renal function must be monitored and caution exercised in the presence of renal impairment. Serum potassium must be closely monitored if ACE inhibitors are used with spironolactone because of hyperkalemia. Left sided obstructive lesions such as mitral or aortic stenosis, and coarctation are contraindications to ACE inhibitors. Angiotensin II receptor blockers may be used if side-effects from ACE inhibitors are troublesome.

*Beta-blockers* are standard therapy for adults with heart failure, where they are used in the management of left ventricular dysfunction and appear to slow left ventricular dilatation and reduce mortality. This suggests that they may be of value in children. They should only be used after stabilization of acute heart failure. The dose must be increased gradually.

*Digoxin* is occasionally used for its positive inotropic effect, but it also reduces vascular tone. It can be of benefit where there is poor ventricular function but there is no evidence that it improves mortality. It is of doubtful value in situations with volume overload, such as a ventricular septal defect.<sup>57</sup> Serum levels are used to check compliance, or when toxicity is suspected.

*Anticoagulants* are necessary when severe heart failure could cause thrombus formation in the left ventricle.

*Other supportive treatment* may include the use of oxygen. Nutrition must be optimized. Anemia should be treated, but caution blood transfusion should only be considered for severe anemia.

### Response to treatment

The child should be monitored carefully for response to therapy and side-effects of the drugs used. Daily examination, including weight, respiratory rate and liver size, will assess improvement or deterioration in heart failure. Regular electrolyte, urea and creatinine measurements will detect imbalance, or deteriorating renal function. Echocardiography is used to monitor changes in left ventricular function.

### In an intensive care setting

Inotropic agents such as dopamine and dobutamine improve cardiac function and urine output. Afterload can be reduced with vasodilators such as nitroprusside. Phosphodiesterase inhibitors (e.g. milrinone) have potent vasodilator and inotropic effects but have not been shown to improve outcomes. Noradrenaline increases systemic vascular resistance, which is beneficial in the management of septic shock. Mechanical ventricular assist devices may be used to temporarily support ventricular function or as a bridge to transplant.<sup>58</sup>

If intervention is not an option, the child should be assessed for cardiac transplantation when heart failure no longer responds to medication. The 5 year survival following heart transplant is approximately 67%.<sup>59</sup>

## INFECTIVE ENDOCARDITIS

Infective endocarditis is rare with an incidence of approximately 0.3 per 100 000 person-years.<sup>60</sup> It is usually superimposed on congenital or rheumatic heart disease, particularly lesions with a high velocity turbulent jet of blood, or cardiovascular prosthetic material. A child with a normal heart can be affected. Mortality remains high, with a late risk of death or significant complications because of valve damage. Primary prevention is therefore important. The Task Force on Infective Endocarditis of the European Society of Cardiology<sup>60</sup> has produced comprehensive guidelines for the prevention, diagnosis and treatment of infective endocarditis.

### PROPHYLAXIS AGAINST INFECTIVE ENDOCARDITIS

Antibiotic prophylaxis is advised in children at risk. This is because of the severe cardiac damage and associated mortality that can result from infection within the heart and great vessels. The precise risk of endocarditis is impossible to measure, but cardiac conditions have been grouped into high, moderate and low risk. Children at low risk do not require prophylaxis. This includes those with closed ventricular septal defects and arterial ducts, mitral valve prolapse without regurgitation or valve thickening and 12 months after transcatheter closure of an atrial septal defect or patent foramen ovale. More controversially, prophylaxis is also not recommended for children with a secundum atrial septal defect, isolated pulmonary stenosis, Ebstein's abnormality of the tricuspid valve and following the Fontan or Mustard operations.<sup>60</sup> Most children with congenital and those with rheumatic heart disease or hypertrophic cardiomyopathy fall into the moderate category risk.<sup>60</sup> Antibiotic prophylaxis regimens are shown in [Table 21.6](#).<sup>60,61</sup> Children at high risk include those who have previously had endocarditis and those with prosthetic heart valves, surgically created conduits, intravascular prosthetic material and complex cyanotic congenital cardiac anomalies. These children usually require intravenous antibiotics ([Table 21.6](#)).

Indications for prophylaxis are extensive,<sup>60</sup> but endocarditis is such a serious condition that little risk should be taken. Surgical and dental procedures cause transient bacteremia. Poor dental hygiene and inflamed gums predispose to endocarditis. Antibiotics should be given before bacteremia is expected, to reduce the ability of the organism to adhere and multiply ([Table 21.6](#)). If given later, antibiotics should be administered intravenously. The probability of bacteremia is highest for dental and other oral procedures, intermediate for procedures of the genitourinary system and lowest for gastrointestinal procedures. It is also likely to be greater for therapeutic than diagnostic interventions. There are a number of procedures that are not regarded as high risk, but bacteremia and/or endocarditis have been reported. These include body piercing and tattooing.<sup>62</sup>

### CLINICAL FEATURES OF INFECTIVE ENDOCARDITIS

Early diagnosis depends on a *high index of suspicion* in any child with heart disease and unexplained fever, even when there are no other features of endocarditis. The clinical features and course of the illness vary depending upon the infecting organism and the stage of the illness. Most children present with nonspecific manifestations such as malaise, anorexia, weight loss, arthralgia and backache. A regurgitant murmur may appear or change in character. Splenomegaly may be found and petechiae occur, particularly on the oral mucosa, eyelids or optic fundi (Roth spot). Clubbing or splinter hemorrhages of the nail bed can occur. Osler's nodes are red, indurated, tender lesions on the pulps of fingers and toes and occasionally the palm. These skin lesions, arthralgia and hematuria are immune complex phenomena and not due to emboli. Embolic phenomena have become less common since the introduction of antimicrobial therapy, but occur particularly with staphylococcal or fungal endocarditis. Janeway lesions are thought to be due to septic embolization

Table 21.6 Antibiotic prophylaxis against infective endocarditis (British National Formulary for Children 2006)

<b>Dental, oral or upper respiratory tract procedures</b>	
<i>Under local anesthesia (child not allergic to penicillin)</i>	
Child under 5 years	oral amoxicillin 750 mg taken under supervision 1 h before procedure
Child 5–10 years	oral amoxicillin 1.5 g taken under supervision 1 h before procedure
Child 10–18 years	oral amoxicillin 3 g taken under supervision 1 h before procedure
<i>Under local anesthesia (child allergic to penicillin)</i>	
Child under 5 years	oral clindamycin 150 mg or azithromycin 200 mg taken under supervision 1 h before procedure
Child 5–10 years	oral clindamycin 300 mg or azithromycin 300 mg taken under supervision 1 h before procedure
Child 10–18 years	oral clindamycin 600 mg or azithromycin 500 mg taken under supervision 1 h before procedure
<i>Under general anesthesia (child not allergic to penicillin)</i>	
Child under 5 years	i.v. amoxicillin 250 mg intravenously at induction of anesthesia or just before procedure
Child 5–10 years	i.v. amoxicillin 500 mg intravenously at induction of anesthesia or just before procedure
Child 10–18 years	i.v. amoxicillin 1 g intravenously at induction of anesthesia or just before procedure
<i>Under general anesthesia (child allergic to penicillin)</i>	
Child under 5 years	i.v. clindamycin 75 mg over at least 10 min at induction of anesthesia or just before procedure
Child 5–10 years	i.v. clindamycin 150 mg over at least 10 min at induction of anesthesia or just before procedure
Child 10–18 years	i.v. clindamycin 300 mg over at least 10 min at induction of anesthesia or just before procedure
<b>Gastrointestinal or genitourinary procedures</b>	
<i>Child not allergic to penicillin</i>	
Child under 5 years	i.v. amoxicillin 250 mg ± i.v. gentamicin* 1.5 mg/kg at induction of anesthesia or just before procedure
Child 5–10 years	i.v. amoxicillin 500 mg ± i.v. gentamicin* 1.5 mg/kg at induction of anesthesia or just before procedure
Child 10–18 years	i.v. amoxicillin 1 g ± i.v. gentamicin* 1.5 mg/kg at induction of anesthesia or just before procedure
<i>Child allergic to penicillin</i>	
Child under 14 years	i.v. teicoplanin 6 mg/kg (max 400 mg) + i.v. gentamicin 1.5 mg/kg at induction of anesthesia or just before procedure
Child 14–18 years	i.v. teicoplanin 400 mg + i.v. gentamicin 1.5 mg/kg at induction of anesthesia or just before procedure
or	
Child under 14 years	i.v. vancomycin 20 mg/kg (max 1 g) over 1–2 h at induction of anesthesia or just before procedure
Child 14–18 years	i.v. vancomycin 1 g over 1–2 h at induction of anesthesia or just before procedure
<b>Child at high risk (previous endocarditis, prosthetic valve, intravascular prosthetic material, complex cyanotic heart disease)</b>	
<i>Child not allergic to penicillin</i>	
Child under 5 years	i.v. amoxicillin 250 mg + i.v. gentamicin 1.5 mg/kg at induction of anesthesia or just before procedure then 125 mg orally 6 h later
Child 5–10 years	i.v. amoxicillin 500 mg + i.v. gentamicin 1.5 mg/kg at induction of anesthesia or just before procedure then 250 mg orally 6 h later
Child 10–18 years	i.v. amoxicillin 1 g + i.v. gentamicin 1.5 mg/kg at induction of anesthesia or just before procedure then 500 mg orally 6 h later
<i>Child allergic to penicillin</i>	
Child under 14 years	i.v. vancomycin 20 mg/kg (max 1 g) over 1–2 h + i.v. gentamicin 1.5 mg/kg at induction of anesthesia or just before procedure
Child 14–18 years	i.v. vancomycin 1 g over 1–2 h + i.v. gentamicin 1.5 mg/kg at induction of anesthesia or just before procedure

\*Recommended by British National Formulary for Children<sup>61</sup> but not by The Task Force on Infective Endocarditis of the European Society of Cardiology.<sup>60</sup>

and are transient, non-tender, macular lesions of the palms or soles of the feet. Chest symptoms are common in right heart endocarditis. Heart failure may develop as a result of valve damage. Acute fulminant infection is seen with *Staphylococcus aureus* infections and in young children with overwhelming septicemia.

## DIAGNOSIS OF INFECTIVE ENDOCARDITIS

Anemia and leukocytosis are usually present and the erythrocyte sedimentation rate and C-reactive protein are invariably elevated. Microscopic hematuria is common. It is important to identify the organism, so blood cultures must be taken *before* starting antibiotics. Three cultures should be performed over a 24 hour period and a further three after 24 hours, if the initial ones are still negative.<sup>60</sup> Bacteremia is a constant feature in infective endocarditis. This makes timing in relation to fever unimportant. Culture media should include those for aerobes, anaerobes and fungi. Repeated sterile blood cultures are strong evidence against infective endocarditis but do not preclude it since about 10% of cases are negative on culture. Recent antimicrobial treatment is the most common reason for this, and cultures

should be repeated once antibiotics have been discontinued for at least 3 days. Other causes of negative cultures include right-sided cardiac lesions, slow-growing microorganisms or infection with nonbacterial agents such as fungi, *Coxiella*, *Chlamydia* or *Rickettsia*. Arterial blood cultures are unreliable. Demonstration of bacterial DNA by broad-spectrum polymerase chain reaction (PCR) aids diagnosis in culture negative endocarditis.

Echocardiography is essential for suspected endocarditis. Identification of a vegetation, peri-valve abscess or fistula, or prosthetic valve dehiscence is diagnostic. Transesophageal echocardiography is necessary if thoracic views do not show evidence of endocarditis. The absence of echocardiographic findings does not rule out endocarditis.

## BACTERIOLOGY OF INFECTIVE ENDOCARDITIS

*Streptococcus viridans*, *Staphylococcus aureus* and *coagulase-negative staphylococci* are the common bacteria isolated in children.<sup>63</sup> A wide variety of other organisms cause infection on rare occasions. In neonates, staphylococcal or fungal infections occur in association with central lines and the prognosis is poor.<sup>64</sup>

## TREATMENT OF INFECTIVE ENDOCARDITIS

It is important to identify the causative organism before starting treatment. Unless there are signs of fulminant infection, antibiotics should be withheld until the organism is identified. Current guidelines for the treatment of endocarditis have been produced by the Task Force on Infective Endocarditis of the European Society of Cardiology<sup>60</sup> and will be updated as new drugs and further evidence become available. Bactericidal drugs are given intravenously by bolus injection in a dose sufficient to reach therapeutic blood levels and provide a satisfactory minimum inhibitory concentration. The choice of antimicrobials, dosage schedule and duration of therapy will depend on the organism and its sensitivity.<sup>60</sup> It is essential to involve the microbiologist from the beginning regarding choice and duration of treatment. Penicillin is fundamental to the antibiotic treatment of endocarditis, and hypersensitivity seriously compromises the range of antibiotics that can be used. Parents should be closely questioned about the nature of any suspected penicillin hypersensitivity reaction.

Active infective endocarditis is not necessarily a contraindication to cardiac surgery.<sup>65</sup> Valve replacement is indicated when valve damage causes moderate or severe heart failure or when recurrent emboli occur. Fungal or Coxiella infections respond poorly to medical therapy and surgery may be the only way to eradicate infection. When endocarditis occurs following cardiac surgery in a child with a cardiovascular prosthetic material, surgical removal of the foreign material is often necessary.

## CONGENITAL HEART DISEASE

### INCIDENCE

The incidence of congenital heart disease is approximately 8 per 1000 live births, with a higher rate in stillbirths.<sup>66</sup> Differences in frequencies between studies are due to the method of ascertainment and detection rates of less severe abnormalities. The use of high resolution echocardiography increases detection<sup>67</sup> but increased antenatal diagnosis and termination rates could reduce the incidence of severe lesions. There is no evidence of racial differences in the incidence of congenital cardiac defects, although there are some differences in the type of lesions. The incidence of recessively inherited lesions such as isomerism (heterotaxy) sequences is increased in consanguineous communities.<sup>5</sup> The relative frequency of the most common lesions varies with different reports, but nine common lesions form 80% of congenital heart disease. They can be divided into three hemodynamic groups (Table 21.7) and more than one lesion may coexist. The other 20% of congenital heart disease consists of many rare or complex lesions.<sup>66,68</sup>

The risk of death from congenital heart disease has decreased from 30% in the 1970s to less than 5%. The outlook remains dependent on the severity of the cardiac lesion and other abnormalities. Between 30 and 40% of early deaths are associated with extracardiac malformations. Prematurity and perinatal complications also contribute to outcome. Early deaths are uncommon in acyanotic lesions with the exception of

coarctation of the aorta and atrioventricular septal defect, and more common in cyanotic lesions, although the outlook is much improved. The majority of survivors enjoy good health but many require life-long expert follow-up and treatment. The incidence of congenital heart disease in adults is now 5 per 1000. As the number of survivors with more complex lesions grows,<sup>69</sup> the requirement for further catheter and surgical interventions, including transplantation, will increase.

### ETIOLOGY

In most children, no specific cause is found. However, maternal, environmental and genetic defects can contribute.

### Maternal and environmental factors

- Maternal diabetes and phenylketonuria increase the incidence of congenital heart disease. There is some evidence that control of the condition before, and in early pregnancy, decreases the risk.<sup>70,71</sup> Maternal obesity is also a risk factor, but this may be related to diabetes.<sup>72</sup> Maternal connective tissue disease such as systemic lupus erythematosus can result in congenital complete heart block.
- Maternal infection, notably rubella in early pregnancy, results in congenital heart disease.<sup>73</sup>
- Maternal drug ingestion. Fetal alcohol syndrome is a well-recognized association.<sup>74</sup> Lithium,<sup>75</sup> antiepileptics<sup>76</sup> and isotretinoin used for acne<sup>77</sup> are all associated with an increased risk.
- Maternal age is associated with an increased risk of trisomy.

### Chromosomal and genetic abnormalities

Cardiac defects are associated with a wide range of chromosomal or genetic abnormalities, other syndromes and associations<sup>78,79</sup> (Table 21.8). Chromosomal abnormalities occur in 10–20% of infants with congenital heart disease. It is thus appropriate to perform chromosomal analysis on infants and children with congenital heart disease who have dysmorphic features, low birth weight, other malformations, developmental delay, failure to thrive or short stature, and those with a cardiac lesion likely to be associated with a chromosomal abnormality. It is also important to involve the clinical geneticist to confirm any syndrome or association. This provides useful information for management and recurrence risk within a family. Autosomal dominant inheritance occurs in a number of conditions that have associated cardiac abnormalities. However, many children with 22q11 deletion, Noonan syndrome and Williams syndrome have a new mutation, resulting in a low recurrence risk. Hypertrophic cardiomyopathy has an estimated prevalence of 1:500 persons.<sup>80</sup> Most patients have a positive family history but sporadic cases occasionally occur. Single gene defects are increasingly being identified and some are associated with heart disease.<sup>80</sup>

### RECURRENCE RISK

The recurrence risk for a cardiac defect depends on the nature of the lesion and relationship of the affected person. The risk for another pregnancy rises to about 2% if one previous child is affected; this tends to be highest (3%) for ventricular septal defect, arterial duct and atrioventricular septal defect. There is a tendency for a related anomaly to recur but this is not necessarily the case. The severity of the cardiac lesion may also vary considerably between individuals in a family. If two previous children are affected the risk rises to 6–8% and there is a similar risk if the father has congenital heart disease. If the mother is affected the risk is 5–15%, depending on the lesion.<sup>4</sup>

When counseling parents, consideration must be given to known recurrence risks, maternal age and health, and exposure to possible teratogens, particularly medication. Fetal echocardiography provides an accurate means of diagnosing serious cardiac abnormalities from about 18 weeks' gestation<sup>81</sup> or earlier. In the majority there will be no defect and the family can be reassured. However, the implications for finding an abnormality are serious and should be discussed before the examination.

Table 21.7 Incidence of common congenital cardiac lesions (Jackson et al 1996<sup>68</sup>)

	Condition	Incidence
Left to right shunt	Ventricular septal defect	36%
	Atrial septal defect	5%
	Patent arterial duct	9%
	Atrioventricular septal defect	4%
Obstructive lesions	Pulmonary stenosis	9%
	Aortic stenosis	5%
	Coarctation	5%
Cyanotic lesions	Transposition of the great arteries	4%
	Tetralogy of Fallot	4%

Table 21.8 Chromosome and genetic associations with congenital heart disease (Harris et al 2003<sup>78</sup>, Manning et al 2005<sup>79</sup>)

	Chromosome or genetic abnormality	Percentage with heart disease (%)	Common cardiovascular lesions
<b>Chromosome disorders</b>			
Down	Trisomy 21	40–50	AVSD, VSD, ASD, ToF
Edwards	Trisomy 18	90–100	VSD, ASD, PDA, polyvalve disease
Patau	Trisomy 13	80	ASD, VSD, Art Trunk, TGA, ToF
Turner	XO	20–35	Coarct, AS, Bicuspid aortic valve
<b>Autosomal dominant</b>			
22Q11	22Q11 deletion	80–85	Art Trunk, Int Ao Arch, ToF
Alagille	20p12 deletion	90	PPS, PS, ToF, Coarct
Beckwith–Wiedemann	11	15	HCM, ASD, VSD, ToF, PDA
Holt–Oram	12q24.1 mutation	85–95	ASD, VSD, conduction defects
Leopard		50	PS, HCM, conduction defects
Marfan	15q21	80–100	Aortic root dilation, mitral valve prolapse
Noonan	12p24 mutation	80	PS, PPS, ASD, HCM
Tuberose sclerosis		60	Rhabdomyomas
Williams	7q11.23 microdeletion	> 80	Supra AS, PPS, renal artery stenosis
<b>Autosomal recessive</b>			
Ellis–van Creveld	4q16	50	ASD, PDA, Coarct, HLHS, TAPVC, TGA
Thrombocytopenia and absent radius	Multiple	30	ASD, ToF
Meckel–Gruber		25	Variable
Smith–Lemli–Opitz	11q12	15	ASD, VSD, PDA
<b>Other associations</b>			
Asymmetric crying facies		44	VSD
CHARGE		85	ToF, DORV, PS, VSD, AVSD
Cornelia de Lange	?3q26	30	VSD, ToF
Cri du chat	5p13.3	30–50	ASD, VSD, PDA, ToF
Diaphragmatic hernia		25	VSD, PDA, TGA, ToF
Intestinal atresia, tracheo-esophageal fistula		10	VSD, ToF
Goldenhar		20–30	ToF
Klippel–Feil	?8q22	25–40	ASD, VSD
Lung agenesis		20	VSD, ToF, PDA, TAPVC
Renal agenesis (unilateral)		17	VSD
VACTRL		73	ASD, VSD, DORV, ToF
Wolf–Hirschhorn	4p16	30	ASD, PS

Note this list is not inclusive, nor are the cardiac lesions always as most commonly seen!

Art Trunk, common arterial trunk; AS, aortic stenosis; ASD, atrial septal defect; AVSD atriocentric septal defects; Coarct, aortic coarctation; DORV, double outlet right ventricle; HCM, hypertrophic cardiomyopathy; Int Ao Arch, interrupted aortic arch; PDA, patent arterial duct; PPS, peripheral pulmonary artery stenosis, PS, pulmonary stenosis; TAPVC, totally anomalous pulmonary venous connection; TGA, transposition of the great arteries; ToF, tetralogy of Fallot; VSD, ventricular septal defect.

## FETAL DIAGNOSIS OF HEART DISEASE

### DIAGNOSIS

The most common method of detection of a cardiac lesion is the routine 20 week fetal anomaly scan. The heart is examined in a four chamber view. Normally, the cardiac apex is to the left of the fetus, the cardiothoracic ratio is less than 50%, the two atria and two ventricles are of similar size, and there is normal tricuspid to mitral valve offsetting. This examination should identify most variations of 'single ventricle' such as hypoplastic left or right ventricle, major atriocentric septal defects (Fig. 21.16) and inlet ventricular septal defects. Disproportion between the atrial sizes can also be identified. However, abnormalities of the cardiac outlets such as tetralogy of Fallot, common arterial trunk, transposition of the great arteries and some ventricular septal defects will not be visible in this view. They can only be detected on more detailed 'outlet screening' where the integrity of the outlet part of the ventricular septum and the ventriculo-arterial connections are also examined. Routine screening of the four chamber view detects 30–50% of fetuses with congenital heart disease.<sup>82,83</sup> Additional examination of the great vessels

increases the incidence to more than 70%.<sup>84</sup> This forms part of the routine 20 week scan in some centers. In some conditions, such as aortic or pulmonary stenosis and coarctation, discrepancy in chamber size increases with advancing gestation. Others may only become apparent postnatally when the normal perinatal adaptations fail to occur or develop abnormally as in coarctation of the aorta, atrial septal defect and patent arterial duct. Small septal defects and minor valve abnormalities are outside the resolution and limits of detection of the ultrasound equipment.

If a fetus is thought to be at increased risk of a cardiac abnormality, specialist fetal echocardiography is indicated. Risk includes:

- Maternal diabetes, phenylketonuria, exposure to drugs such as anticonvulsants, lithium, alcohol or retinoic acid.
- Family history of congenital heart disease in a previous child, sibling or parent. History of an inherited condition such as tuberose sclerosis, or 22q11 deletion in a parent. Parental consanguinity increases the risk of complex heart disease.
- Fetal extracardiac or chromosome abnormality, arrhythmia or increased nuchal translucency detected at the 10–12 week scan.

**Fig. 21.16** Four chamber view of a fetal heart showing complete atrioventricular septal defect. The left and right components of the atrioventricular valves are at the same level. There is a ventricular septal defect and a primum atrial septal defect. DAO, descending aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Specialist fetal echocardiography is usually performed at 18–20 weeks' gestation. However, with improved training and equipment, preliminary specialist scans as early as 12–14 weeks may provide some information,<sup>85</sup> although a further scan at 20 weeks is indicated. Further scans beyond 20 weeks are required for conditions that may progress during the pregnancy.

Most fetal cardiac abnormalities occur in 'low risk' pregnancies. The incidence of detection will increase as more ultrasonographers are trained to look at the great vessels as well as the four chamber view at the routine 20 week scan. Increased nuchal translucency at the 10–12 week scan also identifies a large proportion of fetuses at high risk of cardiac lesions.<sup>86</sup>

Once a diagnosis of a fetal cardiac abnormality is made, a detailed examination of the rest of the fetus is essential. Cardiac lesions are commonly associated with extracardiac lesions<sup>87</sup> such as exomphalos or diaphragmatic hernia, or chromosomal abnormalities. This has prognostic implications. Fetal karyotype can be obtained from placental tissue, amniocytes or fetal blood. Chromosomal abnormalities such as trisomy 13, 18 or 21, Turner syndrome and 22q11 deletion can be identified. When fetal heart block is detected, measurement of maternal autoantibodies (anti-Ro antibodies) will inform diagnosis and indicate recurrence risks.

## MANAGEMENT

The rationale for prenatal detection of congenital heart disease remains controversial. Detecting a serious cardiac lesion increases parental choice, allowing the option of termination or continuation of the pregnancy. The termination rate is in the region of 30–50%<sup>87,88</sup> and this is often dependent on the severity of the cardiac lesion and the presence of other abnormalities.

Prenatal diagnosis also has implications for perinatal management. Most fetuses with congenital heart disease can be delivered

according to normal obstetric parameters, the exceptions being some fetal arrhythmias where intrapartum monitoring may be compromised. Fetuses with known transposition of the great arteries should be delivered in close proximity to a pediatric cardiac center to allow urgent atrial septostomy if the atrial septum is very restrictive. All fetuses must be delivered in a center where adequate neonatal and transport facilities are available for duct-dependent neonates. Such infants should be discussed in advance with both obstetricians and neonatologists.

## OUTCOME

Operative mortality for most congenital heart disease, other than hypoplastic left heart syndrome is less than 5%, but this is not reflected in the outcome of prenatally diagnosed lesions.<sup>87–89</sup> Analysis is complicated by the fact that the more severe end of the spectrum of congenital heart disease is diagnosed prenatally, and these infants have a much higher incidence of chromosomal and extracardiac abnormalities<sup>87,89</sup> than children diagnosed with congenital heart disease after birth. Prematurity<sup>89</sup> and fetal growth restriction<sup>90</sup> also increase the risk for infants with complex congenital heart disease, particularly those with a single functioning ventricle. Other risk factors include arrhythmia associated with congenital heart disease. Complete heart block with an atrial rate of less than 100 per minute or a ventricular rate of less than 45 per minute carries a poor prognosis.<sup>91</sup> Most deaths in infants with prenatally diagnosed congenital heart disease occur in the neonatal period.

There is evidence that antenatal diagnosis reduces morbidity.<sup>92</sup> Antenatal diagnosis permits timely and appropriate postnatal management and helps prevent hemodynamic deterioration and acidosis in duct-dependent lesions. There is also some evidence that it reduces mortality in neonates with two functioning ventricles.<sup>93</sup> Mortality in transposition of the great arteries was found to be significantly lower when diagnosed antenatally.<sup>94</sup> With regard to the prognosis of hypoplastic left heart syndrome, the findings are mixed. Brackley et al<sup>95</sup> found that infants with antenatally diagnosed hypoplastic left heart syndrome had lower survival than those diagnosed postnatally. Tworetzky et al<sup>96</sup> found an improved survival and reduced morbidity in an antenatally diagnosed group. Andrews et al<sup>97</sup> found similar survival rates in both groups.

## THE NEONATE WITH A CONGENITAL HEART DISEASE

This section describes the timing and mode of presentation of heart disease in the newborn, focusing on the commonest conditions and those that are frequently missed or misdiagnosed. The emphasis is on structural heart disease and the anatomy and physiology of each is described. It discusses the clues and common pitfalls in making the diagnoses and outlines the management.

## DIAGNOSIS

### Making the diagnosis

Studies of infants with congenital heart disease who died found that in 10–30% of cases the diagnosis of a cardiac lesion was not made during life.<sup>98,99</sup> Some had complex cardiac lesions or severe noncardiac abnormalities, but if the cardiac diagnosis had been made during life, many were likely to have had a good outcome with treatment.<sup>100</sup> Early detection is therefore critical. A neonatal detection rate up to 90% can be achieved with a systematic clinical examination and pulse oximetry check, with a formal very early follow-up protocol for persistent heart murmurs or other physical signs.<sup>101,102</sup> Clinicians must be alert for early signs and refer to the specialist centers quickly, as deterioration can be extremely rapid.

### Why is diagnosis delayed?

- *Most infants appear outwardly normal.* Delays in diagnosis occur partly due to false preconceptions that the majority of infants with serious heart disease will have a condition such as Down syndrome, or appear unwell immediately after birth. Most infants with serious heart disease have no associated syndromes or dysmorphic features. They are often well initially and do not have obvious physical signs until the arterial duct begins to close.
- *Cyanosis is not detected.* Transposition of the great arteries and pulmonary atresia have no associated respiratory distress or other clues to the diagnosis. Central cyanosis must be looked for deliberately on every neonatal check. Diagnosis is more difficult with dark skinned races, but the tongue and buccal mucosa are reliable in a well-lit room or with a torch. If there is a suspicion of cyanosis, pulse oximetry should be obtained. Normal values for the neonatal period have been established. Different oximetry machines produce different values<sup>103</sup> but new-generation machines are more accurate. A foot saturation of below 95% is suspicious, and below 90% definitively abnormal. Saturations from both the right hand (pre-ductal) and a foot (post-ductal) are even more accurate and a difference of  $\geq 3\%$  is likely to be abnormal.<sup>103</sup>
- *Too much reliance is placed on auscultation.* Shortly after birth, murmurs are common in minor lesions such as small ventricular septal defects, and less common in the most severe conditions such as underdevelopment of the left heart or transposition of the great arteries. Although auscultation is important, serious heart disease is more likely to be revealed by careful observation of the infant's color and respiratory pattern, assessment of peripheral perfusion and palpation of brachial and femoral pulses and of the precordium for a prominent pulsation. A normal neonatal examination does not rule out serious heart disease that may present later, usually when the arterial duct closes.<sup>100</sup> Equally important is to listen to the parents when they express concern. They often know instinctively that something is wrong!

### Practical points

- Most infants with life-threatening heart disease have no associated syndrome, a normal outward appearance, are perfectly well and have a normal physical examination for the first day or two after birth.
- Look carefully inside the mouth for central cyanosis.
- Routine use of pulse oximetry in the foot should be encouraged as part of newborn screening for heart disease.
- Rely more on observation and palpation than the stethoscope.
- Always consider heart disease in a sick infant.

### Hyperoxia test

The normal newborn should have a  $\text{PaO}_2$  greater than 70 mmHg (9 kPa). Cyanosis detected clinically is usually less than 40 mmHg (5 kPa). In a cyanosed infant, if the arterial  $\text{PaO}_2$  rises above 150 mmHg (20 kPa) in 90–100% oxygen, a major right to left shunt is unlikely. The test is not completely reliable, but a failure of the  $\text{PaO}_2$  to rise strongly suggests a cardiac defect. The  $\text{PaO}_2$  can fail to rise for two other reasons:

1. Intrapulmonary shunting in lung disease. Areas of collapsed lung tend to be perfused with blood as well as the well-aerated sections, so some blood returning to the heart is not oxygenated.
2. Failure of the transitional circulation (persistent fetal circulation or persistent pulmonary hypertension of the newborn – see Ch. 12). In this condition, the pulmonary vascular resistance fails to fall normally, and right to left shunting occurs across the fetal channels, the patent oval foramen and arterial duct. It often coexists with severe neonatal lung disease, causing diagnostic and management dilemmas. Once congenital heart disease is excluded, management is aimed at reducing pulmonary vascular resistance by the treatment of acidosis and the use of pulmonary vasodilators, in particular inhaled nitric oxide.

### THE IMPORTANCE OF THE OVAL FORAMEN IN NEONATAL HEART DISEASE

Patency of the oval foramen is critical for survival where the mitral or tricuspid flow is absent or inadequate, or when mixing at atrial level is essential as in transposition of the great vessels. In mitral atresia (or hypoplastic left heart), postnatal survival depends on a patent foramen to allow the pulmonary venous blood to enter the right atrium and thence the right ventricle. Blood then reaches the main pulmonary artery and divides between the lungs and the aorta (via the arterial duct). Closure of the oval foramen or arterial duct will result in death. Similarly, in tricuspid atresia, a widely patent foramen is essential for venous return to reach the ventricles via the left atrium. In transposition, the most effective mixing between the systemic and pulmonary circulations is at atrial level and an inadequate or severely restrictive foramen can be life threatening even when the arterial duct is patent.<sup>100</sup> If the oval foramen is inadequate it must be enlarged by cardiac catheter intervention (Fig. 21.13) or surgery.

### THE IMPORTANCE OF THE ARTERIAL DUCT IN NEONATAL HEART DISEASE

Prostaglandin  $\text{E}_2$  (dinoprostone) is a physiological compound, critical in maintaining duct patency during fetal life. It is used intravenously in duct-dependent cyanotic and left heart obstructive lesions. The starting dose is 5–10 ng/kg/min and this can be increased to achieve duct patency. Although the arterial duct is functionally closed in most healthy term infants by the second day of life and usually completely closed by day 5,<sup>104</sup> persistent or episodic hypoxemia can delay duct closure. Prostaglandin  $\text{E}_2$  can be an effective therapy even into the second or third week of life, provided the duct has not completely closed.

### Side-effects of prostaglandin therapy

Apnea is a serious side-effect and resuscitation equipment should be available. Doses higher than 10 ng/kg/min may result in apnea. Lower doses can cause apnea in premature infants. If transport to the tertiary center is required, many centers will electively intubate and ventilate such infants.<sup>100</sup> Other common side-effects are jitteriness, pyrexia, hypotension due to systemic vasodilatation, and occasionally hypoglycemia.

### PRESENTATION OF HEART DISEASE IN THE NEWBORN

#### Mode of presentation

##### *Antenatal*

As fetal ultrasonographers become increasingly skilled in the detection of heart disease, more than 40% of infants with severe congenital heart disease are born with their diagnosis already made.<sup>83,84</sup> However, the majority still present after birth and rely on the vigilance of the clinicians, parents and midwives to be detected.

##### *Symptoms and signs after birth*

Neonates almost always present with one of the following:

- Cyanosis, with or without respiratory distress.
- Heart failure, with or without cyanosis.
- Collapse.
- An associated lesion or syndrome.
- An abnormal clinical sign detected on routine examination such as absent femoral pulses or a heart murmur.

##### *Timing of presentation*

The age of presentation depends on the effect that the transition from fetal to postnatal circulation has upon the specific lesion. This relates to how the abnormal heart responds to the high pulmonary vascular resistance at birth, the gradual fall of this resistance, and the closure of the arterial duct. Here are three examples:

1. An infant born with a poorly functioning right ventricle and severe tricuspid regurgitation (as with Ebstein's anomaly of the tricuspid valve) will present at birth. This is because the high pulmonary

vascular resistance prevents the impaired right ventricle from delivering blood effectively into the pulmonary arteries.

2. An infant with pulmonary atresia, despite having no forward flow from the right ventricle into the pulmonary artery, does not present at birth because the arterial duct is open. Blood fills the pulmonary arteries from the aorta. Clinical presentation with severe cyanosis occurs when the duct starts to close a few hours to days after birth.
3. An infant with a large ventricular septal defect has no difficulties at birth because the high pulmonary vascular resistance results in a high systolic pressure in the right ventricle. This prevents excessive flow across the defect from the left to right ventricle. Pulmonary vascular resistance gradually falls after a few weeks and presentation with cardiac failure, due to the large left to right shunt through the defect, typically occurs at 4–6 weeks of age.

When making a diagnosis in a newborn, it is therefore helpful to consider not only the *type* of presentation (cyanosis with or without respiratory distress, cardiac failure, collapse) but also the usual *timing* of presentation (Table 21.9) and the clinical, electrocardiographic and X-ray findings (Table 21.10).

### PRESENTATION WITH CYANOSIS WITHOUT RESPIRATORY DISTRESS

The commonest causes of isolated cyanosis are transposition of the great arteries and pulmonary atresia or severe (critical) pulmonary stenosis. Pulmonary atresia can occur with a ventricular septal defect (a variant of tetralogy of Fallot) or without when the right ventricle may be hypoplastic. Other causes include tricuspid atresia and other complex lesions with restricted pulmonary blood flow.

#### Transposition of the great arteries

This is the most common cyanotic lesion to present in the neonate, accounting for 4–5% of congenital heart disease<sup>66,68</sup> and occurring more commonly in males.

#### Anatomy and physiology

In this condition, the aorta and pulmonary arteries are transposed. The right ventricle, receiving deoxygenated blood as usual from the right

Table 21.9 Typical timing and mode of presentation of congenital heart disease in the neonate

	EARLY 0–24 hours High pulmonary vascular resistance, arterial duct open	INTERMEDIATE 4 hours–2 weeks Duct closing – ‘duct dependent’ lesions present	LATE After 2 weeks Duct closed. Pulmonary vascular resistance continues to fall and lesions with left to right shunts present
Cyanosis (without congestive failure or respiratory distress)	TGA	<i>Duct dependent for pulmonary blood flow, e.g.</i> Pulmonary atresia with or without VSD Critical pulmonary stenosis (with right to left interatrial flow) Tricuspid atresia with small VSD Complex lesions with severe pulmonary stenosis <sup>b</sup>  <i>Duct dependent for mixing,</i> TGA (simple and complex)	Tetralogy of Fallot with severe pulmonary stenosis <sup>a</sup> Complex lesions with pulmonary stenosis <sup>b</sup>
Cyanosis with congestive failure or respiratory distress	Obstructed TAPVD (usually infradiaphragmatic) Severe Ebstein’s anomaly	Pulmonary arteriovenous fistulae (rare) Partially obstructed TAPVD	<i>Mixed circulations with unobstructed pulmonary blood flow, e.g.</i> Unobstructed TAPVD (cardiac or supracardiac) Common arterial trunk Tricuspid atresia with a large VSD Some complex lesions with high pulmonary blood flow <sup>c</sup>
Collapse/shock		<i>Left heart obstruction, e.g.</i> Aortic coarctation or interruption HLHS Aortic stenosis	
Congestive cardiac failure (without cyanosis)		Left heart obstruction with a left-to-right shunt e.g. Aortic coarctation ± VSD <i>Systemic arteriovenous fistulae, e.g. cerebral</i>	<i>Left to right shunts, e.g.</i> Large VSD, complete AV septal defect, PDA, aortopulmonary window Complex lesions <sup>d</sup>

N.B. It is important to use this table as a guideline only – each condition can present unusually late or early! Tachyarrhythmias, usually SVT, can present with heart failure or collapse in any of these age groups, as can myocardial failure due to heart muscle disease such as hypertrophic cardiomyopathy or myocardial ischemia secondary to perinatal distress. Cardiovascular collapse in the first few hours is usually related to such myocardial dysfunction; sepsis and metabolic disease should be considered.

TAPVD, totally anomalous pulmonary venous drainage; HLHS, hypoplastic left heart syndrome; TGA, transposition of the great arteries – those without a VSD and a small oval foramen present earlier; VSD, ventricular septal defect; PDA, persistent ductus arteriosus.

<sup>a</sup> In tetralogy of Fallot, only the most severe present as a cyanotic neonate. The less severe forms present typically with cyanotic spells, or with a loud murmur on routine check.

<sup>b</sup> Examples of complex lesions with low pulmonary blood flow include:

1. Any single ventricle with severe pulmonary or subpulmonary stenosis.
2. Double outlet right ventricle with severe pulmonary stenosis.

<sup>c</sup> Examples of complex lesions with high pulmonary blood flow and cyanosis include:

1. Double outlet right ventricle with transposed great arteries.
2. Pulmonary atresia with large aortopulmonary collateral arteries or large arterial duct.

<sup>d</sup> Examples of complex lesions with high pulmonary blood flow without cyanosis include:

1. Single ventricle without pulmonary stenosis.
2. Double outlet right ventricle with normally related great arteries and *without* pulmonary stenosis.

**Table 21.10** Flow chart for the differential diagnosis of central cyanosis. Assessment of whether pulmonary blood flow is increased or diminished combined with the electrocardiographic findings helps to narrow the diagnostic possibilities

PBF, pulmonary blood flow; RVH, right ventricular hypertrophy; LVH, left ventricular hypertrophy; BVH, biventricular hypertrophy; TGA, transposition of great arteries; VSD, ventricular septal defect.

**Fig. 21.17** Transposition of the great arteries (atrioventricular concordance, arterioventricular discordance). Shading indicates desaturated/un-oxygenated blood. AO, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

atrium, delivers this blood into the aorta (Fig. 21.17). The oxygenated blood returning from the pulmonary veins drains into the left atrium and left ventricle but is pumped directly back into the pulmonary arteries (Fig. 21.10d). These two circulations do not mix and this is not compatible with life. Survival in the first few hours is due to mixing at atrial level via a patent oval foramen and at arterial level via the patent arterial duct. Some infants have a ventricular septal defect, pulmonary stenosis or aortic coarctation.

### Clinical features

Cyanosis is sometimes detected at birth. More commonly presentation is over the next 1–3 days, the cyanosis becoming more obvious as the arterial duct closes (Table 21.9). If the atrial communication is small, the infant deteriorates rapidly and will die if the duct is not reopened with intravenous prostaglandin therapy or the foramen enlarged by atrial septostomy. No murmurs or other physical signs are present unless there are additional lesions. When there is an associated large ventricular septal defect with pulmonary stenosis, the severity of stenosis determines the degree of cyanosis and timing of presentation.

### Investigations

The neonate will fail the hyperoxia test and a metabolic acidosis may be present. Right ventricular hypertrophy on the electrocardiogram becomes more obvious with time. Chest radiography shows increased pulmonary vascularity (Table 21.10). Transposition of the great arteries is unlike most other cyanotic conditions that present early, which have reduced pulmonary blood flow. This is because there is both left to right and right to left shunting at atrial and ductal levels, combined

with hypoxia that causes myocardial dysfunction. The upper mediastinum is narrow because the aorta lies in front, and slightly to the right, of the pulmonary artery. The 'egg on side' appearance of the heart is not usually seen in the neonatal period, as the thymic shadow is often present. Echocardiography shows the pulmonary artery arising from the left ventricle (Fig. 21.10d) and the aorta from the right ventricle. A characteristic finding is the parallel relationship of the great vessels (Fig. 21.18). Additional lesions such as a ventricular septal defect, pulmonary stenosis or aortic coarctation can be identified.

### Management and prognosis

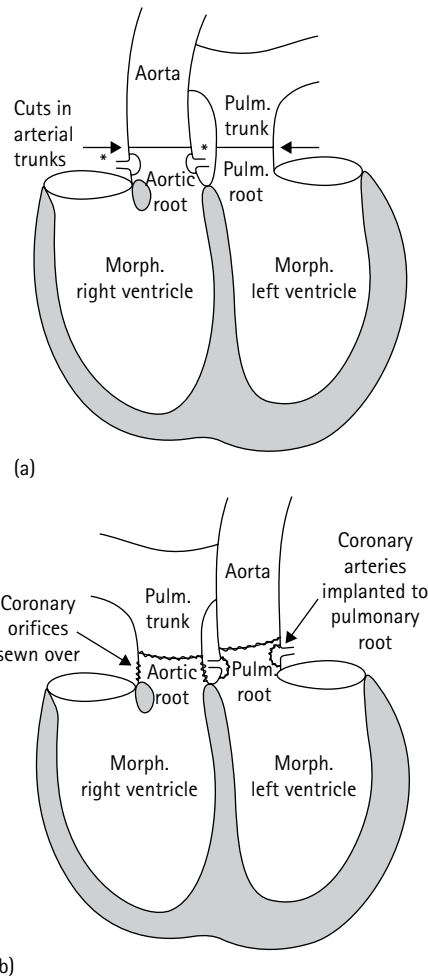

Prostaglandin infusion should be commenced immediately without waiting for the diagnosis to be confirmed. Any metabolic acidosis should be corrected.

**Balloon atrial septostomy.** This is usually performed to enlarge the oval foramen and promote mixing at this level. This can be done with echocardiographic guidance on the intensive care unit, or in the cardiac catheterization theater. A catheter with a balloon mounted on the end is advanced from the umbilical or femoral vein into the right atrium and, via the patent oval foramen, across into the left atrium. The balloon is inflated and pulled back to tear the septum (Fig. 21.13).

**Surgical management.** The arterial switch operation (Fig. 21.19) is performed within the next few days, using cardiopulmonary bypass. The arterial trunks are transected, the main pulmonary artery pulled forward, and the ascending aorta moved posteriorly such that the branch pulmonary arteries straddle the ascending aorta. The coronary arter-

**Fig. 21.18** Echocardiogram in long-axis view showing parallel great vessels with the aorta arising anteriorly from the right ventricle and the pulmonary artery arising posteriorly from the left ventricle. Ao, Aorta; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

**Fig. 21.19** Diagrammatic representations of the arterial switch (a) before and (b) after the procedure. Morph., morphological; Pulm., pulmonary. (From Anderson et al 2002<sup>105</sup>.)

ies are removed with a small button of surrounding arterial wall, and re-sutured into the new ascending aorta. This operation is usually performed in the neonatal period, before the left ventricle becomes adapted to pumping against a low pulmonary vascular resistance. This results in thinning of the left ventricular wall, which is then unable to cope with pumping at systemic pressure after the switch operation. In older infants, a band placed around the pulmonary artery will increase left ventricular pressure and ‘re-train’ it to cope with the pressure of the

systemic circulation. Early mortality from the arterial switch operation is now less than 2%, and 10 year survival is 94%.<sup>106</sup> The commonest complication is narrowing of the branch pulmonary arteries as they stretch over the aorta. Myocardial infarction is rare.

**Previous surgical procedures.** Before the mid-1980s surgery consisted of an atrial re-routing operation, the Senning or Mustard procedure. Systemic venous blood is directed from the right atrium by means of a baffle across the atrial septum to the mitral valve, into the left ventricle and out to the pulmonary arteries. Pulmonary venous blood passes via left atrium to the right atrium, right ventricle and aorta. The morphological right ventricle, designed for pumping through a low pressure circuit to the lungs, pumps blood around the body under high pressure. Although patients do well for the first two decades of life, the right ventricle gradually fails, typically in the third and fourth decade of life, and there is a risk of sudden death from atrial and ventricular arrhythmias. Actuarial survival at 30 years is 80%.<sup>107</sup>

**Surgical options for transposition with pulmonary stenosis.** It is inappropriate to perform the switch operation when there is significant pulmonary stenosis, as this problem is transferred to the new aorta. Aortic valve stenosis carries a significant lifetime morbidity. If there is an associated large outlet ventricular septal defect, it is sometimes possible to patch the ventricular septal defect so that the left ventricle leads into the aorta anteriorly, and then place a tube graft (conduit) from the right ventricle to the pulmonary artery (Fig. 21.20). This is known as the Rastelli procedure. The conduit must be replaced as the child grows, increasing the cumulative mortality risk.

**Tetralogy of Fallot with pulmonary atresia**

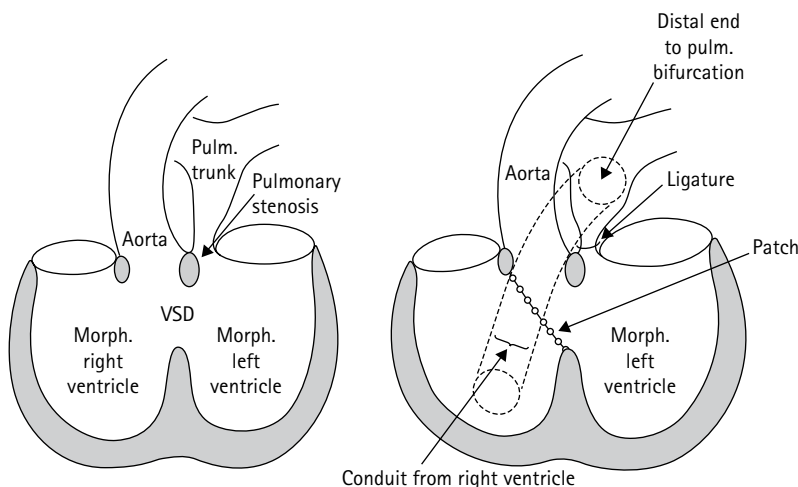

This condition represents the severe end of the spectrum of this condition. Most children with tetralogy of Fallot have stenosis rather than atresia of the right ventricular outflow tract and, as they present outside the neonatal period, are described later (p. 788).

**Anatomy and physiology**

Pulmonary atresia is a complete obstruction between the right ventricle and pulmonary arteries. The intracardiac anatomy resembles that of tetralogy of Fallot with a large ventricular septal defect, but the pulmonary arteries are frequently abnormal. The central pulmonary arteries may be confluent and supplied by the arterial duct. Alternatively, or in addition, collateral arteries from the aorta, major aortopulmonary collateral arteries (MAPCAs), supply the lungs and connect with the pulmonary arteries.

**Clinical features**

When the infant is dependent on the arterial duct, cyanosis develops when it closes in the first days of life (Table 21.9). Major aortopulmonary collateral arteries provide a more stable source of pulmonary blood flow, and cyanosis may be mild. A few infants have exces-

**Fig. 21.20** A diagrammatic representation of the steps involved in the Rastelli procedure. Morph., morphological; Pulm., pulmonary; VSD, ventricular septal defect. (From Anderson et al 2002<sup>105</sup>.)

sive pulmonary blood flow from these collateral vessels and present in heart failure with minimal cyanosis. The right ventricle is prominent on palpation. The first sound is frequently followed by an aortic ejection click related to the dilated ascending aorta, and the second heart sound is single. Continuous murmurs from the collateral vessels are heard widely over the precordium. Almost 50% of children have 22q11 deletion.<sup>108</sup>

### Investigations

The electrocardiogram shows right ventricular hypertrophy with persistence of the upright T wave in lead V1. Chest radiography shows pulmonary oligemia (Table 21.10). Right ventricular hypertrophy may produce a 'boot-shaped' cardiac shadow and 25–30% of infants have a right aortic arch. Echocardiography shows the subaortic ventricular septal defect and identifies the central pulmonary arteries. Additional muscular ventricular septal defects and other abnormalities can be identified. Cardiac catheterization or MRI may be needed, prior to definitive surgery, to accurately define the pulmonary arterial anatomy and aortopulmonary collateral arteries.

### Management and prognosis

Prostaglandin infusion maintains duct patency until the anatomy of the pulmonary arteries is delineated. The metabolic acidosis should be corrected.

**Infants with duct-dependent pulmonary circulation.** Stability is usually achieved by creating a shunt, usually a Gore-Tex™ tube, from the innominate or subclavian artery to the pulmonary artery (modified Blalock–Taussig shunt). This encourages pulmonary arterial growth in preparation for definitive surgery. This consists of closing the ventricular septal defect and placing a tissue conduit from right ventricle to pulmonary artery. It is preferable to defer definitive surgery until the child is older to reduce the number of conduit replacements needed during growth.

**Infants with major aortopulmonary collateral arteries (MAPCAs).** Surgery varies depending on the anatomy of the pulmonary arteries and MAPCAs. The aim is to connect important MAPCAs to the central pulmonary arteries, and to place a conduit between the right ventricle and pulmonary artery. The ventricular septal defect is closed. Several staged operations may be needed.

Prognosis in children without 22q11 deletion is good, with a 90% 5 year survival. However, children with 22q11 deletion have only a 36% 5 year survival, mainly related to less favorable pulmonary artery anatomy.<sup>109</sup>

### Pulmonary atresia with intact ventricular septum/critical pulmonary valve stenosis

This accounts for about 2.5% of all congenital heart defects.

#### Anatomy and physiology

The pulmonary valve is imperforate (atresia) or has a tiny orifice (critical stenosis). The ventricular septum is intact and the right ventricle is always abnormal, varying in size from slightly small to severely hypoplastic. The tricuspid valve is usually small. Pulmonary blood flow depends on the arterial duct. Cyanosis is caused by right to left shunting at atrial level, through a stretched oval foramen. In some infants with an atretic valve, the muscle-bound, hypertensive right ventricle has fistulous connections to the coronary arteries. The coronary arteries may be stenosed, so that the distal part of the coronary circulation depends entirely on retrograde flow from the right ventricle. Relief of the pulmonary valve obstruction is dangerous, because the right ventricular pressure falls, reducing coronary arterial flow and causing myocardial infarction.

#### Clinical features

Neonates present with cyanosis when the arterial duct closes (Table 21.9). There is a single second sound and there may be a soft ductal murmur and a systolic murmur of tricuspid regurgitation. Infants with

critical pulmonary stenosis have an ejection systolic murmur audible in the pulmonary area.

### Investigations

The electrocardiogram shows right atrial enlargement with tall P waves, and occasionally ST segment changes if there is coronary ischemia. When the right ventricle is hypoplastic, the R wave in V1 is small. Chest radiography shows pulmonary oligemia, with cardiomegaly if tricuspid regurgitation is severe (Table 21.10). Echocardiography shows right ventricular hypertrophy with a varying degree of hypoplasia. The tricuspid valve is abnormal, and pulmonary arteries fill through the arterial duct. Infants with critical stenosis have flow through the pulmonary valve. If coronary fistulae are demonstrated with continuous color Doppler signals within the right ventricular wall, or suspected because of enlarged coronary origins, cardiac catheterization will delineate them more clearly.

### Management and prognosis

Prostaglandin infusion should be commenced without waiting for the diagnosis to be confirmed. Any metabolic acidosis should be corrected. Initial intervention consists of transcatheter perforation and balloon dilatation of the stenosed or atretic valve (Fig. 21.21), surgical valvotomy or a systemic to pulmonary shunt. The ultimate clinical course depends on the size of the right ventricle.<sup>110</sup>

**Infant with an adequate right ventricle.** Infants with critical pulmonary valve stenosis and some with atresia will have a right ventricle of adequate size. With relief of the obstruction, it will eventually function well.<sup>32</sup>

**Infant with a severely hypoplastic right ventricle.** If the right ventricle is hypoplastic, the heart has functionally only a left ventricle. Palliation for all children with a single ventricle circulation is outlined later (p. 789).

The 5 year survival for pulmonary atresia and intact ventricular septum is approximately 70%.<sup>110</sup> Death is rare following balloon dilatation for critical pulmonary stenosis.<sup>32</sup>

### Tricuspid atresia

This spectrum of conditions, accounting for 1% of congenital heart defects, has in common an absent right atrioventricular connection. Survival requires a large oval foramen, allowing systemic and pulmonary venous return to mix in the left atrium. There are many anatomic and hemodynamic variations, producing widely different clinical features. These depend on the atrial and ventricular and septal defects, the size of the right ventricle and the ventriculoarterial connections (Fig. 21.22). If the ventricular septal defect is small, there will be reduced pulmonary blood flow (discussed below). If the ventricular septal defect is large, excessive pulmonary blood flow will result in cyanosis and heart failure (p. 775). When the pulmonary artery arises from the left ventricle and the aorta from the hypoplastic right ventricle, this constitutes a form of hypoplastic 'left' heart syndrome (p. 778).

### Tricuspid atresia with reduced pulmonary blood flow

#### Anatomy and physiology

Flow to the pulmonary arteries is via the left ventricle, either through a restrictive ventricular septal defect to the right ventricle and pulmonary artery or through an arterial duct if the pulmonary valve is atretic (Fig. 21.22).

#### Clinical features

Infants present, in the first few days, with cyanosis (Table 21.9). There is usually a systolic murmur and the second heart sound is single.

#### Investigations

The electrocardiogram shows a superior (left) axis, left ventricular dominant forces, and prominent P waves if the right atrium is enlarged. The lung fields are oligemic on chest radiography (Table 21.10).

Fig. 21.21 (a) Right ventricular (RV) angiogram showing pulmonary atresia with an obstruction of the right ventricular outflow tract. (b) Following radiofrequency perforation and balloon dilatation, there is flow through the pulmonary valve and into the pulmonary arteries. PV, pulmonary valve.

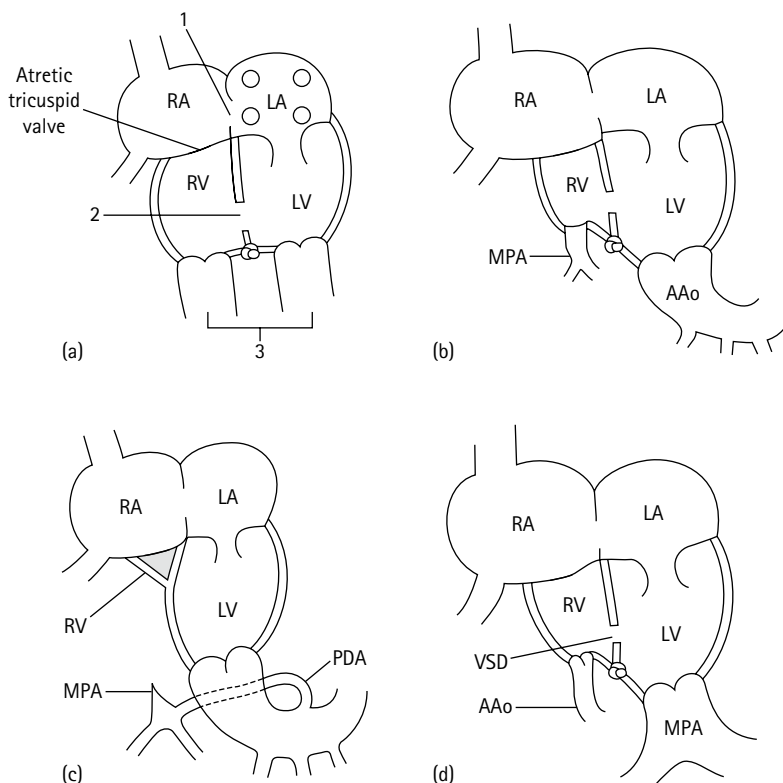

Fig. 21.22 Tricuspid atresia: anatomical variations and physiological implications. (a) The basic structural elements are identified with an atretic tricuspid valve and the three key anatomical–pathophysiological factors: (1) status of the atrial septal defect (ASD), (2) size of the ventricular septal defect (VSD), and (3) great artery connections (normal or transposed). (b) A common form of tricuspid atresia with a large ASD, small-to-moderate VSD resulting in a small right ventricle (RV) and, with normally related great arteries, a small (stenotic) main pulmonary artery (MPA). This patient is likely to have inadequate pulmonary blood flow and need a neonatal shunt. (c) When there is no VSD and normally related great arteries, the RV is absent and MPA is atretic; pulmonary blood flow is dependent on ductal patency. Such patients always need a systemic-to-pulmonary shunt. (d) A small VSD and transposition results in hypoplasia of the RV and aorta; effectively, this is hypoplastic left heart syndrome. (From Skinner et al 2000<sup>28</sup>.)

Echocardiography demonstrates the absent tricuspid valve (Fig. 21.10b) and other relevant anatomy.<sup>111</sup>

### Management and prognosis

The neonate usually requires prostaglandin to maintain duct patency and a systemic to pulmonary shunt to provide a reliable source of pulmonary blood flow. The absent tricuspid valve means that the heart has functionally only a left ventricle. Palliation and prognosis for all children with a single ventricle circulation is outlined under this condition (p. 789).

## PRESENTATION WITH CYANOSIS AND RESPIRATORY DISTRESS

The combination of cyanosis with respiratory distress at birth usually indicates a lung rather than a heart problem. These include meconium aspiration syndrome, neonatal pneumonia or surfactant deficiency in the preterm infant. There is often a history suggesting a respiratory problem. Chest radiography may indicate pneumonia or aspiration with areas of focal lung collapse (atelectasis), hyperexpanded or underdeveloped lungs, a pneumothorax or diaphragmatic hernia. However, it is vital not to miss cyanotic heart disease since the management is so different. Persistent cyanosis in a newborn with respiratory distress is a clear indication for echocardiography. A *hyperoxia test* (p. 768) is useful when this is not immediately available.

Two uncommon congenital heart lesions that present in this way are Ebstein's anomaly of the tricuspid valve and obstructed total anomalous pulmonary venous connection. In Ebstein's anomaly there is typically a huge ('wall-to-wall') heart on chest radiography. Total anomalous pulmonary venous connection is, however, often missed or diagnosed late. Differentiation from persistent fetal circulation or primary lung pathology can be difficult.<sup>100</sup> Since the only effective therapy is urgent surgery, late diagnosis may result in death. Delayed diagnosis also occurs when an infant with a lung problem has a coincident cyanotic heart disease.

### Ebstein's anomaly of the tricuspid valve

This is uncommon, comprising less than 1% of congenital heart disease.

#### Anatomy and physiology

The tricuspid valve is displaced down the interventricular septum (Fig. 21.23) towards the apex of the right ventricle, resulting in 'atrialization' of this chamber. The degree of displacement, together with dysplasia and regurgitation of the tricuspid valve, dictates the clinical spectrum. Antenatally, a hugely dilated right heart occupies much of the thorax and the lungs cannot develop normally. Right to left shunting at atrial level and little forward flow across the pulmonary valve may result in pulmonary valve stenosis or atresia.

#### Clinical features

The most severe form results in marked tricuspid valve regurgitation and a poorly functioning thin-walled right ventricle, causing fetal or neonatal death. At birth, the infant is deeply cyanosed with severe respiratory distress due to the hypoplastic lungs and reduced pulmonary blood flow (Table 21.10). The pansystolic murmur of tricuspid regurgitation, together with tricuspid valve clicks, may be audible. The liver is markedly enlarged.

Mild forms are asymptomatic, presenting with cyanosis, a murmur or supraventricular tachycardia due to the commonly associated Wolff-Parkinson-White syndrome.<sup>112</sup>

#### Investigations

The electrocardiogram shows right atrial enlargement with large P waves and an incomplete right bundle branch block pattern. Chest radiography shows a markedly enlarged heart and vascularity may be reduced. Echocardiography (Fig. 21.23) defines the severity of the lesion.<sup>111</sup>

### Management and prognosis

Fetal and neonatal presentation is associated with a poor outcome as it represents the severe end of the clinical spectrum. Early therapy includes intensive ventilatory support and treatment with nitric oxide to encourage a fall in pulmonary vascular resistance. Early mortality is high although outcome has improved more recently.<sup>112,113</sup> Children with a milder form have a better outlook, but some require surgery to the tricuspid valve in later life.<sup>112,114</sup>

### Total anomalous pulmonary venous connection

This is uncommon, accounting for less than 1% of congenital heart disease.<sup>115</sup> The pulmonary veins join to form a confluence or channel behind the left atrium and eventually drain into the right atrium to mix with the deoxygenated blood returning from the body. The route from the pulmonary venous confluence can be of three types (Fig. 21.24), the commonest being the supracardiac.<sup>115,116</sup> The mode and timing of the clinical presentation depend on whether an obstruction prevents free drainage of the pulmonary venous blood into the right heart (Table 21.9). Infants with obstruction present shortly after birth with respiratory distress, cyanosis and cardiac failure. Those without obstruction present at 2–8 weeks of age with mild cyanosis and progressive cardiac failure.

### Obstructed total anomalous pulmonary venous connection

#### Anatomy

The infracardiac type is almost always severely obstructed (Fig. 21.24c). The cardiac and supracardiac types are rarely obstructed but this can occur when narrowing is present in other parts of the channel or when a small foramen prevents right to left flow at atrial level.

#### Clinical features

The infant becomes unwell shortly after birth as the pulmonary venous obstruction results in severe pulmonary venous hypertension, cyanosis, cardiac failure and respiratory distress, similar to the picture of persistent fetal circulation.

#### Investigations

Chest radiography shows pulmonary venous hypertension but the heart is often not greatly enlarged. The streaky appearance due to the prominent pulmonary veins can be mistaken for lung disease, particularly meconium aspiration. Once the diagnosis is suspected, echocardiography is extremely urgent. Differentiation from persistent pulmonary hypertension of the newborn is difficult. In both conditions the left atrium and ventricle are under-filled and compressed by the enlarged right ventricle. There is right to left flow across the atrial septum. Diagnosis depends on recognizing the pulmonary venous chamber behind the left atrium but not connecting with it (Fig. 21.10a).<sup>111</sup>

Fig. 21.23 Echocardiogram in four chamber view showing displacement of the abnormal tricuspid valve into the body of the right ventricle. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; TV, tricuspid valve.

**Fig. 21.24** Total anomalous pulmonary venous connection. The three common varieties are shown: (a) supracardiac with the four pulmonary veins draining into a common pulmonary venous channel (CPV) and then via a vertical (ascending) vein to the innominate vein and the right heart; (b) cardiac with the pulmonary veins draining directly to the coronary sinus (CS) as shown or directly to the right atrium (not shown); (c) infracardiac draining into the inferior vena caval or portal vein.

### Management and prognosis

Maintaining arterial duct patency with prostaglandin will not help. Ventilatory and circulatory support is necessary and the child must be transferred urgently for surgery, which is performed without delay. The pulmonary venous chamber is opened into the back of the left atrium, and the abnormal connecting vein ligated. Surgical mortality is high if the infant is extremely acidotic prior to surgery, but overall mortality as low as 7% has been reported.<sup>116</sup> There is a risk of later pulmonary vein stenosis (11%) which can be extremely difficult to manage successfully.

### PRESENTATION WITH CYANOSIS AND CARDIAC FAILURE

This presentation is rare, and usually caused by unobstructed total anomalous pulmonary venous connection, tricuspid atresia with a large ventricular septal defect or common arterial trunk.

### Unobstructed total anomalous pulmonary venous connection

#### Anatomy and physiology

The majority of supracardiac and intracardiac types (Fig. 21.24 a, b) are unobstructed. Deoxygenated blood from the caval veins mixes with the oxygenated blood from the pulmonary veins in the right atrium. The moderate cyanosis is often not detected clinically. As pulmonary vascular resistance falls, the path of least resistance for the blood is through the tricuspid valve rather than through the oval foramen and the mitral valve. Congestive cardiac failure develops due to excessive pulmonary blood flow.

#### Clinical features

The infant presents between 2 weeks and several months of age with congestive cardiac failure and moderate cyanosis (Table 21.9). A right ventricular heave is palpable, and the second sound is loud and split. There may be a soft ejection systolic murmur caused by increased pulmonary blood flow.

#### Investigations

The electrocardiogram shows prominent P waves due to right atrial enlargement, and right ventricular hypertrophy develops. Chest radiography shows cardiomegaly with right atrial dilatation and pulmonary plethora. The supracardiac type frequently has a broad mediastinum due

to the ascending vein, the 'snowman' appearance. Echocardiography shows a dilated right atrium and right ventricle. There is a chamber behind the left atrium (Fig. 21.10a) and a vein draining to superior caval vein or right atrium

### Management and prognosis

Initial management includes treatment of heart failure with diuretics (p. 762). Early, but not urgent, surgical correction is performed. The pulmonary venous chamber is opened into the back of the left atrium, and the connecting vein is ligated. The results of surgery are good with few long term complications although early postoperative pulmonary venous obstruction rarely occurs.<sup>116</sup>

### Tricuspid atresia with excessive pulmonary blood flow

#### Anatomy and physiology

There is absence of the right atrioventricular connection and the great vessels are normally related. Systemic venous return passes across the atrial septum to mix with pulmonary venous blood in the left atrium. Flow to the lungs is via the left ventricle, across a large ventricular septal defect to the right ventricle and pulmonary arteries (Fig. 21.22). As the ventricular septal defect is large, pulmonary blood flow is excessive when pulmonary vascular resistance falls.

#### Clinical features

These infants present with mild cyanosis and congestive cardiac failure after 2 weeks of age (Table 21.9). There may be a soft pulmonary ejection murmur caused by increased blood flow across the pulmonary valve.

#### Investigations

The electrocardiogram shows a superior axis, and P waves are prominent if the right atrium is enlarged. Chest radiography shows plethoric lung fields (Table 21.10). Echocardiography shows the anatomical features necessary to make the diagnosis (Fig. 21.10b).<sup>111</sup>

### Management and prognosis

As the tricuspid valve is atretic, the right ventricle can never function as a normal ventricle. Management and prognosis are those of a child with a single ventricle circulation (p. 789). Initially a pulmonary artery band will be required to limit pulmonary blood flow.

## Common arterial trunk (truncus arteriosus)

This comprises about 1% of congenital heart defects.

### Anatomy and physiology

The common arterial trunk fails to divide into aortic and pulmonary arteries. There is a large ventricular septal defect below the common outlet (truncal) valve, which overrides the ventricular septum. This valve is usually abnormal, and may have more than three leaflets. It may be stenotic or regurgitant. The condition is subdivided according to the origin of the pulmonary arteries from the arterial trunk (Fig. 21.25).

- Type 1 – common origin of pulmonary arteries.
- Type 2 – pulmonary arteries arise separately but adjacent, from posterior of the trunk.
- Type 3 – pulmonary arteries arise separately, from lateral walls of the trunk.

Aortic coarctation or interruption is occasionally present.

### Clinical features

Cyanosis is mild, and congestive cardiac failure occurs after 2 weeks of age due to the high pulmonary blood flow (Table 21.9). Clinical signs include brisk pulses, an ejection click from the abnormal valve and cardiac failure. Systolic or early diastolic murmurs occur with truncal valve stenosis or regurgitation. Approximately 40% of children have 22q11 deletion<sup>117</sup> or other syndromes.

### Investigations

The electrocardiogram may show biventricular hypertrophy. Chest radiography shows cardiomegaly and plethora, and > 30% have a right aortic arch. Echocardiography shows the ventricular septal defect with overriding truncal valve similar to that in tetralogy of Fallot, but the pulmonary arteries arise from the arterial trunk.<sup>111</sup> Cardiac catheterization is unnecessary unless there is a suspicion of irreversible pulmonary hypertension.

### Management and prognosis

Cardiac failure is managed medically. Prostaglandin is necessary if there is aortic arch obstruction. The large left to right shunt and rapid development of pulmonary vascular disease make early surgery necessary. The ventricular septal defect is closed and a valved conduit is placed from the right ventricle to the pulmonary artery branches after they are detached from the trunk.

Mortality is in the region of 5%<sup>118</sup> and prognosis is worse if there is a stenotic or regurgitant valve, aortic arch obstruction, low weight or older age at intervention. The right ventricle to pulmonary artery conduit will need to be replaced as the child grows. Late mortality is approximately 10%.<sup>118,119</sup>

## PRESENTATION WITH CARDIOVASCULAR COLLAPSE

Heart disease, especially left heart obstruction, should always be considered in a shocked infant. It is important to feel all the pulses and examine the heart size on chest radiography. Cardiomegaly is usually present with cardiac causes and rare in other conditions.<sup>120</sup> If there is any suspicion of a cardiac lesion, echocardiography is indicated. Other causes of collapse in the neonate include sepsis,<sup>120</sup> respiratory and metabolic disease.

Common cardiac causes are the left heart obstructive lesions. Supraventricular tachycardia should be considered if the heart rate is over 250 beats per minute.<sup>100</sup> Myocardial disease such as cardiomyopathy (p. 802), either dilated or hypertrophic, myocardial ischaemia following perinatal distress and anomalous origin of the left coronary artery (p. 792) are rare causes. Pericardial effusion with tamponade occasionally presents in this way.

### Left heart obstructive lesions

These are due to severe aortic coarctation or arch interruption, hypoplastic left heart or critical aortic stenosis. Mitral stenosis and pulmonary vein stenosis are rare in isolation. Obstructed total anomalous pulmonary venous connection can present with precipitous cardiovascular collapse, but severe cyanosis and respiratory distress due to pulmonary venous hypertension is usually the dominant feature. Pulmonary venous hypertension does not occur to the same degree in left heart obstructive lesions, since the left atrium usually decompresses via the oval foramen into the right atrium.

### The importance of the arterial duct with critical left heart obstructive lesions

At birth the arterial duct is widely patent. When there is obstruction within the left heart or aorta, the right ventricle is able to supply blood (albeit deoxygenated) to the descending aorta, and the femoral pulses will be palpable.

- Infants with coarctation or arch interruption usually have a lower saturation in the legs than the right arm.
- In severe aortic stenosis or left heart hypoplasia, the deoxygenated blood from the duct also travels retrogradely around the arch, into the head, arms and down the ascending aorta to the coronary arteries. Oximetry in all limbs will reveal deoxygenation.

### When the arterial duct closes

Since neonates are used to lower blood oxygen levels before birth, they remain well until the duct closes. Flow in the aorta falls, with decreased perfusion of vital organs, and the deterioration is often dramatic. This effect is made worse in infants with coarctation, as ductal tissue around the coarctation site in the aorta produces further narrowing.

Fig. 21.25 Common arterial trunk: (a) in type 1 the pulmonary arteries arise from the truncus (Tr) with a common origin; (b) in type 2 the pulmonary arteries arise separately from the back. In type 3 (not shown) the pulmonary arteries are more widely separate at their origins and arise posteriorly/laterally from the trunk.

### Clinical features

All the left heart obstructions share common clinical features related to duct closure (Table 21.9). Presentation is usually within 48 hours of birth and symptoms include poor feeding, lethargy and pallor. Deterioration is extremely rapid with poor peripheral perfusion resulting in delayed capillary refill time and mottled skin. The pulses are poor and the blood pressure is low. The right ventricle is forceful and murmurs are unremarkable. The infant is usually tachypneic with grunting respiration, the liver is markedly enlarged and urine output is poor.

### Investigations

There is a marked metabolic acidosis with abnormal renal and hepatic function, which may result in an abnormal coagulation profile. The electrocardiogram shows right ventricular hypertrophy, and there may be ST depression in the left precordial leads from myocardial ischemia. Chest radiography shows cardiomegaly with a combination of pulmonary plethora and edema. The echocardiographic findings are described under the individual lesions.

### Management

Intravenous prostaglandin causes the arterial duct to dilate but the precipitous collapse means that these infants often require endotracheal intubation, inotropic and intensive support. Death can occur if acidosis and renal dysfunction are not corrected. The specific management of individual conditions is discussed below.

### Aortic coarctation and interruption of the aortic arch

Aortic coarctation accounts for 5% of congenital heart disease. Interrupted aortic arch is extremely rare.

### Anatomy and physiology

Narrowing of the aortic arch commonly occurs at its isthmus between the left subclavian artery and the origin of the arterial duct. This is usually due to a shelf-like obstruction but it can be tubular (Fig. 21.26) and is sometimes associated with hypoplasia of the transverse aorta. About 70% of infants with a coarctation have at least one other associated lesion. The most common are ventricular septal defect, left ventricular outflow obstruction and mitral valve anomalies.<sup>121</sup>

Interruption of the aortic arch is a complete occlusion, which can be classified according to the position. Type A is beyond the left subclavian, type B between the left common carotid and the left subclavian arteries and type C between the carotid arteries.

### Clinical features

Most infants present in the first 2 weeks with rapid onset of cardiac failure progressing to cardiovascular collapse as described above. In milder forms the presentation is more insidious, with failure to thrive and cardiac failure. The right arm pulse is strong unless the cardiac function is poor, there is coincident aortic stenosis, or the right subclavian artery has an abnormal origin below the coarctation (aberrant right subclavian artery). The left arm pulse is weak if the left subclavian artery

Fig. 21.26 (a) High parasternal greatly magnified view of the isthmus of the aorta, the origin of the left subclavian artery (LSCA) and the descending aorta (DAO). Narrowed area of coarctation is arrowed. (b) Suprasternal view of a baby with coarctation of the aorta. The arch is of reasonable size and the area of coarctation is only clearly identified by the presence of turbulence on the color flow map. (c) Continuous wave Doppler from descending aorta via the suprasternal approach. The classic continuous flow which is seen in coarctation is present. The peak velocity is high and the diastolic velocity never returns to the baseline. (d) Hypoplastic aortic arch in a child who also had coarctation of the aorta. Coarctectomy has been carried out, but there is still isthmal narrowing. AA, ascending aorta; DA, descending aorta. (From Skinner et al 2000<sup>23</sup>.)

arises after the coarctation. The femoral pulses are absent. The right arm blood pressure is high and the blood pressure in the leg is more than 10 mmHg lower. Oscillometric techniques (Dynamap) are not reliable in this setting to record blood pressure in the legs and Doppler sphygmomanometry is more accurate. The right ventricular impulse is prominent and there may be a murmur of mitral regurgitation if the left ventricle is dilated. Murmurs can also be due to associated lesions. Turner syndrome should be considered in girls with coarctation.<sup>79</sup> Over 50% of infants with interruption of the aortic arch have 22q11 deletion.<sup>108,122</sup>

### Investigations

In addition to the investigations described, echocardiography defines the lesion. The right ventricle and pulmonary artery are enlarged. In infants with coarctation, an area of narrowing with turbulent flow is seen on color Doppler. The Doppler flow pattern through the coarctation has a characteristic 'saw-tooth' appearance with flow continuing into diastole (diastolic tail) (Fig. 21.26). Left ventricular dysfunction may be present. Associated lesions must be assessed, together with the size of the arterial duct. Interruption of the aortic arch will be visible on echocardiography.

### Management and prognosis

Surgery is performed when the infant has been stabilized and the acidosis corrected.

Infants with coarctation usually have repair through a lateral thoracotomy, with excision of the coarctation, ligation of the patent arterial duct and end-to-end anastomosis of the aorta. Cardiopulmonary bypass is required for severe hypoplasia or interruption of the transverse aortic arch. Closure of the associated ventricular septal defect is usually performed.

Prognosis depends on the extent of the aortic obstruction and the associated cardiac<sup>121</sup> and noncardiac lesions. Re-coarctation can occur so long term follow-up is essential. Antibiotic prophylaxis is necessary.

## Hypoplastic left heart

### Anatomy

This is a group of conditions characterized by underdevelopment of the left ventricle, with mitral and aortic atresia or stenosis to a degree that the left ventricle cannot sustain a systemic cardiac output. It accounts for 4% of congenital heart disease. The ascending aorta is small, and most infants also have coarctation. The milder forms overlap with the severest forms of critical aortic stenosis. Pulmonary venous return is diverted across the oval foramen to the right atrium and ventricle and flow in the aorta is dependent on the arterial duct. As the duct supplies both the systemic and pulmo-

nary circulations, the balance between flow to the body and lungs is critical.<sup>123</sup>

### Clinical features

The infant presents acutely with profound collapse (Table 21.9) when the arterial duct closes as described above.

### Investigations

The electrocardiogram shows right axis deviation and low left ventricular forces with small R waves in V6. Echocardiography reveals a small left ventricle with stenotic or atretic mitral and aortic valves. The aortic arch is hypoplastic. The right atrium and ventricle are enlarged, as is the pulmonary artery.

### Management and prognosis

An increasing number of infants, often with an antenatal diagnosis of this condition, are started on prostaglandin infusion soon after birth. Many are stable enough to undergo the high risk, palliative Norwood operation (Fig. 21.27) in the first days. The aorta is enlarged using part of the pulmonary artery and the distal pulmonary artery is detached and supplied by a modified Blalock–Taussig shunt. Recent modification, using a right ventricle to pulmonary artery conduit instead of a shunt, has improved prognosis.<sup>124</sup> Further surgery is similar to that for other children with a single ventricle circulation (p. 789). One year survival is up to 60% and 10 year as high as 50%.<sup>125,126</sup>

### Critical aortic stenosis

This represents approximately 10% of children with aortic stenosis.<sup>127</sup>

### Anatomy and physiology

The aortic valve is thickened, dysplastic and often unicuspid. The right heart is enlarged as it supplies both the pulmonary and systemic circulations through the arterial duct.

### Clinical features

These are similar to infants presenting with a hypoplastic left heart. A soft ejection murmur may be audible in the aortic area. An aortic ejection click is seldom audible, as the valve is usually thickened and immobile.

### Investigations

These are the same as those described for other infants with left heart obstructive lesions, but there may be left ventricular hypertrophy with a strain pattern on the electrocardiogram. Echocardiography distinguishes it from the other conditions, demonstrating an adequate sized left ventricle, which is either hypertrophied or dilated. The function is usually reduced. The aortic valve is thickened with restricted opening,

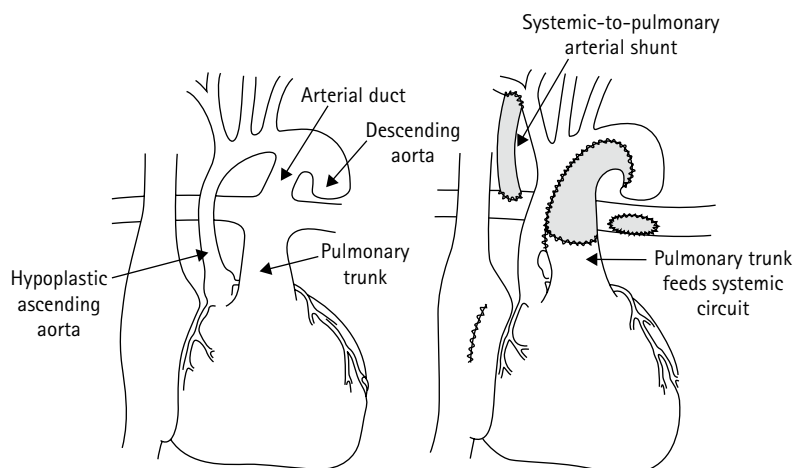

Fig. 21.27 These diagrams show the arrangement of the circulations before and after the classic Norwood procedure, which is the first stage of palliative surgery.

and turbulence is seen on color Doppler. The Doppler velocity across the valve may be increased, or reduced because of poor ventricular function.

### Management and prognosis

Once the infant has been resuscitated and stabilized, transcatheter balloon aortic valvuloplasty or open surgical valvotomy is performed. The results from the two procedures are similar<sup>14,36</sup> but recurrence of the stenosis occurs, requiring further intervention later in life.<sup>127</sup>

## PRESENTATION WITH CARDIAC FAILURE WITHOUT CYANOSIS

A number of conditions present in early infancy with cardiac failure. These children usually present outside the neonatal period and are discussed later. These conditions include ventricular septal defect (p. 781), atrioventricular septal defect (p. 783), aortopulmonary window (p. 785), anomalous origin of the left coronary artery (p. 792) and persistent arterial duct (p. 783), which is also covered in the neonatal section. Occasionally infants with cardiomyopathy (p. 802) present in the neonatal period and failure can also be caused by supraventricular tachycardia (p. 793).

## PRESENTATION WITH AN ASSOCIATED LESION OR SYNDROME

The more common syndromes associated with congenital heart disease are shown in Table 21.5. Congenital heart disease should always be considered in infants with a syndrome or dysmorphism. These are discussed in the section on the etiology of congenital heart disease (p. 765).

## PRESENTATION WITH AN ASYMPTOMATIC MURMUR

Innocent murmurs are common in the first few days, usually related to pulmonary or ductal flow. They are of lower pitch than pathological murmurs, varying with time and heart rate. Physiological branch pulmonary artery stenosis, occurring after duct closure, produces a pulmonary systolic murmur audible in the back. Though more common in the preterm, it can occur in term infants and is usually benign, resolving in a few months.<sup>128</sup>

Less than 5% of neonates with a significant murmur will have life-threatening heart disease.<sup>129</sup> Congenital heart lesions that cause a systolic murmur audible from birth are aortic and pulmonary stenosis and tetralogy of Fallot. Small ventricular septal defects are the most common single lesion causing an asymptomatic murmur. This becomes audible as the right ventricular pressure falls, with postnatal reduction in pulmonary arterial pressure. A patent arterial duct generates a murmur if there is some constriction, allowing the aortic pressure to be higher than pulmonary arterial pressure, but still enough flow through it to generate a noise. In the preterm infant a large left to right ductal shunt typically has a systolic rather than a continuous murmur because the aortic and pulmonary arterial pressures are similar in diastole. Tricuspid or mitral regurgitation causes a pansystolic murmur, most commonly in myocardial ischaemia following perinatal distress but can represent an isolated valve lesion or be part of a more complex condition such as an atrioventricular septal defect. A diastolic murmur is always pathological, most commonly due to a large left to right shunt later in the first month of life.

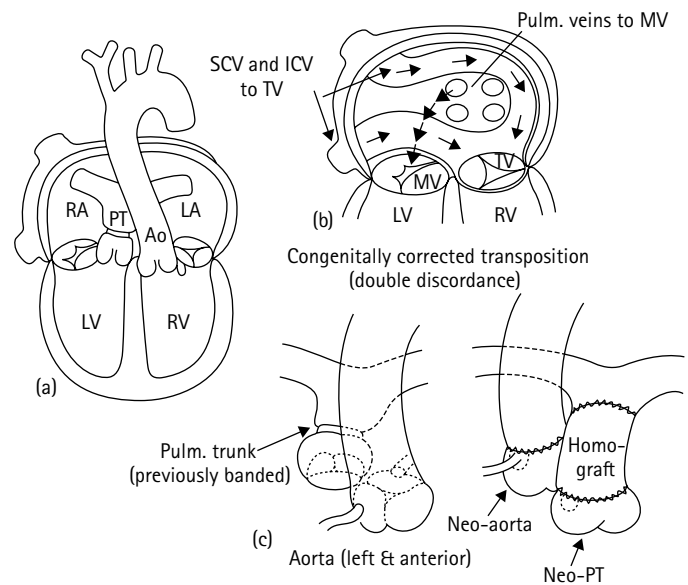

## MISCELLANEOUS COMPLEX LESIONS

### Congenitally corrected transposition of the great arteries

This rare lesion accounts for less than 1% of congenital heart disease.

#### Anatomy and physiology

This condition is characterized by discordance of both the atrioventricular and the ventriculo-arterial connection (Fig. 21.28a). The deoxygenated right atrial blood passes through the mitral valve into a

**Fig. 21.28** The steps involved in the so-called 'double switch procedure' involve, first, (a) banding of the pulmonary trunk (PT) unless associated lesions have already 'prepared' the left ventricle. (b) An atrial redirection procedure is then combined with (c) an arterial switch. This then produces both physiological and anatomical correction. Ao, aorta; LA, left atrium; LV, left ventricle; MV, mitral valve; Pulm., pulmonary; RA, right atrium; RV, right ventricle; SCV and ICV, superior and inferior caval veins; TV, tricuspid valve.

morphological left ventricle, from which the pulmonary artery arises. The oxygenated pulmonary venous blood passes from the left atrium, through the tricuspid valve, into the morphological right ventricle and thence into the aorta. Thus, although there is transposition, the anatomical fault is functionally corrected by the presence of atrioventricular discordance. The aorta is usually located anterior and to the left of the pulmonary artery. Ventricular septal defect is the most frequently associated lesion and commonly occurs with pulmonary stenosis. This may result in cyanosis from shunting of deoxygenated blood into the aorta. A few patients have no other lesions, and remain pink. The condition is commonly associated with dextrocardia.

### Clinical presentation and course

Associated cardiac lesions usually dictate the clinical presentation and course. If a large ventricular septal defect is present, heart failure develops early. Those infants with a ventricular septal defect and pulmonary stenosis present with cyanosis, and clinically resemble tetralogy of Fallot. In the absence of associated defects the condition may not be recognized for many years, but left-sided atrioventricular valve (tricuspid) regurgitation may progress. Tachyarrhythmias and complete heart block are common.

### Investigations

Inversion of the ventricles alters the direction of ventricular septal depolarization and produces the characteristic electrocardiographic finding of the absence of Q waves in V5 and V6, and the presence of Q waves in V4R or V1. The electrocardiogram may show heart block, arrhythmias or Wolff-Parkinson-White syndrome. Radiologically, the condition is suspected by the presence of a straight upper left heart border produced by the left-sided anterior aorta. Echocardiography will determine the abnormal atrioventricular and ventriculo-arterial connections and define any associated abnormality.

### Management and prognosis

The management is usually that of the associated lesion. Severely cyanosed infants require a systemic to pulmonary shunt. Infants with

heart failure secondary to a large ventricular septal defect require pulmonary artery banding. Closure of the ventricular septal defect is associated with a high incidence of complete heart block (30%) and significant mortality. Because of gradual deterioration of the systemic right ventricle and progressive tricuspid regurgitation, surgery can be performed to restore the left ventricle to pump to the systemic circulation. This can be achieved by means of the double switch operation (Figs 21.28b, c).

Prognosis depends on associated lesions and presence of heart block. Anatomic repair (double switch) significantly improves prognosis.<sup>130</sup>

### Double inlet (single) ventricle

This condition is more common than previously recognized and may account for up to 2–3% of congenital heart disease. Both atria are connected to a dominant ventricle (Fig. 21.10c), usually the left ventricle, the other ventricle being rudimentary (Fig. 21.29).

The main ventricle usually has the morphology of a left ventricle with two inlet valves, and the right ventricle is a small outflow chamber. The ventriculo-arterial connection can vary, but most commonly the aorta arises from the small right ventricle, and the pulmonary artery from the left ventricle. The small right ventricle communicates with the left ventricle via a ventricular septal defect. The severity of any associated coarctation or pulmonary stenosis determines the initial presentation and treatment. Further management is the same as for other children with a single ventricle circulation (p. 789).

### Double outlet right ventricle

**Anatomy and physiology.** The aorta and pulmonary artery both arise from the right ventricle. There are two common types. In one variation there is a large ventricular septal defect, with no pulmonary stenosis. This is commonly associated with a posterior pulmonary artery and an anterior aorta. The ventricular septal defect is related to the large pulmonary valve and has obvious similarities to transposition with a large ventricular septal defect (known as the Taussig–Bing malformation). In the other variation there is a large ventricular septal defect with pulmonary stenosis and the features mimic the tetralogy of Fallot.

### Clinical features

Depending upon the position of the great vessels and associated lesions, the clinical features mimic other lesions such as transposition, ventricular septal defect or tetralogy of Fallot. Echocardiography defines the anatomy and excludes other conditions.

Fig. 21.29 Double inlet ventricle or single ventricle. In the most common variety as here, both atrioventricular valves connect to a morphologically normal left ventricle (LV) and the right ventricle is represented by a small rudimentary outflow chamber from which the aorta arises. There is usually arterioventricular discordance.

### Management

Infants with high pulmonary blood flow require pulmonary artery banding whereas those with severe cyanosis, because of restrictive pulmonary blood flow, may require a Blalock–Taussig shunt. Definitive repair depends upon the site of the ventricular septal defect. Occasionally, only an intracardiac patch may be required, but in other children arterial switch and closure of a ventricular septal defect or major reconstruction with the use of a conduit may be necessary.

### ABNORMAL CARDIAC POSITIONS

*Dextrocardia* refers only to the situation in which more than half the heart is situated in the right chest. It does not necessarily have implications for the anatomy of the heart itself. Dextrocardia may thus be a primary abnormality of the heart or secondary to other thoracic pathology. Primary dextrocardia is often associated with abnormal positions of the abdominal organs. Complete situs inversus refers to the mirror image arrangement of the organs. It occurs in approximately 1 per 10 000 of the population and over 90% of these individuals have a normal heart. When dextrocardia is associated with normal abdominal visceral arrangements (i.e. the stomach on the left), or ambiguous visceral arrangement, the heart is usually abnormal. Malformations include atrioventricular discordance, univentricular heart, anomalous pulmonary venous drainage and pulmonary atresia. About one third of patients with asplenia or polysplenia have dextrocardia. The combination of situs inversus, bronchiectasis and paranasal sinusitis (Kartagener syndrome) occurs in 10–15% of patients with mirror-image dextrocardia.

*Mesocardia* indicates the position of the heart in the center of the thorax, prominent neither to the right nor to the left. It is usually not recognized clinically and is apparent only from chest radiography. The term *levocardia* need be used only when the left-sided heart is associated with abnormal visceral situs.

The possibility of abnormal cardiac position should always be remembered. The cardiac apex and impulse should be palpated over the right chest if it is not apparent on the left side, and heart sounds should be auscultated on both sides. Abnormal location of the liver edge in the midline or the left side, or the stomach resonance on the right side of the abdomen suggests abnormal abdominal situs, often associated with cardiac malposition. Chest radiography confirms the position of the heart. The morphology of the bronchi will suggest the thoracic situs, and the position of the stomach and liver the abdominal situs. Abnormal cardiac or visceral situs is an indication for cardiac review. The electrocardiogram should be performed with the addition of right-sided chest leads (V3R to V7R). In dextrocardia, the QRS complexes are characteristically taller in the right chest leads and become progressively smaller from V3 to V7 in the left-sided chest leads. A negative P wave in lead I indicates reversed atrial arrangement (atrial situs inversus), but does not specify the position of the heart in the chest. Echocardiography provides the best non-invasive means of identifying the arrangements and anatomy of the atria, ventricles and great vessels and any associated malformations.

Mesocardia and levocardia, with abnormal visceral situs, are commonly associated with asplenia or polysplenia.<sup>131</sup> When asplenia or polysplenia is suspected, splenic ultrasound and examination of the peripheral blood for Howell–Jolly bodies are appropriate. Patients with asplenia should receive pneumococcal vaccine and prophylactic antibiotic therapy.

### THE INFANT AND CHILD WITH CONGENITAL HEART DISEASE

The range of cardiac lesions, together with their presentation and management, is somewhat different from that of neonates. However, there is overlap with a number of cyanotic and acyanotic lesions presenting in infancy. Acyanotic lesions fall broadly into two groups: those with heart disease that causes an increased volume load, and those with a lesion that results in pressure loading of the heart.

## ACYANOTIC HEART DISEASE WITH INCREASED VOLUME LOAD

Increased volume load is usually caused by a left to right shunt, such as an atrial or ventricular septal defect, persistent arterial duct or atrioventricular septal defect. Rare causes include aorticopulmonary window and large arteriovenous fistula. Valvar regurgitation also produces an increased volume load to the heart.

### Ventricular septal defect

#### Anatomy

Ventricular septal defects are usually small and occur in any part of the membranous or muscular interventricular septum (Fig. 21.30). Those in the membranous septum are called perimembranous, as they extend into the adjacent muscle. They are the most common variant and are usually single. They can extend:

- Posteriorly into the muscular inlet between the atrioventricular valves.
- Inferiorly into the trabecular portion of the interventricular septum.
- Anteriorly into the muscular outlet between the right and left ventricular outflow tracts (as in tetralogy of Fallot). Rarely outlet defects are associated with prolapse of the aortic valve into the defect, causing regurgitation.

Muscular defects are completely surrounded by muscle. They occur in the inlet, outlet or trabecular portions of the muscular septum, where they are frequently multiple.

Ventricular septal defects occur in association with other cardiac lesions in 22% of patients.<sup>132</sup> These are most commonly pulmonary stenosis, aortic valve prolapse, atrial septal defect, patent arterial duct or coarctation.

#### Physiology

The clinical features and prognosis depend on the size and number of defects, and the volume of blood passing into the right ventricle. Small defects limit the shunt, so pulmonary artery pressure and blood flow are close to normal (restrictive defect). If the defect is large, left and right ventricular pressures are equal (nonrestrictive defect) and the volume of shunt depends on the systemic and pulmonary vascular resistances. The fall in pulmonary vascular resistance after birth is delayed and if the pulmonary blood flow remains excessive, irreversible pulmonary hypertension develops (p. 805).

### Small ventricular septal defect

#### Clinical features

Infants present with an asymptomatic murmur, audible in the first few weeks of life, as the pulmonary vascular resistance falls. A perimembra-

Fig. 21.30 Types of ventricular septal defect: (1) perimembranous; (2) outlet or subarterial; (3) trabecular; (4) inlet.

nous defect produces a loud, harsh pansystolic murmur at the fourth left intercostal space, usually associated with a thrill. It radiates to the apex and back. A muscular defect gives a short early systolic murmur localized to the fourth left intercostal space that disappears late in systole as the defect closes with ventricular contraction. The rest of the cardiovascular examination is normal unless there are other cardiac lesions.

*Differential diagnosis of small perimembranous ventricular septal defect* includes mitral regurgitation, where the murmur radiates to the axilla, and tricuspid regurgitation, where the murmur varies in intensity with respiration. The long ejection systolic murmur of tetralogy of Fallot, or severe subaortic aortic stenosis, can mimic a pansystolic murmur and the site of maximum intensity is similar. In severe aortic or pulmonary valve stenosis, the site of maximum intensity is in the second intercostal space.

*Differential diagnosis of small muscular ventricular septal defect* includes innocent vibratory murmur, mitral valve prolapse, bicuspid aortic valve, mild aortic or pulmonary stenosis and atrial septal defect.

#### Investigations

The electrocardiogram is normal and chest radiography is not indicated. Echocardiogram confirms the diagnosis. Perimembranous defects often have a small aneurysm of the membranous septum. Color Doppler flow also identifies small muscular defects. The velocity across the defect will be over 4 m/s, indicating that the right ventricular pressure is normal. Echocardiography will also identify additional lesions.<sup>132</sup>

#### Management and prognosis

Over two thirds of muscular defects and almost one third of perimembranous defects close spontaneously within 6 years.<sup>133</sup> Initially it is necessary to confirm that the pulmonary artery pressure is normal. Thereafter the child is reviewed at infrequent intervals until it has closed. This is most likely in early childhood, but closure into adult life has been reported.<sup>134</sup> Children should be encouraged to lead a normal life. Surgical closure is indicated for patients with aortic regurgitation caused by prolapse of a leaflet into the defect<sup>135</sup> and following endocarditis. A small number of patients (5%) develop subaortic stenosis or right ventricular outflow obstruction (8%). Surgery may be indicated for these or other lesions. Late arrhythmias have been reported<sup>134,136</sup> and sudden death has been described. Antibiotic prophylaxis is necessary for procedures until the defect has closed. Long term survival is excellent with a 96% 25 year survival.<sup>136</sup>

### Large ventricular septal defects

#### Clinical features

Infants present at 2–8 weeks of age as pulmonary vascular resistance falls and blood flow increases. They develop symptoms of heart failure and recurrent respiratory infections. The infant is tachypneic with intercostal and subcostal recession. The left precordium is prominent with a right ventricular lift and displaced apex indicating biventricular enlargement. A thrill may be associated with the pansystolic murmur that is maximal at the fourth left intercostal space and radiates to the apex and the back. A mid-diastolic murmur is caused by excessive pulmonary blood flow returning to the left atrium, resulting in turbulent flow across the mitral valve. It is present at the apex but may be inaudible because of tachypnea and tachycardia. A gallop rhythm may be heard and the liver is enlarged. Some infants, particularly those with Down syndrome, have minimal symptoms because persistently high pulmonary vascular resistance prevents excessive blood flow. Over time, the pulmonary vascular resistance increases, symptoms disappear, the murmur becomes softer and the pulmonary component of the second heart sound louder. Older infants and children have signs of established pulmonary hypertension (p. 805), with reversal of the shunt causing cyanosis (Eisenmenger syndrome).

*Differential diagnosis* includes a large persistent arterial duct or complete atrioventricular septal defect. Rare conditions include aorticopulmonary window, cardiomyopathy, severe mitral regurgitation, anomalous origin of the left coronary artery from the pulmonary artery,

total anomalous pulmonary venous drainage and complex lesions with unrestricted pulmonary blood flow.

### Investigations

The electrocardiogram shows biventricular hypertrophy.<sup>13</sup> The QRS axis is usually normal, but children with inlet or multiple muscular defects may have left axis deviation. The presence of other cardiac lesions may modify the electrocardiogram. When pulmonary hypertension develops, right ventricular hypertrophy is dominant. Chest radiography shows cardiomegaly with biventricular and left atrial enlargement with plethora. As pulmonary hypertension develops, the cardiac shadow becomes smaller, the proximal pulmonary arteries larger and the peripheral vessels less prominent ('peripheral pruning').

Echocardiography identifies the site, size and number of defects<sup>137</sup> and other cardiac lesions. Enlargement of the left atrium, left ventricle and pulmonary artery indicates a large shunt. The Doppler velocity across the defect may be low, reflecting an elevated right ventricular pressure. Cardiac catheterization is rarely performed, as the information necessary for monitoring and surgical closure can be obtained from echocardiography.<sup>138</sup> It is indicated if there is concern about irreversible pulmonary hypertension, especially in a child who presents late, or to obtain information about other lesions. The increase in oxygen saturation between the systemic veins and pulmonary artery allows calculation of pulmonary blood flow, which is more than twice systemic. Measurement of the pulmonary artery pressure allows assessment of pulmonary hypertension. A high concentration of inspired oxygen or nitric oxide will indicate whether pulmonary hypertension is reversible. Angiography in the left ventricle demonstrates the site, size and number of defects. Further angiography may be performed to evaluate other lesions.

### Management and prognosis

Treatment is initially for heart failure (p. 762). Nasogastric feeding may help to achieve adequate intake. Added calories are beneficial, but poor weight gain is also due to increased energy expenditure.<sup>2</sup> Limiting the volume of feeds is only necessary for intractable heart failure. Children with large defects can develop pulmonary hypertension in infancy. Surgery is indicated between 2 and 5 months of age to prevent this, and to promote growth. The operative mortality is less than 5%, with a similar risk of re-operation. Children with more complex lesions such as multiple muscular defects or chronic lung disease may be unsuitable for primary repair. This may also not be possible if facilities for infant surgery are unavailable. Pulmonary artery banding is palliative, limiting pulmonary blood flow and preventing irreversible pulmonary hypertension until the defects become smaller or the other problems improve. Transcatheter device closure is available for muscular defects that are difficult to close surgically.<sup>43</sup>

Some children have moderate sized defects without pulmonary hypertension. Intervention can be delayed if weight gain is satisfactory and there are signs of closure on the echocardiogram. If the pulmonary blood flow remains more than twice systemic, the defect should be closed because of the late development of pulmonary hypertension or chronic volume loading of the heart. Transcatheter devices are being developed for use in these children.<sup>28,49</sup>

Rarely a large defect will close spontaneously by apposition of part of the tricuspid valve or prolapse of an aortic leaflet into the defect. Muscular defects are more likely, and outlet defects less likely, to close spontaneously. Antibiotic prophylaxis is essential for procedures until the defect is closed. The long term survival after repair of a ventricular septal defect is excellent, with few late complications.<sup>136</sup>

## Atrial septal defect

### Anatomy

Atrial septal defects are classified according to their position in the atrial septum (Fig. 21.31). The most common type is the secundum defect, situated in the region of the oval fossa. It is usually single, but may consist of multiple small defects (fenestrated). Sinus venosus

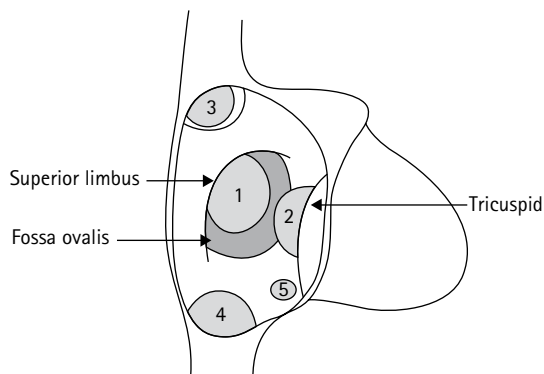

Fig. 21.31 Types of atrial septal defect: (1) ostium secundum; (2) ostium primum; (3) superior sinus venosus; (4) inferior sinus venosus; (5) coronary sinus.

defects occur in the superior part of the atrial septum and are associated with partial anomalous venous drainage of the right upper pulmonary vein to the superior vena cava or right atrium. Ostium primum defects, at the lower margin of the interatrial septum, are partial atrioventricular septal defects (p. 783). Rarely defects are related to the inferior vena cava or coronary sinus. Occasionally there can be an almost complete absence of the atrial septum (common atrium). A patent oval foramen is normal in infancy and occasionally persists into adult life.

### Physiology

The volume of the left to right shunt depends on the size of the defect and the relative compliance of the ventricles. This determines the size of the right atrium, right ventricle, pulmonary artery and left atrium that receive the excessive blood flow. Pulmonary hypertension does not develop until adult life. A patent oval foramen is not usually hemodynamically significant, but if the right atrial pressure is increased due to another cardiac abnormality, right to left shunting can occur with systemic desaturation. It may also be a cause of paradoxical systemic emboli.

### Clinical features

Most children present between 1 and 5 years of age with an asymptomatic murmur. Rarely this condition is familial. Few have failure to thrive or symptoms of heart failure. The right ventricular enlargement results in a slight precordial bulge and diffuse impulse on palpation. Because of excessive pulmonary blood flow, the pulmonary component of the second heart sound is delayed and does not become single during expiration (fixed splitting). This excessive blood flow also accounts for the murmurs, as flow across the actual defect is silent. The ejection systolic murmur in the pulmonary area is due to flow across the pulmonary valve and is usually audible in the back. The mid-diastolic murmur at the fourth left intercostal space is caused by increased flow across the tricuspid valve.

*Differential diagnosis* includes innocent murmur, mild pulmonary or aortic stenosis, aortic coarctation and persistent arterial duct with pulmonary hypertension.

### Investigations

The electrocardiogram shows incomplete right bundle branch block in over 90% of patients, but this is present in 10% of normal children. Chest radiography shows right atrial, right ventricular and pulmonary artery enlargement with plethora. Echocardiography confirms the size and type of defect, together with a large right atrium, right ventricle and pulmonary artery. The velocity across the pulmonary valve is usually normal, but may be increased due to flow. Cardiac catheterization is unnecessary for diagnosis, except for sinus venosus defects when the

pulmonary venous drainage is unclear. Pulmonary artery pressures are normal or slightly elevated. The increase in oxygen saturation between systemic veins and pulmonary artery allows calculation of the left to right shunt. Angiography can identify the site of pulmonary venous drainage. Transesophageal echocardiography also defines the defect and is particularly useful in identifying the pulmonary veins in sinus venosus defects.

### Management and prognosis

The majority of secundum defects seen in the neonatal period will close,<sup>139</sup> as will those smaller than 6 mm in diameter.<sup>140</sup> Defects more than 8 mm are unlikely to close. It is now possible to close central defects by transcatheter route with various devices.<sup>43,141</sup> This technique carries a low risk in selected patients and results in a high closure rate that is comparable with surgery.<sup>45,46,48</sup> Surgical closure is either by direct suture or patch. Mortality is less than 1%, with a 10% chance of post-cardiotomy syndrome with pericardial effusion, which usually resolves with anti-inflammatory treatment. Closure during early childhood results in long term survival similar to the general population.<sup>142</sup> Closure after 7 years of age results in a progressive increase in the risk of late supraventricular tachycardia, because of chronic right atrial dilatation. Pulmonary hypertension may develop in adult life. Infective endocarditis is rare, and antibiotic prophylaxis for procedures is controversial.<sup>60,62</sup>

## Patent arterial duct

### Anatomy

The arterial duct connects the pulmonary artery and descending aorta. It closes in the first few days of life by smooth muscle contraction. This is delayed in premature infants (Ch. 12), those with respiratory or cardiac disease, and infants born at high altitudes. It also remains open if there is an abnormality of the duct wall. It may coexist with other cardiac defects. In the presence of inadequate systemic or pulmonary blood flow, it provides a temporary conduit to compensate for the lesion.

### Physiology

Flow across an arterial duct depends on its size and the difference between the systemic and pulmonary vascular resistances. The duct is usually constricted and the pulmonary arterial pressure is lower than systemic, producing continuous systolic and diastolic flow. If it remains large, pulmonary arterial and aortic pressures equalize, and flow depends on the relative resistances. The increased pulmonary blood flow results in enlargement of the left atrium and ventricle. A large shunt causes pulmonary hypertension and flow becomes limited to systole or even reversed (Eisenmenger syndrome).

## Small patent arterial duct

### Clinical features

The child usually presents with an asymptomatic murmur. A history of prematurity or maternal rubella should arouse suspicion of an arterial duct. Rarely it is familial. Pulses and precordial palpation are normal. A continuous murmur is best heard at the left infraclavicular area.

*Differential diagnosis* includes venous hum (varies with posture and is best heard on the right), arteriovenous connection (e.g. coronary, cerebral, chest wall or pulmonary), ventricular septal defect with aortic regurgitation, and ruptured sinus of Valsalva aneurysm.

### Investigations

Electrocardiogram and chest radiography are normal. Echocardiography confirms the presence and size of the duct. There is no chamber enlargement and a high velocity flow across the duct confirms that the pulmonary artery pressure is normal. Cardiac catheterization is not necessary for diagnosis, but transcatheter closure with a device is possible.

### Management and prognosis

Arterial ducts are unlikely to close spontaneously in an infant more than a few months after term. Although the risk of endocarditis is small,

closure is usually recommended as this, together with mild left ventricular volume overload, may cause long term problems.<sup>143</sup> Transcatheter closure, by a variety of coils or devices, is the method of choice if this is available, with a successful occlusion rate of over 98%.<sup>43,44,144</sup> Significant complications are rare and embolized coils or devices are usually retrieved by catheter. Alternatively, surgical ligation is performed through a lateral thoracotomy. Echocardiography has allowed visualization of ducts so tiny that they do not produce an audible murmur. The consensus is that they should not be occluded, as this is technically difficult and the risk of endocarditis is remote.<sup>143</sup>

## Large patent arterial duct

### Clinical features

Large arterial ducts are rare and symptoms are similar to those found in infants with a large ventricular septal defect. The pulse is rapid and bounding with a wide pulse pressure, and there are signs of heart failure. The heart sounds are loud and there may be a third sound at the apex. The murmur is best heard in the pulmonary area but radiates down the left sternal border. It peaks late in systole with a soft, short diastolic component. A mid-diastolic murmur at the apex is caused by increased blood flow returning from the lungs to the left atrium and causing turbulence across the mitral valve. If pulmonary hypertension is present, there will be a right ventricular lift, a short systolic murmur and a loud second heart sound. No mid-diastolic murmur will be heard because pulmonary blood flow is reduced.

Differential diagnosis includes:

- Other conditions presenting with heart failure and a continuous murmur: aorticopulmonary window, pulmonary atresia with major aorticopulmonary collateral arteries, absent pulmonary valve syndrome, arteriovenous connection.
- Other conditions presenting with heart failure and a systolic murmur: as for a large ventricular septal defect.

### Investigations

The electrocardiogram shows biventricular hypertrophy.<sup>13</sup> Chest radiography shows left atrial, left ventricular and pulmonary artery enlargement with plethora. As pulmonary hypertension develops, the cardiac shadow becomes smaller, the proximal pulmonary arteries larger and peripheral vessels less prominent ('peripheral pruning'). Echocardiography shows left atrial, left ventricular and pulmonary artery enlargement. The right ventricle is hypertrophied if there is pulmonary hypertension. The duct can be imaged, and Doppler evaluation allows an estimation of pulmonary artery pressure.

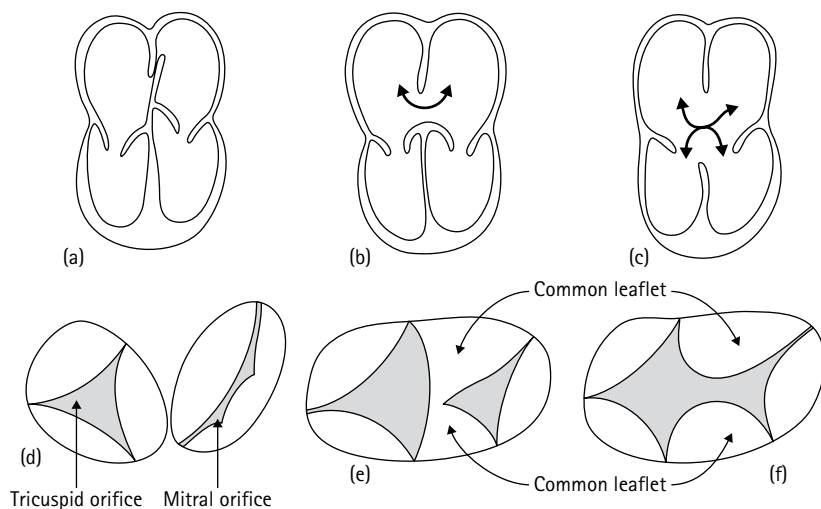

### Management and prognosis

Initial management includes the treatment of heart failure (p. 762). Surgical ligation is necessary if the duct is too large for transcatheter closure. Risks include recurrent laryngeal nerve damage, recanalization and inadvertent ligation of the left pulmonary artery. The operative mortality is less than 0.5%.<sup>143</sup> Transcatheter device closure is possible in infants over a year of age.<sup>44</sup> If the duct is closed before the development of irreversible pulmonary hypertension, the outcome is excellent.<sup>144</sup>

## Atrioventricular septal defect

### Anatomy

Atrioventricular septal defects represent a spectrum of conditions that have in common a deficiency of the atrioventricular septum and adjacent valves (Fig. 21.32). A partial atrioventricular septal defect is an ostium primum atrial septal defect. A complete atrioventricular septal defect has both atrial and ventricular components (Fig. 21.16). The atrioventricular valves are always abnormal. Partial defects usually have two separate atrioventricular valves at the same level. In the complete atrioventricular septal defect there is a single (common) atrioventricular valve. Occasionally left ventricular outflow tract obstruction<sup>145</sup> or a hypoplastic ventricle can complicate the clinical picture. Tetralogy of Fallot, coarctation or atrial isomerism

**Fig. 21.32** Anatomy of the atrioventricular junction: (a and d) normal septation with no septal communication and separate valve orifices at different levels; (b and e) partial atrioventricular septal defect with atrial shunting, two valve orifices at the same level and a 'cleft' anterior mitral leaflet; (c and f) complete atrioventricular septal defect with interatrial and interventricular communications and a common atrioventricular valve.

with asplenia may coexist. Down syndrome occurs in over 65% of children with a complete atrioventricular septal defect<sup>146,147</sup> and 25% of those with a partial defect. This lesion was previously called an endocardial cushion defect or atrioventricular canal.

### Physiology

Children with partial atrioventricular septal defects have hemodynamics similar to an atrial septal defect. Those with a complete atrioventricular septal defect have features of a ventricular septal defect. The atrioventricular valves are always regurgitant. If this is severe, the hemodynamic effect adds to that of the septal defect. Infants with a complete atrioventricular septal defect may have mild desaturation because of common mixing and pulmonary hypertension. Those with Down syndrome develop pulmonary vascular obstructive disease at a younger age.<sup>148</sup>

### Clinical features

Infants may present because of the diagnosis of Down syndrome. The other clinical features are those of an atrial or ventricular septal defect. There is also a pansystolic murmur of left atrioventricular valve regurgitation. If this is severe, it will contribute to the clinical features of pulmonary congestion and heart failure.

### Investigations

Chest radiography and electrocardiogram correspond to the type of septal defect. There is also left axis deviation on the electrocardiogram. Echocardiography identifies the anatomical type of atrioventricular septal defect and the size of the atrial and ventricular components. It allows evaluation of ventricular size, atrioventricular valve regurgitation and other cardiac lesions. It also provides information on the degree of pulmonary hypertension. Cardiac catheterization may be required to assess pulmonary vascular resistance in older infants and children. Angiography defines the atrial and ventricular septal defects and atrioventricular valve regurgitation.

### Management and prognosis

Complete atrioventricular septal defects require surgery at 3–6 months of age<sup>148</sup> to prevent the development of irreversible pulmonary hypertension. Pulmonary artery banding may be performed to defer definitive surgery in infants with other conditions, or when surgery carries a high risk. At the time of repair the left atrioventricular valve is sutured to reduce regurgitation and improve outcome.<sup>145</sup> Early mortality following repair of complete atrioventricular septal defect is less than 5%, with a 10 year survival of over 80%.<sup>146</sup> The prognosis is better for children with Down syndrome, as those who do not have Down syndrome more frequently have complex anatomy with unbalanced ventricles,<sup>149</sup> severely regurgitant atrioventricular valves or atrial isomerism. Partial

atrioventricular septal defects are closed surgically between 2 and 5 years of age. Survival after repair of partial atrioventricular septal defect is excellent with less than 3% early mortality and a 20 year survival of 87%.<sup>145</sup>

Re-operation is occasionally necessary for left atrioventricular valve regurgitation or stenosis, or left ventricular outflow tract obstruction.<sup>149</sup> A few patients require a pacemaker for complete heart block after surgery, or develop late supraventricular tachyarrhythmias.

### Mitral regurgitation

#### Anatomy

Mitral valve prolapse, cleft mitral valve leaflet and atrioventricular septal defect produce mitral regurgitation. A parachute mitral valve, with abnormal papillary muscles that restrict opening, may also cause regurgitation. Left ventricular dilatation, due to cardiomyopathy or certain congenital lesions, may result in stretching of the mitral valve and produce regurgitation. Infants with anomalous origin of the left coronary artery have myocardial ischaemia that results in left ventricular dilatation. Infarction of the papillary muscles of the mitral valve also causes regurgitation.

#### Physiology

Mild regurgitation has little hemodynamic effect. Increasing severity results in volume loading of the left atrium. Excessive flow returning through the mitral valve into the left ventricle causes dilatation.

#### Clinical features

Mild regurgitation is asymptomatic. A blowing pansystolic murmur is maximal at the apex, radiating to the axilla. When regurgitation is severe, the child may experience effort dyspnea or palpitation. Severe regurgitation is also associated with a forceful, displaced apex beat, a third heart sound and a mid-diastolic murmur caused by increased blood flow across the mitral valve. Pulmonary hypertension may develop with right ventricular hypertrophy and a loud pulmonary component of the second heart sound.

#### Investigations

If the regurgitation is severe, the electrocardiogram shows left atrial enlargement and left ventricular hypertrophy. Chest radiography shows cardiomegaly with left atrial enlargement. Echocardiography demonstrates the severity of the regurgitation and the anatomy of the valve. Cardiac catheterization is seldom necessary for diagnosis or management.

#### Management and prognosis

Mild regurgitation requires only observation for increasing severity and antibiotic prophylaxis for surgical procedures. Moderate regurgitation

is treated medically with afterload-reducing drugs such as angiotensin converting enzyme inhibitors and diuretics. Severe regurgitation with symptoms is an indication for surgery. This consists of mitral valve repair or replacement.

### Aortic regurgitation

Aortic regurgitation rarely occurs in isolation in children. It is most commonly associated with a bicuspid aortic valve or ventricular septal defect. Aortic regurgitation does not cause symptoms unless there is severe regurgitation with left ventricular dysfunction, when palpitations, sweating and effort dyspnea occur. The pulse is collapsing, the pulse pressure wide, and the apical impulse of left ventricular type. The murmur is a high pitched blowing early diastole murmur, best heard at the upper and middle left sternal edge with the child leaning forward and breath-holding in expiration. Severe regurgitation is associated with an ejection systolic murmur, representing increased flow across the aortic valve. An apical mid-diastolic murmur (Austin Flint) can also be heard with severe aortic regurgitation. This is caused by the mitral valve, which is prevented from opening fully in diastole by the aortic regurgitant jet. It may be indistinguishable from organic mitral stenosis but occurs without mitral valve disease. Signs of pulmonary edema due to left ventricular failure are late features of severe regurgitation.

With moderate or severe regurgitation there will be left ventricular hypertrophy on the electrocardiogram and enlargement on the chest radiograph. Echocardiography will demonstrate a dilated and hypercontractile left ventricle. Color Doppler shows regurgitant flow from the aorta to left ventricle. This may restrict opening of the anterior leaflet of the mitral valve in diastole. Cardiac catheterization adds little further information.

### Tricuspid regurgitation

Tricuspid regurgitation is usually associated with Ebstein's anomaly of the tricuspid valve (Fig. 21.23) (p. 776). Occasionally a dysplastic but not displaced tricuspid valve will cause similar hemodynamic and clinical features.

### Pulmonary regurgitation

Isolated pulmonary regurgitation is rare. Trivial regurgitation detected on color Doppler echocardiography is a normal finding. Pulmonary regurgitation is usually well tolerated. Severe regurgitation results in right ventricular volume overload with dilatation.

### Aorticopulmonary window

This rare condition consists of a direct communication between the ascending aorta and the pulmonary trunk, usually between the left side of the ascending aorta and the right side of the pulmonary artery. Additional cardiac lesions are common.

Most defects are large and increased pulmonary blood flow and pulmonary hypertension occur early. Dyspnea, failure to thrive and congestive heart failure are common in infancy. The pulse is collapsing and there is cardiomegaly on palpation. The pulmonary second heart sound is loud and a systolic rather than continuous murmur is heard over the left sternal border. A mid-diastolic flow murmur may be present at the apex. The findings mimic a large ventricular septal defect or patent arterial duct with pulmonary hypertension.

Chest radiography shows cardiomegaly with prominent pulmonary trunk and plethoric lung fields. The electrocardiogram shows biventricular hypertrophy. The defect is visible on cross-sectional echocardiography and color Doppler imaging. Further definition sometimes requires angiography or MRI. Surgical closure of the defect should be performed early because pulmonary hypertension is likely to develop.

### Arteriovenous fistulae

Fistulae between a systemic artery and vein can be present anywhere in the body. The common sites are between a cerebral artery and the vein of Galen,<sup>150</sup> the subclavian artery and vein, the hepatic

artery and portal vein, the internal mammary artery and the internal mammary vein or the ductus venosus. Cavernous hemangiomas can involve the skin, pelvis or liver. Acquired fistulae are usually the result of trauma.

The arteriovenous fistula allows run-off of blood from the aorta and increases systemic venous return. Small communications are asymptomatic, but large ones result in high output heart failure. A continuous murmur is audible over the involved area, sometimes accompanied by a palpable thrill. Other signs include bounding pulses, systemic venous congestion, cardiomegaly and hepatomegaly. Hepatic artery fistulae may produce liver enlargement. In any infant with heart failure and no obvious precordial or echocardiographic findings, a bruit suggestive of an arteriovenous fistula should be sought over the skull, chest wall and abdomen.

Large fistulae produce cardiomegaly on chest radiography and biventricular hypertrophy on the electrocardiogram. Echocardiography is useful in excluding cardiac pathology, while ultrasound of the affected area may reveal dilated arteriovenous channels. Definitive diagnosis is obtained by MRI or angiography. Aggressive anti-failure treatment and transcatheter occlusion have improved prognosis, but mortality and significant morbidity remain high.<sup>150</sup>

### Coronary artery fistula

A coronary artery fistula usually occurs as an isolated malformation. The right coronary artery is more often involved and most commonly drains into the right heart. The left to right shunt is seldom large. However, a large fistula produces exercise intolerance, dyspnea or angina because of the 'stealing' of blood from the normal coronary circulation. Heart failure is rare. The characteristic finding is a continuous murmur heard over the site of drainage into the heart. It is therefore maximal over the lower right or left sternal border when the fistula drains into the right atrium or right ventricle, and over the upper left sternal border when the fistula drains into the pulmonary artery or left atrium. Diagnosis is confirmed by echocardiography. Treatment is by surgery or transcatheter occlusion.<sup>151</sup>

### Sinus of Valsalva aneurysm

Congenital aneurysm of the aortic sinus (of Valsalva) may rupture into the right ventricle or atrium producing a left to right shunt. Symptoms of heart failure develop acutely and a continuous murmur is audible over the mid-left sternal area. Diagnosis is made by echocardiography and treatment is surgical.

## ACYANOTIC HEART DISEASE WITH INCREASED PRESSURE LOAD

### Pulmonary stenosis

#### Anatomy

Valve stenosis is the most common level of obstruction, but subvalvar or supra-valvar stenosis can occur. Thickened and fused valve leaflets open incompletely during systole, producing a jet that causes post-stenotic dilatation of the pulmonary artery. Muscular obstruction develops below a severely narrowed valve. Peripheral pulmonary stenosis consists of single or multiple stenoses of the pulmonary arteries distal to the valve. Rarely rhabdomyomas cause right ventricular outflow obstruction. Associated lesions include atrial and ventricular septal defects.

#### Physiology

Obstruction to outflow increases right ventricular systolic pressure, causing hypertrophy. Severe obstruction can cause supra-systemic right ventricular pressure. The noncompliant right ventricle causes elevated right atrial pressures, stretching of the oval foramen, and right to left shunting with cyanosis.

#### Clinical features

Most children present with an asymptomatic murmur before 4 years of age.<sup>152</sup> Supra-valvar and peripheral pulmonary stenosis occur with

Williams, Alagille<sup>153</sup> and congenital rubella syndromes.<sup>73</sup> Noonan syndrome is associated with a dysplastic valve.

**Mild stenosis.** The pulses, precordial pulsation and second heart sound are normal. A short, soft ejection systolic murmur maximal at the second left intercostal space usually radiates to the back. If the valve is mobile, a pulmonary ejection click is heard in the same area. It varies with respiration and is not related to the severity of stenosis.

*Differential diagnosis:* innocent murmur, atrial septal defect, aortic coarctation, mild aortic stenosis, small muscular ventricular septal defect.<sup>154</sup>

**Severe stenosis.** Infants may be cyanosed because of right to left shunting at atrial level. Older children are usually asymptomatic, but rarely there is a history of dyspnea, exercise intolerance or syncope. A prominent 'a' wave is seen in the jugular venous pulse. There is a right ventricular lift, and a systolic thrill may be palpable at the second left intercostal space. The long, harsh ejection systolic murmur increases in intensity late in systole, radiating to the back and neck. The pulmonary component of the second heart sound is soft and late, as right ventricular ejection is prolonged. A pulmonary ejection click may be heard.

*Differential diagnosis:* tetralogy of Fallot, severe aortic stenosis, aortic coarctation, perimembranous ventricular septal defect.

### Investigations

Severe obstruction causes right ventricular hypertrophy on the electrocardiogram. Chest radiography may show post-stenotic dilatation of the pulmonary artery. The vascular markings are normal if there is no right to left shunt, as blood returning to the right heart must pass through the lungs. However, substantial right to left shunting at atrial level results in pulmonary oligemia. Echocardiography usually shows a thickened pulmonary valve and pulmonary artery dilatation. Color Doppler shows turbulence distal to the site of obstruction and the measured velocity indicates severity. Severe stenosis is associated with right ventricular hypertrophy, muscular subvalve obstruction, tricuspid regurgitation and right atrial enlargement. Cardiac catheterization is not necessary for diagnosis, but transcatheter balloon dilatation is the treatment of choice (Fig. 21.14). Right ventricular angiography identifies the levels of obstruction and usually shows a thickened, doming pulmonary valve.

### Management and prognosis

Pulmonary valve and peripheral pulmonary stenosis often decreases spontaneously over time, but 27% of children have increasing obstruction.<sup>152</sup> This is frequently gradual, but rapid progression occurs in neonates.<sup>155</sup> The electrocardiogram and Doppler echocardiography allow accurate assessment of increasing stenosis. Approximately 17% of children require intervention.<sup>152</sup> This is performed when the pressure gradient exceeds 50 mmHg. Balloon dilatation is the treatment of choice,<sup>29,32</sup> and the gradient is usually markedly reduced or abolished.<sup>30</sup> Pulmonary regurgitation occurs but is well tolerated. The long term results are excellent<sup>31</sup> but repeat balloon dilatation is occasionally necessary. Occasionally a surgical valvotomy is performed, particularly if the valve is dysplastic or other lesions require surgery. Results are similar to balloon dilatation.<sup>156</sup> Infective endocarditis is rare and antibiotic prophylaxis for procedures is controversial.<sup>60,62</sup>

## Aortic stenosis

### Anatomy

Aortic valve stenosis is the most common level of obstruction. Subaortic or supra-aortic stenosis occurs less frequently, and occasionally children have more than one level of obstruction.<sup>157</sup>

- **Aortic valve stenosis** is due to a thickened valve that is often bicuspid. Post-stenotic dilatation of the ascending aorta may occur. A bicuspid aortic valve without stenosis occurs in 2% of the population.
- **Subaortic stenosis** is usually due to fibromuscular tissue below the aortic valve which may be damaged by the high velocity jet through the narrowed subaortic area. Muscular subaortic obstruction

occasionally occurs. Rarely cardiac rhabdomyoma or accessory atrioventricular valve tissue causes subaortic obstruction.

- **Supra-aortic stenosis** is due to localized or diffuse thickening of the ascending aorta. It is associated with Williams syndrome or a positive family history (autosomal dominant inheritance), but 25% of cases are sporadic.<sup>158</sup> Coronary artery abnormalities occur.

### Clinical features

Children usually present at about 2 years of age with an asymptomatic murmur and features of mild stenosis.<sup>157</sup> The pulses and apex beat are normal. A systolic thrill may be palpable in the suprasternal notch. An ejection systolic murmur is maximal in the aortic area, with radiation to the neck and left sternal border. If the stenosed valve remains mobile, an ejection click may be audible at the lower left sternal border. The murmur of subaortic stenosis is loudest at the lower left sternal edge. A soft, early diastolic murmur of aortic regurgitation is more common with subaortic stenosis, but may occur with valve stenosis.

**Severe aortic stenosis.** Symptoms include dyspnea, syncope or angina on exertion but severe stenosis may be asymptomatic. The pulse is weak and slow rising with reduced pulse pressure. The aortic component of the second heart sound is soft and delayed, resulting in a single second heart sound or paradoxical (expiratory) splitting. The more severe the stenosis, the longer and later the accentuation of the systolic murmur. A long ejection systolic murmur can be difficult to distinguish from the pansystolic murmur of a ventricular septal defect. Most infants with severe (critical) stenosis present with collapse in the neonatal period (p. 780), but some develop heart failure in infancy. The pulses are weak and cardiomegaly is present. A gallop rhythm may be heard, and the ejection systolic murmur is soft if left ventricle function is poor. An ejection click is rare, as the valve is thick and immobile.

### Investigations

The electrocardiogram is usually normal but left ventricular strain pattern, with inverted T waves in the left precordial leads, indicates severe stenosis. Chest radiography does not show cardiomegaly in the absence of heart failure. Post-stenotic dilatation of the ascending aorta produces a prominent ascending aorta. Echocardiography shows the site of obstruction and whether left ventricular hypertrophy is present. The Doppler velocity across the outflow tract provides an indication of severity. Turbulence occurs on color Doppler at the level of obstruction. Cardiac catheterization is unnecessary for diagnosis, but is undertaken for therapeutic balloon dilatation of the stenotic valve.

### Management and prognosis

- **Aortic valve stenosis** progresses with time. Less than 20% of patients will have mild stenosis after 30 years.<sup>127</sup> Rapid progression may occur in early childhood and adolescence. Surgical valvotomy is undertaken when the pressure gradient across the valve exceeds 50 mmHg, or if there are features of severe stenosis. Transcatheter balloon dilatation is an alternative to surgery.<sup>33,36</sup> Reduction of valve gradient and the incidence of valve regurgitation are comparable to surgery.<sup>34,159</sup> Treatment is palliative as re-stenosis and progressive aortic regurgitation occur. Once severe aortic regurgitation develops, or if obstruction cannot be relieved, valve replacement is necessary. Both aortic homograft and prosthetic valve replacements have potential problems. The Ross procedure appears to carry a lower risk.<sup>160</sup> The aortic valve is replaced by the patient's own pulmonary valve, and a tissue conduit replaces the pulmonary valve.
- **Subaortic stenosis** is rarely significant during infancy but subsequent progression may be rapid, and most children require surgery. Subaortic obstruction is not usually relieved by balloon dilatation and surgery is indicated for increasing gradient or aortic regurgitation.
- **Supra-aortic stenosis** usually responds well to surgery, and re-operation is rarely necessary.<sup>158,161</sup> Surgery for diffuse narrowing of the ascending aorta produces less favorable results. Balloon

dilatation is not recommended, because of the nature of the narrowing and the proximity of the coronary arteries.

- *Multilevel obstruction* is more severe at presentation and has a worse prognosis than a single level of stenosis. Children are more likely to undergo operation, and have a higher incidence of re-operation.<sup>157</sup> Mortality is higher, emphasizing the difficult surgical problems that these children present.

*Sudden death of patients with aortic stenosis* is rare, accounting for only 2% of sudden cardiac deaths under 35 years of age.<sup>162</sup> It occurs in less than 2% of patients with aortic stenosis and only in those with severe aortic stenosis.<sup>157</sup> It is unnecessary to restrict activities of children with mild aortic stenosis<sup>163</sup> but regular review and antibiotic prophylaxis for procedures remain essential throughout life.

## Coarctation of the aorta

Coarctation most commonly presents acutely in the neonatal period when the arterial duct closes (p. 779). In older infants and children, the signs are more subtle.

### Anatomy

The aorta is narrowed at the isthmus between the left subclavian artery and the insertion of the arterial duct. Ductal tissue extending into the aortic wall constricts after birth, producing or increasing an obstruction that is usually discrete. Diffuse hypoplasia of the transverse aortic arch may occur. Rarely constriction occurs in the lower thoracic or abdominal aorta. Collateral vessels from intercostal, mammary and subclavian arteries develop, bypassing the obstruction and augmenting perfusion to the lower body. Associated cardiac lesions are common,<sup>164</sup> including a bicuspid or stenotic aortic valve, ventricular septal defect and mitral stenosis. Shone syndrome consists of left-sided obstructive lesions including supramitral membrane, mitral valve abnormalities, subaortic stenosis and coarctation. More than 15% of girls with Turner syndrome have coarctation.<sup>79</sup>

### Physiology

Obstruction of the aorta results in pressure overload of the left ventricle. Systemic hypertension is due to mechanical obstruction and neurohumoral mechanisms related to reduced renal perfusion.

### Clinical features

Infants may present with heart failure. More commonly, children have an asymptomatic murmur, weak femoral pulses or systemic hypertension detected on routine examination. The femoral pulses are less easily felt than the right brachial. The blood pressure in the right arm exceeds the 95th percentile for height<sup>8</sup> and is > 10 mmHg higher than in the legs. The left arm blood pressure depends on the site of coarctation. The left ventricular impulse is prominent, with a short ejection systolic murmur maximal at the second left intercostal space and below the left scapula posteriorly. A continuous murmur from the coarctation or collateral arteries may be heard in older children. Murmurs from other cardiac lesions are frequently audible.

### Investigations

The electrocardiogram is usually normal, but left ventricular hypertrophy may be present. Chest radiography may show an abnormal aortic contour (3 sign) caused by localized constriction of the aorta at the coarctation site. Dilated intercostal arteries cause rib notching in older children. Echocardiography demonstrates the coarctation site (Fig. 21.26a, b). Hypoplasia of the aortic arch (Fig. 21.26d) and other lesions can also be identified. Turbulence on color Doppler occurs at the obstruction, with increased velocity and continuous flow into diastole (Fig. 21.26c). MRI, CT or angiography demonstrates the anatomy of coarctation (Fig. 21.16).

### Management and prognosis

Early treatment improves life expectancy.<sup>165</sup> It is undertaken soon after diagnosis, as the incidence of residual systemic hypertension is related

to the age at intervention. Severe hypertension results in premature cardiovascular disease, aortic dissection or cerebrovascular accident. There are no clinical trials which determine the optimum form of treatment.<sup>40,166</sup> Surgical repair consists of excision of the narrowed segment and end-to-end anastomosis of the aorta, or left subclavian flap repair. Rarely a patch or tube graft is used to relieve the obstruction. The risks of surgery include transient severe hypertension, paraplegia from spinal cord ischaemia (1%),<sup>40,164</sup> recurrent laryngeal or phrenic nerve injury, chylothorax and re-coarctation (<4%). Transcatheter balloon angioplasty has been used as the initial treatment for coarctation<sup>39</sup> and is the treatment of choice for re-coarctation following surgery.<sup>37</sup> Complications include femoral artery damage and aortic aneurysm formation. The risks of surgery and angioplasty are similar and mortality is rare in the absence of other lesions. Balloon-expandable stents have been used to prevent re-coarctation<sup>164</sup> and reduce the risk of aneurysm formation but there are concerns about their use in children.<sup>40</sup>

Hypertension may remain, and other lesions such as left ventricular outflow tract obstruction may require treatment. Follow-up is essential and the risk of infective endocarditis remains.

## Left ventricular inflow obstructions

### Anatomy

Obstruction between pulmonary venous return and the left ventricle is rare. It is caused by:

- stenosis of pulmonary veins entering the left atrium;
- cor triatriatum, which comprises a fibrous diaphragm dividing the left atrium into two chambers, with a restrictive communication between them;
- supramitral stenotic ring, which is a circumferential ridge of tissue in the left atrium immediately above the mitral valve;
- congenital mitral valve stenosis.

### Physiology

Obstructive lesions produce elevated pressure proximal to the site of obstruction and pulmonary venous congestion. Pulmonary hypertension develops, causing right heart failure.

### Clinical features

The clinical signs are of pulmonary venous congestion and pulmonary hypertension. When the obstruction at any level is severe, symptoms begin in early infancy with dyspnea, respiratory infections and poor weight gain. Tachypnea, tachycardia, recession and hepatomegaly are present. An apical mid-diastolic murmur is more often audible in mitral valve stenosis or supramitral ring than in cor triatriatum. Children with a mitral valve abnormality frequently present with associated malformations such as aortic coarctation or ventricular septal defect, and the mitral lesion may not be recognized initially.

### Investigations

The electrocardiogram shows right atrial and right ventricular hypertrophy. Left atrial enlargement is seen in mitral valve stenosis or supramitral ring but not in cor triatriatum. Chest radiography shows cardiomegaly with left atrial enlargement, producing a double shadow at the right heart border. There is a prominent pulmonary artery and pulmonary venous congestion with 'butterfly wing' distribution of vascular markings or ground glass appearance if pulmonary edema is present. Echocardiography provides definitive diagnosis and Doppler velocity across the obstruction indicates the severity. The tricuspid regurgitant velocity indicates the severity of pulmonary hypertension. Cardiac catheterization is not usually required, but an end-diastolic pressure difference of more than 5 mmHg across the obstruction is significant. Angiography confirms the site of obstruction, but this is better seen on transthoracic or transesophageal echocardiography.

### Management and prognosis

Surgical excision of the obstructive membrane is the definitive treatment for cor triatriatum and supramitral ring. For congenital mitral stenosis,

the deformity of the valve dictates the surgical approach. Valvotomy, with attempts to conserve the native valve, is preferred to mitral valve replacement.

### Double chambered right ventricle

This is a rare condition resulting from a hypertrophied muscular band in the mid-portion of the right ventricle. It may be associated with a ventricular septal defect and is usually not severe at birth, the obstruction developing with time. The clinical features are similar to pulmonary valve stenosis, but there is no ejection click and the murmur is maximal lower down the left sternal border. Diagnosis is confirmed by echocardiography or cardiac catheterization with right ventricular angiography. Surgery is indicated for significant obstruction, and the long term outlook is excellent.

## CYANOTIC CONGENITAL HEART DISEASE

The majority of children with cyanotic heart disease present in the neonatal period (p. 769). Tetralogy of Fallot is the commonest cyanotic cardiac defect presenting in infancy.

### Tetralogy of Fallot Anatomy

This condition consists of right ventricular outflow obstruction, right ventricular hypertrophy, a large perimembranous ventricular septal defect and an aorta that overrides the ventricular septal defect (Fig. 21.33). The hilar pulmonary arteries are usually small. When more than 50% of the aorta arises from the right ventricle, it is termed 'double outlet right ventricle'. Other lesions include a right-sided aortic arch (20%), atrial septal defect or persistent arterial duct. Tetralogy of Fallot with an atrioventricular septal defect occurs with Down syndrome. 22q11 deletion is found in 16% of infants.<sup>122</sup>

### Physiology

Because the ventricular septal defect is large and nonrestrictive, pressures in both ventricles are similar. The obstruction varies in severity but is always sufficient to result in normal or low pulmonary artery pressure. If it is mild, flow across the ventricular septal defect will be from left to right. Increasing obstruction causes right to left shunting and cyanosis. The hemodynamic effect is labile, depending on the degree of right ventricular outflow obstruction and systemic vascular resistance.

### Clinical features

Neonates with severe outflow obstruction present with cyanosis and duct-dependent pulmonary circulation (p. 771). More commonly, infants present with an asymptomatic murmur, minimal cyanosis or heart failure caused by a left to right shunt. As right ventricular outflow obstruction increases, cyanosis becomes more noticeable and clubbing develops. Right ventricular hypertrophy is palpable. The second heart sound is single as the pulmonary component is inaudible. An aortic ejection click is occasionally heard. The long, loud ejection systolic murmur caused by subpulmonary obstruction is maximal at the third left intercostal space, radiating to the back. With increasing obstruction the murmur becomes shorter and the child develops effort intolerance. The characteristic 'squatting' is not seen if children undergo palliative or definitive surgery in infancy. This maneuver increases systemic vascular resistance, promoting pulmonary blood flow.

*Differential diagnosis:* ventricular septal defect, severe left or right ventricular outflow obstruction, other complex cyanotic lesions with pulmonary stenosis.

### Investigations

The electrocardiogram shows right ventricular hypertrophy. Chest radiography shows a normal sized heart with an uptilted apex. Concavity of the left heart border (pulmonary bay) indicates a small pulmonary artery. Oligemic lung fields reflect reduced pulmonary blood flow. A right-sided aortic arch (present in 20%) will cause deviation of the

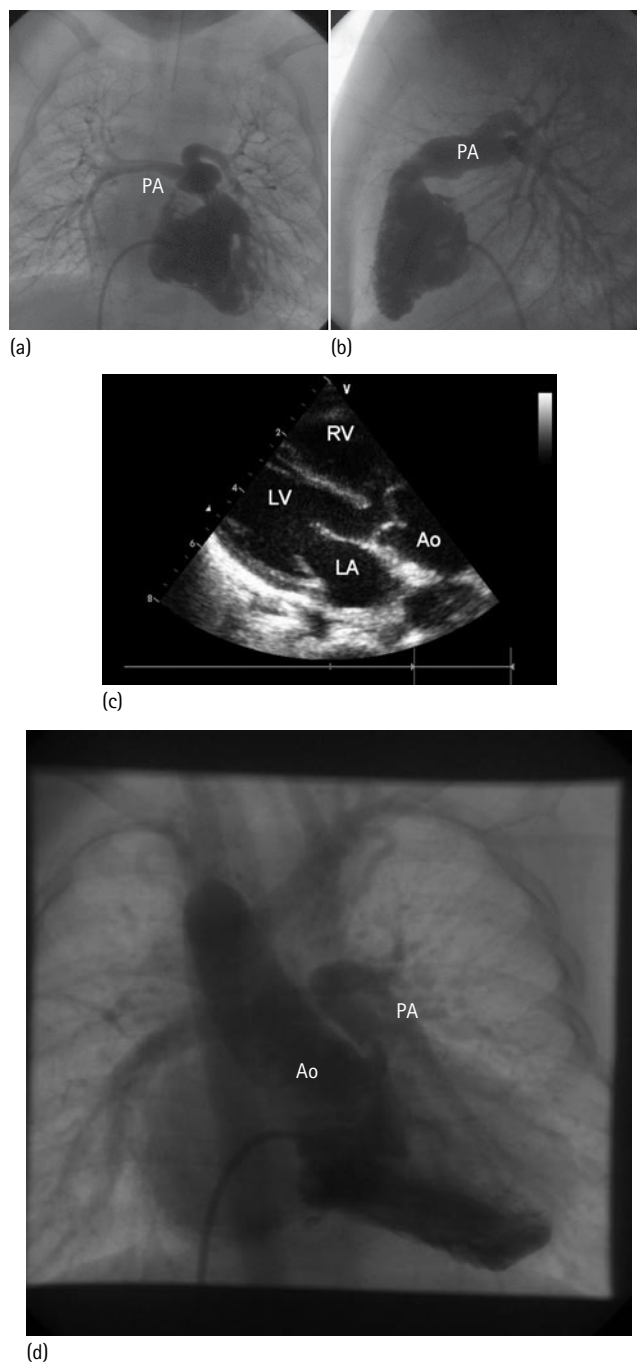

Fig. 21.33 Tetralogy of Fallot: This demonstrates (a) the anteroposterior and (b) lateral view of the right ventricular angiogram. There is infundibular narrowing below the pulmonary valve and small pulmonary arteries. (c) The echocardiogram in the long-axis view demonstrates the ventricular septal defect with aortic override. (d) Right ventricular angiogram shows opacification of the right-sided aortic arch to the right of the trachea and indicates the reason for the characteristic picture on chest radiography. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RV right ventricle.

trachea to the left and a bulge in the right upper mediastinum (Fig. 21.33d). Echocardiography establishes the diagnosis showing the ventricular septal defect, overriding aorta and right ventricular hypertrophy with outflow obstruction. The pulmonary arteries can be measured and a right aortic arch identified. The Doppler velocity will indicate the pressure difference between the right ventricle and pulmonary artery. Color Doppler shows turbulence below the pulmonary valve, extending

into the pulmonary arteries. Chromosome analysis for 22q11 deletion should be considered. Cardiac catheterization and angiography provide further information on the anatomy of the coronary and pulmonary arteries if they are not seen on echocardiography.

### Complications

With a move to earlier definitive surgery, complications are less common.

- Hypercyanotic attacks (*hypoxic spells*) occur in young children, particularly those with minimal cyanosis. A sudden decrease in pulmonary blood flow causes severe cyanosis and distress. Spells occur in the early morning or after a warm bath and may be initiated by crying, exertion and feeding. The precise cause is unknown but decreased systemic vascular resistance with increased right to left shunting may contribute. The murmur becomes short and soft. The child may lose consciousness and spells are life threatening. Treatment consists of flexing the legs onto the abdomen (knee–chest position) which increases systemic vascular resistance. Administration of oxygen maximizes inspired oxygen. Morphine appears to have a specific effect in addition to sedation. If there is no immediate venous access, intramuscular morphine injection (0.1 mg/kg) helps to relieve the spell, allowing valuable time to site a cannula. Severe metabolic acidosis is common and should be corrected with sodium bicarbonate to prevent further episodes. Intravenous propranolol 0.1 mg/kg is effective but should be used with caution in children on beta-blockers. Intravenous phenylephrine is effective in increasing systemic vascular resistance and promoting pulmonary blood flow, but should only be used with direct arterial pressure monitoring. A hypoxic spell is an indication for urgent surgical intervention to increase pulmonary blood flow. Prevention of spells with regular beta-adrenergic blockade is beneficial prior to surgery.
- Cerebral events. Thrombosis can result from polycythemia, particularly in association with dehydration. The incidence of brain abscess is also increased in children with cyanotic heart disease. Iron deficiency anemia with microcytosis increases the risk of cerebrovascular complications<sup>167</sup> and should be prevented with iron supplements.
- Infective endocarditis is most likely in children with a systemic to pulmonary artery shunt.

### Management and prognosis

*Palliative surgery* may be necessary in symptomatic infants with hypoplastic right ventricular outflow tracts and small pulmonary arteries. This may also be preferred in neonates with a duct-dependent pulmonary circulation. It involves insertion of a Gore-Tex tube between the pulmonary and subclavian arteries (modified Blalock–Taussig shunt) (Fig. 21.34). Complications include chylothorax, diaphragmatic paralysis and Horner syndrome. Definitive repair can then be delayed until the second year of life. Low dose aspirin is necessary to prevent platelet aggregation in the shunt. Clinical findings include cyanosis and a continuous murmur loudest over the site of the shunt.

*Definitive surgery* is now commonly performed in the first year of life.<sup>168</sup> The ventricular septal defect is closed with a patch and the right ventricular outflow tract is enlarged by muscle resection, pulmonary valvotomy and sometimes patch augmentation. Early mortality is less than 5% and complications include right ventricular dysfunction, pleural effusion and complete heart block. The residual systolic murmur reflects turbulence in the right ventricular outflow tract and the diastolic murmur is due to pulmonary regurgitation. Right bundle branch block may present on the electrocardiogram. Most patients lead normal lives with good effort tolerance. There is a small risk of reoperation for residual ventricular septal defect, pulmonary stenosis or regurgitation.<sup>168</sup> The 20 year survival is over 90%.<sup>169</sup> Patients require follow-up because of a late incidence of ventricular arrhythmias, complete heart block<sup>170</sup> and sudden death. Endocarditis prophylaxis must continue.

Fig. 21.34 Blalock–Taussig shunt: An angiogram into the right subclavian artery (RSA) at the site of the shunt showing contrast filling the shunt and the pulmonary arteries. The pulmonary valve is atretic. PA, pulmonary artery; RPA, right pulmonary artery.

### Pulmonary atresia and ventricular septal defect

Pulmonary atresia with ventricular septal defect is the extreme form of tetralogy of Fallot. Most present in the neonatal period (p. 771), but diagnosis may be delayed when major aortopulmonary collateral arteries (MAPCAs) provide adequate pulmonary blood flow. Clinical features may include heart failure, mild cyanosis and a continuous murmur in the lung fields.

### Tetralogy of Fallot with absent pulmonary valve

This occurs in 3–6% of patients with tetralogy of Fallot. A rudimentary pulmonary valve leaflet causes severe regurgitation and the valve ring is narrowed causing stenosis. The pulmonary arteries are usually markedly dilated and compress the bronchi, causing obstruction. The bronchi are also intrinsically abnormal. This may produce severe airways obstruction in infancy with wheeze and recurrent pneumonia. There is mild cyanosis and an ejection systolic murmur is followed by a long diastolic murmur in the pulmonary area. Definitive surgery is similar to that for tetralogy of Fallot.

## THE SINGLE VENTRICLE CIRCULATION

This is a complex and diverse group of conditions that have in common only one ventricle, which provides the majority of both the systemic and pulmonary blood flow. Surgical correction is not possible, and effective palliation is directed towards optimizing the circulation. This consists of a series of operations that allow the functional ventricle to supply the systemic circulation. Blood returning from the superior and inferior caval veins is directed into the pulmonary arteries driven by the central venous pressure and the negative forces generated by inspiration and ventricular diastole. This separates the pulmonary and systemic venous returns.

### Anatomy

The range of conditions is diverse and the specific abnormality is less important than early identification that the anatomy is unsuitable for two-ventricle repair. It includes conditions with hypoplasia or atresia of the mitral or tricuspid valves, or significant hypoplasia of either ventricle.

Fig. 21.35 Pulmonary artery band: (a) An angiogram into the main pulmonary artery shows the constriction from the pulmonary artery band distal to the pulmonary valve, before the bifurcation into right and left pulmonary arteries. (b) A lateral projection of the same angiogram. LPA, left pulmonary artery; MPA, main pulmonary artery; RPA, right pulmonary artery.

### Physiology

Infants may have:

- inadequate pulmonary blood flow (tricuspid atresia with a small ventricular septal defect and pulmonary stenosis, double inlet left ventricle with pulmonary stenosis, pulmonary atresia with intact ventricular septum and hypoplastic right ventricle, severe Ebstein's anomaly of the tricuspid valve);
- inadequate systemic blood flow (hypoplastic left heart, tricuspid atresia with transposition and a small ventricular septal defect);
- unrestricted pulmonary blood flow (double outlet right ventricle with hypoplastic left ventricle).

### Clinical features

At birth the arterial duct compensates for inadequate pulmonary or systemic circulation and symptoms only develop when the duct closes. Infants with unrestricted pulmonary blood flow develop symptoms when the pulmonary vascular resistance falls and pulmonary blood flow becomes excessive. The clinical features depend on the physiology. Infants with inadequate pulmonary blood flow present with cyanosis. Those with inadequate systemic blood flow present with cardiovascular collapse. Those with unrestricted pulmonary blood flow present with signs of heart failure. Some infants will be diagnosed antenatally, and others will present with cyanosis, collapse, heart failure, a murmur or poor femoral pulses.

### Investigations

Findings on electrocardiogram and chest radiography will depend on the underlying condition. Echocardiography will identify the details of the specific cardiac lesion. The segmental chamber localization (p. 754) will ensure that all details of the cardiac diagnosis are identified.

### Management and prognosis

Effective early palliation is critical to achieve a satisfactory long term outcome. It involves at least three staged procedures.

**Stage 1: optimizing systemic and pulmonary blood flow.** From infancy the blood flow into the lungs must be adequate but at low pressure. Neonates with inadequate pulmonary blood flow require a systemic to

pulmonary (modified Blalock–Taussig) (Fig. 21.34) shunt. Those with inadequate systemic blood flow require a Norwood (Fig. 21.27) or similar operation. Those with excessive pulmonary blood flow require a pulmonary artery band to reduce pulmonary blood flow (Fig. 21.35). A few infants have a cardiac lesion that results in optimal systemic and pulmonary blood flow with effective pulmonary stenosis and unobstructed systemic blood flow, and therefore do not require surgery in the neonatal period.

The definitive palliative procedure is the Fontan operation. It is usually carried out in two further stages. This consists of surgery to direct the systemic venous return initially from the superior vena cava, and later from the inferior vena cava, directly into the pulmonary artery to allow oxygenation and separate the pulmonary and systemic blood flow. Successful surgery depends on a low pulmonary vascular resistance as blood returning from the body flows directly into the pulmonary arteries, driven by the systemic venous pressure. Any anatomical or physiological abnormality that impedes this must be corrected and other transcatheter and surgical interventions may be necessary to achieve the optimal hemodynamics. The pulmonary artery pressure must be low and the pulmonary arteries of adequate size without localized narrowing. There must also be unobstructed pulmonary venous return, a normal left atrial pressure, good systemic ventricular function and unobstructed systemic outflow.

**Stage 2: superior (bidirectional) cavopulmonary anastomosis.** This relieves the systemic ventricle of chronic volume and pressure loads that occur regardless of the type of neonatal palliation. It usually decreases the cyanosis and reduces the risks at subsequent surgery. It is performed at 6–12 months of age. The superior caval vein is anastomosed to the proximal right pulmonary artery (Fig. 21.36). If a left superior vena cava is present, this is anastomosed to the left pulmonary artery at the same procedure. If a Blalock–Taussig shunt is present it is ligated. Forward flow through the main pulmonary artery may also be occluded. Residual lesions that may increase the risk of subsequent surgery, such as pulmonary artery narrowing or re-coarctation, are corrected. The superior cavopulmonary anastomosis is well tolerated, even when combined with other procedures. A superior vena caval syndrome with upper body swelling may occur postoperatively if the pulmonary

**Fig. 21.36** The superior cavopulmonary anastomosis: The angiogram in the superior caval vein shows the connection to the proximal right pulmonary artery. Contrast also fills the innominate vein on the left. Coils have been used to occlude some of the collateral veins from the innominate vein. An intravascular stent was expanded in the proximal left pulmonary artery at the time of surgery. LPA, left pulmonary artery; RPA, right pulmonary artery; SVC, superior caval vein.

**Fig. 21.37** The Fontan operation: The angiogram shows the lateral tunnel connecting the inferior caval vein to the pulmonary arteries. The position of the connection between the superior caval vein and the pulmonary arteries is shown by the pacemaker lead, which passes from the subclavian vein, via the superior caval vein to the atrial wall. The transesophageal probe is visible in the esophagus. IVC, inferior caval vein; LPA, left pulmonary artery; RPA, right pulmonary artery; SVC, superior caval vein; TOE, transesophageal echocardiographic probe.

artery pressure is elevated. During early childhood the relative size of the lower body increases, and the ratio of blood returning from the inferior and superior caval veins alters. This results in increasing cyanosis, which may also occur due to venous collaterals that develop between the upper and lower body.

**Stage 3: completion of modified Fontan operation.** This is usually performed at 2–5 years of age. The inferior vena cava is anastomosed to the pulmonary arteries, either by a baffle that is created inside the lateral wall of the right atrium, or an extracardiac conduit (Fig. 21.37). Creation of a small hole or fenestration between this tunnel or conduit and the left-sided (systemic) circulation produces a small right to left shunt. This lowers the central venous pressure, preventing severe venous congestion in the postoperative period but producing systemic desaturation. The fenestration can be closed at a later time if the hemodynamics are suitable.

Prognosis depends on the underlying condition, the success of the various interventions and the long term function of the systemic ventricle. The 30 day mortality is less than 5%, but the postoperative period may be protracted with high central venous pressure, ascites, pleural effusions and poor cardiac output. Atrial arrhythmias can further destabilize the hemodynamics. The highest death rate is in the first year after operation.<sup>171</sup> Recent figures suggest a 5 year survival of more than 70%, but deaths are likely to continue to occur with longer follow-up and the 20 year survival is just under 60%.<sup>171</sup> The quality of life in survivors is satisfactory<sup>172</sup> but a number of late complications account for a continuing mortality. They include cardiac failure, systemic venous obstruction, persistent fluid accumulation and protein-losing enteropathy. Reports of thromboembolism, both pulmonary and systemic (if a fenestration is present), have resulted in the common practice of long term anticoagulation. Arrhythmias can produce significant hemodynamic deterioration and need urgent treatment. Some children will not be suitable for the procedure because of adverse risk factors such as poor sys-

temic ventricular function or elevated pulmonary artery pressure. The only option for a child with a failing 'Fontan' circulation is heart transplantation.

## MISCELLANEOUS CARDIOVASCULAR LESIONS

### Vascular ring

#### Anatomy

A vascular ring is a malformation of the aortic arch or its brachiocephalic branches encircling and compressing the trachea and esophagus. Double aortic arch is the most common type. The ascending aorta divides into two vessels that reunite to form the descending aorta. A pulmonary artery sling is the anomalous origin of the left pulmonary artery from the right pulmonary artery crossing the midline between the trachea and esophagus and producing tracheal compression.

#### Clinical features

Airway obstruction resulting from tracheal compression is progressive and causes inspiratory stridor, which is usually present soon after birth. Wheezing, cough and recurrent respiratory tract infections are common. Dysphagia due to esophageal compression is rare. The diagnosis is often delayed because of the failure to consider it in the child with respiratory difficulties.

#### Investigations

A barium swallow demonstrates an indentation of the posterior aspect of the esophagus by a vascular ring. A pulmonary artery sling characteristically produces an anterior indentation, sometimes accompanied by a posterior impression on the air column in the trachea at the same level. Echocardiography may show a double arch or pulmonary sling, but a more complete diagnosis requires further investigation such as MRI, CT or angiography.

### Treatment

Surgery is always indicated. Outcome is generally good although persistent respiratory symptoms may result from tracheomalacia.

### Anomalous origin of the left coronary artery from the pulmonary artery

Anomalous origin of a coronary artery (usually the left) from the pulmonary artery is rare. Perfusion of the left ventricle depends on pulmonary artery pressure and collateral circulation from the right coronary artery. Ischemia occurs with the postnatal fall in the pulmonary pressure, its severity depending on the amount of collateral circulation. The infant usually presents in the second month of life with 'anginal attacks', manifested as acute distress with crying, sweating and pallor, often during feeding or defecation. Heart failure develops, the heart is enlarged and a gallop rhythm is common. There is often a murmur of mitral regurgitation secondary to left ventricular dilatation. There is marked cardiomegaly and pulmonary venous congestion on chest X-ray. The electrocardiogram characteristically shows an anterior infarction pattern with T wave inversion and deep Q waves in the left chest leads, lead I and aVL. Echocardiography reveals a dilated and poorly contractile left ventricle, with an enlarged right coronary artery. The abnormal origin of the left coronary artery may be visualized causing turbulence on color Doppler as it drains into the pulmonary artery. Angiography is necessary if ultrasound studies are inconclusive. An aortogram shows a large right coronary artery and its distal anastomosis with the left coronary artery, which then drains into the pulmonary artery.

### Marfan syndrome

This is an autosomal dominant inherited disorder of connective tissue (see also Ch. 29, p. 1398). It is characterized by musculoskeletal, cardiovascular and ocular abnormalities, two of which should be present to make the diagnosis. It is caused by various mutations in the FBN1 gene on chromosome 15q and is inherited in about 75% of children, the rest arising because of a new mutation.<sup>173</sup>

### Clinical features

Cardiovascular manifestations include dilatation of the ascending aorta (and occasionally the descending) due to medial necrosis, aortic regurgitation and mitral valve prolapse and regurgitation. Disturbances in cardiac rhythm can occur. A family history should always be sought.

### Investigations

Children should be reviewed regularly with echocardiography to measure the aortic root dimensions and these should be plotted against normal values. Transesophageal echocardiography or MRI gives additional information, particularly when dissection is suspected.

### Management

Beta-blockers have been shown to slow the aortic root dilatation.<sup>174</sup> Children should be advised against competitive and contact sports. Surgical aortic root replacement should be considered when the aortic diameter reaches 5 cm, with earlier surgery if there is a rapid increase in diameter, and in families with a history of aortic dissection.

## CARDIAC ARRHYTHMIAS

The past few years have seen significant advances in our understanding and treatment of cardiac arrhythmias in children. There is now widespread awareness amongst pediatricians that most arrhythmias result from primary electrical abnormalities of the heart. We also have a greater understanding of the anatomical substrates and electrophysiological mechanisms of arrhythmia. There are now available better non-invasive diagnostic techniques, safer and more effective drugs for acute and long term treatment and the possibility of cure by catheter ablation.

## IDENTIFICATION OF THE ARRHYTHMIA

Cardiac arrhythmias usually affect children with otherwise normal hearts but they may also develop in those with cardiovascular malformations. They make up a significant proportion of the work of pediatric cardiologists and are one of the more common ways in which babies and children with cardiac problems present to the general pediatrician. For this reason it is important for pediatricians to have some understanding of the types of arrhythmia, and familiarity with non-invasive diagnostic techniques and treatment strategies.

Knowing the age at onset of an arrhythmia, with recordings of the electrocardiogram (ECG) in sinus rhythm, during arrhythmia and during adenosine administration we can often predict accurately the mechanism of the arrhythmia. This will help to define the prognosis and will guide the choice of treatment. Available diagnostic techniques include standard surface electrocardiography, ambulatory 24 h electrocardiography (Holter monitoring), patient-activated event recorders, invasive electrophysiology studies and implantable loop recorders. The first three are widely available whilst the last two are reserved for specialist assessment.

## CLINICAL PRESENTATION OF ARRHYTHMIAS

Cardiac arrhythmias may occur at any age and their differential diagnosis depends upon the age of onset. The commonest presentation in infancy is with heart failure, usually caused by sustained tachycardia, but arrhythmias may also be noticed incidentally because of bradycardia, tachycardia or an irregular rhythm. The most common presentation in childhood is with palpitations, usually as a result of paroxysmal tachycardia. Some less common, incessant tachycardias may present in childhood with heart failure due to secondary myocardial dysfunction. Arrhythmias presenting with syncope are rare but are important to recognize. A few rare but dangerous arrhythmias may result in (and may even present with) sudden death.<sup>175,176</sup> Some arrhythmic causes of sudden death are familial, so a precise diagnosis is very important. Children who develop arrhythmias after heart surgery should already be under the care of a pediatric cardiologist but may present acutely to a pediatrician.

## CLASSIFICATION OF ARRHYTHMIAS

Tachycardias have conventionally been considered as either supraventricular or ventricular but, as there are many mechanisms of each, this broad classification is relatively unhelpful. The ECG in tachycardia will show QRS complexes that are either normal or wide so these are two clinically useful groups. Arrhythmias in infancy differ in important aspects from those seen in children and so it is helpful to consider them separately.

## MECHANISMS OF TACHYCARDIAS

Most tachycardias encountered in clinical practice are due to re-entry, by which we mean that there is recirculating electrical activation traveling around an anatomical circuit. Such arrhythmias are often (but not always) paroxysmal. Re-entry tachycardias usually have fairly constant rates and can be started by pacing and stopped by drugs, pacing and electrical cardioversion. The circuit usually involves an anatomically abnormal structure – the best example is the accessory atrioventricular connection in Wolff–Parkinson–White syndrome – which is really a form of structural congenital heart disease.<sup>177</sup> In other cases, the circuit probably develops during growth – as in atrioventricular (AV) nodal re-entry tachycardia. Other examples of re-entry include atrial flutter, permanent junctional re-entry tachycardia and late postoperative ventricular tachycardia.

A less common arrhythmia mechanism is automaticity. Automatic arrhythmias arise from an ectopic focus and overdrive pacing or cardioversion is ineffective. They are usually incessant and may show significant variation in rate. Those most

commonly encountered in children are atrial ectopic tachycardia and early postoperative junctional ectopic tachycardia (His bundle tachycardia).

## TACHYCARDIA IN INFANCY

### Atrioventricular Re-Entry Tachycardia in Infancy

The commonest type of supraventricular tachycardia (SVT) presenting in infancy is orthodromic AV re-entry via an accessory pathway (Fig. 21.38). The term orthodromic implies that there is normal conduction over the AV node and retrograde conduction over an accessory muscular atrioventricular connection (accessory pathway). About a third of accessory connections encountered in infants show anterograde conduction in sinus rhythm, producing ventricular pre-excitation that is recognized as Wolff–Parkinson–White syndrome. More commonly the pathway can only conduct retrogradely so the ECG is normal in sinus rhythm. In tachycardia the QRS is usually normal in infancy although transient rate-related bundle branch block at the onset of tachycardia is not unusual (Fig. 21.39). Tachycardia usually presents with heart failure, more often causing pallor, breathlessness and poor feeding but sometimes severe enough to cause collapse. The differential diagnosis includes infection and metabolic problems. Sinus tachycardia in an ill baby may exceed 200 beats/min but AV re-entry tachycardia in infancy is rarely slower than 270 beats/min. It is difficult or impossible to distinguish between these heart rates clinically and some ECG monitors are unreliable at high heart rates. Recording a 12 lead ECG on paper will allow accurate measurement of the rate and confirmation of the diagnosis.

The treatment of choice for acute termination of AV re-entry tachycardia is intravenous administration of adenosine. The dose is 150–300 mcg/kg/dose (occasionally higher) given by rapid bolus injection followed by a saline flush (Fig. 21.39).<sup>178</sup> Adenosine is metabolized very quickly and

the dose can be repeated or increased if necessary. An ECG should always be recorded during administration of adenosine to evaluate the rhythm. Facial immersion in iced water or facial application of an ice pack is also usually effective but is only appropriate in early infancy. Other drugs are not often required for termination of tachycardia in infancy. Verapamil is contraindicated in early infancy because it may cause acute cardiac decompensation and death.<sup>179</sup> Synchronized electrical cardioversion is effective but, because it requires general anesthetic, is not easily repeated.

The baby's condition will improve once sinus rhythm has been restored. Recurrence of tachycardia in the short term is common so prophylactic drug treatment is usually advised. There are no controlled trials of drug treatment in this situation but digoxin seems to have relatively little effect. Treatment with a beta-blocker, flecainide, propafenone, or amiodarone<sup>180</sup> (or a combination of these in difficult cases) will usually prevent recurrence of the arrhythmia. The liability to attacks of tachycardia will resolve in about two thirds to three quarters of babies before the end of infancy so that prophylactic drug treatment is usually withdrawn after 6 or 12 months if there has been good control. Sometimes, when the problem seems to have resolved, there will be a recurrence later in childhood.

### Other 'supraventricular' tachycardias in infancy

Other, less common tachycardias may be encountered in infancy. *Atrial flutter* is usually easy to recognize on the ECG at this age as there are often prominent flutter waves with 2:1 AV conduction (Fig. 21.40). Atrial flutter can be terminated by direct current cardioversion or transesophageal overdrive pacing. Recurrence is rare and prophylactic treatment is not usually required. *Chaotic* or *multifocal atrial tachycardia* causes an irregular rhythm with multiple nonconducted P waves of varying morphology (Fig. 21.41). There is usually sufficient AV block to give a more or less normal ventricular rate so treatment may not be necessary. Resolution during early infancy is likely. *Atrial ectopic tachycardia* may present as

Fig. 21.38 Typical atrioventricular (AV) re-entry tachycardia in a neonate. The ventricular rate is 290 per minute and the QRS is normal. A retrograde P wave is clearly seen in lead C1 (arrow). The timing of the P wave and the age of patient make orthodromic AV re-entry tachycardia via an accessory pathway an almost certain diagnosis.

Fig. 21.39 Administration of intravenous adenosine during atrioventricular (AV) re-entry tachycardia in a neonate. Adenosine produces transient AV block and the tachycardia terminates with a non-conducted P wave (black arrow). This is followed by sinus rhythm which for seven beats shows clear evidence of ventricular pre-excitation (gray arrow). As the sinus rhythm speeds up slightly the pre-excitation disappears and there is no delta wave for the next four sinus beats. AV re-entry tachycardia then reinitiates with rate-related bundle branch block during the first two beats of tachycardia.

**Fig. 21.40** Neonatal atrial flutter. The atrial rate is 460 per minute which, with 2:1 AV conduction, gives a ventricular rate of 230 per minute. Saw-tooth flutter waves are clearly seen in leads II, III, aVF, and V1.

**Fig. 21.41** Chaotic atrial tachycardia in infancy. This is also known as multifocal atrial tachycardia. There are several different P wave morphologies and many more P waves than QRS complexes. Many of the P waves are not conducted so the ventricular rate is in fact slightly slow. The extra or early P waves differ in morphology from the sinus beats.

a sustained arrhythmia in early infancy (Fig. 21.42). Drug treatment (beta-blocker, flecainide or amiodarone) may be required in the short term, but the problem usually resolves within a few months.<sup>181</sup>

One unusual but important variety of AV re-entry tachycardia presenting with an incessant tachycardia is *permanent junctional reciprocating tachycardia* (PJRT).<sup>182</sup> It is recognized on the ECG from the long RP interval and the inverted P waves in inferior leads (Fig. 21.43). Treatment with a beta-blocker, flecainide, or amiodarone will suppress the arrhythmia or control the rate. Spontaneous resolution of PJRT is less common and radiofrequency ablation may be required later in childhood (see below). *Congenital junctional ectopic tachycardia* (*His bundle tachycardia*) is rare and is recognized by the presence of slower dissociated P waves. Long term drug treatment is required. This arrhythmia is more common early after infant cardiac surgery.

### Ventricular tachycardia in infancy

Pediatricians are often reluctant to consider the diagnosis of ventricular tachycardia (VT) in infants, and most cases are initially mistaken for some form of supraventricular tachycardia. Widening of the QRS can be subtle in infancy but if the QRS is abnormal the diagnosis of VT should be considered. VT may be relatively slow and well tolerated, in which case treatment may not be required and resolution is likely.<sup>183</sup> The most significant type of VT encountered is incessant infant ventricular tachycardia. It usually presents between 3 months and 2 years of age. The QRS most often shows a right bundle branch block pattern with a superior axis indicating a posterior left ventricular origin for the tachycardia (Fig. 21.44). The cause is probably a tiny myocardial hamartoma that is beyond the resolution of imaging techniques. The most effective drug for suppression of incessant VT is amiodarone or flecainide, often used in combination with a beta-blocker. This arrhythmia usually resolves before school age and treatment can be withdrawn without recurrence. Other ventricular tachycardias in infancy are rare and require specialist evaluation.<sup>19</sup>

## TACHYCARDIA IN CHILDHOOD WITH NORMAL QRS COMPLEXES

### Atrioventricular re-entry tachycardia

As in infancy, the commonest significant arrhythmia in childhood is orthodromic atrioventricular re-entry tachycardia (Fig. 21.38). Few new cases present between 1 and 4 years of age and at this age they are often triggered by fevers. New presentation after early childhood (usually with palpitation) implies only a small chance of long term natural resolution. As in infancy, the ECG may show ventricular pre-excitation in sinus rhythm (Fig. 21.45) but it is more common for the pathway to be 'concealed', that is, to be capable of only retrograde conduction. Most episodes of tachycardia during childhood revert to sinus rhythm spontaneously. In some children vagal stimulation slows AV nodal conduction sufficiently to break tachycardia.<sup>184</sup> The most effective techniques include a Valsalva maneuver (such as trying to blow up a balloon) and other methods of breath-holding, facial application of an ice pack or inversion into a headstand. Carotid sinus massage and eyeball pressure are usually ineffective and the latter may cause injury. If tachycardia is sustained, sinus rhythm can be restored with a rapid intravenous bolus of adenosine 150–500 mcg/kg/dose, or with intravenous verapamil. As AV re-entry tachycardia in childhood is not intrinsically dangerous, the choice of long term treatment depends on the frequency, severity and duration of episodes. If attacks are mild and infrequent, treatment may not be required. Long term treatment involves a choice between prophylactic medication and catheter ablation. Many children and their parents prefer the prospect of a cure with catheter ablation to the alternative of prolonged drug treatment.

Many drugs can be used to suppress AV re-entry tachycardia. The literature relating to their use is mainly a series of retrospective reports. There are no blinded or placebo-controlled trials and very few comparisons between drugs. Most anti-arrhythmic drugs have been tried for control of this common arrhythmia. Those most likely to be effective

**Fig. 21.42** Atrial ectopic tachycardia in a 5-year-old boy. At first glance this looks like a sinus tachycardia but the rate is inappropriately high for the age and clinical situation. The P waves are abnormal and their morphology suggests an ectopic focus in the right atrium. In this example there is 1:1 conduction throughout but transient AV block is not unusual.

**Fig. 21.43** Permanent junctional reciprocating tachycardia. This arrhythmia is characterized by a long RP interval and an abnormal P wave axis with inverted P waves in leads II, III, and aVF. It is usually incessant but will stop transiently with adenosine.

**Fig. 21.44** Ventricular tachycardia in an 11-month-old boy. The QRS complexes have an appearance similar to right bundle branch block but the initial R wave in V1 is taller than the secondary R. There is very subtle evidence of ventriculo-atrial dissociation, perhaps best shown by the variable height of the T waves in the rhythm strip at the bottom caused by intermittent superimposition of P waves.

include beta-blockers, flecainide, amiodarone and sotalol. Drug treatment may occasionally produce new arrhythmias, a so-called ‘pro-arrhythmic’ effect.

Catheter ablation was introduced to clinical practice in the early 1990s and is regarded as the standard treatment for many arrhythmias. In experienced hands, success rates are high and serious complications are rare.<sup>185</sup> The procedure involves the use of a high frequency electric current to induce a small burn at the point of contact between the catheter and the heart. If the catheter is accurately positioned the arrhythmia substrate will be destroyed.

### Atrioventricular nodal re-entry tachycardia

This arrhythmia is rare before school age but becomes an increasingly important mechanism of SVT during later childhood (Fig. 21.46). It may be difficult to differentiate from atrioventricular re-entry but the difference is only important if catheter ablation is being considered and diagnosis is easy at electrophysiology study. Both arrhythmias can be stopped with vagal maneuvers or intravenous adenosine. The AV nodal re-entry circuit includes the AV node and adjacent low right atrium<sup>186</sup> (it would perhaps be more accurately termed atrio-nodal re-entry tachycardia). Drug treatment is often relatively ineffective or poorly tolerated.

**Fig. 21.45** Ventricular pre-excitation in sinus rhythm. In this case pre-excitation produces a pseudo-left bundle branch block pattern and the QRS morphology predicts a right-sided accessory pathway.

**Fig. 21.46** AV nodal re-entry tachycardia in a 14-year-old girl. The ventricular rate is 220 per minute and the QRS is normal. P waves are not easily seen. However, the 'pseudo-R' appearance in lead V1 (arrow) strongly suggests that the P wave is within the terminal portion of the QRS. Comparison with the ECG in sinus rhythm showed this appearance was not present in sinus rhythm, making it probable that this is indeed the P wave.

Radiofrequency modification of the AV node is often effective and offers the prospect of a cure but is associated with a small risk of atrioventricular block.<sup>185,186</sup>

### Other tachycardias

Other tachycardias with a normal QRS are unusual in childhood. They include *atrial ectopic tachycardia*, which often presents with heart failure rather than palpitations and may be mistaken for dilated cardiomyopathy (Fig. 21.42). Improvement or normalization of ventricular function usually follows if suppression of the tachycardia is effective. Some cases may resolve spontaneously in the long term but this arrhythmia is also amenable to radiofrequency ablation. *Permanent junctional reciprocating tachycardia* may also present during childhood and is often incessant (Fig. 21.43). Long term resolution is unusual, but radiofrequency ablation has a high chance of cure.<sup>182</sup>

## TACHYCARDIA IN CHILDHOOD WITH WIDE QRS COMPLEXES

### 'Supraventricular' tachycardias

Almost any of the tachycardias with normal QRS morphology discussed above may also occur with a wide QRS. This may be due to an underlying permanent right (RBBB) or left bundle branch block (LBBB), or, more commonly, to rate-related bundle branch block or aberration (Fig. 21.39). In these cases the bundle branch block has no influence on the natural history or choice of treatment but does affect the differential diagnosis. Children with Wolff–Parkinson–White syndrome may occasionally have antidromic AV re-entry in which the re-entry is in the opposite direction to the orthodromic or more common re-entry circuit. There is retrograde conduction through the normal conduction

axis and anterograde conduction over the accessory pathway producing maximal pre-excitation and a slow slurred upstroke to the QRS. This is more commonly encountered in the presence of multiple pathways and right-sided pathways. An *irregular* tachycardia with a similar appearance is due to atrial fibrillation in the Wolff–Parkinson–White syndrome (Fig. 21.47). This is rare in childhood but more often seen in teenage or young adult life. It is potentially dangerous, particularly if the pathway will permit rapid conduction to the ventricle (that is, it has a short refractory period). This arrhythmia may present with syncope and is potentially life threatening so it requires urgent specialist evaluation. Radiofrequency ablation of the pathway offers a cure.

### Ventricular tachycardia

Ventricular tachycardia is an uncommon but important diagnosis in childhood. It can be conveniently divided into monomorphic and polymorphic forms, based on the ECG appearance. Many subtypes of each of these are recognized, but in some cases precise subclassification is difficult.

In most types of VT the QRS complexes are regular and the obvious differential diagnosis is with the various types of supraventricular tachycardia with wide QRS described above. The presence or absence of symptoms is no real guide in differential diagnosis, nor is the ventricular rate. The diagnosis of VT is proven in the presence of ventriculoatrial block (slower dissociated P waves) and can be strongly suspected from the QRS morphology (Fig. 21.48).

Once the diagnosis of VT is established, the clinical situation and the ECG appearance should be compared with the many types of ventricular tachycardia which are recognized in childhood. This will define the prognosis and the response to treatment. There is more variation between individual cases of VT than is seen with supraventricular tachycardia.

**Fig. 21.47** Atrial fibrillation in Wolff–Parkinson–White syndrome. A recording from a 10-year-old girl who presented with syncope. The QRS is very abnormal, being broad with a slurred upstroke. The rhythm is irregularly irregular and the QRS axis is constant. The ECG in sinus rhythm in the same girl showed ventricular pre-excitation with the same activation pattern.

**Fig. 21.48** Ventricular tachycardia. The QRS is broad and mostly regular. There is clear evidence of ventriculoatrial dissociation (dissociated P waves – solid arrow). The rhythm is occasionally disturbed by fusion beats (f). The QRS shows a right bundle branch block pattern with a superior axis predicting a left posterior origin for the ventricular tachycardia.

### Monomorphic ventricular tachycardia

Idiopathic left ventricular tachycardia has become better recognized in recent years. The commonest type is left posterior fascicular tachycardia that is often precipitated by exercise or emotion. The ECG has a RBBB pattern with a superior axis reflecting the origin of the arrhythmia in the left side of the ventricular septum. It is thought to be due to localized re-entry and may respond to drug treatment or catheter ablation.

Idiopathic right ventricular tachycardia is also described. The commonest type is right ventricular outflow tachycardia and is most frequently seen in older children or teenagers. The ECG in tachycardia shows a LBBB pattern with an inferior axis. The tachycardia usually originates just below the pulmonary valve and can be treated by catheter ablation although the need for and wisdom of such treatment has been questioned. Monomorphic VT may also occur in association with underlying myocardial disease such as myocarditis, dilated cardiomyopathy or arrhythmogenic right ventricular cardiomyopathy.

### Polymorphic ventricular tachycardia

Irregular VT with varying QRS morphology is described as ‘polymorphic’. It is a rare but potentially very dangerous arrhythmia. It may indicate an intrinsic problem or can be acquired, most often as a pro-arrhythmic effect of drugs. The clinical situation with which it is usually associated is the congenital long QT syndrome, in which life-threatening polymorphic VT (torsades de pointes) is associated with an underlying prolongation of the QT interval (Fig. 21.49).<sup>187</sup> Syncope or sudden death may occur in long QT syndrome during emotional or physical stress. The more common type has a dominant inheritance (Romano–Ward syndrome) and there is a rare autosomal recessive variety with deafness

(Jervell and Lange–Nielsen syndrome). The underlying abnormality is a genetic mutation producing defective sodium or potassium channel function in the myocardial cell wall.<sup>188</sup> Because of the high risk of sudden death treatment is required even in the absence of symptoms during childhood. Treatment with a beta-blocker, most often nadolol, produces a dramatic reduction in mortality.<sup>189</sup> Patients who remain symptomatic despite treatment with beta-blocking drugs may require pacemaker or defibrillator implantation. Coumel<sup>190</sup> and Brugada<sup>191</sup> have described other rare varieties of polymorphic ventricular tachycardia.

### BRADYCARDIA

Bradycardia may result from defective impulse formation or from conduction block. The latter is more common and more significant in pediatric practice.

### Complete atrioventricular block

Complete atrioventricular block usually presents in infancy or is detected during labor. The ECG shows a normal atrial rate and a ventricular bradycardia with atrioventricular dissociation (Fig. 21.50). The heart is usually structurally normal and the AV block is caused by transplacental passage of anti-Ro and anti-La antibodies found in mothers with connective tissue disease, particularly systemic lupus erythematosus. The risk of recurrence in subsequent pregnancies for antibody positive mothers is around 1 in 6. The main decision to be made in the newborn is whether to implant a permanent pacemaker. The presence of symptoms or a ventricular rate consistently below 55 per minute will usually be taken as an indication for pacemaker

**Fig. 21.49** Congenital long QT syndrome. A recording from a 14-year-old boy who presented with syncope. The QT interval is markedly prolonged.

**Fig. 21.50** Complete atrioventricular block in a neonate. The atrial rate is 140 per minute. The QRS complexes are regular with a normal morphology at a rate of 67 per minute. The baby's mother has Sjögren syndrome. Pacing was not required during infancy.

implantation.<sup>192</sup> A few infants with complete AV block have underlying structural heart disease, most commonly left atrial isomerism or congenitally corrected transposition (atrioventricular and ventricular arterial discordance). Complete AV block also occurs after surgical repair of heart disease, in which case pacemaker implantation is almost always required.

While AV block in infancy is rare (with a prevalence at live birth of 1:20 000), a much more common arrhythmia, which may be mistaken for AV block, is produced by atrial premature beats or atrial ectopic beats. These are benign, asymptomatic and usually disappear during infancy. Depending on their timing they may be conducted normally, or with a bundle branch block pattern, or may be blocked (Fig. 21.51).

Complete AV block may be detected for the first time in childhood but it is probably most often congenital in origin. An average daytime ventricular rate below 50 per minute may be an indication for pacemaker implantation, even in the absence of symptoms. The presence of symptoms such as syncope, breathlessness or tiredness implies a significant risk and is an absolute indication for a pacemaker.

### Other primary bradycardias

Bradycardia may also result from primary failure of impulse formation, known as sinoatrial disease. This is rare in childhood and pacemaker implantation is required only if there are symptoms. It is most often encountered late after cardiac surgery.

## CARDIAC ARRHYTHMIAS IN OTHER SITUATIONS

### Arrhythmias occurring late after surgery for congenital heart disease

Several cardiac operations are associated with late postoperative arrhythmias that have a significant impact on late morbidity and mortality.<sup>193</sup> Atrial flutter most often complicates atrial repair of transposition of the great arteries (Mustard or Senning operations) or right heart bypass operations for complex malformations (Fontan operation). It may also be a late complication of simpler operations such as repair of atrial septal defect or repair of tetralogy of Fallot. Atrial flutter may be associated with syncope or sudden death and demands expert evaluation and treatment. Postoperative ventricular tachycardia usually complicates

**Fig. 21.51** Atrial premature beats in a neonate. The majority of the beats are sinus in origin but several are followed by premature P waves. Some of these are not conducted to the ventricles (black arrow) while others are conducted with a slightly different QRS morphology (gray arrow).

operations that involve surgery on the ventricles such as repair of tetralogy of Fallot or Rastelli operation. Again the arrhythmia is potentially dangerous and requires expert assessment.

### Asymptomatic Wolff–Parkinson–White syndrome

Ventricular pre-excitation may be found unexpectedly on an ECG. Population studies have shown that two thirds of children with ventricular pre-excitation have no symptoms. It is likely that the majority will never develop an arrhythmia and the risk associated with asymptomatic ventricular pre-excitation is very small. The consensus at present is that treatment is not required although expert assessment and discussion is appropriate.<sup>194</sup>

## SYNCOPE

Syncope is a common symptom in childhood and in most cases is benign.<sup>52</sup> The commonest mechanism is vasovagal syncope (so-called 'simple faint') in which there is a transient vagally mediated bradycardia. Other causes of syncope may be associated with transient bradycardia – such as in reflex asystolic syncope in preschool children and in neurocardiogenic syncope in older children. Documentation of bradycardia during syncope in this situation does not necessarily mean that there is a primary cardiac arrhythmia. In most cases the significance of the syncope and the likely underlying cause will be evident from the history.

A few rare but potentially dangerous arrhythmias may present with syncope. They include polymorphic VT, other types of VT, and atrial fibrillation in the Wolff–Parkinson–White syndrome (all discussed above). An ECG should be part of routine assessment of children with syncope but clinical evaluation is necessary before embarking on further investigation. Children with syncope on exertion, or physical signs of possible cardiovascular abnormality, or a family history of syncope or sudden death, or an abnormal ECG should be referred for expert evaluation.<sup>52</sup>

## FAMILY HISTORY OF SUDDEN DEATH

The sudden death of a parent or sibling is a devastating event with many consequences. Some causes of sudden cardiac death are familial. Structural abnormalities include hypertrophic cardiomyopathy, Marfan syndrome, dilated cardiomyopathy and other cardiomyopathies. Primary electrical abnormalities may cause sudden death with an anatomically normal heart. They include long QT syndrome, catecholaminergic polymorphic VT and Brugada syndrome. Although they all have a genetic basis, genetic testing is not widely clinically available, other than for long QT syndrome. All first-degree relatives of victims of sudden cardiac death at a young age should be referred for specialist assessment which will include a detailed history, clinical examination, ECG and echocardiogram. Further assessment may be appropriate if the diagnosis is known in the proband or if initial investigations show abnormalities.<sup>195</sup>

## CONCLUSION

Recent years have seen an increased awareness of cardiac arrhythmias amongst pediatricians and pediatric cardiologists and a rapid advance in our understanding of the mechanisms. Non-invasive evaluation will usually identify precisely the type of arrhythmia and will help to define the prognosis and guide treatment. The outlook for most children with arrhythmias is good, especially in the present era of improved acute and long term treatment.

## ACQUIRED CARDIOVASCULAR DISORDERS

### MYOCARDITIS

Myocarditis is an acute infective, toxic or autoimmune inflammation of the myocardium.<sup>196</sup> Viral infections (coxsackie B and adenovirus) are

the most common, but protozoal and bacterial myocarditis occurs. A genetic predisposition with subsequent autoimmune response may be responsible.

### Clinical features

The clinical spectrum varies from asymptomatic to severe heart failure. There is frequently a recent history of a flu-like illness or gastroenteritis. There is a persistent, unexplained tachycardia and signs of heart failure (p. 762). Arrhythmias are common. Chest pain may also occur, due to associated pericarditis.

### Investigations

The erythrocyte sedimentation rate, C-reactive protein and cardiac muscle enzyme levels are usually elevated. Evidence of viral infection should be sought. Serology with rising or falling titers indicates a viral infection. Electrocardiogram shows a sinus tachycardia, ST segment and T wave changes, and conduction disturbances. Ectopic beats and arrhythmias are common. Decreased QRS voltage with T wave flattening and inversion occur. Chest radiography shows cardiomegaly. Echocardiography demonstrates a dilated, poorly contracting left ventricle. Mitral regurgitation and a pericardial effusion may be present. Myocardial biopsy is rarely performed in children as inflammatory changes are patchy, and the procedure carries a risk of cardiac perforation.

### Management and prognosis

Treatment depends on severity of the myocarditis. Cardiac monitoring and rest are advisable. Heart failure is managed as described previously (p. 763). Inotropic support is often necessary. Arrhythmias should be treated aggressively. The use of steroids, other immunosuppressive therapy and immunoglobulin is controversial.<sup>196,197</sup> Mechanical cardiac support can be used as a bridge to recovery or transplant.

If adequate support can be given for the severe heart failure that usually occurs at presentation, the outcome is often favorable.<sup>198</sup> Survivors may recover completely, or develop cardiomyopathy.<sup>197</sup>

## PERICARDITIS AND PERICARDIAL EFFUSION

### Etiology

Infection, other inflammatory diseases or trauma produce an effusion which may be fibrinous, purulent or hemorrhagic. Viral pericarditis is often associated with a myocarditis caused by similar viruses. Small pericardial effusions occur as part of the pancarditis of rheumatic fever and Kawasaki disease. Large pericardial effusions are most common in children with neoplasia, chronic renal failure, connective tissue diseases, and after cardiac surgery. Purulent or tuberculous pericarditis is rare in resource rich countries. Sometimes no cause is found.

### Clinical features

Signs vary with the primary illness, and with the volume and rate of accumulation of pericardial fluid. Rapid accumulation is more likely to produce cardiac tamponade. Chest pain is uncommon in children. Fever is prominent with bacterial infection. A pericardial friction rub may be audible. Signs of tamponade include neck vein distension, hepatomegaly, faint heart sounds and pulsus paradoxus (a fall in systolic blood pressure of >10 mmHg on inspiration).<sup>199</sup> Other signs of cardiac failure are also present. Any underlying cause must be identified. Bacterial pericarditis is usually secondary to other infection such as bronchopneumonia, empyema, lung abscess, osteomyelitis or pyelonephritis.

### Investigations

Electrocardiogram shows diminished QRS voltage and diffuse ST segment elevation. There may be cardiomegaly on chest radiography. Echocardiography indicates the size of the effusion (Fig. 21.52). Collapse of the atria and right ventricle indicates tamponade. If infective pericarditis is suspected, a primary focus must be sought and blood cultures and pericardiocentesis performed. The pericardial fluid is examined for cells and organisms and cultured for bacteria, viruses and fungi. When

Fig. 21.52 Four chamber echocardiogram view of a pericardial effusion. PE, pericardial effusion; RV, right ventricle; LV, left ventricle; RA, right atrium; LA, left atrium.

appropriate, serological evidence of a viral infection or autoimmune disease should be sought.

### Treatment

Symptomatic treatment includes anti-inflammatory drugs. Treatment is also directed at the cause. Purulent or tuberculous pericarditis requires appropriate intravenous antibiotics and surgical drainage may be necessary. Pericardial effusions due to leukemia will usually resolve with appropriate chemotherapy.

Pericardiocentesis is essential for cardiac tamponade. Except in an emergency, this is carried out under ultrasound or fluoroscopic guidance, using a subxiphoid approach. A drain is usually left in situ until the effusion has resolved. Constriction is rare in children and usually due to tuberculous pericarditis.

## RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Rheumatic fever is an endemic disease in resource limited countries, where it remains a major cause of morbidity and mortality.<sup>200</sup> Acute carditis, with the subsequent development of rheumatic heart disease, is the most serious consequence. The pathogenesis and noncardiac manifestations are discussed in Chapter 29. The most common age of onset is between 5 and 15 years.

### Acute carditis

This is a pancarditis, affecting the endocardium with valve involvement, myocardium and pericardium. It occurs in over 50% of children with rheumatic fever, usually within the first 3 weeks of the illness. It is most frequent in younger children, in those who had carditis in the initial attack, and with recurrences. The prime clinical indicator of carditis is a murmur that has developed recently or changed in character. The most common is an apical pansystolic murmur of mitral regurgitation. This may be due to endocarditis with edema of the mitral valve, or myocarditis with dilatation of the left ventricle and stretching of the mitral valve. This murmur must be differentiated from an innocent murmur in association with a febrile illness, and an organic murmur due to pre-existing congenital or rheumatic heart disease. A short apical mid-diastolic flow murmur may be heard. This frequently resolves when the child recovers. Less commonly, the early diastolic murmur of aortic regurgitation is heard in the aortic area and left sternal edge.

Cardiac failure is an uncommon presenting feature but may result from valve regurgitation or ventricular dysfunction caused by myocar-

ditis. Pericarditis, recognized by a friction rub, never occurs in isolation and indicates underlying myocarditis. Sinus tachycardia is also suggestive of carditis, particularly when it occurs during sleep in the afebrile child. Sinus bradycardia occasionally occurs.

### Investigations

Electrocardiographic changes include prolongation of the PR interval (first degree heart block), second degree or complete heart block. Flattened or inverted T waves over the left precordial leads are a characteristic finding of myopericarditis. Other investigations are discussed in Chapter 29. Echocardiography may demonstrate a small pericardial effusion. A dilated left ventricle occurs with significant myocardial disease or severe valve regurgitation. Contractility is decreased with myocarditis, but normal or increased with mitral or aortic regurgitation. Approximately 50% of children with rheumatic fever have clinical evidence of carditis, but Doppler and color flow mapping demonstrates valve regurgitation in up to 70%. Echocardiography may be accepted in the future to diagnose carditis<sup>201</sup> but strict criteria must be applied, as minimal mitral regurgitation is physiological.

### Treatment

Eradication of streptococcal infection is essential, even in the absence of evidence of active infection. Oral penicillin is given for 10 days. Alternatively a dose of (long-acting) benzathine penicillin 0.6–1.2 million units is given intramuscularly. Erythromycin is used in children allergic to penicillin. Aspirin relieves symptoms, but does not prevent the development of rheumatic heart disease. Steroids shorten the duration of the illness but symptoms often return when they are discontinued. Some clinicians use aspirin as the steroids are reduced. Studies have failed to demonstrate a lower risk of heart disease in children receiving steroids or immunoglobulin.<sup>202</sup> Heart failure is treated as described previously (p. 762).

Rheumatic fever recurs most commonly in young children and in the first 5 years following an episode. Each attack carries an increasing risk of carditis with permanent cardiac damage and death. It is therefore essential that *continuous* antimicrobial prophylaxis against further streptococcal infection be started after the therapeutic course of penicillin. The most effective form of prophylaxis is an intramuscular injection of 0.6–1.2 million units of benzathine penicillin every 3–4 weeks.<sup>203</sup> Alternatively oral phenoxymethylpenicillin (penicillin V) 250 mg is given twice daily. Sulfadiazine is recommended for children allergic to penicillin. Prophylactic therapy must be continued throughout childhood and into early adult life. The decision whether to discontinue prophylaxis thereafter depends on the severity of cardiac involvement, time since the last attack, social circumstances and risk of exposure to further streptococcal infections.

### Prognosis

There has been a marked decrease in mortality and morbidity as a result of improved socioeconomic standards and treatment with penicillin, particularly as prophylaxis to prevent recurrences. The prognosis is still much worse in countries where severe rheumatic heart disease develops during childhood. The prognosis is also worse in children who have severe cardiac involvement in the initial attack, and those who have recurrences with carditis. Mitral regurgitation can improve with time but aortic regurgitation is likely to be permanent. The prognosis is excellent for patients who escape carditis during an initial attack of rheumatic fever, but this does not preclude carditis in a subsequent episode, so prophylaxis is indicated.

### Rheumatic heart disease

Rheumatic heart disease occurs in childhood in countries where the incidence of rheumatic fever remains high. The prevalence is approximately 6 per 1000 school-aged children.<sup>200</sup> The mitral valve is affected in 85% of children, the aortic valve in 55%, and the tricuspid and pulmonary valves in less than 5%. Isolated aortic valve disease is rare.

*Mitral regurgitation* is the commonest lesion. The clinical findings are the same as congenital mitral regurgitation (p. 784). In older children it is often associated with mitral stenosis. Echocardiography shows enlargement of the left atrium and left ventricle, and color Doppler confirms the presence of regurgitation and its severity. The mitral valve leaflets are thickened and tethered, with cordal rupture and prolapse. Cardiac catheterization adds little further information, apart from measurement of pulmonary arterial resistance.

*Mitral stenosis* may be asymptomatic initially but effort intolerance and dyspnea progress to orthopnea, paroxysmal nocturnal dyspnea and hemoptysis. The apex beat is not displaced unless there is significant additional mitral regurgitation. The pulse volume may be reduced and the first heart sound is loud. An opening snap early in diastole is followed by a low-pitched rumbling mitral mid-diastolic murmur. Increasing mitral stenosis causes progressive lengthening of the murmur resulting in presystolic accentuation. Atrial fibrillation is rare in children but, if it occurs, the presystolic component (related to atrial contraction) disappears. A right ventricular parasternal impulse is palpable and the pulmonary second sound is accentuated when pulmonary hypertension occurs.

On chest radiography the cardiothoracic ratio is usually normal, with left atrial enlargement. Increased left atrial pressure causes dilatation of the upper lobe pulmonary veins and edema of the interlobular septa (Kerley B lines). The electrocardiogram demonstrates the broad, notched P waves of left atrial hypertrophy if there is moderate or severe mitral obstruction and right ventricular hypertrophy when pulmonary hypertension develops. Echocardiography shows a large left atrium with thickened and tethered mitral valve leaflets. Fibrosis and calcification of the valve and subvalvar apparatus reduce mobility of the leaflets. The Doppler signal shows an increased velocity and reduced rate of pressure fall across the valve throughout diastole, a quantitative assessment being given by the pressure half-time. This provides some assessment of the severity of the obstruction. Cardiac catheterization is performed to assess pulmonary vascular resistance or as part of therapeutic balloon dilatation of the mitral valve.

*Aortic regurgitation* has the same clinical features as for congenital causes of aortic regurgitation (p. 785).

### Management

Children with mild valve disease require follow-up and antimicrobial prophylaxis. In addition, life-long prophylaxis against bacterial endocarditis is necessary for dental and other surgical procedures (Table 21.6).<sup>60</sup> Indications and timing of mitral and aortic valve surgery remain controversial. Children who are asymptomatic with significant regurgitation and normal left ventricular function on echocardiography should be observed closely. Symptoms, deterioration of left ventricular dysfunction or pulmonary hypertension are indications for surgery. A good result may sometimes be achieved with anuloplasty for mitral regurgitation, or valvotomy for mitral stenosis. Valve replacement is required for severe aortic regurgitation.

## KAWASAKI DISEASE

Kawasaki disease is the most common acquired heart disease in children in resource rich countries.<sup>204</sup> The incidence peaks in toddlers, most cases occurring in children under 5 years and rarely in infants under 3 months of age. The cause is multifactorial, probably requiring an infectious agent in association with specific genetic and immunological factors.<sup>204</sup>

### Clinical features

Diagnosis is based on the presence of clinical criteria in Table 29.15 and the exclusion of other diagnosis.<sup>204,205</sup> The general clinical features are described in Chapter 29, p. 1424.

Cardiac involvement occurs in the second week after the onset of symptoms. In the acute phase, there may be medium and large vessel arteritis with arterial aneurysms, particularly in the coronary arteries.

Coronary aneurysms occur in up to 30% of untreated children. This is significantly reduced by the early administration of immunoglobulin. A friction rub of pericarditis, or gallop rhythm of cardiac failure from myocarditis may be present.

### Investigations

Electrocardiographic abnormalities include sinus tachycardia, reduction in QRS amplitude, flattening of T waves, prolongation of rate-adjusted PR and QT intervals and occasional dysrhythmias. Serial echocardiograms are required to evaluate and follow up myocardial and coronary artery abnormalities. The initial echocardiogram should be performed at the time of diagnosis, although aneurysms are rarely seen before the tenth day of illness. Treatment with immunoglobulin should *not be delayed* until after the echocardiogram has been performed. Echocardiograms should be repeated at approximately 14 days into the illness, and at 6–8 weeks.

### Acute management

Initial management is described in Chapter 29. The risk of death is greatest in the first 60 days, from coronary artery thrombosis and myocardial infarction.<sup>204</sup> Children with large (giant) aneurysms (> 8 mm) should be started on warfarin in addition to low dose aspirin to prevent clot developing in the aneurysm. If a child has clinical features of coronary thrombosis, thrombolysis with tissue plasminogen activator (tPA) is indicated.<sup>205</sup>

### Long term management and prognosis

Approximately 50% of coronary artery aneurysms regress in 5 years following an episode of Kawasaki disease. Small aneurysms (< 5 mm) commonly disappear, but large aneurysms (> 8 mm) seldom resolve completely. Long term morbidity results from initial thickening of the coronary artery wall and accelerated atheroma in later life. These changes may also occur in children who have not had aneurysms during the acute episode.

Risk stratification is carried out after the clinical evaluation and echocardiogram done at 6–8 weeks.<sup>205</sup> If there is:

- *No coronary artery change at any stage of illness.* Discontinue antiplatelet therapy. No further physical restriction. Cardiovascular assessment at 5 year intervals.
- *Transient coronary artery dilatation, disappearing within 6–8 weeks.* Discontinue antiplatelet therapy. No further physical restriction. Cardiovascular assessment at 3–5 year intervals.
- *One small or medium sized coronary artery aneurysm.* Aspirin 3–5 mg/kg/day. Avoid contact and high impact sports. No further physical restriction for patients less than 11 years old. Patients 11–20 years – biennial stress test/myocardial perfusion scan. Annual cardiovascular assessment. Angiography if non-invasive test suggests ischemia.
- *Multiple or giant coronary artery aneurysm (Fig. 21.53).* Aspirin 3–5 mg/kg/day. Additional warfarin if giant coronary artery aneurysm present. Avoid contact and high impact sports. Other physical activity recommendations guided by annual stress test/myocardial perfusion scan. Biannual cardiovascular assessment. Angiography at 6–12 months. Further angiography if non-invasive test suggests ischemia.
- *Coronary artery obstruction.* Aspirin 3–5 mg/kg/day. Additional warfarin if giant coronary artery aneurysm persists. Avoid contact and high impact sports. Other physical activity recommendations guided by annual stress test/myocardial perfusion scan. Angiography to address therapeutic options.

## CONNECTIVE TISSUE DISEASE

Cardiac involvement can occur in all connective tissue diseases, most frequently in systemic lupus erythematosus.

- *Systemic lupus erythematosus.* Small pericardial effusions and valvar lesions (Libman–Sacks) are the most common features. Congenital

Fig. 21.53 Left coronary arteriogram showing an aneurysm of the main left and anterior descending coronary arteries in a child with Kawasaki disease. LCA, left coronary artery.

complete heart block can occur in infants of mothers suffering from connective tissue disease who are seropositive for anti-Ro.

- *Juvenile rheumatoid arthritis*. Cardiac abnormalities usually occur in the acute systemic form of the disease with pericarditis, myocarditis and occasionally mitral regurgitation. Cardiac failure is an uncommon complication.
- *HLA B27 associated juvenile arthritis*. Aortic regurgitation can occur.
- *Scleroderma*. Diffuse fibrosis within the myocardium can produce ventricular dysfunction.
- *Polyarteritis nodosa*. Coronary artery lesions can result in myocardial ischemia.

## CARDIOMYOPATHY

Dilated cardiomyopathy occurs twice as frequently as hypertrophic cardiomyopathy in children. Restrictive cardiomyopathy is rare. Recently, left ventricular noncompaction has been recognized as an important cause of cardiomyopathy, accounting for nearly 10% of cases.<sup>206</sup>

### Dilated cardiomyopathy

This is characterized by ventricular dilatation with impaired function. Possible causes are outlined in Table 21.11. Familial cardiomyopathy accounts for up to 30% of patients. Inheritance is usually autosomal dominant, but various other modes have been identified.<sup>207</sup>

#### Clinical features

Symptoms vary with the age of the child, and severity of dysfunction. Some present with symptoms of easy fatigue and decreased exercise tolerance, while others have severe cardiac failure. Less commonly the child presents with an arrhythmia. Clinical examination shows signs of heart failure (p. 762). Mitral regurgitation can be present, caused by dilatation of the mitral valve ring. Pulmonary or systemic emboli can result from intracardiac thrombosis.

#### Investigations

A cause should always be sought, and Table 21.12 contains a list of initial investigations. Chest radiography shows cardiomegaly, and there is usually hypertrophy and strain on the electrocardiogram. If there are ischemic changes, an anomalous left coronary artery from the pulmo-

Table 21.11 Conditions producing dilated cardiomyopathy

Cardiovascular
Anomalous origin of left coronary artery
Coarctation of the aorta/critical aortic stenosis

nary artery should be excluded (p. 785). A 24 hour electrocardiogram should be performed to rule out incessant tachycardia as the cause, and to document arrhythmias secondary to cardiomyopathy. Echocardiography will demonstrate a dilated, poorly contracting left ventricle (Fig. 21.54) and mitral regurgitation.

(a)

(b)

The dashed line marks the line through which the (b) M-mode recording was made and demonstrates poor contractility. Ao, aortic root; IVS, interventricular septum; LA, left atrium; LV, left ventricle; LVPW, posterior wall of the left ventricle; MV, mitral valve; RV, right ventricle.

**Treatment and prognosis**

Initial management is for heart failure (p. 762). Arrhythmias should be treated, avoiding drugs that are negatively inotropic. The outcome is related to severity and whether a cause can be found which is amenable to treatment. Incessant supraventricular tachycardia is treated with radiofrequency ablation, which improves ventricular function. Carnitine deficiency responds to carnitine, with resolution of the cardiomyopathy.<sup>208</sup> Transfusion for anemia must be carried out very cautiously as it can result in acute cardiac decompensation.

Approximately one third of children improve with time, a third stay the same and a third get worse. Older age at presentation and lack of improvement in systolic function are associated with adverse outcome. If ventricular function remains poor, referral for cardiac transplantation should be considered. Left ventricular assist devices may be used as a bridge to transplant.

**Hypertrophic cardiomyopathy**

Hypertrophic cardiomyopathy is characterized by unexplained ventricular hypertrophy with dysfunction. It is usually inherited as an auto-

somal dominant. A number of other conditions are associated with hypertrophic cardiomyopathy (Table 21.13).<sup>209</sup> It is seen in up to 20% of children with Noonan syndrome. Neonatal hypertrophic cardiomyopathy is commonly due to maternal diabetes and is caused by the increased insulin acting as a fetal growth factor. It usually resolves spontaneously. This is also seen in infants with Beckwith–Wiedemann syndrome.

**Clinical features**

The diagnosis may be made because of the referral of an asymptomatic child for family screening. Infants may present with cardiac failure. In older children, dyspnea or excessive fatigue on exertion is most common but angina, dizziness, syncope and palpitations also occur. An ejection systolic murmur may be audible at the lower left sternal edge or apex and it may be possible to feel a ‘jerky’ arterial pulse or a double apical impulse.

**Investigations**

Electrocardiographic changes include left ventricular hypertrophy, ST and T wave abnormalities, deep Q waves, and prolongation of the QT interval. Echocardiography characteristically shows thickening of the septum and posterior left ventricular wall (Fig. 21.55), often with asymmetric septal hypertrophy and systolic anterior motion of the mitral valve. There is also left ventricular diastolic dysfunction with reduced distensibility and impaired relaxation. Doppler ultrasound may demonstrate increased velocity in the left ventricular outflow tract. Typical changes may only become apparent in the teenage years. Genetic testing is becoming possible, to identify children at risk in affected families.

**Treatment and prognosis**

The course of the disease is variable. Sudden death occurs in 1–6% of patients per year,<sup>210</sup> probably from ventricular tachycardia, and may be the presenting feature. No single feature can reliably predict risk of sudden death. A number have been identified:

- A family history of hypertrophic cardiomyopathy related cardiac arrest or sudden death.
- Nonsustained ventricular tachycardia.
- Severe ventricular hypertrophy.
- Syncope or cardiac arrest.
- Exercise-induced hypotension.

Note the marked hypertrophy of the posterior wall of the left ventricle (LVPW) and the interventricular septum (IVS), which results in significant subaortic obstruction at end systole. Ao, aortic root; LA, left atrium.

In adults, two or more risk factors indicate a high risk of sudden death, but in children their predictive value is unknown.<sup>176</sup>

Beta-blockers and verapamil may help with symptoms but they do not prevent sudden death. Amiodarone may be protective but side-effects prevent its long term use.<sup>210</sup> Implantable defibrillators are now small enough to implant in children at high risk of sudden death. Children with severe left ventricular outflow gradients may benefit from a septal myomectomy. Physical activities should be restricted, as severe exertion is considered a risk factor. However, in most cases, sudden death is unrelated to exertion. Advances in the genetics of hypertrophic cardiomyopathy may identify those most at risk. Screening of first-degree relatives is necessary.

### Other cardiomyopathies

**Noncompaction of the ventricular myocardium** is recognized as an important cause of cardiomyopathy in children.<sup>206</sup> Presentation is in infancy and may be associated with structural heart disease. Some children have dysmorphic features. Echocardiographic features include ventricular dilatation with reduced function. There are alternating finger-like myocardial trabeculations and deep myocardial recesses constituting a large proportion of the myocardium. Either ventricle may be involved. Arrhythmias occur and thrombus may form in the ventricle, with the potential for embolization. Some children improve with time.<sup>211</sup> It may be familial and first-degree relatives should be screened.

**Restrictive cardiomyopathies** are rare in children. Radiation therapy for malignancies, pseudoxanthoma elasticum and hypereosinophilic syndromes are unusual causes in children. Amyloid, sarcoid and Fabry disease are extremely rare in children.

Endomyocardial fibrosis is a progressive and usually fatal disease of unknown etiology occurring mainly in children and young adults living in specific regions of tropical Africa. The main pathological finding is an endocardial layer of dense fibrous tissue spreading from the apex of the ventricle. Endocardial fibroelastosis has similar clinical features and evolution to dilated cardiomyopathy and may be present as part of that

disease. It is also seen secondary to left ventricular outflow tract obstruction or coarctation of the aorta.

**Arrhythmogenic right ventricular dysplasia** is characterized by fatty infiltration and fibrosis of the free wall of the right ventricle. The disease is familial, and symptoms and risk of sudden death due to ventricular tachycardias increase with age.<sup>212</sup>

### CARDIAC TUMORS

Primary cardiac tumors are rare in children.<sup>213</sup> The majority are histologically benign but may cause hemodynamic compromise from obstruction or arrhythmia. Rhabdomyomas are the most common tumor in the pediatric age group.<sup>213</sup> If they are multiple, they usually indicate tuberous sclerosis. Fibromas and teratomas can occur in infants and young children. Hemangiomas and myxomas occur only rarely in older children.

Clinical features depend on the site and size of the tumor. It can cause ventricular outflow obstruction, or obstruction or regurgitation of the atrioventricular valves. Arrhythmias and embolic phenomena can also occur. Echocardiography and MRI are both useful techniques to demonstrate tumors.<sup>213</sup> Surgery is indicated if there is an intractable arrhythmia, or obstruction to the outflow or inflow tracts. Rhabdomyomas usually regress spontaneously during infancy.

### SYSTEMIC HYPERTENSION

This is defined as a systolic or diastolic blood pressure that is  $\geq 95$ th percentile for sex, age and height on  $\geq 3$  occasions (Tables 21.2 and 21.3). Hypertension in children is underdiagnosed and, in adolescents, is frequently primary.<sup>8</sup> Measurement of blood pressure should be part of the clinical examination in all children over 3 years old who are seen in a medical setting. Younger children with specific risk factors should also have their blood pressure measured. Risk factors include:

- prematurity, neonatal intensive care;
- congenital heart disease or family history of heart disease;

- renal disease;
- systemic disease associated with hypertension;
- evidence of raised intracranial pressure;
- malignancy;
- drug treatment which can cause hypertension.

### Etiology

Primary hypertension is most common in adolescents, particularly in those who have a hypertensive first-degree relative or who are overweight. Renal disease accounts for about 95% of cases of secondary hypertension (Table 18.12). Other causes include aortic coarctation, Takayashu disease and endocrine conditions (p. 487). Rare causes include neurofibromatosis, familial dysautonomia, porphyria, Turner syndrome and lead poisoning.

### Clinical features

Hypertension is frequently discovered on routine examination of a child who has no symptoms directly attributable to it. Techniques of blood pressure measurement are discussed on page 744. In general, the younger the child and the higher the blood pressure, the more likely it is that hypertension is secondary. Children whose blood pressure is consistently above the 95th percentile for sex, age and height (Tables 21.2 and 21.3) should be investigated and treatment should aim to achieve a reduction to below the 95th percentile.<sup>8</sup> Ideally, an obese child with moderate hypertension should be encouraged to lose weight and the blood pressure subsequently repeated before undergoing extensive investigation and treatment.

When symptoms occur, they result from the cause or the complications of hypertension.

**Symptoms of the cause.** The history may suggest a renal cause (past or present kidney disease), pheochromocytoma (episodes of palpitations, excessive sweating, headache), aldosteronism (weakness, polyuria, muscle cramps) or drug ingestion (corticosteroid, oral contraceptive). Inquiry should be made for a family history of eclampsia, essential hypertension, premature coronary artery or cerebrovascular disease, diabetes mellitus, inherited renal conditions and neurofibromatosis.

**Symptoms of the complications.** Hypertension may cause raised intracranial pressure resulting in headache or vomiting. Eventually seizures or other neurological disturbances occur. All children should have their blood pressure measured after a first seizure. Visual problems, tiredness, irritability and epistaxis are described. Cardiac failure, respiratory distress, vomiting, irritability or convulsions may be the presenting feature in infants.

**Signs of hypertension.** Physical examination may be normal initially but with established hypertension changes occur in the optic fundi and evidence of left ventricular hypertrophy becomes apparent. Signs of heart failure may be present.

**Signs of the cause of hypertension.** Physical examination must include palpation of the femoral pulses and kidneys, and auscultation of the abdomen and flanks for a bruit suggesting renal artery stenosis. The clinical features of Williams and Turner syndromes must be considered. Because primary hypertension has a strong association with obesity, body mass index should be calculated from the height and weight.

### Investigation

This will depend on the child's age, blood pressure level, and the clinical findings. Those with severe hypertension, symptoms, or advanced retinopathy require urgent investigation and treatment. A full blood count, urinalysis and culture, serum electrolytes, urea, creatinine and uric acid concentrations should be performed. The presence of associated hyperlipidemia, a further risk factor in coronary artery disease, should be excluded.

Other studies may be warranted on the basis of the history or physical or laboratory findings with the aim of excluding renal and endocrine disease, as detailed in Chapters 18 and 15 respectively. Echocardiography can identify aortic coarctation. Children with established hypertension should have regular cardiac monitoring with echocardiography to assess left ventricular hypertrophy.

### Management and prognosis

Borderline hypertension (between the 90th and 95th percentile) does not require drug therapy (Tables 21.2 and 21.3). Obese children should be encouraged to lose weight. All should be advised not to smoke and to avoid excessive salt intake. Girls must be warned of the hypertensive effects of oral contraceptives. Blood pressure should be measured annually. Children with undoubtedly high levels (persistently above the 95th percentile) or symptoms and signs caused by the hypertension must be treated (p. 585).<sup>8</sup> Overweight and hypertension are components of the metabolic syndrome, a condition of multiple risk factors for cardiovascular disease as well as for type 2 diabetes.

## PULMONARY HYPERTENSION

Pulmonary hypertension is defined as a mean pulmonary artery pressure > 25 mmHg at rest or 30 mmHg with exercise.<sup>214</sup> The main causes of pulmonary hypertension are listed in Table 21.14. Pulmonary hypertension secondary to congenital heart disease has become less prevalent, as surgery is now usually performed before irreversible pulmonary vascular disease develops. Primary pulmonary hypertension is rare. It can be familial.

### Clinical features

Symptoms are nonspecific but breathlessness is a common feature. Cyanosis occurs once the right heart pressure rises above systemic, provided there is communication between the two circulations (Eisenmenger syndrome). The cardiac impulse is hyperdynamic, with a prominent right ventricular impulse, and the pulmonary component of the second heart is loud. A soft pulmonary ejection systolic murmur may be followed by an early diastolic murmur of pulmonary regurgitation. If there is no communication between the systemic and pulmonary circulations, elevated right heart pressures will result in failure

Table 21.14 Causes of pulmonary hypertension

- |   |
|---|
| 1. Congenital heart diseases  |
| With increased pulmonary blood flow                                   |
| – left to right shunts, e.g. VSD, PDA, truncus arteriosus             |
| – disconnected pulmonary artery                                       |
| – total anomalous pulmonary venous drainage                           |
| – transposition of great arteries                                     |
| With pulmonary venous obstruction                                     |
| – left ventricular inflow or outflow obstruction                      |
| – obstructed total anomalous pulmonary venous drainage                |
| – pulmonary vein stenosis or veno-occlusive disease                   |
| 2. Chronic lung diseases producing hypoxemia                          |
| – airway obstructions, e.g. upper airways obstruction, chronic asthma |
| – parenchymal disorders, e.g. cystic fibrosis, neonatal lung disease  |
| – restrictive disorders, e.g. kyphoscoliosis                          |
| 3. Pulmonary vascular diseases  |
| – primary (idiopathic) pulmonary hypertension                         |
| – persistent pulmonary hypertension of the newborn                    |
| – collagen vascular diseases, e.g. systemic lupus erythematosus       |
| – thromboembolism, e.g. ventriculoatrial shunts for hydrocephalus     |
| – sickle cell disease   |
| 4. Others   |
| – high altitude   |
| – drugs and toxins  |
| – neuromuscular disorders producing hypoventilation                   |
| – familial  |
| – HIV infection   |
| – sarcoidosis   |

PDA, persistent arterial duct; VSD, ventricular septal defect.

with hepatic congestion, elevated jugular venous pressure and peripheral edema.

### Investigation

The electrocardiogram demonstrates right ventricular hypertrophy. Chest radiography shows large proximal pulmonary vessels with small distal branches (peripheral pruning of the pulmonary arterial tree). Echocardiography demonstrates the congenital cardiac lesion if present. The Doppler velocity of tricuspid regurgitation reflects right ventricular pressure. Pulse oximetry performed at rest and during submaximal exercise testing demonstrates the degree of desaturation and exercise capacity. Further investigations depend on the most likely cause. Pulmonary function tests, ventilation perfusion scan, CT scan of the lungs and thrombophilia screen may be indicated.<sup>214</sup> Lung biopsy may be indicated.

Cardiac catheterization confirms the diagnosis and measures the response of the pulmonary vascular bed (pulmonary vascular resistance) to vasodilators such as oxygen, prostacyclin and nitric oxide. This identifies patients who may respond to long term oral vasodilator treatment.<sup>214</sup>

### Management and prognosis

Children with a large left to right shunt who have a fall in pulmonary vascular resistance in response to an acute vasodilatation are suitable for definitive correction of the underlying lesion.

In all other children, therapy is directed at ameliorating symptoms and improving survival.<sup>215</sup>

- Oxygen therapy may slow the progression of polycythemia and provide symptomatic improvement, especially during intercurrent respiratory infections.
- Digoxin may improve cardiac output in children with right heart failure.
- Diuretics may be useful for severe right heart failure, to relieve hepatic congestion.
- Anticoagulation with warfarin and antiplatelet agents are recommended as patients are at risk of thrombotic events.
- Phlebotomy with replacement fluids is indicated when the hematocrit reaches 65% or if a patient is severely symptomatic. Hypovolemia and iron deficiency must be avoided, as they can increase viscosity.<sup>167</sup>
- Patients should receive immunization against pneumococcal infection and influenza.
- Pulmonary vasodilator therapy. Response is evaluated at cardiac catheterization. The youngest and those without a cardiac lesion are most likely to have a positive response. These children should be treated with chronic oral calcium blockade. Most recently, sildenafil and bosentan have been used with apparent success, but long term studies are awaited.
- Children with right heart failure or syncope should be palliated with an atrial septostomy.<sup>216</sup>
- The results of heart and lung transplantation are poor in children.

## THE NEUROLOGICAL CONSULTATION

### THE SETTING

Neurological consultations require time. Our role is to help understand causation, inform on future outlook, deal with the attendant medical problems, give specific treatment where possible, and arrange genetic counseling and supportive services. Special investigation is only part of this process: clinical skills are equally important. A child's appearance, pattern of movement, or mode of presentation all give important diagnostic clues and help shape the approach to investigation.

Histories are often complex; physical examination requires care; and there are often attendant psychological and educational issues which need definition and planned intervention. Consultations need space as gait assessment is an essential feature as is observation of patterns of play. Correct choice of room and a correct scheduling for families therefore demands adequate attention.

First impressions are very important and it is helpful to families to be greeted in a friendly way and for those in the room to be introduced to them. Cunningham and Newton<sup>1</sup> showed that parents and children attending hospital consultations still had difficulty in asking about things that worried them most despite a welcoming environment. These questions are often centered on fears and misunderstandings that would not necessarily be on the doctor's standard consultation agenda. An attractive, clear question sheet proved to be a simple but effective intervention. Parents felt empowered to take control. Its use often led to the adoption of a new consultation format that ensured that all parents' questions were addressed and limited time was used to its best advantage.

### THE HISTORY

Good history taking takes time. Concentrate on detail; ask yourself if you would be able to describe all relevant events with all relevant details to a third party at the end. If not, go back and finish off! For paroxysmal events consider the value that video recordings might offer.

In history taking it is important to listen to what the child has to say. In their 1998 study Viswanathan et al<sup>2</sup> showed that children's descriptions of their headaches cannot be tidily 'pigeonholed' into traditionally held views on headache classification. It is important to use language appropriate for the particular age of the child and to acknowledge that some things are difficult to describe. It is therefore perhaps better to note an 'indescribable feeling in the head' than trying to persuade them to accede to a proffered descriptive checklist.

Common clinical scenarios demand individual consideration:

#### **Paroxysmal disorders: including seizure disorders, headaches and paroxysmal movement disorders**

In the histories related to paroxysmal disorders an accurate description of the episodes, prodromal features, auras, and situations or activities that trigger the bouts should be taken. The child's views and experiences ought to be sought as well as those of witnesses.

#### **Gait disturbance**

For gait disturbance a description of the pattern of early ambulation is necessary along with the evolution of the disorder. For subtle difficulties it is good to ask about when the motor system is put to its greatest test: how is the child able to ascend stairs? How does the child fare in school races? Are they picked for the cricket or rounders teams? Is the disorder intermittent? Is there a hint of fatigability or diurnal variation?

## Developmental or speech delay

If there is difficulty with expressive language it is useful to determine whether the child has a good understanding of imitative gesture. This will signify that some fundamental language concept is present. Method of sentence construction will indicate if there is a syntax problem and insight into their sense of humor at a later stage will indicate whether there is a semantic/pragmatic language problem. Speech and language disorders are common in childhood, boys being affected twice as often as girls.<sup>3,4</sup> The history highlights whether the language problem is isolated or associated with global developmental delay. An assessment should be made of language opportunity for the child and whether there is any social disadvantage. Children brought up in a bilingual environment tend to develop speech later, but then catch up. Left handedness or ambidexterity is associated with speech disorder in half the children involved. Elective mutism, commoner in boys, can usually be recognized in the context of unresolved predicament. Children with elective mutism often talk freely in certain situations and continue to communicate with gesture.

For children with suspected global learning difficulties, the consultation enables one to determine whether the problems are indeed global or confined to verbal skills, nonverbal skills and/or social issues. Children with learning difficulties present in relatively few, well circumscribed ways: hypotonia in the newborn period, recognized developmental delay later in infancy or in the early toddler age group, language delay, arrest of development, or difficulties at school (see below). In each of these groups the history should detail the pregnancy, including any drug ingestion or early threatened abortion. A history of fetal distress should lead to careful scrutiny of the obstetric notes, though it is now generally accepted that in order to attribute causation to birth asphyxia the presence of neonatal hypoxic–ischemic encephalopathy must be established and there is nearly always an associated motor difficulty compatible with the type of injury sustained (see section on cerebral palsy below). A record of cord, or early, pH measurements, as well as neonatal behavior are important in this respect as not all early neonatal encephalopathy is due to hypoxic–ischemic insult.<sup>5</sup> Parents, in their own minds, often attribute their child's difficulties to the events of labor and it can be helpful for them to be taken through details of the birth.

A detailed family history is clearly of value especially if supplemented by perusal of the family photograph album. These, together with home video recordings, can give a surprisingly clear idea of the evolution of a disorder. Many motor disorders such as the spasticity in cerebral palsy or the extrapyramidal involvement in Rett syndrome may evolve over a period of time, raising the possibility of a neurodegenerative disorder. Careful scrutiny of the history often reveals that whereas things have changed, skills may not actually have been lost.

All these issues will be dealt with in more detail under separate headings in this chapter, but it is important to say at this early stage that the consultation should give the doctor a clear idea of the pattern of developmental delay, conveniently considered under the headings which follow.

## Abnormal behavior in the neonatal period

Dysmorphic features, disordered tone, feeding difficulties, irritability and seizures may all signify continuing neurological abnormality. Hypotonia in the limbs and axis raise the possibility of a neuromuscular disorder, the Prader–Willi syndrome and other causes of learning disability. Where hypotonia is confined to the axis, there is usually a central nervous system abnormality such as a neuronal migration disorder, or hypoxic–ischemic encephalopathy. In the latter cases there may be associated full fontanel (due to cerebral edema), irritability, feeding difficulties and seizures.

The commonest cause of persisting hypotonia or feeding difficulty is the presence of one of the recognizable forms of learning difficulty, of which Down syndrome is the commonest. Of the metabolic disorders, it should be remembered that the cerebrohepato-renal syndrome of Zellweger (one of the peroxisomal disorders) can mimic Down syndrome. It is associated with profound hypotonia as well as a craniofacial

dysmorphism, similar to trisomy 21. The use of one of the computer-based databases of dysmorphology can be helpful when attempting to establish a dysmorphic diagnosis.

Arthrogryposis should make one think of a neuromuscular problem or a neuronal migration defect particularly if the hands and arms are held in a 'decorticate' posture. Half of the children with arthrogryposis who are ventilator dependent will have a developmental brain abnormality. The presence of scoliosis and pooling of secretions with aspiration makes a congenital myopathy, and particularly nemaline rod myopathy, likely.

## Abnormal head size

This common cause of referrals to pediatricians is dealt with below under 'investigation' – but always start with parental head size!<sup>6</sup>

## Syndromes of developmental arrest

A number of conditions lead to similar developmental profiles; for example that of a 'ceiling effect'. Here a child will show normal development for a while, learning then slows, arrests, some skills may then actually be lost, and then learning continues at a slower rate. The child with hydranencephaly (e.g. due to pyruvate dehydrogenase deficiency) may well return the mother's smile before this smile is lost. Deaf children may babble but then, lacking input, their language development will subsequently become deviant if the problem is not identified and treated.

Children with autism often make reasonable developmental progress in the first year or so, their problems only becoming evident when there is a greater demand on social contact and language function. Words originally attained may be lost before the depth of communication difficulty is revealed. A very similar profile is seen in the age-related epileptic encephalopathies. West syndrome often begins too early in infancy for much difference with other children to be noticed, but in the Lennox–Gastaut syndrome, which usually presents in the third or fourth year, there is very often an arrest of developmental progress at the time of onset of the seizure disorder. In Rett syndrome, although in retrospect movements may have had a 'jerky' quality throughout infancy, there is often reasonable early developmental attainment before the process slows and the extrapyramidal features and loss of useful hand function become evident.

## GENERAL POINTS ON EXAMINATION

Although this is dealt with in detail in Chapter 8 some aspects of clinical examination will be emphasized here: starting with an approach to a shortened neurological examination that can be used in everyday clinical practice. Hopefully this will avoid the practice seen in some clinical records of simply noting, CNS ✓.

Look for dysmorphism, signs of a neurocutaneous syndrome or the visceromegaly, heart murmur or the skeletal abnormality one might associate with a storage disorder. Examination of the eyes should include not only a search for papilloedema (which is rare even in the presence of raised intracranial pressure in pediatric practice) but also a careful look at the retina to look for degenerative features or pigmentation that one might associate with a mitochondrial cytopathy, or peroxisomal disorder.

From the age of 5 onwards children will usually cooperate with a formal examination of cranial nerves, coordination and power where required. For the younger child eye movements can be tested through distraction through the various fields of movement. Close inspection of facial expression will reveal any facial weakness. If there is any doubt about hearing, it should be tested formally. Observation of speech and questions about the child's pattern of chewing and swallowing and the ability to handle liquids and solids avoid the need for tongue depressors and more intrusive aspects of physical examination. They will give a good indication of the function of muscles of mastication and the lower brainstem.

Observation of the pattern of movement is more useful than the traditional 'hands-on' approach. Cerebellar function can be tested by

holding the arms outstretched and looking for 'drift'. Up to 6% of boys will show choreiform movement of the outstretched hands until the age of about 10. Carrying out the finger/nose test, assessing alternating movements and touching each finger in turn can then further test cerebellar function. The ability to play a musical instrument is a good reflection of coordination.

The gait should be observed with particular features in mind. The first question always is whether this is a heel-toe gait, or a toe-heel gait. If there is any doubt the shoes can be inspected for uneven wear. A toe-heel gait may be due to pyramidal or extrapyramidal motor dysfunction, a foot drop due to a lateral popliteal nerve palsy or tight tendo-Achilles due to a neuromuscular problem. Corticospinal posturing in the upper limb leads to adduction, elbow and wrist flexion and pronation; in the lower limb, adduction, internal rotation and flexion at the hip, knee and plantar flexion at the ankle.

Fog's test may reveal these patterns when subtle. Fog's test involves walking on the heels, then walking on the outside of the feet and then walking on the inside of the feet. At each stage, children are observed for the degree of associated movement in the upper limb. An undue degree of associated movement is often related to poor sequencing and balance and coordination seen in children with a developmental dyspraxia/developmental coordination disorder (see below). Asymmetry over and above what one would see in the dominant hand, as opposed to the non-dominant hand, often reflects contralateral hemisphere dysfunction, which can reflect the presence of a dysgenesis, a space occupying lesion or the site of an epileptogenic focus.

Children with a cerebellar problem have a wide-based gait for additional stability and this is often accompanied by a moderate amplitude truncal tremor, deviations off the path, overcorrection and then restitution. Extrapyramidal disorders will give a paucity of movement with a stiff-legged gait or too much movement, as in a dyskinesia.

A wide base, seen continuing for some months after children first begin to walk, may suggest a cerebellar problem, the general hypotonia of the recognizable forms of learning difficulty or a carbohydrate deficient glycoprotein syndrome.

If learning difficulties are present then think of Duchenne muscular dystrophy. The average age at which boys with this disorder are taken to doctors with developmental concerns is 2.5 years, whereas the average age of diagnosis is 5.5 years. A large contribution to this delay is a misunderstanding of Gower sign.<sup>7</sup> Most clinicians remember the sign as the need to climb up the legs using the hands when rising from a supine to standing position. The most important component, however, is the need to turn prone and in so doing adopting a 'Moslem prayer position' before rising. This overcomes difficulties sustained in attaining a sitting position if the rectus abdominus is weak and furthermore allows the hips to be extended more than is possible in the almost full hip flexion position seen in the normal squatting position. Most children show a Gower or modified Gower maneuver before the age of 3 years. If it is seen after the age of 3 then it is highly likely that there is a neuromuscular problem, or a central nervous system disorder with hypotonia.

Neuromuscular problems leading to proximal weakness often lead to a waddling pattern. The weak gluteal muscles lead the body weight to be transferred outside the weight bearing leg; the resulting mechanical advantage avoids dropping of the pelvis away from the weight bearing side.

The presence of choreoathetosis naturally would lead to investigations for basal ganglia dysfunction, but the erratic movements of Angelman syndrome may certainly imitate this, particularly in infancy and it may also be an early feature of Friedreich ataxia.

If one side of the body 'mirrors' movement seen on the other then agenesis of the corpus callosum should be considered.

Whenever the motor system is examined the examiner should have on their mind, is this normal or abnormal? If it is abnormal is it central nervous or peripheral nervous system, and if it is central nervous system is it corticospinal (voluntary movement), extrapyramidal (where patterns of movement are stored) or cerebellar (the 'air traffic controller')? This in turn will help guide investigation.

Sensory testing is only indicated when the history indicates it should be done (that is sensory symptoms or perhaps features of a peripheral neuropathy or spinal cord lesion). In this eventuality all modalities should be tested working from the point of perceived maximum sensory loss toward more normal areas.

## INVESTIGATION OF SUSPECTED NEUROLOGICAL DISORDERS

### INVESTIGATION OF NEUROLOGICAL DISEASE

The investigation of a child with suspected neurological disease can be challenging. The differential diagnosis may be very broad. Advances in neuroimaging (primarily MRI), molecular genetics and neurometabolic investigations mean that the label 'undiagnosed neurological disorder' is becoming increasingly rare.

The bewildering number of possible investigations, together with a litigation conscious society, may lead some clinicians to adopt a blanket or fishing net approach to investigation. This is wasteful of resources, subjects the child to unnecessary distress and is intellectually lazy. Many of these 'screening' tests can produce false negatives which will not be recognized as such if the clinician does not recognize the clinical features of a given disorder.

Some investigations are simple and inexpensive whereas others may be invasive, complicated and expensive. For the best results, the clinician should communicate with the laboratory personnel to discuss optimal sample requirements, or local factors that may influence the quality of the sample or procedure. This is as relevant for neuroimaging and neurophysiology as for biochemical or genetic investigations. Where many such investigations are performed, regular meetings between clinicians and nonclinical staff are of great benefit.

Certain principles should underlie the investigation of any child:

- Unfortunately many children have large numbers of investigations performed on the basis of a cursory history or examination (particularly in the investigation of paroxysmal disorders). If the clinical history or signs are unclear, then rather than requesting investigations blindly it may be more appropriate to ask for advice from a more specialized clinician.
- Complete clinical assessment may require evaluation by other professionals such as neuropsychologist, physiotherapist or speech therapist.
- Planning investigations in a logical sequence is important. For example, if the differential diagnosis includes hydrocephalus or a space-occupying lesion in a child with progressive neurological signs or symptoms, neuroimaging should be performed prior to expensive metabolic or genetic investigations.
- Perform simple investigations first. Urea and electrolytes, full blood count and urinalysis are cheap and easy and may suggest the diagnosis, e.g. hyponatremia in coma, leukocytosis in leukemia, or proteinuria due to lupus.
- Investigation often involves building up a picture from multiple clues rather than one single test. While there are exceptions to this, the clinician should not reject a putative diagnosis on the basis of one negative test. For example, a normal blood or CSF lactate does not exclude mitochondrial disease. Evidence of muscle disease might include: clinical signs, blood creatine kinase (CK) level, EMG, muscle imaging or muscle biopsy.
- Repeating tests is important when clinical suspicion is strong.
- Good record keeping with clear summaries of results of investigations facilitates clinical review.
- The purpose of any given investigation should be clear before it is performed. An investigation may be done to help clarify the clinical features, e.g. is there a retinal dystrophy? Is there a peripheral neuropathy? Results from these may then indicate other investigations. Investigation may be seeking a specific etiology, or to monitor the course of a disease or the effects of treatment. It is particularly important that the aim of the investigation is made

clear to the personnel who will be doing the procedure (e.g. biochemist, pathologist, radiologist).

- When the diagnosis is not clear or the results of tests confusing, consultation with colleagues is often helpful. Electronic communication has greatly facilitated this and parents themselves may initiate it. The development of clinical networks and referral pathways should facilitate this. Clinical and scientific meetings also provide an important forum for the discussion of diagnostic problems.
- Psychological disorders commonly present with symptoms or signs that could have a neurological basis. Investigation to exclude increasingly unlikely diagnoses is often inappropriate and will reinforce the notion that there is an obscure or serious underlying disorder in the mind of the child, family or other professionals often delaying appropriate management.

In spite of optimal investigations, the diagnosis in some children with severe neurological disorders remains elusive. Figure 22.1 illustrates how the likely diagnostic yield of investigations becomes less the more investigations that are required and the more invasive or specialized they become.

## NEUROIMAGING

In most situations MR is the imaging modality of choice; but the value of imaging has to be balanced against the need in infants and young children for sedation or general anaesthetic.

Consideration needs to be given to 'quality control' and imaging protocols should be agreed with specialist colleagues in the regional neuroscience center (e.g. ILAE protocols for epilepsy). MR imaging is particularly useful in the diagnosis of brain malformations and neurometabolic disease (Figs 22.2, 22.3).

MR angiography allows noninvasive assessment of cerebral arterial and venous anatomy to a high degree of resolution. It does not have the resolution of formal angiography which may still be indicated if there is a high level of suspicion of cerebrovascular disease. Perfusion and diffusion MR imaging are being increasingly used to demonstrate the topography and nature of acute brain insults, particularly ischemic

insults such as stroke. Very early detection may allow appropriate therapeutic interventions.

MR spectroscopy allows *in vivo* chemical analysis of areas of interest in the brain. It is of particular value in the investigation of neuro-metabolic disease, some of which can be diagnosed by the MRS pattern. (e.g. Canavan disease and disorders of creatine biosynthesis).

Functional MR (fMR) allows the anatomical location of areas of increased blood flow that have been activated by the initiation of specific functions such as motor, linguistic or visual. This has been of particular value in presurgical evaluation of children with epilepsy and in cognitive research.

The role of MR continues to evolve both as a research and a clinical tool and there are many other potential applications of MR technology which are beyond the scope of this text.

CT scanning remains the imaging modality of choice for immediate assessment of traumatic brain injury, intracranial calcification and for bone imaging (eg craniostylosis).

## NEUROPHYSIOLOGICAL INVESTIGATIONS

The electroencephalogram (EEG) is the most widely used neurophysiological investigation in pediatrics.

Three types of information can be obtained from an EEG: (i) the presence or absence of paroxysmal activity; (ii) the nature of the background activity; and (iii) the topography or asymmetries of any abnormality. The most common reason for requesting an EEG is in the investigation of paroxysmal disorders, especially the epilepsies. It is important to recognize that an EEG is usually unhelpful in the investigation of a paroxysmal disorder when it is unclear from the history whether it is epileptic or non-epileptic.

Both background changes and asymmetries in the EEG are of value in the investigation of acute and chronic neurological disorders, indicating previously unsuspected CNS disturbance (e.g. in organic cognitive or behavioral disorders). In acute disorders they may indicate widespread or focal pathology. The EEG should always be performed in unexplained encephalopathy, particularly to exclude various types of status epilepticus. In coma the EEG is also a good guide to prognosis and very occasionally has a role in the evaluation of brainstem death.

Evoked potentials (EPs) are recordings of EEG waveforms that are seen in response to specific stimuli. The potential recorded is averaged from many single stimuli and considerably amplified. Visual, brainstem (including auditory) and somatosensory EPs provide information on the integrity of pathways within the CNS and on neuronal function in the brainstem or cortex. EPs provide valuable additional information in the investigation of a wide range of acute and chronic neurological disorders. Visual EPs are of most value in assessing potential optic nerve disease (e.g. neuritis or glioma). Serial recordings allow monitoring of response to treatment or disease progression.

Evoked response audiometry is of great value in assessing hearing impairment in small children.

The electroretinogram (ERG) records electrical activity generated from the rods and cones in the retina. Its main role is in the evaluation of possible retinal dystrophies in children with visual impairment or who have a suspected neurodegenerative disease where retinal dystrophy is a prominent feature (e.g. mitochondrial disease, neuronal ceroid lipofuscinoses). While detailed assessment of rod and cone function by ERG studies is possible in older children and adults, this is generally not feasible in infants. In these children it is often only possible to assess whether the ERG is normal or absent; results in between should be interpreted with caution.

Peripheral neurophysiological investigations, electromyogram (EMG) and nerve conduction studies (NCS), are of value in the investigation of suspected neuromuscular disease. In the acute context NCS are of most value in the diagnosis of Guillain-Barré syndrome or other much rarer causes of acute neuropathy. In chronic disorders NCS will identify neuropathy and can indicate whether it is demyelinating or axonal. The EMG is of most value in identifying anterior horn cell disease, disorders

Fig. 22.1 Schematic representation of investigation of neurological disorders. As investigations become more complex and specialized (effort), the likelihood of a final diagnosis becomes smaller (chance). The majority of diagnoses can be made with a comprehensive history, detailed clinical examination and a limited number of relevant tests. (Modified from Dr Joerg Klepper 2006, with permission.)

Fig. 22.2 Examples of specific MR patterns in leukodystrophies. (a) Diffuse hypomyelination in recessive Pelizaeous–Merzbacher like disorder. (b) Frontal predominance in Alexander disease. (c) Posterior predominance in X-linked adrenoleukodystrophy. (d) Cerebellar white matter involvement in infantile Krabbe disease. (e) Diffuse white matter involvement in late infantile metachromatic leukodystrophy. (f) Leukodystrophy with vanishing white matter.

of the neuromuscular junction and polymyositis. It is of less value in primary myopathies.

Quality control is important. The best results come from those laboratories that carry out these procedures on children on a regular basis and that are interpreted by a neurophysiologist familiar with both the technical limitations of these procedures in children and age-related norms. The clinician should always be prepared to question an apparently aberrant result and to consider repeating it if doubt persists.

## BIOCHEMICAL INVESTIGATIONS

Specific disorders will be considered in the relevant sections below; however some principles will be considered here. Clinicians often request a 'metabolic screen' without specifying what they are looking for. While most centers now perform a very similar batch of investigations, it is essential to know specifically which tests are included by your local laboratory. Most metabolic screens on urine will include amino acids, organic acids, mucopolysaccharides, oligosaccharides, sugar chromatography and ketones. In general if metabolic disease is suspected several samples should be sent. It is helpful to the biochemist to know if a specific disorder is being considered as they may look at a particular area of the spectrograph in detail (e.g. sulphite oxidase deficiency). It is also important to be aware of diseases where false negatives may occur (e.g. glutaric aciduria type 1).

Acyl carnitine assays on blood (or blood spot) are very useful and may detect fatty acid oxidation disorders, organic acidemias or mitochondrial disease (see Ch. 26, pp. 1067).

Routine analysis of blood amino acids is not usually necessary, although in specific situations it may be helpful.

For most conditions and investigations one negative result does not completely exclude the diagnosis. Screening investigations often look for evidence of abnormalities in the function of an organelle which performs many biochemical activities. Therefore it is often useful to look for several different biochemical clues that point to a given type of metabolic disorder, e.g. peroxisomal or mitochondrial (see Ch. 26, pp. 1081 & 1113). In this context discussing the patient with a specialist colleague before further investigation is advisable.

Lysosomal (or white cell) enzymes are often requested by nonspecialists early in the investigation of neurological disease (see Ch. 26, pp. 1101). Many of these children have none of the clinical features of the conditions that are being tested for or have a static disorder. In general these expensive investigations should not be requested without a specific diagnosis in mind. False positives and negatives may occur which may not be recognized as such if these investigations are used indiscriminately.

An increasing number of conditions can be detected by investigation of the CSF, some of these are simple (CSF sugar), some highly specialized (e.g. neurotransmitters) (Table 22.1).

To diagnose some disorders functional assays of specific biochemical pathways are necessary. For example respiratory chain enzyme activity in muscle or cholesterol handling in fibroblasts in Niemann–Pick type C. Close liaison between the clinicians and laboratory staff is essential for such investigations to be successful.

Fig. 22.3 Examples of MRI diagnoses in children with a diagnosis of cerebral palsy. (a) Bilateral frontoparietal polymicrogyria. (b) Typical MRI features of congenital cytomegalovirus infection (CMV). (c) Bilateral putaminal high signal and atrophy secondary to term hypoxia ischemia. (d) Pontocerebellar hypoplasia. (e) Progressive cerebellar atrophy due to CACNA1A mutation. (f) Molar tooth appearance of midbrain in a child with Joubert syndrome.

Table 22.1 CSF investigations for metabolic disorders

Glucose	CSF/plasma ratio <0.5 suggests glucose transporter deficiency GLUT1
Lactate	High in mitochondrial disease, low in GLUT 1
Glycine	High in nonketotic hyperglycinemia
Serine	Low in serine biosynthesis disorders
Neurotransmitters	Various diagnostic patterns (e.g. dopa responsive dystonia)
Pterins	Various diagnostic patterns (e.g. disorders of tetrahydrobiopterin pathways)

## INVESTIGATIONS FOR INFECTIOUS OR INFLAMMATORY DISORDERS

Many neurological disorders in childhood have an infectious or inflammatory etiology. Sometimes the presence of infection is obvious, and the aim of investigation is to determine which is the causative organism. Sometimes however investigation is necessary to determine *whether* a given clinical syndrome could have an infectious or inflammatory etiology.

For bacterial infection the most useful sample is always direct culture and microscopy of the relevant tissue/body fluid, prior to antibiotics having been started. This is not always possible.

The diagnosis of neurotuberculosis (TB) may still prove challenging. The 'T spot' test which looks at gamma interferon release in blood has shown promise as a diagnostic test for TB. However its role in the diagnosis of neurotuberculosis is not yet established (see Ch. 28).

If a possible viral etiology is suspected then evidence for infection should be sought from multiple sources including stool, urine, respiratory secretions, throat swab, blood and CSF. Serology, culture, immunological studies, electron microscopy and PCR studies may all be required before a diagnosis is made.

If an inflammatory disorder is suspected evidence for this should be sought both in and out of the CNS. CSF examination should include cell count, protein and electrophoresis. An oligoclonal pattern suggests possible intrathecal antibody production and should be investigated further by looking at the IgG index which will confirm whether the abnormal IgGs are being produced in the CNS. Evidence for antibody production against specific organisms can be sought in the same way (e.g. varicella)

Many vasculitic disorders are multisystem and diagnostic clues may come from other organs such as kidneys, skin, joints, eyes. Blood autoantibody screens, complement levels, ESR, CRP, urinalysis, renal ultrasound and sometimes angiography or biopsy may be necessary.

An increasing number of autoantibodies directed against neural tissue in the central and/or peripheral nervous system are being identified. At present the specificity of such antibodies in the pathogenesis and diagnosis of neurological disorders is not completely clear.

## GENETIC INVESTIGATIONS

The investigation of neurological disorders has been revolutionized in the past decade by the increasing availability of tests that allow detection of the molecular abnormalities that are the cause of genetic disease. The technology that has developed (e.g. PCR and other DNA amplification techniques) has also found widespread uses in non-genetic contexts such as the investigation of CNS infections and in the diagnosis and management of CNS tumors.

Identification of chromosomal abnormalities has in turn been greatly enhanced by molecular technology. The field is developing rapidly and ultimately it should be possible to look for large numbers of possible mutations with quick and inexpensive tests. However at present many of the available tests are time consuming and expensive whereas others may only be available in research laboratories. For optimal results, therefore, investigations should be planned in discussion with clinical and laboratory geneticists. Email has greatly facilitated this process, and there is increasing international collaboration in the investigation of patients.

When genetic disease seems possible or likely, but the diagnosis is not yet known, it is important to store DNA (from blood or skin fibroblasts) for future reference. This is particularly important in the acute situation when a child is likely to die from the disease.

## PATHOLOGICAL INVESTIGATIONS

The need for a 'tissue' diagnosis of neurological disorders has lessened markedly with improvements in imaging, molecular and biochemical investigations. Nonetheless there are still situations where a tissue diagnosis is essential or provides the necessary clues to direct further investigation.

The most obvious example is in the management of CNS tumors where histology is the necessary starting point for planning further management and therapy. The only exception to this would be in certain intrinsic tumors such as brainstem glioma or optic pathway glioma, where (i) the differential diagnosis is very small and (ii) biopsy or resection carries significant risks without adding information that would significantly alter management.

The indications for carrying out a brain biopsy are very few outside the need to exclude a CNS tumor. Other modalities of investigation usually will provide the answer. However in the face of an evolving brain process with progressive radiological 'lesions' a biopsy is sometimes warranted. This might for example be the case in unusual inflammatory, infectious or demyelinating disorders where widely differing treatments might be offered depending on the etiology. Brain biopsy is now virtually never required for the diagnosis of neurodegenerative disease.

Cortical and leptomeningeal biopsy may still be necessary to diagnose the very rare cases of pure cerebral vasculitis.

Muscle histology is necessary for the diagnosis of many muscle disorders. However a rapidly increasing number of genetic tests are reducing the need for muscle biopsy in many disorders. Often, however, both investigations are necessary. Histochemical examination of muscle may be useful in the identification of mitochondrial disease.

Nerve biopsies are only occasionally required (i) in a rapidly progressive neuropathy without a specific diagnosis or (ii) when a chronic inflammatory neuropathy is possible.

Peripheral biopsies (rectal, skin or conjunctival) are still useful for the diagnosis of some neurodegenerative diseases, particularly if there are atypical features. For example, in variants of juvenile or late infantile neuronal ceroid lipofuscinosis.

## GIVING THE NEWS OF DISABILITY

Key points of the Good Practice guidelines, expanding on work originally carried out by Cunningham et al<sup>8</sup> and formulated in the British Pediatric Association guideline<sup>9</sup> are as follows:

1. Parents like to be given the news of disability by someone they are familiar with.
2. They like to be given the news together and if a single parent is involved then a partner, close friend or relative should also be encouraged to attend.
3. They like to be given the truth as soon as it becomes known. If there is initial doubt, doctors are respected for sharing it.
4. The surroundings need to be quiet, private and adequate time should be given to the process.
5. If possible, the child should be present to indicate inclusion and not rejection.
6. They value time spent alone after the event to muster their thoughts and begin to adapt.
7. They value the opportunity to meet again soon to go over things they have not fully understood. In the interim it is good for them to have access to another health worker perhaps more familiar to them, such as a health visitor, who can act as a support and source of information.
8. They should be directed to useful written material and support groups.

Parents often go through a bereavement-like process with its initial shock, disbelief, anger and then resolution. It is helpful to discuss how they are feeling about things, how each of them may feel differently at different times, emphasizing the need to support each other as they adjust, and to help them recognize that their feelings are quite separate from the child's problem. It must be emphasized that they will not always feel this way, that the family will learn to adjust, to laugh again, and to accommodate to the child's disability and grow strong together once more.

For many conditions, such as Down syndrome, there is a clear-cut diagnosis and this model for giving the news is relatively straightforward. With an evolving condition, such as cerebral palsy, the approach needs modification. Here the situation is that at a fairly early stage a doctor may share the concern raised by a parent that motor development is not proceeding satisfactorily. However, in one longitudinal study,<sup>10</sup> which followed 229 children with cerebral palsy, 118 were free from motor disability at the age of 7 (although up to 25% retained a learning disability). The best approach would seem to be to acknowledge what is seen and what the observation might represent, to lay out a plan of investigation and observation and explain that at that stage it is just too early to tell. Later if the fears come to be confirmed and a diagnosis of cerebral palsy is established then the process of news giving can be followed in the usual way, but with the family much better prepared. Parents are rarely angry at an honest approach; they are angry if they feel the truth has been withheld.

A third scenario arises where risk factors for cerebral palsy are identified, for example, grade IV intraventricular hemorrhage will lead to 40% of the children affected having a motor deficit. The reason for continuing observation in clinics should be explained. This honest approach often turns out to be a more solid foundation for a continuing professional relationship, rather than the alternative 'conspiracy of silence'.

Other conditions bring different challenges where the issue of giving the news is concerned. In a recent study of how 32 UK pediatric neurologists gave the news of epilepsy three approaches were identified:<sup>11</sup>

1. A proactive approach where many issues surrounding the diagnosis were discussed, including the type of epilepsy, prognosis, stigma, treatment, investigation plan, how to contact and tell others, sources of information, help and reactions and feelings. This approach runs the risk of overload but recognizes the right of parents to information.

2. A reactive approach which was more individually tailored but assumes that the doctors involved can intuitively judge parental reactions.
3. A drip feed approach being rather more protective in preselecting topics to meet any given particular situation.

There was little consensus in relation to the use of analogy in explanation and there is often no good knowledge on the usefulness and awareness of available unevaluated literature. All acknowledged the value of a specialist epilepsy nurse, in this context, who is able to visit the family and answer any continuing questions. The doctors involved largely determined consultation content intuitively, rather than on a shared knowledge of the process involved. It is clear that, in this, and in other situations, more study as to the most effective approach is required.

Houston et al<sup>12</sup> studied the information needs and understanding of 5–10-year-old children with epilepsy, asthma or diabetes. They were asked about their knowledge of their condition, psychological effects, medication, restrictions on lifestyle and where they obtained their information if they had unanswered questions. The children with epilepsy had far more unanswered questions and felt excluded from discussions with doctors. They felt reluctant to tell their friends about their diagnosis and often felt stigmatized. The study highlighted a contrast in the understanding of children with epilepsy compared to those with asthma and diabetes. The authors proposed that a simple biological model used to explain epilepsy could aid a child's understanding and reduce their reluctance to disclose the diagnosis.

The subject of written information is important. It is often written using analogy or paradigms that do not specifically relate to biology. It is almost always written without due attention to the reading age of the material involved, and the fact that children at different ages respond to different approaches in this respect. This is an area of research that needs pursuing and with the advent of information technology it should be possible for core information documents to be identified and developed to suit this information need on a national, if not international, basis. Shared web-based sources of information, written to a national standard, are within our grasp.

## DEVELOPMENT OF THE HUMAN BRAIN

Knowledge of normal embryogenesis is the key to understanding the myriad of conditions that may present with motor and/or intellectual impairment. It helps us explain to families the biological processes leading to their child's disability. No longer is it acceptable for pediatricians to say, 'We just do not know'; we may not know the particular gene involved but the sort of process that is likely to have occurred and its timing can usually be deduced and a good explanation of that process delivered. This level of understanding should take distress away from many families and help them adjust.

So how do 100 000 million neurones get to the right place? There are a number of well-defined phases:

1. isolation of the neural groove;
2. germinal zone cellular proliferation;
3. neuronal migration;
4. ventral and horizontal organization;
5. synaptogenesis;
6. myelination.

### ISOLATION OF THE NEURAL GROOVE

The neural plate begins to form between 18 and 19 days postfertilization. Two neural folds emerge which then fuse at the level of the first pair of somites at 20/21 days, giving the embryonic disc a tubular shape. The neural tube then closes in a zip-like fashion. On day 27 the caudal neuropore closes at what will ultimately become the second sacral segment (Figs 22.4, 22.5).

Rapid differential growth then leads to the emergence of flexures with segmentation. At 35 days a midbrain and pontine flexure are seen. At 29 days three brain vesicles, the prosencephalon, the mesencephalon and the rhombencephalon (Fig. 22.6) appear.

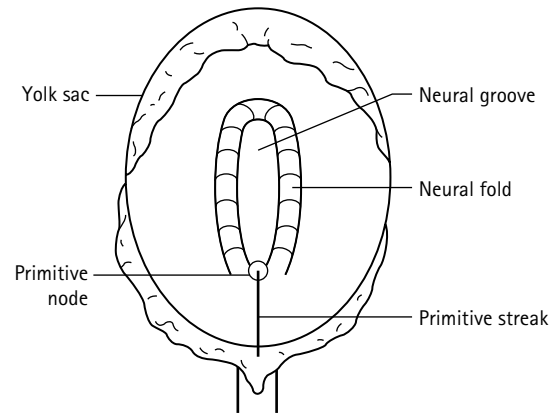

Fig. 22.4 The amnioembryonic vesicle.

At about 29 days postfertilization two telencephalic vesicles appear on the prosencephalon or forebrain, which by the end of the embryonic period (8 weeks' gestation) can be recognized as the developing cerebral hemispheres. After 12 weeks' gestation gyri emerge on the medial aspect.

The mesencephalon changes least but will later contribute the cerebral aqueduct, the cerebral peduncles, and the tegmentum and substantia nigra, which are derived from the basal plate.

The pontine flexure is a prominent feature in the rhombencephalon at 34 days made up by the rhombic lips (destined to form a large part of the cerebellum) at the cephalic end and by the developing floor of the fourth ventricle at its caudal end. Cerebellar foliation follows from 14 weeks' gestation.

### GERMINAL ZONE CELLULAR PROLIFERATION OF NEURONES

New neurones then proliferate in cycles involving asymmetrical division from the pseudostratified ventricular epithelium (PVE). One cell migrates, and then ceases to proliferate while another returns to the PVE to undergo a new cell cycle. Most neurones are formed between the 8th and 18th week of gestation and there is probably no significant neurogenesis after birth, in the human. Neuronal and glial lineaging then occurs and specific neurones and glial cells target a particular destination.

The primitive neuroepithelial cells of the embryonic neural tube are the precursors of neurones, astrocytes and oligodendroglia. These cells undergo many proliferation cycles in the ventricular zone and then exit from the cell cycle, leave the ventricular zone and migrate centrifugally in a series of waves. They pass through the intermediate zone to form the layered structure of the cerebral cortex between the 8th and 14th week of postfertilization development (Fig. 22.7).

The earliest migrating neuroblasts form a transient structure, the preplate, and most are lost by programmed cell death (apoptosis). The deep component of the preplate, called the subplate, plays a role in axonal guidance by serving as an intermediate target for the axons of thalamic neurones during their ascent to synapse with cortical plate neurones. The superficial layer of the preplate forms the cells' sparse marginal zone where the Cajal–Retzius neurones lie (see below).

### NEURONAL MIGRATION

Later cells migrate into the preplate and split it into an outer marginal zone (or future layer I) and an inner subplate. Later formed cells migrate past these cells. The cells in layer II are therefore formed after those in layer VI (between 12 and 24 weeks).

Migrating neurones advance along columns of radial glial cells between the PVE and the pia. Radial glial cells contain rich amounts of particulate glycogen, an energy source for migrating neurones which depend on anaerobic glycolysis. The migrating neurones then transform

Fig. 22.5 Development of the neural tube from the neural plate 22 days onwards.

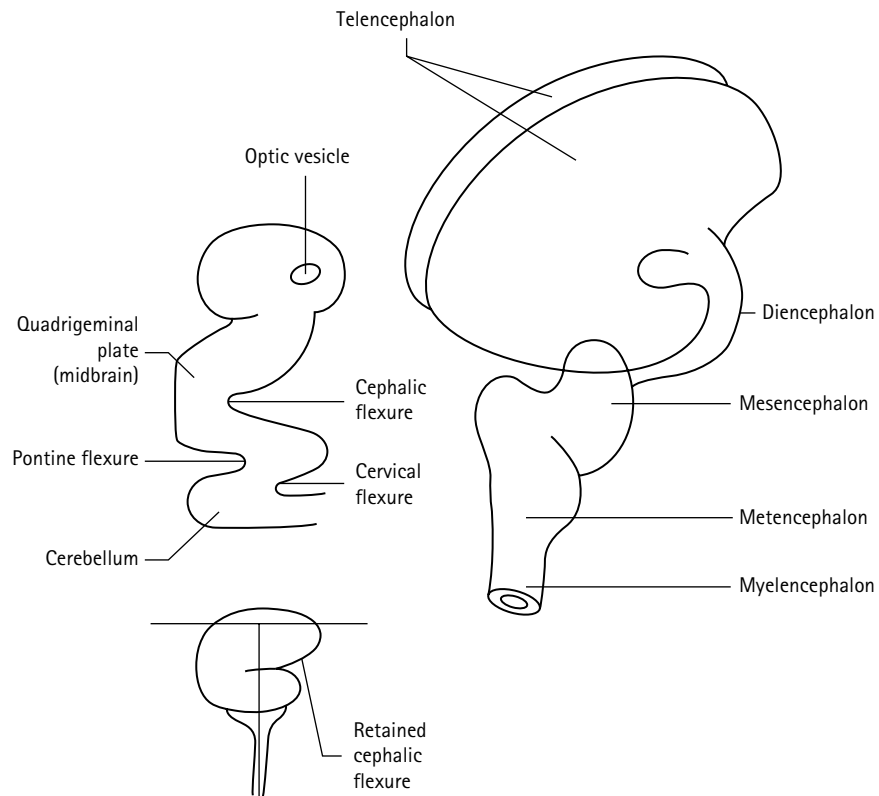

Fig. 22.6 Embryonic flexures of the brain 6 weeks onwards.

Fig. 22.7 Neuroblasts exit cell cycles and migrate centrifugally along radial glia. Those migrating later pass those migrated earlier to take up more superficial positions. mz, marginal zone; cp, cortical plate; sp, superficial plate; iz, intermediate zone; vz, ventricular zone; wm, white matter.

from anaerobic to aerobic metabolism in the postmigratory settlement areas where they can rely on a vascularized cortical plate.

Some of the neurones formed early in the marginal zone secrete a substance known as reelin. These are the Cajal–Retzius cells. Correct cortical lamination depends on reelin, which appears to instruct neurones on when to cease their migratory activity.

Neurones have differentiated growth cones at their leading end, which respond to signals, categorized as: chemo-attractive, chemo-repellent, contact-attractive or contact-repellent. The chemical signals are diffusible molecules, which create gradients over a distance, whereas contact modulating molecules are cell membrane bound, or in the extracellular matrix.

Many ligand receptor families are known including the semaphorins, with over 30 members. The growth cones probably carry receptors for several classes of these axon guidance molecules.

Nerve growth factors are diffusible peptides acting on specific receptors and define targets for migrating neurones.

**Programmed cell death (apoptosis).** Most of the subplate neurones are transient and are eliminated by apoptosis. Anomalies of apoptosis have been implicated in the pathogenesis of certain types of neuronal migration disorder, particularly the heterotopias. It seems that ‘pro-death’ genes (e.g. Bax, Bad) and ‘anti-death’ genes (e.g. Dcl) are expressed in cells in varying combinations and amounts under exogenous influences such as survival factors. It is the balance between pro- and anti-death genes that determines whether a cell will survive or die. A disruption in this process or an alteration in the local environment leads to the persistence of cells normally destined to die yielding a neuronal heterotopia.

## SYNAPTOGENESIS

In monkey experiments, distinct phases have been identified for this process.

In phase 1 (from 6 to 8 weeks’ gestation) synaptogenesis is limited to lower structures like the subplate. Phase 2 begins from 12 to 17 weeks, and occurs in the cortical plate. These early synapses are sparse and form contacts in the dendritic shafts of the neurones. Phase 3 is much more rapid and occurs from 20 to 24 weeks and persists up to 8 months after birth. It occurs in conjunction with arborization of axons and dendrites. Phase 4 then proceeds at a very high rate and lasts until puberty. Phase 5 continues up to the age of 70 years, during which time there is also considerable loss. Stage 3 is partially dependent on sensory input, phase 4 much more so.

Excitatory amino acids are the primary neurotransmitter in approximately 50% of mammalian synapses and have an important function in

the development of the CNS. They participate in neuronal signal transduction and exert trophic influences on neuronal development. They affect differentiation, growth and survival as well as neuronal circuitry.

Huttenlocher and Dabholkar<sup>13</sup> indicate that maximum synaptic density is not seen until after 15 months of age. It occurs concurrently with dendritic and axonal growth and with myelination of the subcortical white matter. Net synapse elimination occurs late in childhood, often extending to mid-adolescence. Synaptogenesis and synapse elimination in humans occur at different times in different cortical regions. Synapse formation is triggered by the contact of two neurites. Initially this appears to be random but then becomes refined selectively through retrograde and anterograde signaling through neurotransmitter release. Stabilization is activity dependent, so synaptic contacts not included in neuronal circuits are gradually eliminated. Early synaptogenesis is intrinsically regulated and not under environmental control.

## MYELINATION

Myelin is formed by oligodendrocytes. Prior to myelin deposition these cells proliferate and there is a marked increase in vascularization. The myelin is laid down first on the fiber close to the nerve cell body, then proceeds along the axon, the oligodendrocyte wrapping its lipoprotein plasma membranes repeatedly around the axon to produce the myelin sheath.

Cycles of myelination progress at different rates and may not be complete for some structures until several years after birth. Table 22.2 summarizes the timetable.<sup>14</sup>

Myelination is a critical process for the development of the brain because it enhances the speed of neural communication. It occurs most rapidly during the first 2 years of life, but probably continues until early adulthood. Klingberg et al<sup>15</sup> studied the degree of myelination of young people’s brains with MRI and showed that the maturation of frontal white matter probably continues into the second decade of life.

## THE DEVELOPMENT OF SPECIFIC BRAIN STRUCTURES

**Forebrain (telencephalon).** Initially the cerebral hemispheres are smooth but with growth the sulci and gyri develop. Many gyri are well defined between 26 and 28 weeks’ gestation with secondary

Table 22.2 Age (in months) at which myelination becomes apparent. (From Hittmair et al 1994<sup>14</sup>)

MR imaging sequence	T1	T2	STIR
Peripheral parts of midcerebellar peduncles	2–3	4	2–3
Folia cerebelli	7 <sup>b</sup>	6–7	6–7

Lobar cerebral white matter (central portion)			
Paracentral	2	5–7	5–6
Occipital	4–6	10–12	7–9
Frontal	5–6	11–14	8–12
Completed cerebral white matter			
Arborization			
Paracentral	3–6	10–12	7–9
Occipital	7–9	18–20	14–16
Frontal	8–10	18–22	14–16

From Hittmair et al 1994<sup>14</sup> T1/T2, T1 or T2 weighted images; STIR, short-inversion-time-inversion recovery images.

and tertiary gyri appearing between 40 and 44 weeks' gestation, initially in the frontotemporal areas and later in the orbital and occipital gyri.

The lateral (sylvian) and central (rolandic) fissures appear in month 4. The callosal sulcus appears around week 14 together with the corpus callosum. At birth the sulci and gyri are similar in arrangement to that of the adult.

The pyramidal tract is the only tract to span the entire length of the central nervous system without synaptic relay. Association fibers connect adjacent areas of the brain while commissures connect equivalent areas on opposite sides (Fig. 22.8).

**Diencephalon.** This is the posterior part of the forebrain. Three swellings emerge to form:

- The thalami – in the superior diencephalon are the main relay nuclei receiving sensory input and projecting on to the cerebral cortex.
- The epithalamus – incorporates the pineal body, the posterior commissure and the nucleus habenulae (an important relay to the thalamus).
- The hypothalamus – arises in the floor of the diencephalon and from here the mammillary bodies, the tuber cinereum and part of the hypophysial stalk of the pituitary arise.

The medial and lateral geniculate bodies appear later to act as important nuclei for auditory, visual and motor activity caudally to the thalami. The optic vesicles and second cranial nerve grow forward from the diencephalon.

**Midbrain (mesencephalon).** The lumen of the midbrain is eventually reduced to the narrow cerebral aqueduct of Sylvius connecting the third and fourth ventricles. The dorsal midbrain roof (the tectum) enlarges as two pairs of protuberances, the rostral superior colliculi and the inferior colliculi. The superior colliculi act as relays for visual reflexes and the inferior for auditory reflexes. Several nuclear groups develop from the basal plate in the midbrain floor (the tegmentum): the reticular formation, the red nucleus, the substantia nigra and the nuclei for the third and fourth cranial nerves. The cerebral peduncles develop as small thickenings from the ventral laminae. In the fourth month they increase rapidly in size as the corticopontine, corticobulbar and corticospinal tracts expand and pass through the midbrain area.

**Hindbrain (metencephalon).** This comprises the cerebellum, the pons and the fourth ventricle lying between the two.

**Hindbrain (myelencephalon).** This forms the medulla oblongata and is continuous caudally with the spinal cord.

## PROTEINS AND GENES ASSOCIATED WITH BRAIN DEVELOPMENT

A number of genes involved in the formation of the brain have been retained phylogenetically and are to be found in insects and lower vertebrates. They are known as homeotic genes and control the orientation of the embryo, segmentation of the body and segment identity. Clustered homeobox-containing genes (the HOX genes) are important. They differentiate the segments of the early embryonic brain. Those expressing many HOX proteins develop as posterior structures, those with lower levels form the anterior part of the axis. EMX and OTX are expressed in the fore- and midbrain region. Mutation of the EMX gene leads to one form of schizencephaly (see below).

Krox-20 is necessary for the development of the cranial nerves in the hindbrain. The Sonic Hedgehog genes determine timing and spacing, for example, which neurones should develop into motor neurones in the spinal cord. If this gene is knocked out all neurones become sensory neurones by default.

Early specification of the forebrain depends on appropriate expression of a number of homeobox and winged helix-containing genes including members of the Otx, Emx, Dlx, BF, Mf, Lhx and Gsh family.

Reelin and Mdnab0001 are needed by neuroblasts to pass one another as they migrate centrifugally. With Cdk5 and p35 mutant genes later migrating neuroblasts do not appear to be able to pass early migrating neurones with resulting disruption of the cortical plate. The LIS1 and doublecortin gene are both implicated in the etiology of lissencephaly. Subcortical band heterotopia arises from cortical plate cells that express the mutant doublecortin gene. The protein kinase C substrate MARCKS is needed to define the pial basement membrane that serves as the external anchoring point for radial glial end feet. Without correct functioning of extracellular matrix models including laminin and collagens at pial limiting membranes, determined by MARCKS, layer II neurones are found heterotopically in the marginal zone or in the subarachnoid space.

The interaction between neuroblasts and radial glia is mediated by a number of molecules including astrotactin and neuroregulin (glial growth factor). Patterning of the cerebral cortex depends on inter-neuronal signaling and the dynamic response of migrating neurones to the local chemical environment. For example Pax6 and em2 are transcription factors expressed in opposing gradients. This graded concentration of antagonizing diffusible molecules restricts the expression of specific transcription factors, which in turn regulate the expression of downstream target genes specific for regional identity.

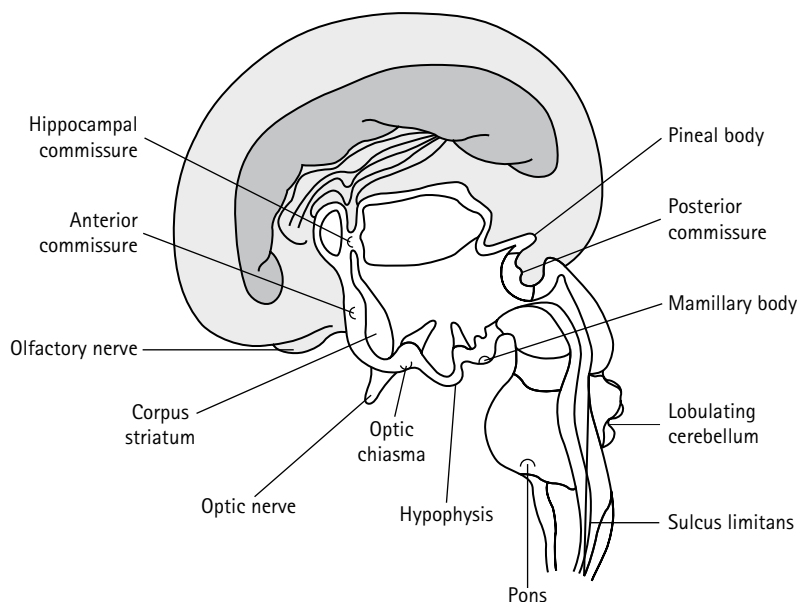

Fig. 22.8 Commissure development at 4 months.

A family of proteins known as the cell adhesion molecules (CAMs) are also important in cell migration. In the cerebellum these have been attributed imaginative names presumably reflecting the likely phenotype when things go wrong!: viz 'reeler', 'weaver', 'staggerer'. Probably the most studied of the cell adhesion molecules is the Down syndrome cell adhesion molecule coded for on chromosome 21. Multiple forms of Dscam are generated through alternative splicing from its four main exons (4, 6, 9 and 17). This gives the amazing possibility of 38 000 possible isoforms indicating what great scope there is for very focused migration targeting. Thus neurones arrive in the target area encouraged by signaling from a variety of growth factors. Having entered the layer they arborize. They are encouraged to enter a specific site and discouraged from leaving, by ephrin and cam gradients which code for different target cells along various axes and layers. The incoming afferents are distinguished by receptors on their surface. These ligand and receptor gradients are the result of very early patterning events in the embryo. Molecular cues from homophilic/heterophilic adhesion molecules aid the process leading to very precise connectivity. Fine tuning then becomes heavily dependent on synaptic activity as previously discussed. Dysplasia may arise when cortical cells mutate and re-express genes normally only seen at an earlier stage of differentiation, or genes that characterize a different cell lineage.

## UNDERSTANDING ABNORMALITIES OF CEREBRAL CORTEX DEVELOPMENT

Barkovich and colleagues<sup>16</sup> proposed a rational classification system for malformations of the cerebral cortex in 1996. It is based on three embryological stages of cortical formation:

1. Cellular proliferation within the germinal zone, which occurs between 7 and 16 weeks' gestational age.
2. Migration of neuroblast cells from the germinal matrix to the developing cortex occurring between 12 and 24 weeks' gestational age.
3. Vertical and horizontal organization of cells within the cortex with the establishment of axonal and dendritic ramifications which begins at approximately 22 weeks' gestational age and continues until after birth.

### Problems of cellular proliferation

Entities in this category include the following.

Radial micro-brain (also known as lissencephaly type IV) results in a brain of dramatically reduced size but with a normal gyral configuration and cortical thickness. Children with this condition have severe microcephaly and often multiple non-CNS abnormalities.

Microcephalia vera (also called lissencephaly type III) results in severe depletion of neurones in cortical layers 2 and 3. A number of genetic and sporadic abnormalities may lead to this condition, which involves a reduced number of neurones in the germinal zones but no evidence of a migratory disorder. Children with this condition often have moderate developmental delay.

Tuberous sclerosis is a disorder of cellular proliferation that results in hamartomatous growths and, at times, neoplasms. The cortical tuber is composed of bizarre giant cells, heterotopic neurones and glial tissue. Defective stem cells in all germ cell layers may underlie the central nervous system manifestations of tuberous sclerosis. The stem cells differentiate into astrocytes and neurones, which lack the ability to integrate themselves further into the brain structure. Some remain in the germinal zone, resulting in the subependymal hamartomas, whereas others migrate along glial fibers in the white matter to the cortex, where they form the disorganized cellular clusters known as tubers.

van der Knaap and Valk<sup>17</sup> in their categorization included the other phakomatoses, such as neurofibromatosis, Sturge-Weber disease, von Hippel-Lindau disease and ataxia telangiectasia, in the category of abnormalities of neuronal proliferation, differentiation and histogenesis.

Hemimegalencephaly consists of unilateral cerebral enlargement with associated hamartomatous parenchymal overgrowth. Children present with developmental delay and intractable seizures. There may be an association with linear sebaceous nevus syndrome and unilateral hypomelanosis of Ito.

Focal transmantle dysplasia is characterized by abnormal cortical lamination, white matter astrogliosis and balloon cells. It arises from the maldifferentiation of germinal zone stem cells. Children present with a focal epilepsy and the focal dysplasia is demonstrable with MRI.

Disorders resulting from a disorder of migration include classic (type I) lissencephaly, which is also called agyria-pachygyria. There is absent or marked underdevelopment of the gyri and sulci. The cortex comprises only four layers and migration appears to have been arrested sometime between 12 and 16 weeks' gestation. Children are generally hypotonic at birth with the subsequent development of corticospinal tract signs and seizures. The most striking clinical presentations are seen in children with the Miller-Dieker syndrome (17p13.3 microdeletion) and there are relatively milder manifestations in those with isolated lissencephaly.

In type II lissencephaly there is a severely disorganized thickened cortex lacking a normal layered pattern. MRI scanning sometimes gives a 'cobblestone' appearance though the cortex is thinner than seen in type I lissencephaly. There is considerable clinical overlap between type II lissencephaly, the Walker-Warberg syndrome and Fukuyama congenital muscular dystrophy which all have autosomal recessive inheritance. MR imaging reveals a thickened disorganized cortex with shallow sulci and hypomyelinated white matter (Fig. 22.9).

Gray matter heterotopia are foci of normal neurones situated in abnormal locations due to an arrest in the migration process. The heterotopia may be localized or diffuse. Subependymal and band heterotopia are examples of neuronal migration anomalies, which are often diffuse.

Subependymal heterotopia has small ovoid masses of gray matter located along the lateral ventricular walls. Young people with this disorder often have normal development and a seizure onset after the first decade of life. MRI demonstrates the nodules which do not enhance with gadolinium, in contrast to the subependymal nodules seen in tuberous sclerosis.

Band heterotopia, also known as 'double cortex' heterotopia, consists of large circumferential layers of heterotopic neurones that have failed to reach the cortex. The resulting gray matter band is uniform, diffuse and bilateral. Those affected often have moderate to severe learning difficulties and intractable seizures.

It should be noted that all of the above neuronal migration anomalies may be very localized as well as diffuse. They have all arisen between 12 and 16 weeks' gestational age. Subcortical heterotopia may exist as an irregular lobulated mass of gray matter situated in the subcortical white matter. These heterotopia tend to be large, extending between lobes. The overlying cortex is thin, with shallow sulci, and there are

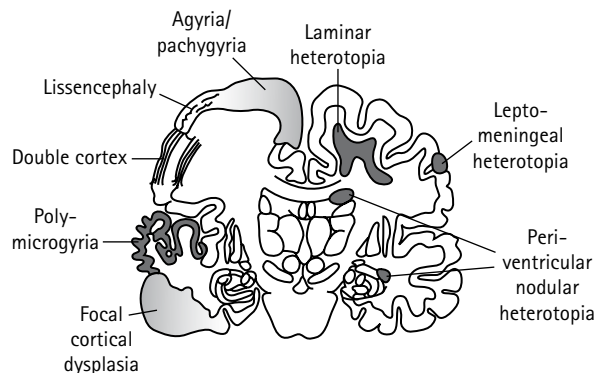

Fig. 22.9 Diagrammatic representation of the more frequent neuronal migration disorders.

often associated dysplastic basal ganglia. Those affected often present with learning difficulties, a hemiplegia, or hemi-hypo-esthesia and localization related epilepsy.

Cortical organization follows 24 weeks of fetal development. Abnormalities occurring in this process include focal or diffuse polymicrogyria and schizencephaly. Polymicrogyria results when neurones reach the cortex but distribute in an abnormal fashion creating multiple small gyri with a deranged sixth layer cortex. It probably represents disruption of cortical maturation and folding in the postmigrational period but does not arise after 28 weeks' gestation. It may be diffuse, symmetrical and bilateral, as in the bilateral opercular syndrome, or focal and unilateral. The clinical presentation depends on the location and extent of involvement but seizures are seen in up to 80% of those affected.

Schizencephaly consists of gray matter lined clefts that extend through the full thickness of the hemisphere from the cortex to the ependymal lining of the ventricles. The gray matter lining the clefts is often polymicrogyric. If the walls of the cleft are fused it is termed 'closed lip' schizencephaly. If not, it is known as 'open lip'. The clinical course often includes seizures, hemiparesis, with the closed lip varieties tending to be associated with the milder clinical course.

Van der Knaap and Valk<sup>17</sup> placed schizencephaly earlier in the migration sequence than polymicrogyria, proposing a time of onset of 2 months' gestational age for schizencephaly and 5 months for polymicrogyria. Whereas mutations of the *EMX2* gene have been found in humans with schizencephaly, the lesion may also be due to tissue loss and infarction.

Agenesis of the corpus callosum involves failure of growth of the main forebrain commissure. It is associated with a number of chromosomal abnormalities, drug ingestion, including valproate, and a number of syndromes. Aicardi syndrome is an X-linked dominant condition in which agenesis of the corpus callosum is associated with infantile spasms, intellectual impairment, vertebral anomalies and retinal lacunae.

## EARLY DEVELOPMENTAL BRAIN ABNORMALITIES

### Abnormalities of dorsal induction

Failure of neural tube fusion results in a range of abnormalities which may also involve adjacent bone and skin coverings. They all arise on or before 28 days of development.

Encephaloceles consist of a bony skull defect through which dura and brain parenchyma protrude. They are identified according to the location of the bony defect, e.g. occipital. The brain parenchyma abnormality reflects many disorders of embryogenesis.

The Chiari II malformation is almost always associated with a spinal myelomeningocele and is a complex hindbrain deformity with caudal displacement of the medulla, pons and portions of the cerebellum through an enlarged foramen magnum. There is often associated callosal dysgenesis and cervicomedullary kinking, which may predispose to hydrocephalus.

### Disorders of ventral induction

Ventral induction involves the further growth and development of the three cerebral vesicles between weeks 5 and 10. Congenital abnormalities arising from disorders of ventral induction include holoprosencephaly, the Dandy–Walker syndrome and callosal dysgenesis/agenesis.

Holoprosencephaly results when the prosencephalon fails to cleave laterally and transversely (12 sites on 11 chromosomes have been implicated). The result is varying degrees of hemisphere and ventricular fusion. In alobar holoprosencephaly there is a complete lack of cleavage leading to a horseshoe-shaped monoventricle and absence of the corpus callosum. In semilobar holoprosencephaly there are rudimentary temporal occipital lobes with some differentiation of the ventricular system. In lobar holoprosencephaly there may be very mild appearances on MRI including hypoplasia of the frontal horns or underdevelopment of the anterior aspect of the falx.

The Dandy–Walker complex is a spectrum of hindbrain abnormalities incorporating varying degrees of hypoplasia of the cerebellar ver-

mis and/or enlargement of cisterna magna. There is often associated hydrocephalus.

Callosal development occurs between 8 and 20 weeks of fetal life and proceeds in an anterior to posterior direction. Abnormalities result in complete absence of the corpus callosum or simply underdevelopment. Septo-optic dysplasia associates hypoplasia of the corpus callosum with midline structure abnormalities including optic nerve hypoplasia, hypothalamic and pituitary dysfunction.

## FUTURE CLASSIFICATION SYSTEM

Traditionally, morphological classification schemes have focused on anatomical or histological abnormalities identified at postmortem, complemented with the findings of more refined imaging systems, especially MRI. The timing of the interruption of the normal developmental process has then been estimated and the disorder classified (as delineated above) according to whether this was a problem with neurulation, cell migration, axonal projection, synaptogenesis or myelination. As our knowledge of gene receptors and chemotactic agents grows, this system requires refining. A new system for classification of the malformations of the nervous system has been proposed by Sarnat and Flores-Sarnat.<sup>18</sup> They make the point that, whereas traditionally a disorder such as holoprosencephaly was subdivided into alobar, semilobar and lobar forms (see above), this classification does not accommodate the four distinct human genes responsible for various cases of holoprosencephaly. Some of these genes have a ventralizing effect in the vertical gradient (e.g. the Sonic Hedgehog gene, *SHH* at 7q36) whereas others have a dorsalizing influence (e.g. *Z1C2* at 13q32). At least seven other defective chromosomal loci have been associated with holoprosencephaly. Thus, holoprosencephaly is a common end stage of several different disturbances in cerebral development. Severity does not always correlate well with the associated midfacial hypoplasia, which may range from mild hypotelorism to extreme forms of cyclopia, or the correlation with diabetes insipidus, in about one third of affected infants. These correlations most likely relate to the rostrocaudal gradient of the genetic expression, bearing in mind that most rostral neural crest tissue arises in the midbrain and forms not only neural structures but also the membranous bones of the face, orbits and much of the eyeball except the retina, lens and cornea. It must be acknowledged that a scheme purely based on genetic analysis would be very difficult to use for radiologists, pathologists and clinicians. Furthermore, disruption in one gene, particularly one involved in a cascade, may lead to disruption of further genes later in the sequence. For example, defective *DAB1* causes underexpression of the downstream genes *LIS1*, *Reelin* and *EMX2*, all of which are important for various stages of neuroblast migration. However nongenetic malformations secondary to acquired lesions in fetal life (e.g. infarction to interrupt radial glial fibers and their guidance of migrating neurones) would not be accommodated within such a genetic scheme.

Sarnat and Flores-Sarnat apply these principles to known patterns of malformation (Table 22.3). A single condition may appear in more than one position in the table, implying that a particular abnormality is a common end point for a number of different mechanisms. Although this proposed classification is likely to change in time, nonetheless it offers clinicians, radiologists and pathologists alike an understanding of some of the complex biological processes involved. It also provides the opportunity to give affected families important understanding and appropriate genetic counseling.

## PRENATAL PRESENTATION OF DEVELOPMENTAL BRAIN ABNORMALITIES

Many of the described abnormalities result in motor and/or intellectual impairment and/or epilepsy and the general pediatrician, or pediatric neurologist, may be called upon to advise and counsel families and advise colleagues in radiology on the relevance of brain abnormalities detected by antenatal ultrasound.

**Table 22.3** Twelve principles cited by Sarnat and Flores-Sarnat<sup>18</sup> involved in genetic programming of the neural tube

Principle 1:	Development genes are re-used repeatedly. For example, an organizer gene establishing axis of growth may appear later in development as a regulator gene for differentiation and maintenance of specific cellular types
Principle 2:	Domains of organizer genes change in successive stages
Principle 3:	Relative gene domains may differ in various neuromeres
Principle 4:	Some genes activate, regulate, activate, regulate or suppress the expression of others
Principle 5:	Defective homeoboxes usually have reduced domains or result in deletions of entire neuromeres
Principle 6:	Some genes may compensate for the loss of others if their domains overlap: redundancy and synergy
Principle 7:	An organizer gene may be upregulated to be expressed in ectopic domains. For example, epithelial growth regulator-2 may be ectopically expressed with the loss of unique identity of those rhombomeres in which specific cranial nerve nuclei and other structures are generated
Principle 8:	Developmental genes regulate cell proliferation to conserve constant ratios of synaptically related neurones. For example the regulation of the ratio of Purkinje cells to granule cells is regulated through Sonic Hedgehog (SHH) and the granule cell receptor product of the gene Patched (PTC) and a related additional receptor gene Smoothed. Hemizygous mutations of the PTC gene in mice result in medulloblastoma. Cellular proliferation may be regulated by mitogenic stimulation or by the rate of apoptosis
Principle 9:	Overexpression of genes programming the ventrodorsal or dorsoventral gradients, manifest as hypoplasia or duplication of paramedian structures of the neuroaxis
Principle 10:	Underexpression of genes programming the ventrodorsal or dorsoventral gradients manifests as aplasia, hypoplasia, or midline fusion of paramedian structures of the neuroaxis
Principle 11:	Minor genetic mutations may change cell lineage within or between traditional embryonic germ layers
Principle 12:	Organizer and regulator genes are conserved in a phylogenetic evolution but may form several distinct varieties with related but distinctive functions in more advanced species

### Agensis of the corpus callosum

Up to 0.7% of the general population have complete or partial agensis of the corpus callosum and 85% of these individuals are asymptomatic. Agensis may, however, be associated with seizures or learning difficulties and be associated with other CNS abnormalities. Many cases are sporadic, but autosomal recessive or X-linked varieties are also described and there is a 1 in 10 risk of an associated chromosomal abnormality, trisomy being the most common.

Three per cent of all fetuses with ventriculomegaly and 10% of all fetuses with mild ventriculomegaly have agensis of the corpus callosum. Those features most commonly associated with a poor prognosis include upward displacement of the third ventricle, widened interhemispheric and atrial diameters, absence of the cavum septum pellucidum, the radial array of the medial gyri and dilated occipital horns.

Approximately 80% of children with partial or complete agensis of the corpus callosum have associated CNS anomalies including ventriculomegaly, porencephaly, microcephaly, encephalocele, holoprosencephaly, lissencephaly, Dandy–Walker malformation and spina bifida. Non-CNS abnormality is also common. Eighty sporadic genetic and chromosomal syndromes have been described with agensis of the corpus callosum.

### Fetal ventriculomegaly

Isolated ventriculomegaly has a prevalence of 1 in 1000 births in the United States. Thirty per cent of fetuses with ventriculomegaly have associated neural tube defects so careful evaluation of the spine should be performed.

Hudgins et al<sup>19</sup> reported that approximately 86% of ventriculomegaly is stable throughout the gestation, 9% progressive and approximately 4–5% resolve. Ventriculomegaly is defined as atrial diameters greater than 10 mm, or above four standard deviations. Measurements are taken at the level of the choroid plexus from the inner border of the medial wall to the inner border of the lateral wall.

Mild idiopathic lateral ventricular dilation defined as atrial dimensions of 10–15 mm encompass approximately 20% of the fetuses with ventriculomegaly and resolution may be seen with ventricular diameters as large as 12 mm. Mild isolated ventriculomegaly during the second trimester has been estimated to occur in 1 in 675 pregnancies. Follow-up shows 80–90% of the fetuses with isolated mild ventriculomegaly develop normally,<sup>20</sup> while up to 50% of fetuses with mild ventriculomegaly and associated congenital defects are developmentally impaired; (seen for example in 23% of children at 2 years of age in a review of 234 reported cases<sup>21</sup> and 12 of 101 fetuses not terminated in a more recent French study of 167 affected pregnancies – assessed after 19 months of age).<sup>22</sup> Fetal hydrocephalus with marked ventriculomegaly is associated with a 55–75% mortality (including elective abortions, intrapartum and postnatal deaths). The prognosis is better where there is no associated abnormality but still 40% survive with severe disability.<sup>23,24</sup> Intrauterine shunting has been shown not to improve outcome.<sup>25</sup> If the ventriculomegaly is due to hydrocephalus infants do best when the shunt is placed postnatally.

### Dandy–Walker malformation

This incorporates cystic dilation of the fourth ventricle, an enlarged posterior fossa with upward displacement of the tentorium and cerebellar vermian hypoplasia. A definitive diagnosis cannot be made until after 18 weeks' gestation as normal cerebellar hemisphere fusion is not complete until 17 weeks' gestation. There is an association of Dandy–Walker malformations with chromosomal abnormality in up to 45%. It should be noted that an enlarged cisterna magna in association with a vermian defect or other cerebellar anomaly may be a benign condition. The outcome for Dandy–Walker malformations and its variants ranges from normal to severe disability. All the clinician can offer is detailed screening for associated abnormality and the assessment of any chromosomal abnormality.

### Cerebellar hypoplasia

Spinal dysraphism may be associated with cerebellar hypoplasia. Other forms are genetically determined, the most prominent of which is probably Joubert syndrome, whose postnatal clinical features include episodes of overbreathing, ataxia, abnormal eye movements and severe learning difficulties. Cerebellar hypoplasia may be associated with abnormality of gait, eye movement, epilepsy and learning difficulties, but is compatible with normal neurodevelopmental outcome.

### Cranial cystic lesions: developmental or destructive in origin

Midline lesions include holoprosencephaly, a Dandy–Walker malformation or cerebral hypoplasia. An arachnoid cyst may also be considered. An arachnoid cyst is often associated with underdevelopment of adjacent brain parenchyma. If a cyst is within the third ventricular region an aneurysm of the great vein of Galen should be considered.

If the cyst is asymmetrical or lateralized this is most often associated with destructive causes, which in turn may result from systemic disease of the fetus, mother or placenta. Prognosis will depend on the site and extent of the lesion.

## DEVELOPMENT OF THE SPINAL CORD

The spinal cord extends into the tail of the embryo until days 44–51. Once the filum terminale and conus medullaris have formed the conus assumes a higher and higher position within the vertebral canal. This is thought to be due to differential growth of the vertebrae, which are growing more rapidly than the spinal cord. By week 31 the spinal cord has reached its adult level of L1.

As the neural folds first fuse to form a tube the walls are composed of a single layer of columnar epithelium. These cells proliferate and the neural tube walls become thickened. The central canal is initially relatively large but as the volume of gray and white matter increases they become smaller. A cycle of growth follows so that cells eventually give rise to all the neural and macroglial cells in the CNS.

Once the neural tube has closed the ventricular layer gives rise to neuroblasts and glioblasts. Radial glial cells form the glia limitans, along with guiding neurones. Neuroepithelial cells produce ependymal cells, which will line the ventricular system of the brain, choroid plexuses and the central canal of the spinal cord.

At 33–43 days a second layer, the marginal zone (subpial or molecular layer), appears outside the ventricular zone. This eventually forms the white matter.

The alar plate forms the dorsal gray columns, the basal plates the ventral and lateral gray columns. Axons from unipolar neurones in the spinal ganglia enter the spinal cord and form the dorsal root ganglia, as axons from the ventral horns grow out of the spinal cord and form the ventral roots of the spinal cord.

From the beginning of week 12 ascending, descending and propriospinal fibers invade the marginal zone.

The third layer of the neural tube, the intermediate layer (middle or mantle layer) formed from neuroblasts by 38–40 days is located between the ventricular and marginal zones. This forms the gray matter.

Three periods of synaptogenesis have been described. These include the spinal reflex activities at 8 weeks when the fibrous connections to the spinal reflex arch are complete, the onset of local activities with a rapid increase in axodendritic synapses (9.5 weeks) and multiple responses at 13–15 weeks with a rapid increase in axosomatic synapses. The first observable movements are seen at 7.5 weeks.

## NEURAL TUBE DEFECTS

The term includes anencephaly, encephaloceles, cranial meningoceles and the various forms of spinal bifida.

Primary nonclosure of the neural tube is the most likely mechanism in the formation of neural tube defects. The process should be complete by 23–26 days. van Allen et al<sup>26</sup> suggested five separate sites of closure along the length of the neural tube. At the lower sacral end a process of neurulation is followed. There is a condensation of mesenchymal cells arriving from the primitive streak followed by canalization.

### Mesodermal defects

There may be bony defects ranging from failure of fusion of the complete spine (total rachischisis) to simple deficiencies of the lower lumbar spinous processes as part of a spina bifida occulta. Hemivertebrae may give a scoliosis and the associated ribs may be absent or fused. Bony spurs occur in diastematomyelia. There may be absence of the sacrum or sacralization of the lower spine. Klippel–Feil anomaly involves fusion of cervical vertebrae, with severe disruption of the cervical spine. This causes marked retroflexion of the head in iniencephalus where there is also complete lack of fusion of the neural tube.

Other mesodermal defects such as angiomas, lipomas, dermoids, renal abnormalities with pelvic kidney or horseshoe kidney may be added to the bony spectrum.

### Ectodermal defects

A defect in the neuroectoderm is known as myelodysplasia. This may manifest as disruption of the histological architecture of the spinal cord (multiple anterior horns, several central canals, abnormal neurones), syringomyelia, failure of fusion of the cord so that there is a flat neural plaque rather than a fused tube (myelocele), double neural tube (diplo-myelia), tethering of the cord or herniation through the bony defect as a meningocele or myelomeningocele.

Other ectodermal defects include dimples, sinuses, skin defects, hairy patches, tails and cutaneous capillary hemangiomas that can occur in any combination.

### INCIDENCE

Cuckle and Wald<sup>27</sup> showed that the birth prevalence of anencephaly and spinal bifida declined by 80% from 3.15 to 0.6 per 1000 births between 1964 to 1972 and 1985. Prenatal diagnosis followed by termination (achieved by measurement of the serum alpha-fetoprotein and by ultrasound) accounted for 31% of the decline. The increased risk in monozygotic twin pairs and in the siblings and half-siblings of affected children indicate a genetic component to the risk. The 1983 UK Medical Research Council trial of folic acid, mineral and vitamin supplementation indicated that folic acid had a protective effect of 72% at a daily dose of 5 mg. The first genetic risk factor for neural tube defects identified at a molecular level is C677T (alanine to valine), polymorphism in the gene encoding for the folate dependent enzyme 5,10-methylene tetrahydrofolate reductase (MTHFR). Following the work of the MRC Vitamin Study Group<sup>28</sup> it is now recommended that folic acid, 0.4 mg, should be given to all women planning a pregnancy.

### SPINA BIFIDA OCCULTA

Spina bifida occulta may present in several ways.

An incidental radiological finding of a narrow split in the fifth lumbar or first sacral spinous process is of no clinical significance. It is very common in young children and the incidence lessens with age.

A cutaneous lesion in the form of a small nevus, hemangioma, tuft of hair, sacral pit or soft lipomatous swelling should be taken as a warning signal that there may be an underlying abnormality. This may consist of a bony abnormality with bifid spinous processes but can also signify an underlying abnormality of the spinal cord with an associated myelodysplasia, lipoma, diastematomyelia or neuroenteric cyst. These cutaneous lesions should be taken as an indication for imaging of the whole neuraxis, using ultrasonography in babies or MRI of the spine in older children, even when there is no neurological deficit.

### Myelodysplasia

This term is used to indicate that there is an abnormality in the development of the spinal cord. There may be several central canals, several anterior horns or disorganization of the 'muscle nuclei' so that specific muscles do not form properly. The characteristic clinical findings are often referred to as myelodysplasia. There is usually a cavovarus deformity of the foot, which may be small so that shoe sizes are different. The leg on the affected side is shorter and appears to be the leg of a younger child. It is cold and often shows erythrocyanosis. It may be difficult to demonstrate definite weakness.

### Tethering

Tethering of the cord refers to persistent caudal attachment through the filum terminale. It may lead to damage from traction and repeated movement of the spine. The child may present with weakness in one leg or with bladder problems and progressive neurological deterioration is a definite indication for surgery. Whether tethering without neurological

deterioration in the legs should be operated upon remains an unanswered question. If operation is not undertaken then careful neurological follow-up is mandatory, especially at peak growth periods. With MRI scanning, it is now possible to diagnose the condition more easily and criteria for operation should become clearer. Serial somatosensory potentials may also assist in diagnosis of progression.

### Diastematomyelia

A different cause of tethering is a bony or fibrocartilagenous spur, which arises from a vertebral body and passes between the halves of a bifid cord – diastematomyelia. In some cases this fixes the cord and results in increasing traction with growth. In other cases the cord divides well above the spur and passes around the diastematomyelia in two separate dural canals, i.e. a diplomyelia.

Damage from tethering or compression may cause spastic paraplegia. More frequently, however, the child presents with distal weakness of the foot, with clawing of the toes and equinovarus posture and weakness of the peronei. Dribbling incontinence of urine may be an early feature and there may be sensory loss in the sacral territory, loss of ankle jerk and anal reflexes and trophic changes in the feet. Neurological deterioration in the presence of bony spur is an indication for removal, but removal of any bony spur demonstrated to put the cord at risk during growth should be considered before the development of neurological signs.

### Intraspinal lipoma

A cutaneous lipoma or lipomeningocele may penetrate in dumb-bell fashion into the spinal canal. It may cause increase in pressure within the canal. Treatment of a lipoma can be difficult as the cord itself as well as nerve roots may be enmeshed in fatty tissue.

### Infection

Infection may be the presenting feature of dermal sinuses. Blind pits over the coccygeal region are rarely associated with communication to the theca but focal infection with abscess formation may be a nuisance. Pits over the sacrum itself, especially at the site of the caudal neuropore, are of much more concern, as there may be a direct communication with the theca and therefore a risk of recurrent meningitis. These should be electively excised in the neonatal period.

## SPINA BIFIDA CYSTICA

### Meningocele

In this condition there is a defect in the spinous processes (spina bifida), together with herniation of the meninges through the defect to form a cystic mass on the back (Fig. 22.10).

There may be cover by thick skin with little risk of rupture or infection or by a thin transparent membrane; there may be skin at the sides and a thin blue membrane over the top. There is no myelodysplasia or cord within the sac in the pure cases and the child is neurologically completely normal. Hydrocephalus is usually absent and simple repair of the defect can be carried out as an elective procedure. The result should be a normal child. Ultrasound of the head should be performed to be sure that there is no associated hydrocephalus and ultrasound of the abdomen to be sure there is no associated renal abnormality.

### Myelomeningocele

#### Spinal lesion

The spinal cord is an open flat plate on the surface of the bulging meninges. It is not known whether the developmental abnormality itself, intrauterine damage, secondary ischemia, trauma to neural tissue during delivery or postnatal infection is the principal cause of the neurological deficit. Exposure of neural tissue, in normal fetal lambs, to amniotic fluid results in neurological dysfunction of legs and bladder.<sup>29</sup> Stimulation of the exposed neural plate shows that all the muscles of the legs have intact innervation to the exposed plaque. The lower motor neurones are intact but these are not connected to

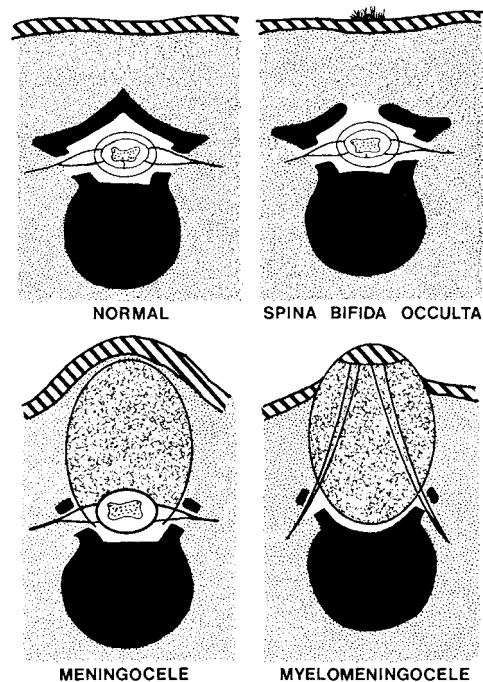

Fig. 22.10 Classification of spina bifida.

higher centers at the upper end of the plaque. These connections are lost as the plaque dries out or is infected. The fetus at 12 weeks of gestation can be shown to have talipes and evidence of neuromuscular imbalance in utero. There is no doubt that secondary postnatal injury may occur, but operation at birth does not reverse all the neurological deficit. An open myelomeningocele is liable to infection (Fig. 22.11). Surface infection leads to meningitis or ventriculitis, which is the usual cause of death in untreated patients. If the open lesion is not closed there is gradual epithelialization of the lesion over a period of weeks or months. The end result is inferior to elective surgical closure; low-grade infection results in further loss of spinal cord function, there is ugly tender scarring on the infant's back and there may be tethering of nerve roots, which can be very difficult to treat at a later date.

#### Patterns of spinal cord involvement

**Type 1 cord lesion.** Complete absence of function below a certain segmental level, which results in a flaccid paralysis, loss of sensation and loss of all reflex movement and tendon reflexes below that level. Knowledge of the segmental innervation of the lower limb muscles allows the segmental level to be determined from examination of the lower limbs.

**Type 2 cord lesion.** Here there is voluntary control of muscles, which have normal innervation and are in direct communication with the long tracts of the brain above the level of the lesion. At the level of the lesion there may be a complete loss of all function, voluntary and reflex, and of sensation. This may extend over a very short area, i.e. one segment, or over several segments of the spinal cord. The cord then resumes reflex function, as an isolated cord segment. There will be no sensation and no voluntary movement of the muscles in this isolated cord segment. Muscles will, however, respond to dermatome stimulation tapping of the muscle, tapping of the tendon and pinprick.

Examination of the lower limbs will determine the neurological level of paraplegia and the prognosis for walking, type of deformity and degree of future handicap. The level of the lesion, level of vertebral abnormality and neurological level are not identical and one should not look at the back lesion and guess the neurology.

Direct stimulation of the muscles which do not move is possible by dermatome-to-myotome stimulation, i.e. as the corresponding

(a)

(b)

Fig. 22.11 (a) Meningomyelocele at birth. (b) Bulging meningomyelocele at a few hours of life.

dermatome is stroked, if there is reflex activity the muscle supplied by that segment will contract. In addition to testing the cremasteric reflex (L1), knee jerk (L3–4), ankle (S1–2), anal and bulbocavernosus reflexes (S4–5), for exaggerated flexor withdrawal reflexes, contraction of the muscles of the perineum on stimulating the perianal region and contraction of the short toe flexors by flicking the toes should be assessed.

Reflexes not normally easily elicited, such as tendon jerks of the hamstring muscles, adductors and tibialis anterior, may be elicited, and in very high lesions, adductor and patella clonus may be seen.

If the isolated cord segment is long, then complex reflexes such as flexor withdrawal responses may occur, giving the impression of voluntary leg movement. This has led to confusion in the past as to the degree of paralysis and the tendency to give a misleadingly good prognosis in the neonatal period.

If the area of isolated cord is limited to the sacral segments, then ankle clonus with a brisk ankle jerk and exaggerated anal reflex will be seen together with a spread of the response when stimulating the perianal region to cause toe flexion and flexion of the lateral hamstrings. Equally, tapping the toes in order to elicit the toe jerk will produce flexion of the knee and a contraction of the anus. The segment of cord showing a lower motor neurone loss of activity is more often in the region of the abdominal muscles, which may be completely paralysed, causing a lumbar hernia and a pot belly.

### Mechanism of deformity

The level of deformity often determines the neurological level, e.g. involvement below T8 is associated with paralysis of the abdominal walls and all the lower limb muscles. The lower limb deformities arise from two mechanisms:

1. Muscle imbalance, e.g. dislocation of the hip when the flexors and adductors (L1–3) overcome the weak gluteal extensors and abductors (S1–2). Hip adduction is a potent cause of posterior hip dislocation. Involvement below L4 causes the lower limb muscles innervated from above this level (hip flexors, hip adductors, quadriceps and tibialis anterior) to be strong and under voluntary control while their antagonists are paralysed. This causes the characteristic flexed hip, extended knee (*genu recurvatum*) and equinovarus foot. If the tibialis anterior is active as a dorsiflexor (L4) while the calf muscles as plantarflexors (S1–2) are paralysed, then dorsiflexion and inversion of the foot will occur.
2. Immobility in utero. The fetus may present as a breech and the immobility results in secondary positional deformities adding to the neurogenic deformity (Fig. 22.12).

In 5% of cases the spinal cord is split with only one half of the cord exposed to the surface; the other half remains in the spinal canal and functions normally. In this case only one leg will have a neurological deficit.

### Counseling families

Parents are concerned as to whether their child will walk. In a 25-year follow-up of 71 children treated at birth in an aggressive, nonselective manner, Bowman et al<sup>30</sup> observed that 46% of young adults (33/71) walked the majority of the time (75–100%). An additional 13% (9/71)

Fig. 22.12 Talipes due to muscle imbalance.

walked 25–50% of the time. Forty-one percent (29/71) got around only with the aid of a wheelchair. As one might expect children with lower defects were more likely to walk the majority of the time [93% of children with a sacral lesion (14/15) walked 100% of the time]. No one with a lesion level of L3 or above walked the majority of the time. These figures closely match those reported from Northern Ireland.<sup>31</sup> Experience shows many, of course, do more than walk, participating in dancing, swimming, basketball, horseback riding, wheelchair sports and so on.

### Intelligence

Bowman et al<sup>30</sup> reported that 85% of the 71 young adults followed by their group were attending or had graduated from high school and/or college, and 63% attended regular classes. Forty-five percent were actively employed, and almost 10% worked as volunteers. Most of the 71 lived with their parents, although 11 lived independently and two were married.

### Hydrocephalus

Historically, almost all newborns with spina bifida received shunts. Recent data indicate that these rates may be too high. The Children's Hospital of Philadelphia published shunt rates among 189 children treated for spina bifida between 1983 and 2000.<sup>32</sup> One hundred percent (35/35) of children with thoracic level lesions received shunts, compared with 88% (100/114) of children with lumbar lesions and only 68% (27/40) of children with lesions confined to the sacrum. The upper level of the spina bifida lesion appears to be a major determinant of the need for shunt placement. Fewer neurosurgeons are automatically placing shunts at the same time as the spinal lesion is closed.

### Continence

Bowman et al<sup>30</sup> noted that 85% of their young adults (60/71) used clean intermittent catheterization (CIC), and 90% of those (54/60) performed their own catheterization. For those on CIC, 15% always had urinary continence, 68% were dry the majority of the time (75–100%) and 7% were dry 50% of the time. Fifty-two percent of the young adults reported bowel control the majority of the time, and 52% reported 100% social bowel continence. McDonnell and McCann<sup>31</sup> reported renal impairment in 48% and 15% were on antihypertensive therapy.

### Other problems

McDonnell and McCann<sup>31</sup> reported 50–70% had scoliosis and 9% epilepsy. Pit-ten Cate et al<sup>33</sup> showed how additional medical problems are associated with poorer quality of life, as one might expect. However, the availability of resources to the family was found to help significantly; a clear message for community-based pediatric services.

## NEONATAL MANAGEMENT OF THE CHILD WITH A NEURAL TUBE DEFECT

Check for associated abnormalities, such as chromosome disorder or other malformations of the heart and kidney. The face of a child with a meningomyelocele may suggest Down syndrome. The head circumference, sutures and fontanel should be measured and cerebral and renal ultrasound should be routinely performed. X-ray of the spine may show hemivertebrae or gross disruption of the spinal architecture, which would make even sitting eventually impossible.

The lesion is carefully examined for tears in the membranes or leakage of CSF suggesting that operation should be early because of the risk of meningitis. The hips are examined for dislocation.

Detailed neurological examination is carried out with the child warm and recovered from the birth. Sensory testing is carried out first with the child quiet; the skin is stimulated with the end of a straightened paper clip, starting in the saddle area and progressing through the sacral and lumbar territory. Look for facial grimace or a cry.

Following sensory testing, and with the baby active and crying so that there is spontaneous movement of the upper limbs, determine the amount of spontaneous movement in the lower limbs as part of the baby's doggy paddling and cycling movements. It should be possible to give each muscle group an MRC grading of 1–5 and a voluntary motor level down to which the child can move in response to cerebral motor drive can be defined.

Gross hydrocephalus at birth is predictive of severe disability, [an occipitofrontal circumference (OFC) more than 20 cm above the 90th centile or a cortical mantle less than 150 mm]. Serious spinal deformity, absence of voluntary movement below L2 and the presence of other major defects are the factors which help in deciding whether early immediate operation should be performed or whether one should delay surgery to see how the child progresses over the first week or so. Delay does not worsen outcome. Later plastic repair of the back that has granulated is still feasible.

If immediate closure is not undertaken and the spinal lesion granulates without meningitis developing, hydrocephalus may progress. This may lead to impairment of intelligence, and should be prevented by insertion of a ventriculoperitoneal shunt. The parents should be encouraged to feed and handle their baby. During this period many questions can be answered, anxieties are allayed and genetic counseling undertaken. The support of a medical social worker, experienced health visitor or community pediatric nurse is invaluable and the parents can be put in touch with one of the local parent support groups.

Bruner et al<sup>34</sup> reported a 35% reduction in hydrocephalus following intrauterine repair of myelomeningoceles probably linked to a 60% reduction in hindbrain herniation. However the risk of oligohydramnios and preterm labor were significantly increased. Their study compared 29 fetuses operated on between 24 and 30 weeks' gestation with 23 historical controls. Further careful assessment of prenatal intervention is required.

More recently the same group's study<sup>35</sup> of 116 fetuses operated on since 1997 has determined which factors present at the time of intrauterine spina bifida repair predict the need for a shunt in the first year of life. Sixty-one of 116 of the fetuses (54%) required the placement of a ventriculoperitoneal shunt before the age of 1 year. The upper level of the lesion was the strongest predictor of shunt requirement [adjusted odds ratio per 1 level increase with the use of continuous variables (S1 through T10), 1.73 (95% CI, 1.22–2.44)]; followed by gestational age at the time of surgery [adjusted odds ratio per 1 week increase with the use of continuous variables, 1.37 (95% CI, 1.06–1.77)]; and preoperative ventricular size [adjusted odds ratio per 1 unit increase with the use of continuous variables, 1.17 (95% CI, 1.01–1.36)]. This study suggests that, among fetuses who underwent operation in utero for spina bifida, fetuses with a ventricular size of less than 14 mm at the time of surgery, fetuses who had surgery at 25 weeks of gestation or sooner, and fetuses with defects that were located at L4 or lower were less likely to require ventriculoperitoneal shunting for hydrocephalus during the first year of life. Only two intrauterine/neonatal deaths occurred. However, clearly this is a specialized intervention and further careful assessment is required.

## THE LATER MANAGEMENT OF THE CHILD WITH A NEURAL TUBE DEFECT

### Motor problems

It should be possible to make a reasonably accurate prediction of the child's future mobility even in the neonatal period if an accurate clinical neurological assessment is made (Table 22.4).

Orthosis refers to lightweight plastic splints which are malleable when hot, but firm when cool and can be molded to any required position. Reciprocal gait orthoses are hinged splints, which invoke forward momentum when the weight of the wearer is swung from side to side at the hip. They follow the same principle as the toy

Table 22.4 Prediction of walking ability in myelomeningocele

Voluntary motor level	Probable walking ability
T6–L2	Chair Crutches – swing through Parapodium Swivel walker RGO, HGO
L3	HKAFO RGO, HGO with sticks or tripods
L4	KAFO, HKAFO AFO
L5	AFO KAFO
Sacral	nil or AFO

AFO, ankle/foot orthosis; RGO, reciprocating gait orthosis; HGO, hip guidance orthosis; HKAFO, hip/knee/ankle/foot orthosis; KAFO, knee/ankle/foot orthosis.

animals that will 'walk' down a slope, each limb rocking from side to side.

The child with a purely sacral lesion, as for example with sacral agenesis, or a very low meningomyelocele, will have problems with the feet due to paralysis of the intrinsic muscles of the feet, weak calf muscles and weak hip extensors. He will walk with a waddle and will need boots to support the ankles. He will also have a neurogenic bladder and will require a bladder regimen.

Paralysis below L3–4 is compatible with walking aided with sticks and below-knee calipers. The effects of the spinal lesion may be compounded by the effects of ataxia from hydrocephalus or hemiplegia as a result of shunt malfunction, ventriculitis or puncture porencephaly. The child with a high lumbar lesion was in the past sentenced to immobility in a wheelchair but the use of reciprocating gait orthoses or hip guidance orthoses means that these children can now be mobile in the erect posture.

It may be necessary for an orthopedic surgeon to perform tenotomies in the neonatal period or later to correct muscle imbalance, for example the very tight tibialis anterior that may occur in an L4 lesion. Talipes will need correcting and hips will need to be released and put back into joint. Scoliosis may require surgery in adolescence.

## Nonmotor neurological problems

### Sensation

The sensory level in myelomeningocele, i.e. the lowest level of normal sensation, is usually within one or two segments of the motor level. As a result of cutaneous anesthesia there is a constant danger of painless ulceration. Pressure sores may develop over the sacral tuberosity, especially if incontinence has led to maceration of the skin. Sensory loss may become more of a problem in the future with the use of reciprocating gait orthoses when the risk of Charcot joints (i.e. neurogenic arthropathy and painless fractures) is added to the list of problems. The feet are often cold, blue and erythrocyanotic due to poor peripheral perfusion.

Burns may occur from hot-water bottles or sitting on radiators. Shoes which are too tight or failure to recognize the effects of intense cold in the winter can both result in gangrene of the toes.

### The neurogenic bladder

The bladder receives its nerve supply from three sources. First, the parasympathetic via the nervi originates from the sacral roots S2–4 which control detrusor contraction. Second, a sympathetic component supplies the trigone and internal sphincter and allows opening of the bladder neck during micturition. It is also important in

sexual function when the internal sphincter is closed without any contraction of the detrusor. The third supply is via the pudendal nerve, which carries the voluntary control of the striated external sphincter.

The bladder and bowel will be involved in most cases, but the type of bladder involvement depends upon the type of lesion.<sup>36</sup>

If the lower limbs show signs of lower motor neurone denervation in the muscles innervated from S2 to S4 (type 1 lesion), i.e. calf, intrinsic muscles of the foot, anal sphincter and pelvic floor, then a weak or totally paralysed bladder (acontractile) is to be expected. Lack of tone in the anal sphincter shows as a patulous anus and loss of the normal gluteal fold so that the anus appears wide open on top of a mountain rather than in a valley. Depending on the degree of resistance of the bladder outlet, such infants may have constant dribbling of urine with an empty bladder or overflow incontinence from a distended bladder. Ureteric reflux may occur at low pressures from such inert bladders in which the valvular effect of the intramural ureter is lacking.

In infants with an isolated cord lesion (type 2 lesion), where examination of the limb shows purely reflex activity in S2–4 (i.e. spastic calves, toe flexors with exaggerated reflexes, a very brisk anal reflex), a reflex type of bladder (contractile) is to be expected. The ideal automatic bladder, i.e. one with periodic complete reflex emptying, is rare in myelomeningocele. At best an intermittent detrusor contraction results in voiding of up to 100 ml of urine; at worst persistent dribbling may result from constant poorly coordinated detrusor contractions. Despite an active detrusor, which may generate pressures of over 100 mmHg in a small infant, the bladder emptying may be poor because of a high urethral resistance. This outlet obstruction is probably due to failure of relaxation of the striated external sphincter, which is normally under voluntary control via the pudendal nerve. This type of spastic bladder neck responds to stretching by further contraction and very high pressures result in back pressure with acute and severe hydronephrosis and hydronephrosis. Bladder rupture and urinary ascites can occur in utero. True bladder neck obstruction is relatively uncommon. Dilatation of the upper urinary tract may occur in both the flaccid and the high pressure bladder. Stagnation with incomplete bladder emptying and dilatation of the upper urinary tract inevitably leads to the risk of infection. Chronic pyelonephritis may lead to renal failure and hypertension before adult life is reached.

### Assessment of the upper renal tract

The presence of hydronephrosis is detected using ultrasound. The presence of ureteric reflux and the adequacy of the bladder neck and urethra can all be assessed using cystourethrography. Renal function is assessed using biochemical estimations such as urea, electrolytes and creatinine together with a chromium or DMSA scan.

### Assessment of the neurogenic bladder

Clinically the most important part of the assessment is to watch the child actually pass urine. If the urine can be passed in a stream one knows that there must be a coordinated detrusor contraction. If the stream is good, i.e. the child can 'pee in a parabola', there can be no serious bladder neck obstruction. In the older child, the rate of passing urine can be measured as ml/unit time by getting the child to pass urine into a container with an electronic measuring device which draws out a graph of the rate of urination. This is a measure of detrusor contraction and bladder neck obstruction. The infant should be held up to see if there is any dribbling dependent on position and light suprapubic pressure applied to assess effective bladder neck contraction to allow continence and bladder filling.

Investigation of the bladder in the neonatal period is undertaken to decide whether early intervention is necessary or not. If the upper renal tract is normal on ultrasound and the baby passes urine or it can be easily expressed, one can wait until 4 months of age for detailed urinary investigations. If there appears to be bladder outlet obstruction, high pressure

bladder and dilation of the upper renal tract then catheterization from birth may be necessary in order to preserve renal function.

### **Cystometrogram**

This is performed either by a urethral catheter into the bladder when the effects of adding small aliquots of saline upon the pressure is monitored or, more physiological but more invasive, a suprapubic cystometrogram is performed using two catheters inserted into the bladder by suprapubic puncture. One of these is used to fill the bladder at the physiological rate of 2 ml/min and the second to measure pressure. The bladder volume, sensation and pressures at which urethral sphincters open can then be measured and it is possible to look at micturition and urethral resistance in a way that is not possible with a catheter per urethra.

### **Management of the neurogenic bladder**

All children with known or suspected spina bifida should have videourodynamic assessment.<sup>37</sup>

**The safe bladder** has a normal upper renal tract with normal renal function and no secondary pressure transmitted to the ureter or renal pelvis. There is a residual urine of less than 20ml with normal pressures and no outlet obstruction, either because the bladder is completely normal (toilet-training program is all that is required), or the child can safely empty the bladder by suprapubic manual pressure. This requires careful monitoring for urinary tract infection as well as regular monitoring of the upper renal tract to be sure that secondary damage is not occurring.

**The unsafe bladder** has associated hydronephrosis and hydro-ureter, a high residual urine, a high intravesical pressure and/or the presence of outlet obstruction. Adequate bladder drainage is needed to avoid progressive damage to the kidneys, with resultant renal failure. The unsafe bladder may require catheterization in the immediate neonatal period. A silicone catheter may be changed every 4–6 weeks in the first few years of life after which intermittent self-catheterization can be taught once the child is old enough. Urinary diversions such as ureterostomy or a colonic loop are now only rarely indicated. Bladder neck obstruction can be treated by per urethral resection or pudendal neurectomy or bladder neck Y-V plasty may be required later to try and achieve relief of bladder neck obstruction without producing incontinence.

Toilet training will occasionally achieve continence for the neurogenic bladder not thought to be under voluntary control. There is a need to regulate fluid intake, e.g. at night, and to go to the toilet regularly, utilizing suprapubic pressure to induce voiding, at first hourly. Constipation should be avoided, urinary tract infections should be carefully monitored, and when there is voluntary control, double micturition should be practiced as a routine. Pelvic floor stimulators are not of proven benefit and can have complications.

Most children are managed either by a simple toilet-training regimen or with indwelling and then intermittent catheterization. Drugs may be used to increase or decrease bladder tone and capacity to keep the child dry between catheterizations. Cholinergic drugs such as carbachol, bethanechol chloride or distigmine bromide will increase detrusor contraction while anticholinergic drugs such as propantheline, imipramine and oxybutynin will decrease detrusor contractions. Beta-adrenergic agonists such as ephedrine will increase the tone in the bladder neck while alpha-adrenergic blockers such as phenoxybenzamine will decrease the tone in the bladder neck. These have a useful but limited place in a small percentage of children.

Urinary tract infection is a constant hazard with the risk of pyelonephritis and this, together with the effects of back pressure on the kidney, may result in renal failure by the teenage years.

### **Sexual function**

Motor problems are likely to lead to physical difficulty and result in problems with sexual intercourse. Only small numbers of young adults with spina bifida have any sexual experience and very few females have children even though there is no reason why they should not become pregnant and have a normal delivery. In the male, impotence will depend

upon the pattern of sympathetic and parasympathetic involvement. Failure of closure of the bladder neck during ejaculation will cause semen to enter the bladder and not the posterior urethra.

### **Bowel**

Chronic constipation, with gross dilation of the descending colon and overflow incontinence, is common. Prolapse of the rectum may occur in infancy, but rarely remains into school age. Chronic fecal retention may further impede bladder drainage. The anal sphincter, like the bladder neck, may be either patulous and incompetent or tight and spastic. Sensation may be absent so that severe constipation, with retention of feces or fecal incontinence, may occur. In spite of the neurogenic problems, the bowel appears to be more amenable to training than the bladder. The child should take a high-fiber diet and it may be necessary to use stimulative laxatives such as Senokot or fecal softeners such as Dioctyl. The time of day when the bowel would naturally empty should be sought. This need not necessarily be the morning and toilet training with abdominal pressure will be successful in at least half of the cases. Fecal impaction should be avoided as this presses on the bladder neck and may result in both urinary incontinence and secondary spurious diarrhoea, which can be cured by emptying the bowel. In occasional patients regular manual evacuation is necessary to maintain continence.

### **Teenage problems**

As the pubertal growth spurt occurs, several problems result other than sexual (see above), and the realization of the degree of disability may lead to a reactive depression. Renal tract problems cause most anxiety, especially if renal damage has progressed to the point of considering the ethics of chronic dialysis or transplantation. Scoliosis may be greatly aggravated by growth and pain at the site of the healed lesion may cause a lot of discomfort. Traction on the nerve roots due to tethering may cause downward pull at the foramen magnum. It is the medullary cervical junction which causes most problems and is the most difficult to deal with. Stretching of the medulla with obstruction at the aqueduct and the fourth ventricular foramina from the Arnold–Chiari formation may cause an isolated fourth ventricular hydrocephalus. This may require separate shunting. The pressure may be projected down the central canal of the spinal cord so that a hydromyelia results with gross distension of the cord, producing a string-of-sausages appearance. A localized dilation may occur as a syringomyelia. These brainstem and cervical spinal abnormalities present as drooping, swallowing difficulties, bilateral sixth and seventh paresis, Erb palsy posture, weakness of shoulder elevation or wasting, weakness and loss of use of the hands. Removal of tethering, shunting fourth ventricles, cerebellar tonsillectomy and removal of the arch of the atlas and part of the foramen magnum-impacted tissue may be attempted to try and prevent progressive loss of function.

## **HYDROCEPHALUS**

### **DEFINITION**

Hydrocephalus denotes an increase in size of the CSF spaces associated with an increase in intracranial pressure (ICP).

### **INCIDENCE**

The incidence of hydrocephalus per 10 000 births around the world is particularly high in Alexandria in Egypt (20.8), and Belfast (12.5) and Dublin (35) in Ireland. A collaborative perinatal survey<sup>38</sup> found an incidence of 15 per 10 000 births, only half of whom were evident at birth. These figures are, however, now too high for the UK, as hydrocephalus associated with spina bifida, secondary to intraventricular hemorrhage in the premature infant and secondary to haemophilus meningitis and tuberculous meningitis, have all declined. The current prevalence<sup>39,40</sup> of congenital and infantile hydrocephalus is between 0.48 and 0.81 per 1000 births (live and still). The ability to diagnose severe hydrocephalus antenatally by ultrasound means that some cases are prevented by termination.

## PATHOPHYSIOLOGY

### Factors that cause ventricular dilation

The normal intracranial pressure in the human represents a balance between the intracranial contents, i.e. blood, brain and CSF. For the CSF compartment, any increase in production or obstruction of flow or absorption will result in ventricular dilation.

### Production of CSF

In normal subjects, CSF is formed at a rate of 0.3–0.5 ml/min. In children with hydrocephalus on external drainage the CSF production rate is similar. CSF production occurs by two mechanisms:

1. That dependent on choroidal capillary blood flow. This is a two-step process with, first, an ultrafiltrate of plasma produced hydrostatically through the lax choroidal capillary endothelium (blood–CSF barrier) and, second, an active process involving secretion of sodium into and out of the apical choroidal villi. The raised osmotic pressure causes water to follow passively.
2. That due to a direct neurogenic stimulation of choroidal villi (which have beta<sub>1</sub>-adrenergic receptors, cholinergic receptors and GABA receptors), which is independent of choroidal blood flow. Stimulation of adrenergic fibers may reduce CSF flow by approximately one third.

The production rate is similar in newborn and older children, despite the obvious difference in size of the choroid plexus. It is postulated that early maturation of enzyme systems may be responsible for the similar production rates.

A number of factors influence the CSF formation rate. Increased secretion may occur with a choroid plexus papilloma. Furosemide and acetazolamide reduce CSF production. Hypothermia will also reduce the rate of production and although the CSF formation rate is usually independent of the intracranial pressure, when high intraventricular pressures exist the production rate falls, due to decreased choroidal perfusion. Ventricular outflow rates appear to be pulsatile so that peaks and troughs of CSF evacuation occur from the ventricles when measured objectively in children undergoing closed ventricular drainage.<sup>41</sup>

### Obstruction

A choroid plexus tumor may not only induce excessive CSF production, but may also block the outlet of the ventricle. Intracranial hemorrhage or meningitis may cause leptomeningeal adhesions and obstruction to the CSF flow as well as impairing absorption by blocking arachnoid granulations. A common site for obstruction is the aqueduct of Sylvius. Congenital atresia may result in an inadequate lumen or a total blind-ending channel with forking of the upper and lower components of the aqueduct. Occasionally there is a filamentous or membranous obstruction, which may be broken down either by an increase in the intraventricular pressure or by surgical bouginage from the fourth ventricle (which rarely succeeds because of inadequate development of the peripheral subarachnoid pathways). The aqueduct of Sylvius may also be occluded by organized blood clot after intracranial hemorrhage, inflammatory exudate following ventriculitis or from an aqueductitis resulting from mumps.

Obstruction to CSF flow at the outlet foramina of the fourth ventricle may be secondary to intracranial hemorrhage or infection or may be due to congenital failure of the foramina of Magendie and Luscka to open during development. Occlusion of the fourth ventricle foramina results in a fourth ventricular cystic dilation with atrophy of the cerebellum (the Dandy–Walker cyst). Tumors or clots, cysts or abscesses within or adjacent to the ventricular system may result in hydrocephalus. Thalamic tumors, and giant cell astroglomas in tuberous sclerosis may obstruct the foramen of Monro and third ventricle and pontine or brainstem gliomas may distort the aqueduct of Sylvius, although frequently such pontine gliomas are invasive throughout the brainstem and do not usually cause a gross hydrocephalus. Cerebellar tumors will affect the CSF flow from the fourth ventricle. A choroid cyst of the third ventricle may give rise to intermittent high pressure and hydrocephalus, by obstructing the

foramen of Monro in a ‘ballcock’ fashion. During distention of the cyst or venous distention about it there is obstruction of CSF flow through the foramen of Monro. With a possible change of posture, the obstruction may be rapidly released and the pressure decline. Children with cysts of the third ventricle frequently present with a ‘bobble-headed doll’ syndrome and progressive loss of intellect with frontal horn dilation.

### Decreased absorption

Decreased absorption may result from obstruction of the arachnoid villi or other peripheral subarachnoid pathways. Absorption (unlike formation) of CSF is a pressure-dependent phenomenon and increases linearly with CSF pressure. Normally CSF absorption begins at a mean pressure of 5 mmHg.

### Factors causing progression of hydrocephalus

Observations in experimental hydrocephalus suggest that after CSF obstruction the ICP rises acutely. This is followed by a stage of periventricular edema with expanded ventricles and subsequently by an increase in CSF absorption. Ventricular dilation and its eventual size depend on the external support of the brain. In infants up to 16 months of age the support of the brain is weak from the poorly myelinated soft parenchyma and there are unfused sutures. Clearly the level of pressure is important at first in the pathogenesis of ventricular dilation, together with the known increase in the outflow resistance and a higher ‘pressure volume index’ (PVI) than could be predicted from the volume of the cranial and spinal axis.

In term and preterm infants we frequently see levels of intraventricular pressure of 5 mmHg (above normal for age) which are sufficient to interfere with the cerebral blood flow velocity and have the potential to cause ischemia.

A number of physiological buffers come into play in response to the hydrocephalus. There is collapse of cerebral veins, a shunting of CSF from the ventricular to the spinal CSF compartment, expansion of the skull and an increase in the CSF absorption from the raised pressure. There may also be increased CSF absorption about the spinal nerve roots and paranasal sinuses. Once these compensatory mechanisms have been exhausted, then further progression of the hydrocephalus will occur.

The sequence of events is that at first the pressure will increase. The dilation of the ventricles in response to this high pressure is termed ‘active or progressive hydrocephalus’. Finally the pressure returns to the normal levels with dilated ventricles, a state of arrest (*compensated or arrested hydrocephalus*). Sometimes the active process may be followed by an intermittent pressure pattern with ventricular dilation until the arrested state is reached. This intermittent pattern may be reversible. However, significant elevation of the pressure with increasing ventricular dimensions to the point where brain perfusion is compromised necessitates CSF diversion procedures before shunt-dependent or compensated arrest occurs.

### The effects of raised ventricular pressure

Raised intracranial pressure results in ischemia and/or brain shift. The ischemia results from a reduced cerebral perfusion pressure (CPP – mean arterial blood pressure minus intracranial pressure). At levels of CPP below 60 mmHg, in the older child, there is a progressive reduction in brain perfusion. At 40–50 mmHg, profound ischemia results. In the newborn, cerebral perfusion pressures of 30 mmHg may be associated with a normal neurodevelopmental outcome.

The subarachnoid space and the aqueduct are obliterated after shunting, presumably because they are used less, and the patient becomes totally shunt dependent.

Fourth ventricular entrapment, with ataxia, vomiting, cranial nerve disturbances and headache, is a result of outlet obstruction. Treatment is shunting of the ventricle itself. Fistulous communications and diverticula of the ventricles are usually an accompaniment of severe ventricular dilation. This produces a complex CT scan appearance and intraventricular contrast studies are needed to distinguish these from primary subarachnoid cysts.

## CLASSIFICATION AND ETIOLOGY

### Terminology

*Internal or noncommunicating hydrocephalus:* excess of CSF within the ventricular system up to the level of the outlet foramina of the fourth ventricle. The common sites of obstruction are at the outlet foramina of the fourth ventricle, the aqueduct of Sylvius or at the foramen of Monro.

*External or communicating hydrocephalus:* an increase in the ventricular volume and the subarachnoid spaces of the cranium and spine. The sites of obstruction are at the arachnoid villi or in the basal cisterns.

*Panventricular hydrocephalus:* dilation of the lateral, third and fourth ventricles (in aqueduct stenosis the fourth ventricle is small or of normal size – ‘triventricular hydrocephalus’). An *isolated fourth ventricle* (‘double compartment hydrocephalus’ or ‘trapped fourth ventricle’) occurs when there is outlet obstruction from that ventricle and stricture of the aqueduct.

*Unilateral hydrocephalus:* abnormal dilation of the body, frontal and/or posterior horn of the lateral ventricle on one side. This may be due to compression of the ventricular system on the opposite side, obstruction to one foramen of Monro, slit ventricle syndrome or a hemiparenchymal atrophy.

*Slit ventricles:* a reduction in the size of the ventricular system seen on CT scan, usually in response to excessive CSF drainage. The slit ventricle *syndrome* is distinguished from radiological slit ventricles by the presence of symptoms and clinical signs attributable to this overdrainage. The etiology of hydrocephalus is given in [Table 22.5](#).

## DIAGNOSIS AND ASSESSMENT

### Clinical features of progressive hydrocephalus

The symptoms and signs of progressive hydrocephalus in infants are shown in [Table 22.6](#).<sup>42</sup> The symptoms of infantile progressive hydrocephalus are vague and consist of irritability and vomiting but about half are without symptoms. The most common clinical sign is an inappropriately increasing head circumference, followed by a tense nonpulsatile fontanel, then clinical and radiological separation of the sutures, scalp vein distension with taut skin over the scalp. It is important to realize that the classic adult presentation of raised intracranial pressure is rare in children (headache, vomiting, papilledema). Vomiting is a nonspecific symptom in childhood, as are behavioral changes (irritability).

The most common sign of hydrocephalus, ‘sunsetting’ – the inability to look upwards, with depression of both eyes – may initially be intermittent and later continuous ([Fig. 22.13](#)). It is due to pressure on the superior quadrigeminal plate against the free edge of the tentorium causing a supranuclear paresis, which may be accompanied by paralysis of the fourth nerve.

Neurogenic stridor is a result of deranged lower brainstem function caused by bilateral corticobulbar disruption and is a feature of pseudobulbar paresis. Abnormalities of sucking and feeding may also occur with seriously raised intracranial pressure. Papilledema is rare, but distended retinal veins are common.

The symptoms of *chronic hydrocephalus* are an insidious deterioration in school performance, intermittent headaches over many months, behavioral and personality changes, failure to thrive and dizziness. These are distinct from the signs and symptoms of *arrested hydrocephalus* of long standing which include features of ataxic and spastic cerebral palsy, precocious puberty, mental retardation and specific learning problems. The clinical features of hydrocephalus with raised intracranial pressure may be extremely variable and any infant with a rapidly increasing head circumference should have cranial imaging.

Hydrocephalus should be considered in the older infant who presents with a large head and developmental delay (other syndromes of macrocephaly including fragile X and neurofibromatosis should also be considered).

Table 22.5 Etiology of hydrocephalus

<b>Causes of prenatally determined hydrocephalus</b>
Congenital (chromosomal) malformations
Maternal diabetes resulting in holoprosencephaly
Neural tube defects
Occipital meningocele and encephalocele
Cleland–Chiari II malformation
Dandy–Walker syndrome
Hydranencephaly
Multicystic encephalomalacia
Schizencephaly
Achondroplasia
Arachnoid cysts
Quadrigeminal plate cysts, retrocerebellar cysts, cysts of the cerebellopontine angle and supracellar cysts
Congenital craniosynostosis (e.g. Apert syndrome)
Agenesis of the corpus callosum and cysts of the cavum septum pellucidum and cavum vergae
Encephalocraniocutaneous lipomatosis
Isolated stenosis of the aqueduct of Sylvius
Sex-linked stenosis of the aqueduct of Sylvius
Hydrocephalus associated with giant hairy nevus (melanosis of the leptomeninges)
Aneurysm of the great vein of Galen
Hurler disease
Basilar impression
Osteogenesis imperfecta (rarely)
Paget disease
Colpocephaly
Lissencephaly
Say–Gerald syndrome
<b>Causes of acquired hydrocephalus</b>
Posthemorrhagic causes
Neonatal intraventricular hemorrhage
Subarachnoid hemorrhage
Subdural hemorrhage
Postmeningitic
Toxoplasmosis
Mumps (aqueductitis, ependymitis)
Pyogenic organisms (pneumococcus, haemophilus, etc.)
Cytomegalovirus
Other viral meningitides
Rubella
Tuberculous meningitis and tuberculoma
Space-occupying lesions
Tumor
Clot
Cyst
Abscess
Postasphyxial
Injury
<b>Other causes</b>
Stenosis of the aqueduct of Sylvius
1. Due to raised intracranial pressure with secondary kinking of the aqueduct
2. Due to aqueductitis and ependymitis associated with mumps, toxoplasma, tuberculomas, pyogenic meningitis, rarely cytomegalovirus, rubella and tumors
Dystrophia myotonia
Otitic hydrocephalus
Choroid plexus papilloma
Intrathecal contrast agents
Fungal infection (cryptococcus and blastomyces)
Cysticercosis
Sarcoidosis
Spinal tumor
Dural venous thrombosis
Isolated Chiari type I deformity

**Table 22.6** Most common clinical features of progressive infantile hydrocephalus (50% of cases are asymptomatic)

<b>Symptoms</b>
Headache or irritability
Vomiting
Anorexia
Drowsiness or lethargy
<b>Signs</b>
Inappropriately increasing occipitofrontal circumference (approx. 75%)
Tense anterior fontanelle
Splayed sutures
Scalp vein distention
Sunsetting (loss of upward gaze)
Neck retraction or rigidity
Pupillary changes
Neurogenic stridor
Decerebration

**Fig. 22.13** 'Sunsetting' due to loss of upward conjugate gaze.

### Clinical features of decompensated hydrocephalus

Additional signs of raised pressure (Table 22.7) suggest the possibility of shunt blockage. The median survival time for a ventriculoperitoneal shunt was 4.31 years in the Edinburgh study.<sup>43</sup>

Unusual features of raised ventricular pressure include neurogenic pulmonary edema, profuse sweating, ptosis, neurogenic stridor, pseudobulbar paresis and skin rashes.<sup>42</sup>

### Imaging

X-ray examinations of the skull, although not routinely indicated, may show a 'copper-beaten' appearance, shallow orbits and splayed sutures. CT, ultrasound or MRI scans will all define ventricular size. Although repeated ultrasound examinations may show progressive hydrocephalus, it is advisable to have a CT or MRI investigation prior to any surgical intervention. The CT scan provides information about the size and symmetry of the ventricles and whether there is any underlying pathology. A single CT scan, like a single ultrasound or MRI scan, may not reveal whether there is a progressive or an arrested hydrocephalus. When there is significantly elevated intraventricular pressure from progressive hydrocephalus, periventricular lucencies, rounding of ventricles, absence of a cortical subarachnoid space and a spherical appearance of the third ventricle (instead of the usual barrel appearance) is seen on CT scan. It is not sufficient to rely on the skull circumference measurements alone and repeated ultrasound scans are the most useful arbiter. Similarly placed signal changes may be seen with MRI which has the additional advantage that phase-contrast MR may quantify CSF flow rates and give more precise information on etiology.

**Table 22.7** Clinical features of decompensated hydrocephalus (children with shunts)

<b>Symptoms</b>
Vomiting
Drowsiness or lethargy
Headache
Behavioral change
Anorexia
Valve malfunction
Sleep disturbance
Seizures
<b>Signs</b>
No clinical signs (approx 25%)
Decreased conscious level
Acute squint
Neck retraction
Distended retinal veins
Sluggish palpable valve mechanism

The most commonly used index of ventricular dilation is the V/P ratio, that is, the ventricular diameter at the mid-portion of the lateral ventricles divided by the biparietal diameter from inner table to inner table. Hydrocephalus is defined as a ratio higher than 0.26.

Antenatal ultrasound for assessment of fetal hydrocephalus is indexed slightly differently. The commonly used parameters are biparietal diameter and the ratio of the lateral ventricular width divided by the width of the head. The latter is approximately 0.61 at 14 weeks, 0.29 at 27 weeks and 0.29 at term. Absolute measurements of ventricular width are done using the atrium as reference point. Ultrasound estimates of ventriculomegaly in utero may be exaggerated by a factor of about 10%, due to the distortion of sound signals passing through two fluids (amniotic and CSF). If hydrocephalus is suspected, ultrasound is done weekly until elective cesarean section at 36 weeks (intraventricular hemorrhage is maximal before 34 weeks). Intracranial Doppler blood flow velocities should be measured in addition to the biparietal diameter.

### Intracranial pressure

Ventricular CSF pressure monitoring is the only accurate way of assessing the activity of the hydrocephalus. This can be achieved by direct puncture of the ventricle via the anterior fontanel until it is closed at 18 months. Repeated ventricular punctures should be avoided by placement of a ventricular access device (Rickham or Ommaya reservoir) into the frontal horn of the right lateral ventricle to allow sequential pressure measurements. Repeated brain puncture may cause a puncture porencephaly. A single measurement of intracranial pressure is of limited value. The cerebral perfusion pressure (CPP) should be calculated by subtracting the intracranial pressure (mean ICP) from the mean systemic arterial pressure. For neonates the mean upper normal limit of intracranial pressure is 3.5 mmHg compared to 5.8 mmHg for infants up to 12 months, 6.4 mmHg from 1 to 3 years and 15 mmHg in adults.<sup>44</sup> ( $10 \text{ cmH}_2\text{O} = 7.36 \text{ mmHg}$ ).

For children who present with symptoms of shunt malfunction, due to blockage or infection, and who already have CSF shunting devices in situ, pressure measurements via a 'CSF access device' may be done continuously or overnight. This can indicate when raised pressure should be treated at the bedside and overnight measurements are a way of assessing whether the hydrocephalus is arrested or whether there is an intermittently active component. The rapid eye movement phase of sleep is associated with an increase of cerebral blood flow of about 40% in certain areas of the brain. This increase in intracranial volume has to be buffered if raised pressure is not to occur. In children with abnormal intracranial dynamics, raised pressure is seen particularly during rapid eye movement (REM) sleep and, to a lesser extent, during stage 2 non-REM sleep.

## Cerebral blood flow

The cerebral perfusion pressure gives an indication of the potential for ischemic damage to the brain. There are a number of methods available for measuring the blood flow velocity or perfusion to the brain, including flow meters, electrical impedance, autoradiography, wash-out and wash-in techniques, microspheres, ultrasound, MRI, single photon emission tomography (SPECT), positron emission tomography (PET) and first pass (mean transit time). Our own studies of the first pass method measuring the net mean cerebral transit time use an isotope (sodium pertechnetate or technetium albumin) and were performed on 11 hydrocephalic children. The transit time values correlated with cerebral perfusion pressure values.<sup>45</sup> Children with arrested hydrocephalus had transit times within the normal range, while those with progressive hydrocephalus had up to 15% of their sleep time with a cerebral perfusion pressure of less than 50 mmHg.

It is possible also to use a resistance index (systolic minus diastolic over systolic pressure (S – D)/S) or the area under the curve obtained by pulsed Doppler measurements of the major cerebral arteries as a measure of the cerebral blood flow velocity. The most useful vessel is the middle cerebral artery and an estimate of the velocity is best obtained through the squamous window of the temporal bone, rather than via the open anterior fontanel (Fig. 22.14).

The resistance index correlates significantly with the intracranial pressure<sup>41</sup> and the mean cerebral blood flow velocities fall with elevated ICP measurements. Doppler measurements can be performed intermittently or even continuously in hydrocephalic infants. Since the main effects of raised intracranial pressure are to produce ischemia and brain shifts, an increase in the ventricular pressure sufficient to impair blood flow is an indication for insertion of a CSF shunt or third ventricular ventriculostomy. Despite the low values of ICP in normal newborn infants and the relatively low values in infantile and neonatal hydrocephalus, small rises may be sufficient to impair cerebral blood flow. It is our practice to measure both the pressure and the cerebral blood flow velocity sequentially on these infants and the volume of CSF which needs to be removed in order to produce and maintain a normal resistance index (normal equals 0.68); this will indicate whether the hydrocephalic process is arresting spontaneously or whether it is progressing.<sup>46</sup>

## TREATMENTS

### Shunts

The usual treatment of progressive hydrocephalus is to divert CSF from the ventricular system to another site. There are numerous valves and shunt systems available, which take CSF out of the head for it to be absorbed elsewhere (Spitz–Holter valve, Pudenz–Hakim, Raimondi, the Indian valve, the Denver, etc.). The author favors the unitised Pudenz with a proximal valve. There are now more sophisticated types (the

Sophy programmable and multiprogrammable and the Cosman ICP telesensor) with various types of opening pressure device incorporated into the shunt system.

The basic shunt system includes a ventricular catheter with a flanged end to cause the choroid plexus to waft away from the drainage holes and so lessen proximal blockage. Some shunt systems have a twin valve, one arranged proximally and another distally, and some include a pump or flushing device. The valve usually has a distinct opening pressure, either 2–4, 4–6 or 6–8 cmH<sub>2</sub>O, the CSF draining when this pressure is exceeded. In the newborn, a device that opens at low pressure is advisable, but as the child grows, it may be necessary to replace this with one opening at a higher pressure to avoid the development of overdrainage and cranio-cerebral disproportion. A valve may be incorporated in the pump (Spitz–Holter system) or it may be a distal 'slit valve' at the peritoneal end. It may be a single continuous stiff tube with radiopaque gradations to avoid kinking, such as the Raimondi system. Many different valves and shunt system combinations therefore exist. Our reason for choosing the unitized system with a proximal valve is to avoid the overdrainage, which frequently results by a siphon effect from a long distal catheter.

The potential complications from ventriculoatrial shunts are serious, with infection occurring in between 10% and 30% (Table 22.8). Infection with these shunts is often accompanied by septicemia and

Table 22.8 Complications of CSF shunting

*Blockage* by choroid plexus, fibrin, neuroglia, blood clot and brain fragments causing raised intracranial pressure

*Fractured tubing*: fracture of the distal tubing may occur in the neck as a result of direct trauma or kinking of the tubing with repeated movements (fracture can also occur over the surface of the chest and exaggerated flexion/extension movements may result in a crack in the distal tube)

*Infection* (colonization and ventriculitis) with raised intracranial pressure

*Shunt dependence*

*Slit ventricle syndrome*

*Other decompressive effects* (e.g. subdural hematoma)

*Migration of the tubing* proximally or distally: cases have been reported of migration of the distal tubing through the gut wall or penetration of other organs. (Cases are known where the tubing has dramatically retracted from the abdominal cavity to the intracranial space. Migration of the distal tubing may cause a volvulus. Commonly if insufficient length is implanted initially, the tubing may retract subcutaneously over the chest wall with growth. Migration of the proximal tubing may result in the proximal catheter extending into a different ventricle or into subcortical structures)

*Intestinal obstruction* (volvulus)

*Peritonitis* and peritoneal fibrosis

*Endocarditis* (VA shunts)

*Chronic pulmonary hypertension* (VA shunts)

*Superior vena caval syndrome* (VA shunts)

*Arrhythmias* (VA shunts)

*Shunt nephritis* (VA shunts): a case has been reported of shunt nephritis following a VP shunt

*Hyperlordosis* (TP shunts)

*Acute noncommunication* (with TP shunts)

*Product failure* due to mechanical deficiency and a faulty valve

*Surgical technique* (malplacement or displacement)

*Ventricular collapse* from excessive drainage causing the tip of the catheter to impinge through the ependyma or brain substance

*Pseudocyst formation* with defective drainage

Fig. 22.14 Ultrasound demonstrating flow pattern in left middle cerebral artery with resistance index of 1.22.

VA, ventriculoatrial; VP, ventriculoperitoneal; TP, thecoperitoneal.

chronic infection with shunt nephritis or unexplained rashes of a vasculitic nature due to complement activation from chronic septic emboli. Other chronic effects include right heart failure from pulmonary hypertension and bacterial endocarditis, thrombosis of the superior vena cava with superior vena caval syndrome arrhythmias and possible perforation of the myocardium. Most centers have now turned to the peritoneal route for drainage.

Ventriculoperitoneal shunts also have complications, and on at least one occasion shunt nephritis has been recorded (Table 22.8). More common is distal blockage due to pocketing of CSF from adhesions, preventing CSF spreading through the peritoneum. This may result eventually in pseudocyst formation. Other complications include penetration of the distal end into a viscus or through the gut wall and it has been known for ventriculoperitoneal (VP) shunts to appear per rectum. When infection of the shunt spreads distally, peritonitis may result.

Thecoperitoneal shunts or lumboperitoneal shunts remain useful in the context of benign intracranial hypertension and occasionally posthemorrhagic hydrocephalus. Lumboperitoneal shunt operations can be performed without laminectomy with associated complications.

### Shunt and separate reservoir

Separate reservoirs have been used for acute surgical decompression since the early 1960s. They have been used to instil chemotherapeutic agents into the CNS in malignant disease and in the management of preterm intraventricular hemorrhage.

A number of centers use both a shunt and a separate CSF access device (reservoir), which is inserted into the frontal horn of the right lateral ventricle at the same time as the primary shunt surgery. A study to assess the risks attendant on this policy showed no extra mortality or morbidity.<sup>43</sup> The separate reservoir greatly eased the detection and management of raised intracranial pressure, shunt infection and ventriculitis. Children with shunts may have optic discs that become scarred and unreliable as indicators of raised intracranial pressure and frequently the presentation may be subtle with, for example, a decline in school performance. Since there are no absolutely reliable signs or symptoms of raised pressure, the only means of detection is by direct measurement of the intraventricular pressure, which is easy when the reservoir is present.

Many children with shunted hydrocephalus will still present with the usual childhood illnesses and infections and symptoms of these are often impossible to differentiate from those due to shunt malfunction. With the facility for intracranial monitoring via a reservoir, the presence of raised pressure or infection can be detected in a matter of minutes rather than with prolonged inpatient observation and repeated CT scanning, etc. In the Edinburgh study,<sup>43</sup> in 58% of admissions where a tap was thought necessary to exclude raised pressure or infection, normal values for both pressure and cell counts were obtained, thus avoiding the need for unnecessary emergency shunt surgery. If raised pressure is found, it can be lowered by CSF removal via the reservoir. If repeated taps do not effectively normalize the pressure, closed external ventricular drainage can be easily instituted via the reservoir, allowing replacement of the shunt by elective rather than emergency surgery.

The presence of a reservoir also has the advantage of an immediate diagnosis or exclusion of ventriculitis and therapy can be immediately instituted by direct instillation of the appropriate antibiotic into the ventricles, with monitoring of the CSF cell counts and antibiotic levels. With this method of management there is virtually no mortality from ventriculitis and one also expects a near zero infection rate from shunt and reservoir replacement (Table 22.8).

### Shunt blockage

The Edinburgh series is shown in Table 22.9.<sup>43</sup> Survival analyses showed no significant relationship between the onset of mechanical blockage and the type of shunt, the age at reservoir insertion, the sex of the child, the etiology of hydrocephalus or the time relationship of the shunt insertion to reservoir insertion. The reduction in complications with the introduction of the reservoir may be due to the ability to measure directly the intracranial pressure and so reduce the number of unnecessary shunt revisions (Table 22.9).

### Ventriculitis

Ventriculitis is diagnosed on the basis of a positive ventricular CSF culture with or without pleocytosis. Eighty percent of shunt infections will occur within 9 months of placement. Many factors influence the incidence of shunt infection, such as the length of operation, the skin preparation and the type of shunt, but infection remains a problem in a significant number of children with shunts. It can be difficult to diagnose and there is still controversy about the optimum management. Several different treatment regimens have been suggested, including vancomycin into the shunt and systemic therapy with oral trimethoprim and rifampicin. Others have advocated that infection can only be eradicated successfully by removal of the shunt.

It is our practice to subject the CSF to cytological techniques of cyto-centrifugation and millipore filter collection. This improves the identification of cell types in the CSF. It is especially useful in cases of mild CSF pleocytosis. Routine biochemistry is also performed on the separated CSF specimen. The vast majority of episodes of ventriculitis are due to *Staphylococcus albus* with occasional cases of *Escherichia coli*, though any organism commonly found on the skin may be responsible including *Staphylococcus aureus* and streptococci. Neurosurgical intervention increases the number of cells in the CSF transiently but infection may occur in the early postoperative period so the need for accurate cell type identification is clear. Macrophages can persist in the CSF for a long time and these need to be distinguished from the mild persisting pleocytosis of active infection when there are equal numbers of neutrophils, lymphocytes and macrophages. Macrophages indicate that there is an active repair process going on. Intrathecal penicillin and cephalosporins can also produce a CSF pleocytosis, i.e. a chemical ventriculitis.

It is imperative that treatment is begun immediately. Intrathecal and intravenous vancomycin is now preferred to gentamicin, complemented by intravenous rifampicin. Where hypersensitivity or resistance is a problem teicoplanin or meropenem offer useful alternatives. Raised ventricular pressure is controlled. Occasionally there may be organisms present in the CSF which have not yet excited a cellular response, and very few cells are found. In only three episodes of ventriculitis, in our series, were there less than 100 cells/ml. Shunt infections may also be

Table 22.9 Incidence of shunt problems before and after reservoir insertion

Period	Number of episodes (episodes per child shunt year)			
	<i>Serious shunt failure</i>	<i>Blockage</i>	<i>Infection</i>	<i>Ventriculitis</i>
<i>Pre-reservoir period</i>				
219 child shunt years	99 (0.45)	75 (0.29)	24 (0.11)	37 (0.17)
<i>Post-reservoir period</i>				
269 child shunt years	77 (0.29)*	55 (0.20)*	22 (0.08) ns	28 (0.10) ns

Figures in brackets = per child shunt year.

\* =  $P < 0.01$  cf. pre- and postreservoir periods.

associated with a negative organism culture. Because many of these children are highly shunt dependent, once the shunt is removed (which is necessary in ventriculitis because the organisms hide within mucoprotein colonies within the shunt tubing) it is imperative that their pressure is managed by tapping or draining CSF from the reservoir. It is also critical that shunt reinsertion is not done before the CSF is sterilized. When CSF infection occurs and a reservoir is not placed the shunt can be externalized. This allows intrathecal antibiotics to be administered and excess CSF to be drained. Subsequently the drain can be removed and the shunt re-inserted.

### Slit ventricle syndrome

**Effects of acute CSF decompression.** This results in a low-pressure headache, delayed valve pump refilling, a depressed fontanel and possibly an upward brainstem cone (apnea, bradycardia, syncope, hypotension, stridor and hemiparesis).

**Effects of chronic CSF decompression.** These include acquired craniosynostosis, skull deformity, a thickened skull vault, microcephaly, hyperpneumatization of the sinuses, pneumocranium (tension), subdural hematoma, hygroma, cephalocranial disproportion, slit ventricle syndrome (total or partial ventricular collapse), enlarged cortical vascular bed, partial stripped ependymal lining, gliotic scar tissue (subependymal and white matter), wide open Virchow–Robin spaces and decreased intracranial compliance.

In children with normotensive hydrocephalus the normal ICP in the sitting position is negative and approximately  $-5$  mmHg. Following a shunt insertion in the erect position, the pressures are approximately  $-18$  mmHg. Therefore, in most situations, with the child upright and mobile during the day, the pressures will be negative, but when supine and during REM sleep, there may be significant elevation of pressure. This has given rise to the concept of slit ventricles and the 'slit ventricle syndrome'. Our own studies suggest 10% have radiological slit ventricles, but only 1% were symptomatic.

The slit ventricle syndrome incorporates three components: intermittent or chronic headache secondary to episodic ventricular catheter obstruction; slit-like (Y shaped) ventricles on CT scan; and a slowed refill of the palpable valve mechanism.

The pathogenesis of the slit ventricle syndrome involves a siphon effect of continuing CSF flow down a shunt tubing (particularly with the ventriculoperitoneal route), excessive drainage from the coperitoneal shunts in patients who are predominantly in the upright posture and the possibility that, with ventriculoatrial shunts, the diastolic phase of blood flow may encourage CSF withdrawal from the distal end of the shunt.

Several procedures have been devised to try and treat the slit ventricle syndrome. These include the use of high-pressure valves, an antisiphon device, a valve upgrade together with an antisiphon device, a subtemporal decompression, a volume-regulated shunt system, an antisiphon ventricular catheter (that is incorporated into the shunt) and lastly the use of steroids and the head-down position.

## OTHER TREATMENTS

### Choroid plexectomy

This operation reduces CSF production rate by about one third but often offered only temporary relief of symptoms and is no longer used.

### Drug effects on CSF production

A number of drugs have been shown to have an effect on the rate of production of CSF, but it is unlikely that even with a substantial reduction in CSF this could be a definitive management for progressive hydrocephalus. However, there may be additional measures to help control CSF pressure in different situations, e.g. with the patient on external ventricular drainage due to ventriculitis. Furosemide and acetazolamide reduce CSF production by virtue of their carbonic anhydrase inhibitory effect. Acetazolamide, while it reduces CSF production, has only a transitory effect and isosorbide (a sorbitol derivative), which acts as an

osmotic diuretic, is unpalatable and may produce hypernatremia and metabolic acidosis. For any acute rise in intracranial pressure associated with hydrocephalus, mannitol may reduce the pressure sufficiently to prevent coning. Other drugs with receptor sites on the choroid plexus may also reduce CSF production without diminishing overall choroidal perfusion.

### Other procedures

Additional procedures include endoscopic third ventriculostomy – ETV – (the opening of the ventricular CSF system into the subarachnoid space via the lamina terminalis) and ventriculocisternostomy (Torkildsen shunt) between the ventricle and the basal cisterns. These are reliant on a block being present in the CSF outflow from the ventricles with an intact subarachnoid space and surface CSF pathways, with a normal reabsorptive capacity. In purely obstructive hydrocephalus, such as aqueduct stenosis, 70% require no further surgical intervention. Its use in other circumstances, and in particular those under 6 months of age, requires further study and definition.<sup>47</sup> Relative contraindications for an ETV are infants younger than 6-months-old, slit-like ventricles, very thin cortical mantle and communicating hydrocephalus. Nevertheless, some neurosurgeons advocate that it should be considered in all children presenting with hydrocephalus, including those who have previously been treated with a shunt.<sup>48</sup> Complication rates may be as high as 20% and include infection and neurological signs which may reflect pressure shifts, such as third nerve palsy or confusion. The rate seems to reflect the experience of the operator.<sup>49</sup> It is important to remember that previously effective ETV can block, giving rise to the same problems as a blocked shunt.

When there is ventriculitis, meningitis, blood in CSF or other factors making the insertion of a CSF shunt impracticable, then a temporary measure may be necessary, such as ventricular tap through the anterior fontanel. As previously mentioned, a puncture may result in porencephaly and it is preferable to have neurosurgical assistance and have a temporary reservoir implanted.

## SPECIFIC TREATMENT REGIMENS

### Posthemorrhagic hydrocephalus

This is common in premature infants following periventricular hemorrhage (PVH) but may occur in other age groups as well. Posthemorrhagic ventricular dilation in prematures may be assessed by serial ultrasound to compare the ventricular index (above) to the centiles for age. Approximately one third of infants with a PVH will develop posthemorrhagic ventricular dilation and one fifth of these will require a CSF shunt. Only about one in five cases of dilation are due to outlet obstruction at the fourth ventricle.

Distinguishing progressive hydrocephalus with high pressure, i.e. pressure-driven ventricular dilation, from brain atrophy in such circumstances requires ultrasound or imaging scans and pressure measurements. In atrophy the ventricles retain their usual configuration and do not have loss of the normal angles of the lateral ventricles.

There is no ideal or single method for managing posthemorrhagic hydrocephalus. Repeated lumbar punctures may prevent the need for shunting and will certainly ameliorate progressive ventricular dilation but the pressure should be measured at the same time with CSF removal to reduce the pressure level to normal. It is associated with an increased risk of infection<sup>50</sup> and it has been suggested that it be replaced with alternatives<sup>51</sup> such as early ventriculosubgaleal shunting.<sup>52</sup>

Acetazolamide in a dose 100 mg/kg per 24 h, and furosemide in a dose of 1 mg/kg per day have been shown to be ineffective in decreasing the rate of shunt placement.<sup>53</sup> Ventriculoperitoneal shunting is not done until the CSF hemorrhage has cleared sufficiently to avoid blocking the shunt. Brydon et al<sup>54,55</sup> indicate that it is cells that adversely affect shunt performance rather than CSF protein concentration.

The elective insertion of a ventricular reservoir will allow measurement and treatment of raised pressure by sequential taps. The

hydrocephalus may arrest or the patient may subsequently need a ventriculoperitoneal shunt.

### Tuberculous meningitis

Details of its presentation and management are given in the central nervous system infection section (see pp. 928–929). Ventricular dilation is uncommon in adults but is seen in nearly 80% of affected children. The immediate management includes CT or MRI scans and to attend to the raised ventricular pressure; the child may sustain serious sequelae, or die, as a result of untreated or unrecognized pressure. The emergency insertion of a ventriculostomy reservoir allows measurement of the ventricular pressure and decompression by CSF removal. A diagnostic lumbar puncture may then be carried out. Pressure is measured at the time of lumbar puncture and comparison can be made with the ventricular measurement to see whether there is any spinal block (Froin syndrome). CSF is then removed for cytocentrifuge cell count, protein, Ziehl–Nielsen, etc. in order to confirm the diagnosis of tuberculous meningitis.

The raised pressure, which may continue for many days, can be treated by intermittent taps of the reservoir, or by closed external ventricular drainage against a pressure head of 10 mmHg. Routine anti-tuberculous chemotherapy is commenced and both the infection and the pressure are monitored and treated carefully over the next 2 weeks. The use of intrathecal steroid preparations may be necessary if there is a spinal block or a basal adhesive arachnoiditis.

Early CSF shunting is an alternative way to control the pressure while treating the infection, but the shunt will need to be replaced if it becomes colonized and shunt dependence continues. Alternatively a temporary shunt may be sufficient to control the pressure while attempting to sterilize the CSF. Although earlier practice was routinely to carry out a lumbar puncture in suspected tuberculous meningitis (in most cases safely), there remains the possibility of coning at the time of diagnosis. These patients, and others who present in coma, must not have a lumbar puncture until a CT scan has been performed and the basal cisterns are seen to be patent.

### Fetal hydrocephalus

See above under the 'Prenatal presentation of developmental brain abnormalities' (see p. 823).

### Prognosis

#### *Natural history of untreated hydrocephalus*

Several studies detail the course of untreated hydrocephalus. An average result from these studies indicates that approximately 50% survive and of the survivors, 25–30% have normal intelligence and 25–30% have severe motor and other handicaps.

### Epilepsy

Localized injury to the frontal cortex raises a theoretical risk of precipitating seizures from frontal reservoirs. Also with a reservoir there are two cortical insults. Seizure disorders follow in about one in six children compared with a one in two risk with the siting of a single VP shunt frontally.

### Hemiplegia

Hemiplegia is the commonest type of cerebral palsy complicating hydrocephalus associated with spina bifida. This accounts for about 20% of children with congenital hemiplegic cerebral palsy. The hemiplegia in hydrocephalus may be due to the etiology (e.g. prematurity or meningitis) or may be a complication of the hydrocephalus as a result of parenchymal hemorrhage from brain puncture, traumatic puncture of the internal capsule, siting of the shunt to involve the motor strip, subdural hematoma as a result of overdrainage, cortical thrombophlebitis or basilar arachnoiditis or precipitation of status epilepticus with postconvulsive hemiplegia or puncture porencephaly. Occasionally also a mixture of corticospinal and cerebellar signs are seen giving a pattern of movement similar to that seen in the genetically determined ataxic diplegic cerebral palsies.

### Vision

Blindness is not a problem of untreated hydrocephalus but sudden total blindness may result from raised pressure due to shunt malfunction. Gaston,<sup>56</sup> in studying a group of spina bifida children, found only 27% of 322 had normal visual function. In the Edinburgh study only one child ( $n = 56$  over 12 years) had visual handicap which was of a severity for the child to be registered as blind and 88% had normal visual function. Visual impairment in children with hydrocephalus may result from optic atrophy secondary to chronic papilledema, distension of the third ventricle with chiasmal compression, posterior cerebral artery compression with ischemia of the optic radiation or calcarine cortex or selective posterior horn dilation leading to gross thinning of the calcarine cortex. These are all due to raised pressure with hydrocephalus.

### Intelligence

Some 50–60% of shunted hydrocephalic children have normal IQs. In our study group 65% of children were in normal education, 29% were educated in special schools and 6% were in residential care for the severely handicapped. The pathophysiological mechanisms whereby learning is impaired include an associated cortical dysplasia, marked thinning of the cortical mantle (less than 15 mm), ventriculitis, chronically reduced cerebral perfusion pressure and coincidental parenchymatous brain damage (meningitis, asphyxia, etc.).

## THE NEURO CUTANEOUS DISEASES

The last decade has seen important advances in the identification of the causes of the neurocutaneous syndromes. Neurofibromatosis 1 (NF1) and NF2 are two diseases caused by separate genes, while tuberous sclerosis (TSC) 1 and 2 is one disease caused by separate genes. Increasing involvement by parents and families, advances in neuroimaging and molecular genetics have all led to important advances in our understanding of these disorders.

### NEUROFIBROMATOSIS 1

NF1 is the most common single gene disorder to affect the human nervous system with an estimated incidence of 1 in 3000.

*Diagnostic criteria for NF1:* Two or more of the following are required:

1. six or more café-au-lait spots (at least 1.5 cm post-puberty, at least 0.5 cm pre-puberty);
2. two or more neurofibromas or one or more plexiform neurofibromata;
3. axillary or inguinal freckling;
4. optic glioma;
5. two or more Lisch nodules (benign iris hamartomas);
6. osseous dysplasia on the sphenoid bone or cortex of a long bone;
7. a first degree relative with NF1.<sup>57</sup>

About a third of young people with NF1 have short stature and almost 50% have a head circumference at or above the 97th centile. NF1 is a multisystem disorder associated with a wide variety of complications. The most common are plexiform neurofibromas, learning disability, optic gliomas and scoliosis occurring in 15–50% of affected individuals. More than 50% of people with NF1 will be mildly affected and may not even know they carry the gene.

Plexiform neurofibromas occur in about 25% of individuals with NF1. They carry the potential for cosmetic disfigurement and malignant transformation often extending deeply into underlying tissues. Here they may cause compression or distortion of adjacent structures.

Specific learning difficulties are most common in NF1 with a frequency of between 30% and 60%. The frequency of global learning difficulties is only slightly higher than in the general population. There is no specific learning disability profile.

Optic nerve gliomas are the most common central nervous system tumors in NF1 occurring in up to 20% but only 30–50% will become symptomatic. They can involve any part of the visual pathway and take

the form of low-grade pilocytic astrocytomas. All symptomatic tumors present before 6 years of age but rarely progress. Thus whereas formal ophthalmological assessment is indicated up to the age of 10 years, after this age annual routine clinical assessment of acuity and visual fields is sufficient.

Scoliosis occurs in up to 20% of those with NF1 and usually appears before the age of 10 years of age.

### Neuroimaging features

Areas of increased signal intensity on T2-weighted images with magnetic resonance imaging occur in 60–70% of children. They have been referred to as UBOs (unidentified bright objects). They generally disappear during late teenage years or the early 20s.

### The genetics of NF1

This is an autosomal dominant disorder although 50% of cases are sporadic. The NF1 gene has been mapped to chromosome 17 and codes the protein neurofibromin. This has a high sequence homology with GAP (GTPase) activator protein. These proteins have an important role in cell growth and differentiation. The genetics of the disorder are dealt with in more detail in Chapter 14.

## NEUROFIBROMATOSIS 2 (NF2)

The diagnosis is based on the following criteria:<sup>57</sup>

1. Bilateral VIII nerve masses detected on neuroimaging.
2. A first degree relative with NF2 and either unilateral VIII nerve mass or two of the following:
  - neurofibroma;
  - meningioma;
  - glioma;
  - schwannoma;
  - juvenile posterior subcapsular lenticular opacity.

NF2 usually presents in adult life, though many childhood cases have been described. Presentation is usually a result of tumors causing progressive loss of hearing, difficulty with walking, loss of sight or chronic pain.

NF2 should be suspected in children presenting with any of the tumors listed above and fewer than six café-au-lait patches.<sup>58</sup> It is unusual for children with NF2 to present with features other than those due to a tumor.

### The genetics of NF2

NF2 is very rare with a birth incidence of 1 in 40 000. It shows autosomal dominant transmission with nearly full penetrance. The NF2 gene maps to the long arm of chromosome 22 and codes a member of the protein 4.1 family of cytoskeletal associated elements. For further details see Chapter 14.

Subtle skin tumors often characterized by small well circumscribed lesions found on the trunk or face, which after adolescence become roughened with overlying coarse hair, are a clue to the disorder, along with the lenticular opacities.

## TUBEROUS SCLEROSIS COMPLEX

Diagnostic criteria for tuberous sclerosis complex (TSC) have been proposed.<sup>59</sup>

Major features:

1. facial or forehead plaque;
2. nontraumatic ungual or periungual fibroma;
3. hypomelanotic macules (more than three);
4. shagreen patch (connective tissue nevus);
5. multiple retinal nodular hamartoma;
6. cortical tuber;
7. subependymal nodule;
8. subependymal giant cell astrocytoma;
9. cardiac rhabdomyoma, single or multiple;

10. lymphangiomyomatosis;

11. renal angiomyolipoma.

Minor features:

1. multiple randomly distributed pits in dental enamel;
2. hamartomatous rectal polyps;
3. bone cyst;
4. cerebral white matter radial migration lines;
5. gingival fibromas;
6. nonrenal hamartoma;
7. retinal achromic patch;
8. 'confetti' skin lesions;
9. multiple renal cysts.

**Definite TCS** Either two major features or one major feature plus two minor features.

**Probable TCS** One major plus one minor feature.

**Possible TCS** Either one major feature or two minor features.

### Clinical presentation

Seizures are by far the most common neurological condition in TSC, occurring at some point in up to 90% of young people with the disorder. Infantile spasms occur in about one third. The earlier the onset of seizures, the greater the risk of them being intractable and being associated with cognitive and behavioral impairments. If seizures present after the age of 2 years then attendant learning difficulties may be mild or absent.

The antiepileptic drug vigabatrin is noted to be particularly efficacious in tuberous sclerosis. The risk of associated retinopathy always needs to be considered carefully when this drug is used. As in all children where the epilepsy is intractable the question of the use of surgery for epilepsy needs to be considered. Multifocal lesions are not an absolute contraindication.

Learning difficulties are commonly (probably up to 40%) found in TSC. There is also a strong association between TSC and autism, particularly as an outcome of infantile spasms. Early reported associations between autism and temporal lobe lesions or a high number of tubers seem not to have been borne out.

It is the skin lesions, hypomelanotic (ash leaves) macules, periungual or gingival fibromas and thickened firm areas of subcutaneous tissue often on the lower back (shagreen patch) or forehead and face (fibrous plaques), which offer the most ready diagnostic clue. Adenoma sebaceum does not occur until late childhood or early adolescence. It is an angiofibroma (cutaneous hamartoma) (Figs 22.15, 22.16) which initially appears as flat reddish macular lesions, which become increasingly erythematous. Papular nodules over the bridge of the nose and higher cheek (in a butterfly distribution), often noted in the presence of examination of a child with epilepsy, bring the disorder to the attention of clinicians. MRI usually then confirms the diagnosis by revealing tubers, subependymal nodules or subependymal giant cell astrocytomas. CT scanning is less sensitive and often fails to identify tubers. Subependymal calcification is often not present until the second year of life. In the first year of life ultrasound of the heart will reveal cardiac rhabdomyomas in up to 60% with TSC. Put the other way round any child with a rhabdomyoma in infancy is likely to have TSC. They later regress but occasionally may be the presenting feature due to obstructive cardiomyopathy.

Angiomyolipomas and renal cysts occur in 45–50% of people with TSC. Renal disease is uncommon in childhood except in cases of polycystic disease. Pulmonary involvement is seen exclusively in adult women where cysts or lymphangioliomyomatosis may be associated with respiratory symptoms and hypertension.

### Managing people with TS

The management of attendant epilepsy and learning difficulties is discussed in the relevant sections. In relation to problems, which are specific for TSC, it has been recommended that neuroimaging be carried out, perhaps 2-yearly, to check for the growth of subependymal giant cell astrocytomas. The cost effectiveness of the screening examinations

Fig. 22.15 Tuberous sclerosis: adenoma sebaceum.

(a)

(b)

Fig. 22.16 Tuberous sclerosis: (a) shagreen patch; (b) depigmented patches.

is not clearly known. Our own policy is to respond to the assessment of new symptoms if they present.

Renal ultrasound needs to be carried out on presentation and then every 2–3 years to assess changes in angiomyolipomas or cysts, hopefully to allow operative intervention before the development of renal

failure. An ECG is useful at presentation to screen for the presence of potentially life threatening cardiac arrhythmias.

### The genetics of TCS

This is an autosomal dominant condition with a high spontaneous mutation rate. Gene loci for TSC have been identified on chromosome 9q34 (TSC1) and on chromosome 16p13 (TSC2). The TSC1 product is hamartin which may act as a tumor suppressor. TSC2 encodes for tuberlin, which has GTPase activating properties and also seems to function as a tumor suppressor. Hamartin and tuberlin cooperate to regulate cellular growth and differentiation. The genetics of TSC will be dealt with in more detail in Chapter 14.

### ATAXIA TELANGIECTASIA

This is a rare autosomal recessive disorder with an incidence between 1 in 40 and 300 000.

#### Presentation

The main neurological feature is the ataxia. Children often learn to walk at a normal age, but throughout the toddler years appear to be clumsy. Then, often after entering school, the clumsiness becomes more evident and leads to referral. They have a wide based gait but often demonstrate excessive adduction of the leg during the passing phase on foot strike causing a stagger to the outside of the base. They may choose a toe-walking gait and prefer to run everywhere rather than walk. More typical features of cerebellar ataxia then ensue often superimposed by choreiform movements, the latter being a variable feature.

Very often children lose the ability to walk independently between the ages of 8 years and about 12 years. Similarly after the age of 5 there is a deterioration of speech, the pattern of which carries the features of cerebellar dysfunction. Bulbar function then becomes increasingly involved raising the risk of aspiration. This often, in due course, leads to the requirement for gastrostomy feeding.

Children with the condition also demonstrate an oculomotor dyspraxia. This involves no problem with vertical eye movement, but when trying to follow an object through the horizontal plane the head is moved quickly to follow the object leaving the eyes behind, the latter then restituting on the object once it has stopped moving. This leads to a characteristic flick of the head that is readily perceived.

Around the age of 10 years an axonal polyneuropathy appears with loss of the deep tendon reflexes.

The associated telangiectasia are often evident across the top of the shoulders, on the ears and on the conjunctiva. They tend to become more obvious as children get older.

Premature aging features often appear in people as they move through the teenage years and early adult life with the appearance of gray hairs and aging of the skin with diminution of subcutaneous tissue. Vitiligo may also appear along with hyperpigmented areas.

Up to 80% of children with the condition will have diminished levels of IgA and IgG 2 (less frequently IgE and IgM). They have a diminished cell-mediated response to intradermal antigens and atrophy of the thymus. Infections of the sinuses and lungs are common with bacterial pneumonia being the major cause of death.

The problem with immunity is also associated with malignancy, tending to lymphoreticular disorders in childhood and solid tumors in adult life.

### Genetics of ataxia telangiectasia (AT)

The gene known as ataxia telangiectasia mutated (ATM) gene is found at chromosome location 11q22–23. ATM-deficient cells lack sensors (check-point proteins) of double stranded DNA breaks, which would normally suppress the mitotic cycle pending repair. Cell division therefore proceeds and is likely to be directly responsible for the frequent chromosomal rearrangements seen in AT cells.

### Diagnostic criteria

The clinical diagnosis is usually straightforward due to the constellation and characteristic features including the oculomotor dyspraxia and deteriorating cerebellar signs. With the identification of the ATM gene a new molecular standard of diagnosis is available. The finding of an elevated alpha-fetoprotein (at least twice the upper limit) along with reduced immunoglobulin levels in the presence of the typical neurological picture, substantiates the case for requesting the genetic study. The gene test has now replaced chromosome fragility studies.

Some children with AT present, before neurological signs have appeared, with acute lymphoblastic leukemia. If these children have an oculomotor dyspraxia then a careful search of the skin ought to be made for the telangiectasis and the ATM gene analyzed.

### OTHER DNA REPAIR DISORDERS

#### Xeroderma pigmentosum

This is also a DNA repair disorder with autosomal recessive inheritance. Its cardinal feature is acute sun sensitivity, often leading in infancy to erythematous and bullous skin lesions. Freckles and hypopigmentation are common, along with dryness, telangiectasis and, at times, skin atrophy. Ectoderm around the eye also shows light sensitivity and may lead to blepharitis, iritis or conjunctivitis with keratitis and edema of the cornea, occasionally leading to ulceration and opacification. Susceptibility to skin neoplasia is very high, and all affected young people should have their eyes and skin inspected weekly for new lesions.

About 20% have associated neurological problems (a much higher percentage in Japan) and, in its severest form, microcephaly, progressive dementia, choreoathetosis, ataxia and spasticity are seen, along with a progressive peripheral neuropathy. Sensorineural deafness may also be progressive. Genetic testing is available with eight mutations in different genes identified to date.

Management is by way of reducing exposure to ultraviolet light as much as possible and the aggressive early treatment of skin cancer.

#### Cockayne syndrome

This autosomal recessive condition leads to small stature, severe sun sensitivity, ocular, skeletal and neurological abnormalities. The most common findings are optic atrophy, pigmentary retinal degeneration, cataracts, sensorineural deafness and an extrapyramidal movement disorder, in addition to spasticity of the lower extremities with flexion contractures.

At birth, babies are of normal size but significant feeding difficulties and subsequent growth failure leads them to become progressively cachectic. At this time they acquire a distinctive facial appearance with a thin prominent nose and zygomatic processes, prognathism, enophthalmos and absent fat. This appearance is usually well developed by the teens, and neurological abnormalities largely resemble those of xeroderma pigmentosum, which may well exist in some young people. Many young people die in their teens in status epilepticus or with malignant hypertension, or renal and pulmonary dysfunction. Cultured skin fibroblasts lack the ability to form colonies when subjected to UV irradiation and assays are available in specialist laboratories. Mutational analysis of the gene associated with Cockayne syndrome is available on a research basis only.

#### Incontinentia pigmenti

As this condition predominantly affects girls, it is thought to be an X-linked dominant condition, probably lethal in males in utero. The central nervous system is involved in 30–50%. A cerebral dysgenesis leads to delayed development with seizures, spastic paralysis and cerebellar signs in some. The degree of learning difficulty varies greatly. Associated with this there may be a retinal dysplasia leading to a retrolental mass and skeletal and teeth abnormalities.

The skin abnormality is seen in three distinct stages. In the first 2 weeks of life erythematous, macular, papular, vesicular, bullous

or pustular lesions occur proximally in a linear distribution. This is in association with an eosinophilia. In the following 2–3 weeks pustular, lichenoid, verrucous, keratotic and dyskeratotic lesions occur more distally and as they resolve, often leave areas of atrophied skin. In the third stage, areas of pigmentation appear over a period of some weeks.

### OTHER NEUROCUTANEOUS SYNDROMES

#### Sturge–Weber syndrome

This is a sporadic condition involving a malformation of cephalic-venous microvasculature. There is an abnormality in the growth of the primordial vascular plexus in cephalic mesenchyme as it lies between the epidermis and the telencephalic vesicles in close proximity to the optic cup. This leads in its fullest form to a cavernous angioma of the leptomeninges, a facial angiomatous nevus and a choroidal angioma of the eye. The lesion may be unilateral or bilateral and in individual children may affect one or all of brain, eye or skin tissue. The lack of cerebral or ocular symptoms does not preclude them developing at a later date where the facial nevus is present. Sturge–Weber syndrome is not usually applied when neither cerebral nor ocular symptoms have appeared.

The port wine-colored stain on the face is evident at birth and always involves the first division of the trigeminal nerve. Involvement of the skin on that side may be more widespread and there is an association in some with the Klippel–Trenaunay syndrome. This syndrome involves angiomatous skin nevi in association with bony hypertrophy, lymphangiomas or varicosities; the genetics are not defined.

In Sturge–Weber syndrome a bilateral facial nevus does not necessarily imply bilateral cerebral involvement. Seizures are seen in up to 90% of those with Sturge–Weber. Abnormal venous return with blood stagnation and hypoxemia coupled with a high metabolic demand of neurones exhibiting seizure activity often lead to a progressive atrophy. Neurological signs emerge, often starting as a post-ictal paresis contralateral to the cerebral involvement but at times consolidating into a permanent paresis as time goes on. Hemianopias, dysphasias or quadriplegia may also occur. Where the seizures are intractable and infrequent there are very often associated learning difficulties.

Buphthalmos or glaucoma may accompany a choroidal angiomatous lesion and may be present at birth. Rarely, hydrocephalus has been reported but intracranial hemorrhage is exceptionally rare.

In the presence of a facial nevus full radiological assessment of the brain should be carried out to define the extent of any brain lesion. This can be with CT with contrast. MRI is, however, more sensitive. Intracerebral angioma may become more obvious with the passing of time. Calcification of the lesion becomes prominent. Management involves regular assessment of ocular pressure. Seizure control is difficult to attain at times. Where the vascular anomalies and seizure discharge are confined to one hemisphere, an early surgical resection of the lesion may offer benefit. The evidence shows that residual handicap is minimized when lobectomy or hemispherectomy is performed in the early weeks with many children surviving with little sign of a hemiparesis or hemianopia. However, exact criteria for this early intervention have yet to be established, as there are some children in whom a seizure disorder presenting at an early stage stabilizes.

#### Hypomelanosis of Ito

In some families, this is an autosomal dominant disorder, but in most there is no clear family history. Chromosomal abnormalities including balanced translocation have been described in at least two children. The skin lesion is of linear vorticeous or irregular areas of hypopigmentation. These may affect one or both sides of the body and be associated with lesions of the iris or hemihypertrophy.

The central nervous system is affected in at least 50%. Those with seizures in the first year of life are most likely to have a static encephalopathy associated with significant learning difficulties.

The pathology of both skin and brain is very reminiscent of that seen in tuberous sclerosis, neurofibromatosis and in incontinentia pigmenti. They are considered the nonspecific result of a dysplasia or embryopathy affecting the central nervous system and the skin. At about 15 weeks' gestation the melanoblasts migrate from the neural crest and mature to melanocytes in the skin. In the sixth month, the hair anlage is present, accounting for an association between abnormalities of cerebral cortex and hair. The number, size and pigment content of melanocytes in the basal area of the epidermis is generally reduced and in the brain the signs are of a neuronal migration defect, with microcephaly and a rostral displacement.

### Linear sebaceous nevus syndrome

In its complete form, this syndrome includes a cutaneous nevus, with neurological and ocular abnormalities. The skin lesion may be of several types. The typical Jadassohn nevus may be visible at birth or in infancy, or become evident only after a few years. It is a slightly raised, yellow-orange, smooth, linear plaque that abuts the midline of the forehead, nose or lips and often involves the scalp. Over years, the lesion tends to become darker and verrucous. Early in life there is little pigment, and sebaceous glands are often not prominent. Later, sebaceous glands proliferate throughout the thickness of the skin.

Neurological manifestations consist mainly of learning disability, seizures and asymmetrical macrocephaly. Seizures are often partial, but infantile spasms have been reported. Hamartomatous tumors may be present and various other abnormalities have been seen including porencephaly arterial aneurysms, abnormal venous return and arachnoid cysts along with hemihypertrophy.

The most common eye abnormalities are dermoids or epidermoids of the conjunctiva and colobomas of the iris, choroid, retina or optic nerve.

The diagnosis may be difficult in early cases without visible nevus. Imaging reveals hypertrophy of one hemisphere, usually on the same side as the nevus, with enlargement of the ipsilateral ventricle and pachygyria with hypodense white matter.

## SEIZURES, EPILEPSY AND OTHER PAROXYSMAL DISORDERS

### INTRODUCTION

A seizure is any sudden clinical event which is nonspecific in etiology and is a result of a neurological or non-neurological disturbance. However, the term is often used synonymously with epileptic seizure, defined as any clinical event arising as a result of epileptic activity of neurones in the brain. Epileptic activity involves the excessive and/or hypersynchronous electrical discharge of neurones, which, for practical purposes, are located within the cerebral cortex. Epilepsy is the tendency to have recurrent epileptic seizures. The term 'fit' is a lay term whose meaning is almost synonymous with epileptic seizure. A convulsion is any seizure (not necessarily epileptic) characterized by excessive, abnormal muscle contractions, which are usually bilateral. Epileptology abounds with terms many of which, though still used, are now obsolete; included are 'grand mal' (big attack) and 'petit mal' (little attack).

The basic mechanisms which underlie seizure generation are incompletely understood, but involve abnormalities at the cell membrane level (ion channels and receptors) and in neuronal circuits. The electrical behavior of neurones is determined by ion channels in the neuronal membrane, which are either voltage-gated or receptor (ligand)-gated. Voltage-gated ion channels determine the excitability of neurones as well as participating in the release of neurotransmitters. They are membrane-spanning proteins with a pore through which the ion can pass. A voltage sensor controls the opening of the pore and a selectivity sensor determines which type of ion can pass through the pore. Three main classes of voltage-gated ion channels have been described: Na<sup>+</sup>, Ca<sup>2+</sup> and K<sup>+</sup>. Sodium currents are involved in the generation of action potentials. Potassium currents cause hyperpolarization and hence

stabilize the neuronal membrane. Both calcium and sodium currents are involved in the generation of burst discharges, generated by certain classes of neurones when excited. They consist of a burst of action potentials produced as an all-or-nothing phenomenon. It is likely that burst discharges and other similar phenomena are important in the generation of some types of seizures. Ligand-gated ion channels are activated by the binding of a neurotransmitter to the ion channel's receptor. Gamma-aminobutyric acid (GABA) and glycine are inhibitory neurotransmitters while glutamate and aspartate are excitatory neurotransmitters. A useful, though simplistic model of epilepsy is that it involves an imbalance of excitatory and inhibitory neurotransmitter systems within the CNS.

Ion channel abnormalities (channelopathies) cause many epilepsies, particularly idiopathic epilepsies. For example, mutations in a neuronal nicotinic acetylcholine receptor have been shown to be associated with familial nocturnal frontal lobe epilepsy, in a potassium channel with benign familial neonatal seizures, and in a sodium channel with generalized epilepsy with febrile seizures and severe myoclonic epilepsy of infancy.<sup>60-63</sup> Many antiepileptic drugs block voltage-gated ion channels. These include carbamazepine and phenytoin, both of which block sodium channels. Other antiepileptic drugs act either at ligand-gated ion channels or else interfere with the production, release, function or catabolism of neurotransmitters. For example, benzodiazepines and barbiturates bind to specific domains on subtypes of the GABA receptor and vigabatrin increases GABA inhibition by preventing the breakdown of GABA at synaptic clefts.<sup>64</sup>

Epileptic seizures involve groups of neurones interacting together abnormally. Neurones within the brain work within physiologically and anatomically defined circuits. Some of these are important in particular types of epilepsy. They include neocortical circuits involved in, for example, frontal and occipital lobe seizures, the limbic system, involved in mesial temporal lobe seizures and thalamocortical circuits involved in generalized epilepsies, particularly absence seizures.

The neocortex comprises six distinct layers. Function occurs within vertically arranged columns. However, there are abundant excitatory horizontal connections. It is thought that it is these connections which allow the rapid seizure propagation, which is a feature of many neocortical epilepsies. Moreover, the neocortex contains intrinsically bursting pyramidal cells, which may be involved in seizure initiation.

At least in adults, mesial temporal lobe epilepsy is the commonest cause of drug-resistant seizures. The mesial temporal lobe structures, including the hippocampus and amygdala, are part of the limbic system. Groups of neurones within parts of the limbic system have relatively low thresholds for seizure generation. Again, this may relate in part to neurones with intrinsic bursting activity and may be augmented by loss of particular classes of neurones caused, for example, by prolonged febrile convulsions. Intimate connections within the limbic system allow seizures to propagate and determine the semiology of mesial temporal lobe seizures.

The thalami have rich connections to the cerebral cortex. Intrinsic membrane properties of thalamic neurones arising as a result of so-called low threshold calcium channels, cause it to generate low frequency oscillatory rhythms which appear to underlie both certain physiological phenomena and also pathological ones such as the 3 Hz spike-wave discharge seen in idiopathic generalized epilepsies. These consist of a spike caused by action potentials in both thalami and cortex followed by an after coming slow wave due to prolonged inhibition within the cortex.

### EPIDEMIOLOGY AND NATURAL HISTORY

Epilepsy is the commonest serious neurological condition of childhood. However, it is not a single condition, but comprises many different conditions. Epidemiological studies are bedevilled with problems of subject inclusion. Rates vary according to whether neonatal, febrile and single seizures are included and according to how 'active epilepsy' is defined.<sup>65</sup>

Fig. 22.17 Age specific incidence and prevalence of epilepsy in children. (From Eriksson & Koivikko 1997,<sup>73</sup> reprinted by permission of the journal *Epilepsia*.)

A metaanalysis of incidence studies found a median incidence of epilepsy in children (excluding neonates) of 82.2/100 000.<sup>66</sup> Rates are lower in resource rich countries compared to resource limited countries. The incidence varies markedly with age (Fig. 22.17).<sup>67</sup> In Europe and North America rates fall from about 150/100 000 in the first year of life to around 60/100 000 at ages 5–9 years and 45–50/1000 000 in older children. Most studies report slightly higher rates in boys. The point prevalence of epilepsy in children is 3–6/1000.<sup>68</sup> Cumulative incidence rates are much higher than annual incidence rates. During childhood, prevalence rates for active epilepsy increase but not as fast as cumulative incidence rates, reflecting the effect of remission (Fig. 22.18). The British National Child Development Study reported cumulative incidence rates for epilepsy of 4, 5, 7 and 8 per 1000 at ages 7, 11, 16 and 23 years respectively and prevalence rates of 4, 4, 5 and 6 per 1000 at the same ages.<sup>69</sup> The lifetime prevalence of nonfebrile seizures is between 1.5% and 5% of the population.<sup>65</sup> In other words, up to 5% of people will have at least one nonfebrile seizure at some point in their life.

Recent data suggest that the incidence of epilepsy is falling in children but rising in the elderly. This may relate to improved standards of pre- and postnatal medical care, to better standards of maternal and child health and to the rise in life expectancy in the elderly coupled with more cerebrovascular disease. Although age-specific incidence and prevalence rates for epilepsy are higher in children than in adults (excluding extreme old age), the rates for treated epilepsy may be higher in adults than in children.<sup>67</sup> The incidence of epilepsy may be increased in those who are socially deprived<sup>70</sup> but the data is conflicting.<sup>71,72</sup> Epidemiological studies in both adults and children, which have taken particular care to classify seizure type, have suggested that focal epilepsies are more common than generalized epilepsies. In the British National Child Development Study after 23 years follow-up about 70% of those whose seizures were classifiable had focal epilepsies and 30% had generalized epilepsy; around 45% of both were symptomatic or probably symptomatic. The type of epilepsy could not be determined in around a fifth of subjects.<sup>69</sup> A number of recent studies have given information on the epidemiology of specific epilepsy syndromes in children.<sup>73–76</sup>

The previous view that epilepsy is a chronic disorder with little prospect of remission was mistaken. The majority of children who have a seizure have a good prognosis both in terms of the likelihood of seizure recurrence and of obtaining remission should recurrent seizures (i.e.

Fig. 22.18 Incidence, prevalence and cumulative incidence rates for epilepsy in an American population. (From Shorvon 1996,<sup>255</sup> reprinted by permission of the journal *Epilepsia*.)

epilepsy) develop. The risk of a further seizure is greatest immediately after the first and declines thereafter. Forty-five percent of children who have a single seizure have a recurrence within 5 years, and once there has been one recurrent seizure further seizures become likely. The risk of having a third after a second, and a fourth after a third seizure at 5 years is 71% and 81% respectively.<sup>77</sup> Etiology is the main determinant of the risk of recurrence.<sup>77–81</sup>

Once epileptic seizures are recurrent, an important issue is the probability of early remission. In a large prospective study 57% of children, 2 years after a diagnosis of epilepsy, had a 'good outcome' (a remission which had lasted more than 12 months), 12% had a 'fair outcome' (a remission which had lasted 6–12 months) and 31% had a 'poor outcome' (a remission which had lasted less than 6 months).<sup>82</sup> Another study reported that at 2 years after diagnosis of epilepsy 53% of children had a 'good outcome' (a remission of more than a year), 8% had a 'bad outcome' (two or more antiepileptic drug failures and at least one seizure

per month over an 18-month period) and 38% had an 'intermediate outcome'.<sup>83</sup> In about 80% of children who were followed for 4 or more years the outcome was similar to that at 2 years. However, around half of those with an intermediate outcome at 2 years achieved remission and 8% became intractable. Factors which are associated with the likelihood of a poor outcome include young age at seizure onset, symptomatic etiology, an initial presentation with status epilepticus or infantile spasms and high initial seizure number.<sup>77,78,80</sup>

Information on the long term prognosis of children with epilepsy is provided by the British National General Practice Study of Epilepsy.<sup>84</sup> In this study 86% of children of all ages, with a diagnosis of definite epilepsy, achieved a 3-year remission and 68% a 5-year remission, after 9 years. 'Remission' referred to a remission at any stage in the 3- or 5-year period. The proportions achieving a terminal remission (i.e. seizure free at the end of the follow-up period) of 3 and 5 years were 68% and 54% respectively, indicating that some children with prolonged remission subsequently relapsed. A very long prospective follow-up study of childhood-onset epilepsy found that after a mean of 37 years follow-up 67% were in terminal remission, on or off medication. Overall about a half of children with epilepsy entered terminal remission without relapse and a further fifth did so after a relapse. One third had persistent seizures either without ever having had a remission or after a remission.<sup>85,86</sup> Long-term outcome studies have shown that epilepsy has adverse social outcomes whether or not the epilepsy is symptomatic and whether or not remission is achieved.<sup>85,87</sup> However, the outlook is considerably better in those with idiopathic seizures who achieve remission. Children with idiopathic epilepsies are reported, as adults, to have similar socioeconomic and/or employment status compared to matched controls without epilepsy, but they are less likely to marry.

The standardized mortality ratio of people with epilepsy (children and adults) is two to three times that of the general population.<sup>88</sup> Causes of death in children with epilepsy include accidents, status epilepticus and occasionally idiosyncratic reactions to drugs. As they enter teenage and adult years, suicide becomes increasingly important. Finally seizure-related death (death during or shortly after a seizure when there is no evidence of status epilepticus or when no other explanation for death is found at autopsy) and sudden unexpected death in epilepsy (SUDEP) (a nontraumatic, unwitnessed death occurring in a child with epilepsy who had previously been relatively healthy and for whom no cause of death is found even after postmortem examination) have been the subject of recent interest. By definition, the cause of such deaths is unknown. However, at least some may be caused by seizure-related cardiac arrhythmias. A population-based study of SUDEP found an incidence of 0.27 per 1000 person-years in those under 14 years of age.<sup>89</sup>

The question as to whether antiepileptic drug treatment affects the prognosis for epilepsy (in terms of eventual remission of seizures) has perplexed clinicians and scientists. Although there are theoretical arguments why it might do, there is no evidence that it does.<sup>78,90,91</sup> Antiepileptic drugs may be used to suppress distressing symptoms, but not in the expectation that they are likely to change the natural history of the condition, at least in the large majority of children. Possible exceptions to this are some of the epileptic encephalopathies.

## INVESTIGATIONS

### EEG and magnetencephalography

#### Introduction

The EEG is the single most useful investigation in children with seizure disorders. However, it is frequently misused, overinterpreted and, because many clinicians are unaware of its full potential, underutilized.

The EEG gives a visual representation of differences in electrical potential between different areas of the brain. These reflect underlying neuronal activity. Most EEGs are recorded from the scalp using an array of 20 electrodes, although smaller numbers are sometimes used, particularly in young children. The EEG does not record the absolute potential at a particular electrode. Rather differences in potential between

consecutive pairs of electrodes may be recorded (bipolar recordings) or else differences in potential between each electrode may be compared to a common reference electrode (referential recording). The EEG was traditionally recorded on paper, with the potential at each electrode used to cause a deflection of a marker pen. The sequence of electrodes displayed on the EEG trace is called the montage. In any one paper recording, a number of different montages using both bipolar and referential recordings are used in order to best detect normal and abnormal EEG features originating from different parts of the brain. Today most EEGs are recorded digitally and displayed on VDU screens. Other than storage considerations, the advantage of digital recording is that once the data are recorded, computerized reformatting and manipulations enable far more information to be obtained than was possible on paper systems. It is, for example, possible to display the same data in numerous different bipolar and referential montages, filters can be added or taken away to remove artefacts which obscure the underlying EEG and EEG features can be precisely timed.

#### Interictal EEG

Most EEGs are recorded between seizures (interictal recording). A standard interictal EEG is usually recorded for 10–60 min. The EEG trace can be analyzed in terms of ongoing or background activity and episodic or paroxysmal activity. For both, normal and abnormal patterns occur. The background activity includes various physiological rhythms, including the well-known alpha rhythm. It is dramatically different in the premature neonate compared with the mature adult. In general, the EEG becomes increasingly synchronized and physiological rhythms become faster with maturity. The background EEG also changes with the level of arousal. For example, as an older child passes from alert to drowsy to light and then to deep sleep, a drop out in the alpha rhythm occurs, followed by progressive slowing.

Paroxysmal EEG activity is any activity which stands out from the background. There are numerous physiological paroxysmal EEG features which, like background features, are age and state dependent.

Most EEGs also contain artefact, which is not caused by electrical activity of the brain. Some artefacts relate to physiological functions such as eye, head and breathing movements and the electrical activity of the heart. Muscle artefact, which is in effect an EMG recording, is also common. Extraneous artefacts may be caused by poor electrode contact, by the mains electrical source and by nearby electrical equipment. Some artefacts can be very difficult to distinguish from cerebral activity.

Abnormalities of the EEG background are usually rather nonspecific and of limited value when investigating children with seizure disorders. Focal background abnormalities, generally with slowing, reduction in amplitude and loss of physiological rhythms may reflect focal brain abnormalities giving rise to seizures, such as brain tumors, infarcts and abscesses. However, all are better diagnosed by neuroimaging. In children whose epilepsy is part of a static or progressive encephalopathy diffuse slowing and attenuation of the background EEG is expected.

Of most use in the investigation of children with seizure disorders is the detection of abnormal paroxysmal activity. Abnormal paroxysmal activity on interictal EEG can be divided into two broad categories: epileptiform and non-epileptiform abnormalities. Epileptiform abnormalities are those which have an association with the occurrence of epileptic seizures. In addition to being paroxysmal they are also usually abrupt and short-lived giving rise to spikes and sharp waves. Interictal spikes and waves are often followed by slow waves (paroxysmal EEG abnormalities which are of longer duration and blunter), constituting spike-wave complexes.

The nonspecialist is often confused by reports of EEG abnormalities. These are often all incorrectly considered to support or even confirm a diagnosis of epilepsy. Common mistakes are:

- The assumption that focal, paroxysmal, slow wave activity supports the diagnosis of epilepsy. This is a nonspecific finding, occurring frequently in normal children, especially younger children and if

the child is drowsy. It can be a postictal phenomenon but this is a relatively rare cause.

- The assumption that all spikes and sharp waves are epileptiform. Although the spike and, to a lesser extent, sharp wave, are considered the paradigm epileptiform abnormality, there are some 'physiological' spike and sharp wave paroxysmal EEG features.
- The assumption that the detection of epileptiform paroxysmal abnormalities necessarily implies that the child has seizures. Some such abnormalities, though more frequent in people with epilepsy than in the general population, are more frequently seen in people with cerebral disease but without seizures. Others have a strong association with epilepsy. They also occur in small numbers of people with other disorders and without seizures. For example, occipital spikes are common in blind people and centrotemporal spikes occur in some children with cerebral palsy and in boys with fragile X syndrome. Finally, a small number of normal children who have never had and never will have a seizure have epileptiform EEG abnormalities.

Certain EEG abnormalities can be activated by physiological maneuvers. These include sleep, hyperventilation and photic stimulation. Sleep (especially light sleep) is a powerful activator of many EEG abnormalities and if an awake recording is unhelpful it is usually worth obtaining a sleep recording. This can be achieved using natural sleep, following partial sleep deprivation or by drug-induced sedation. When sleep is induced by drugs it should be remembered that these may influence the EEG beyond causing sleep. Benzodiazepines and barbiturates often cause excessive fast activity and suppress many EEG abnormalities; they are therefore best avoided. Major tranquilizers such as chlorpromazine can decrease seizure threshold and may activate EEG abnormalities through mechanisms other than by sleep induction. Chloral hydrate and melatonin appear not to have significant effects on the EEG. The recording should be continued while the person is awakening as this may also provoke epileptiform abnormalities.

Hyperventilation, which should be included in the protocol for standard EEG recordings, is of particular use in investigating subjects with idiopathic generalized epilepsies in whom it frequently activates generalized spike-wave discharges. Apparently 'subclinical' discharges can often be shown to be associated with transient cognitive impairment if combined with breath counting during hyperventilation. Other epileptiform abnormalities are less reliably activated by hyperventilation. Hyperventilation often causes bilaterally synchronous slow wave activity in normal children. This physiological response must not be misinterpreted as indicating the likelihood of a seizure disorder.

Photic stimulation should also routinely be applied during standard EEG recordings. 'Photic-driving' or 'following' is a normal response and the 'photomyoclonic response' is a non-epileptiform abnormality often seen in anxious subjects. Photoparoxysmal responses are epileptiform abnormalities in which spikes and/or spike-wave discharges are produced by intermittent photic stimulation (Fig. 22.19). They are usually generalized but can be confined to the occipital regions. Generalized photoconvulsive responses are most often seen in subjects with idiopathic generalized epilepsies but occur in a variety of other epilepsies and rarely in normal children. Occipital photoconvulsive responses are occasionally seen in subjects with occipital lobe seizures.

### ***Ictal EEG***

During routine EEG recordings it is rare to record a seizure. An exception to this is in children with typical absences, which often occur during recordings, especially during hyperventilation. Ictal records usually require prolonged recording (24 hours or more) and even then are only likely to be obtained if seizures are frequent. Two types of prolonged EEG are commonly employed. Ambulatory cassette EEG usually records eight channels of EEG using a cassette recorder. The EEG is later analyzed at high speed on a VDU screen with events electronically marked by the child or witness analyzed in detail. Video-EEG telemetry involves the subject staying in hospital while a 20-lead EEG is recorded, usually digitally, with simultaneous time-locked video recording. Again the whole record

can be viewed at high speed with events analyzed in detail. Prolonged recordings are useful to:

- Help decide if paroxysmal clinical events are epileptic.
- Localize the onset of focal seizures. This is usually done as part of a presurgical workup in refractory epilepsy and requires video telemetry rather than a cassette recording.
- Establish the frequency of seizures and interictal epileptiform discharges. This may be useful if a child with epilepsy is performing less well at school than expected and it is considered that this might reflect under-recognized seizure activity.

### ***Special techniques***

The sensitivity of EEG recordings can be increased by using additional electrodes. Foramen ovale and sphenoidal electrodes are semi-invasive electrodes used to increase the detection of temporal lobe discharges. They are rarely used in children, in whom cheek electrodes have been suggested as an alternative. Invasive EEG recordings, with recording directly from the surface of the brain (subdural recordings) or from within the substance of the brain (intracerebral recordings), are used in a minority of children undergoing presurgical evaluation. They are employed to precisely localize the onset of seizures and are available only in specialized centers.

Polygraphic recordings, in which a number of physiological variables such as ECG, chest and abdominal wall movements, airflow at the nose and esophageal pH are recorded simultaneously with the EEG, and often video, are particularly useful in investigating children with recurrent apnea and life-threatening events, including Munchausen syndrome by proxy. It should be noted that all EEG recordings should routinely include an ECG lead and if subtle myoclonus is suspected an EMG lead may be useful.

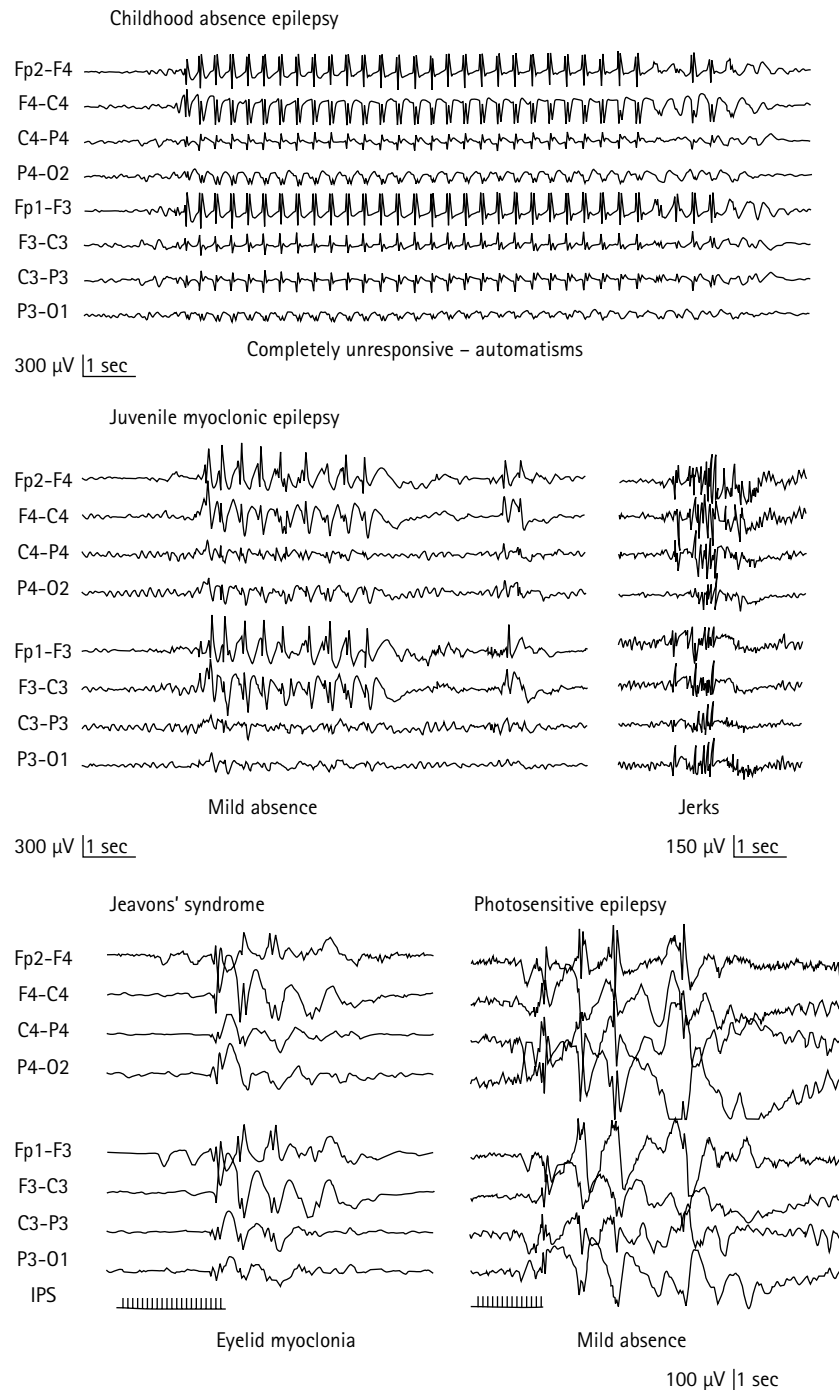

### ***Using the EEG in clinical practice***

The EEG is used for six principal purposes:

- to help establish the likely diagnosis of epilepsy;
- to help establish the type of epilepsy;
- to help identify possible precipitants to epileptic seizures;
- to investigate the cause of cognitive decline;
- to help localize the onset of focal seizures;
- to monitor treatment, including the timing of drug withdrawal.

The usefulness of any investigation in helping to establish a diagnosis depends on its sensitivity and specificity. Between 2.2% and 3.5% of normal children have interictal epileptiform abnormalities while, in children with infrequent seizures, the yield of interictal epileptiform EEG abnormalities on initial EEG is probably under 30%.<sup>92</sup> Over-reliance on interictal EEG for diagnosing epilepsy leads to frequent misdiagnoses. The clinical utility of recording interictal epileptiform discharges is exponentially related to the strength of the clinical suspicion of epilepsy.<sup>93</sup>

Some children with epilepsy have persistently normal interictal EEGs. This is often because the epileptiform discharges are infrequent and likely to be missed during a 30–60 min recording. Increasing the length and/or number of recordings or activating discharges, for example, by obtaining a sleep recording will increase the yield in these children. However, in some children, interictal abnormalities may be highly localized and/or attenuated by the dura, skull and scalp and therefore not detected by the standard array of electrodes used with a surface EEG. Many areas of the cortex, including the basal frontal and medial temporal regions, are not directly accessible to scalp recordings and therefore only discharges which propagate will be detected. Obtaining an ictal recording may be the best strategy here. Antiepileptic drug treatment can affect the yield of EEG recordings.<sup>94</sup> Barbiturates and benzodiazepines are reported to reduce the abundance of epileptiform abnormalities and drugs effective in controlling typical absence seizures are likely to reduce epileptiform abnormalities in absence epilepsies. Drugs effective against photosensitive seizures reduce the likelihood of detecting photosensitivity on intermittent photic stimulation. Most antiepileptic drugs have little effect on the EEG of children with focal epilepsies.

**Fig. 22.19** Samples of video-EEG in some idiopathic generalized epilepsies of childhood. **Top:** Childhood absence epilepsy, a regular spike-wave discharge at 3 Hz is associated with complete unresponsiveness and automatisms. **Middle:** Juvenile myoclonic epilepsy. Left: An irregular and brief spike and polyspike discharge is associated with mild impairment of cognition. Right: A brief multiple spike discharge associates with myoclonic jerks without absence. **Bottom:** Response to intermittent photic stimulation. Left: A generalized discharge of irregular spike and wave is associated with marked eyelid myoclonia in eyelid myoclonia with absences (Jeavons syndrome). Right: A similar generalized discharge is associated with a mild absence in another child with idiopathic generalized epilepsy and photosensitivity. (With thanks to CP Panayiotopoulos.)

It is unusual for an ictal EEG recording not to show epileptiform activity. However, it may fail to clarify whether a paroxysmal attack is epileptic or not because of obscuration by artefact. Moreover, focal seizures in which there is no disturbance of consciousness (simple focal seizures) often show no EEG changes because of the highly localized nature of the discharges. This is less common in focal seizures in which there is impairment of consciousness (complex focal seizures) but may occur, particularly when the origin is frontal.<sup>95</sup>

In routine clinical practice the EEG is at its most useful in helping to classify the type of epilepsy. Generalized epilepsies and focal epilepsies are commonly associated with generalized and focal interictal epileptiform discharges respectively. However this is not absolute, and in young children in particular, focal epilepsies are not infrequently associated with apparently generalized discharges. In idiopathic epilepsies the background is expected to be normal. Focal background abnormalities are frequent in symptomatic focal epilepsies. Generalized background abnormalities are suggestive

of symptomatic generalized epilepsies and epileptic encephalopathies. Finally many more-or-less specific EEG abnormalities have been described for specific epilepsy syndromes (Figs 22.19–22.21). These will be described when the relevant syndrome is discussed.

A small minority of people with epilepsy have specific seizure precipitants. This is exemplified by photosensitive epilepsies, the evaluation of which is greatly aided by photic stimulation. In children in whom other precipitants appear important the recording conditions of the EEG can often be modified to investigate a particular precipitant's role.

Occasionally children with epilepsy show a stagnation or decline in their cognitive performance. The EEG can be useful in investigating the possible role of epileptiform activity in causing this. In some children, especially those with idiopathic generalized epilepsies, frequent interictal and subtle ictal discharges are responsible and can be detected on prolonged EEG recordings, preferably with simultaneous video record-

ing. In others, electrical status during slow wave sleep may be responsible for cognitive problems and this possibility should be investigated by a sleep recording. Finally, some children with apparent cognitive decline are in nonconvulsive status epilepticus. This is usually obvious on a standard EEG.

The EEG has an important role in the localization of the site of onset of focal seizures. However, it is important to remember its limitations. If ictal or interictal discharges originate from areas of the cortex 'hidden' to the scalp EEG, any associated EEG abnormalities will reflect discharge propagation rather than site of origin. Additionally, some discharges rapidly spread giving rise to bilateral EEG abnormalities. Finally, interictal epileptiform abnormalities may originate from sites remote from those giving rise to habitual seizures. For example, in mesial temporal lobe epilepsy it is common to find independent bilateral interictal discharges in people whose seizures all originate from one side.

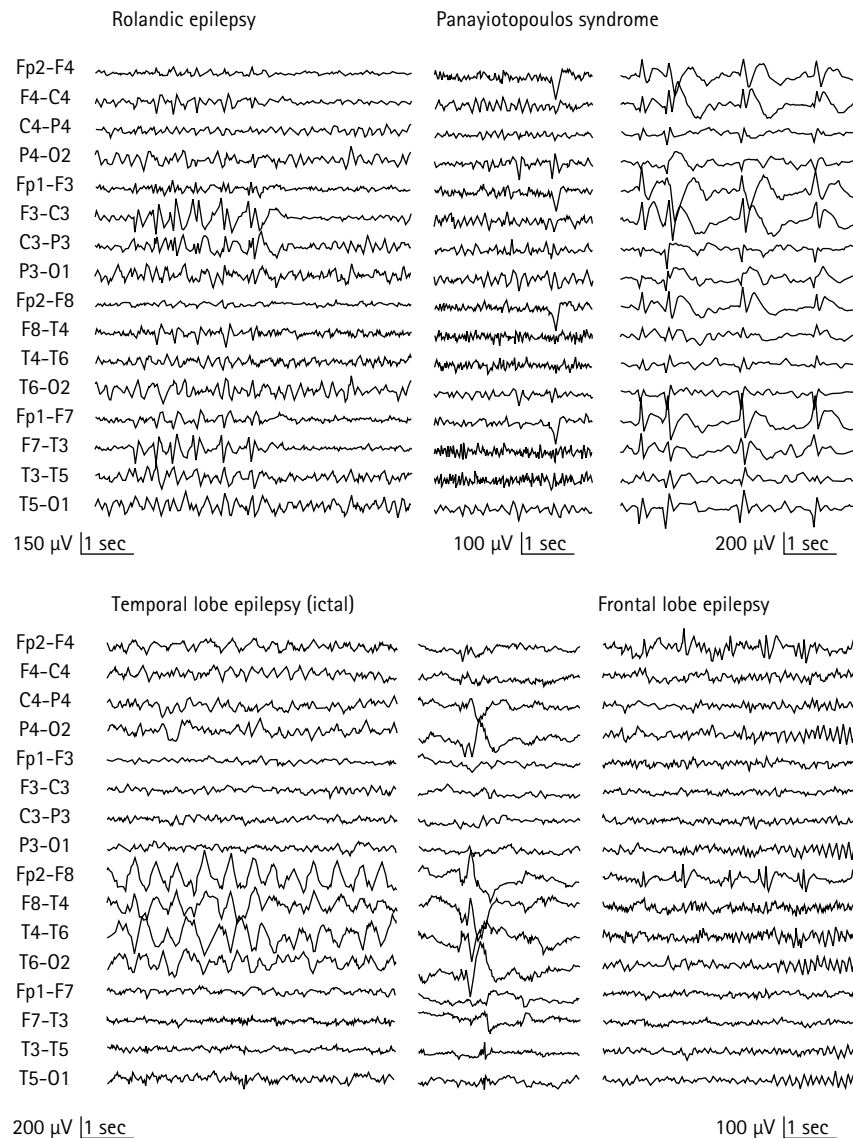

Fig. 22.20 EEGs in some focal epilepsies of childhood. Top: Benign childhood epilepsies. Left: Benign childhood epilepsy with centroposterior spikes (Rolandic epilepsy) – focal high amplitude spike-wave discharges occur mainly in the left centroposterior regions. These are typical of the EEG abnormalities expected in this syndrome. Some independent sharp waves are also seen in the posterior regions. These are less typical of the syndrome but nevertheless common. Middle and Right: EEG of two different children with Panayiotopoulos syndrome. Despite similar lengthy seizure typical of the syndrome, EEG shows occipital spikes in the first (middle) and cloned-like repetitive multifocal spike-wave complexes, which are mainly frontal in the other (left).

Bottom: Focal symptomatic epilepsies. Left and middle: Temporal lobe seizure of a child with right hippocampal sclerosis. High amplitude rhythmic slow wave activity over the right hemisphere occurred during the seizure; the child complained of 'tummy ache and panic' (left). High amplitude sharp and slow waves in the same regions persisted postictally (middle). Right: Frontal lobe epilepsy. Frequent spike and slow wave complexes are strictly localized in the right frontal regions. (With thanks to CP Panayiotopoulos.)

**Fig. 22.21** The EEGs in some epileptic encephalopathies of childhood. **Top:** West syndrome showing typical hypsarrhythmia – the arrow indicates the onset of an epileptic spasm. This is accompanied by a high amplitude slow wave followed by flattening of the EEG (an electrodecremental response). **Middle:** Nonconvulsive status epilepticus in Lennox–Gastaut syndrome showing continuous slow spike and wave. **Bottom:** A tonic seizure in Lennox–Gastaut syndrome – the onset of the seizure (arrow) is accompanied by a generalized discharge of spikes (fast spike discharge). (With thanks to CP Panayiotopoulos.)

Intuitively, it would seem likely that the EEG could help predict the likelihood of recurrence after an initial seizure and the prognosis for seizure recurrence after drug withdrawal. Studies have confirmed that this is the case.<sup>92</sup> However, a lack of sensitivity means that, clinically, its role in this regard is limited. The type of epilepsy, including the syndromic diagnosis, is probably a more useful guide. Illustrative examples may be helpful. In benign childhood epilepsy, with centrotemporal spikes, the abundance of interictal discharges varies markedly between EEGs done in the same child. Moreover, they often persist

long after clinical remission of seizures has occurred. It would be inappropriate to use the EEG to predict how frequent seizures were likely to be or to help decide when to withdraw antiepileptic drug medication. On the other hand a child with an idiopathic generalized epilepsy whose EEG continues to show frequent spike–wave discharges and a positive response to photic stimulation, despite clinical remission of seizures, would have a high chance of relapse and the EEG result might reasonably help in the decision to continue antiepileptic drug medication.

## Magnetencephalography (MEG)

MEG is the newest technique used in the investigation of children with seizure disorders.<sup>96</sup> It is completely non-invasive but requires a degree of cooperation from the child. It is based on the principle that all electric currents, including those produced by neurones, generate a magnetic field, which if large enough can be detected externally using an array of up to 300 sensors distributed over the head. It can be used to localize epileptic activity and when superimposed on MRI (magnetic source imaging) has better spatial resolution than surface EEG. It can also be used to map eloquent cortex during pre-surgical evaluation.

## Neuroimaging

For the majority of children with seizure disorders, MRI is the only brain imaging method of importance. Skull X-rays are only now indicated if a child presents with a seizure following a head injury in order to detect skull fractures. The main role of CT is also in the acute situation, in which its ability, unlike MRI, to detect skull fractures, its superior ability to detect fresh blood, and its ready availability, makes it the imaging method of choice when an unwell child presents with seizures of obscure origin. CT may also be useful in young children with seizures in whom neuroimaging is indicated to exclude, for example, space-occupying lesions, but in whom MRI would require a general anesthetic. The reassurance of a normal CT may reasonably enable the clinician to delay obtaining an MRI until this can be obtained without anesthetic. Cranial ultrasound is a useful imaging method in the neonatal period. However, its limitations must be appreciated. In particular it will miss many important lesions encountered in children with seizures.

MRI (Fig. 22.22) enables the following conditions associated with epilepsy to be detected:

- Brain malformations and maldevelopments such as agenesis of the corpus callosum, septo-optic dysplasia, holoprosencephaly, hemimegalencephaly, abnormalities of cortical development and lesions associated with neurocutaneous disorders including tuberous sclerosis and Sturge–Weber syndrome.
- Vascular disorders such as arteriovenous malformations.
- Areas of sclerosis and gliosis associated with old infarcts, hypoxic–ischemic insults and infection.
- Tumors, including low grade gliomas and dysembryoplastic neuroepithelial tumors.

There is an almost limitless number of potential MRI sequences. Close liaison between the clinician and radiologist is essential in order to ensure the most appropriate ones are obtained in an individual child. There are many excellent reviews on the role of MRI in the investigation of children with epilepsy.<sup>97,98</sup> Most brain malformations and maldevelopments comprise 'normal' brain tissue arranged abnormally and are best detected with sequences which give good anatomical definition, such as T1-weighted images. On the other hand 'foreign' tissue including tumors and gliotic tissue is usually best detected with T2-weighted images. The contrast agent gadolinium is rarely helpful and is not indicated as a routine. However, it can be helpful in conditions associated with breakdown in the blood–brain barrier, such as some tumors and vascular malformations. Proton density and fluid attenuated inversion recovery (FLAIR) sequences give improved contrast between brain lesions and CSF.

Detection of mesial temporal sclerosis, the pathological substrate underlying mesial temporal lobe epilepsy, deserves special mention (Fig. 22.22). It is usually not detected with 'standard' T1- and T2-weighted axial images. The important features are decreased volume (atrophy) and increased signal on T2-weighted and FLAIR sequences in the hippocampus and/or amygdala often with dilation of the temporal horn. Its detection requires thin heavily T1-weighted and T2-weighted coronal images taken orthogonal to the long axis of the temporal lobe. More specialist techniques, which may improve detection further but which are not widely available, include T2 relaxometry and volumetric analysis.

An important question for the clinician is which children with epilepsy require neuroimaging. One reasonable approach is to image all children with focal epilepsies except those with a pattern of epilepsy which corresponds clinically and on EEG with the syndrome of benign epilepsy of childhood with centrotemporal spikes. Children with features of one of the idiopathic generalized epilepsies do not require imaging provided they respond as expected to appropriate medication. Another approach is to image children only if there are interictal neurological signs, or if seizures do not come under complete control after the first line antiepileptic drug.

Currently, functional brain imaging's role in the investigation of childhood epilepsy is confined to those in whom epilepsy surgery is being considered. During seizures, seizure foci are metabolically more active and require an increased blood flow. Between seizures, they are often less metabolically active and require less blood. In positron emission tomography (PET) a positron emitting ligand is injected into the subject and is then distributed around the body. In epilepsy studies, the ligand is usually <sup>18</sup>fluorodeoxyglucose (FDG), which is an analog of glucose. FDG enters the glycolytic pathway but cannot proceed beyond the initial steps. It therefore accumulates within tissues, the accumulation being proportional to the metabolic activity of the tissue. The rate of positron emission is detected by the PET scanner. FDG PET is, for a variety of reasons, unsuitable for ictal studies; the vast majority of FDG PET studies are interictal with the aim of detecting focal areas of hypometabolism. Single photon emission tomography (SPECT) is based upon the emission of photons from radioligands. These can be detected using conventional gamma cameras. In epilepsy studies, <sup>99m</sup>Tc-hexamethyl-propyleneamine (HMPAO) is the most widely used radioligand. Its distribution around the body reflects blood flow. The main advantage of SPECT over PET is its wider availability, as it utilizes commercially prepared radioligands and conventional gamma cameras which are available in all nuclear medicine departments. In addition, the pharmacokinetics of the distribution of HMPAO make it suitable for injection ictally. Unfortunately interictal SPECT has proved relatively insensitive in the detection of surgical foci and has largely been abandoned. Interictal PET and ictal SPECT appear to have similar sensitivities for the detection of temporal and extratemporal epileptic foci. The reader is referred to recent reviews for more details on these methods.<sup>99–103</sup>

In older children who can undergo MRI without anesthetic or sedation, functional MRI is increasingly used to map eloquent cortex, lateralize language dominance and localize epileptic foci before epilepsy surgery.

## Other investigations

Most children with seizure disorders require no investigations other than EEG and structural brain imaging. However, there are children in whom seizures dominate the clinical picture but who have other features which suggest the possibility of an underlying genetic, metabolic or degenerative condition. These include:

- Early onset of refractory seizures in the neonatal or early postnatal period.
- Stormy onset of seizures in the previously well child.
- Occurrence of seizures in children with mental retardation of unknown cause (suggesting the possibility of a genetic or chromosomal disorder).
- Occurrence of seizures in children with dysmorphic features (suggesting genetic and chromosomal disorders; peroxisomal disorders and the carbohydrate-deficient glycoprotein syndrome are also associated with dysmorphism).
- Occurrence of seizures in children with episodes of unexplained drowsiness or confusion (suggesting the possibility of an amino or organic acid disorder, a urea cycle defect or a mitochondrial disorder).
- Occurrence of seizures in children with neurological abnormalities on examination; ataxia should particularly raise suspicion (many degenerative disorders can produce this picture).

**Fig. 22.22** Neuroimaging in some symptomatic childhood epilepsies. **Top left:** Nonenhanced CT showing calcified subependymal nodules (arrowheads) and multiple cortical tubers manifested as low attenuation areas (open arrows). **Top right:** T1-weighted axial MRI image showing subcortical band heterotopia ('double cortex') (arrow). **Middle left:** T2-weighted axial MRI image showing extensive right-sided temporoparieto-occipital polymicrogyria (arrows). The child presented with very frequent occipital seizures and episodes of focal status epilepticus. All seizures ceased following a right temporoparieto-occipital resection. **Middle right:** T2-weighted coronal MRI image showing left mesial temporal sclerosis (arrow). The hippocampus is shrunken and of high signal and there is associated dilation of the temporal horn. **Bottom left:** T2-weighted coronal image showing a right-sided dysembryoplastic neuroepithelial tumor in the right mesial temporal lobe (arrow). The tumor is cortical and of moderately high signal. **Bottom right:** T2-weighted image of a child with hemiconvulsion-epilepsy syndrome (HHE syndrome) following haemophilus meningitis. There is left hemiatrophy. (With thanks to JH Livingston and S Yeung.)

- Occurrence of seizures in children in whom there is a documented loss of skills, including visual skills (suggesting the possibility of degenerative disorders; the ceroid lipofuscinoses are particularly important to consider in children).
- Occurrence of seizures in children in whom there is evidence of dysfunction in systems outwith the CNS (suggesting mitochondrial disorders in particular).

The investigation of many of these disorders is best undertaken by a pediatric neurologist in conjunction with a metabolic pediatrician and clinical geneticist. However, the general pediatrician will not wish to miss potentially treatable conditions and should understand the rationale for the various investigations performed (Table 22.10).

A genetic etiology is present in about 40% of subjects with epilepsy.<sup>104</sup> The 'genetic epilepsies' include: chromosomal disorders; Mendelian epilepsies;<sup>105</sup> and 'complex epilepsies' in which the interaction of several genetic loci together with environmental factors are thought to lead to the epilepsy phenotype. The first two of these probably account for only about 1% of all epilepsies – hence genetic tests do not currently play a significant role, although this may change.

Seizures are a prominent feature of many chromosomal disorders<sup>106</sup> and therefore chromosomal analysis should be a routine part of the investigation of children in whom seizures are accompanied by learning difficulties and/or dysmorphic features. In addition, there are many

Table 22.10 Investigations useful in children with seizure disorders in whom neurometabolic conditions are suspected

Disorder	Available tests	Comment
Biotinidase deficiency Amino acid disorders	Plasma biotinidase Plasma and urine amino acids	Treatable; worth excluding in all refractory childhood epilepsies Wide range of phenotypes. Worth performing in all children with early onset seizures and in all children in whom seizures are associated with mental retardation or loss of skills
Organic acidurias	Plasma organic acids	Worth performing in all children in whom seizures occur in association with intermittent vomiting and/or lethargy
Peroxisomal disorders	Very long chain fatty acids and phytanic acid	Consider especially in children with 'Zellweger' facies, mental retardation and profound hypotonia
Carbohydrate-deficient glycoprotein syndromes	Transferrin electrophoresis	Wide, incompletely described phenotype. Characteristic dysmorphic features
Menke disease	Serum copper and ceruloplasmin levels	Consider in boys with neonatal and early postnatal seizures
Folate and B <sub>12</sub> disorders	Plasma and urine amino acids, urine organic acids, blood and CSF folate	Extremely rare; present in infancy
Molybdenum cofactor deficiency	Plasma urate level (low) and urinary sulfite excretion on dipstick test	Extremely rare
Purine and pyrimidine disorders	Urine purine and pyrimidine studies	Extremely rare
Creatine deficiency syndrome	Consistently low plasma creatinine levels	Extremely rare
Mitochondrial disorders	Plasma and CSF lactate levels	Huge variation in clinical phenotype. Suspect when there is evidence of multisystem disease
Storage disorders	White cell enzymes. Specific enzyme assays for the ceroid lipofuscinoses	The main disorders which can present primarily as an epilepsy are the sialidoses, type 3 Gaucher disease and the ceroid lipofuscinoses
Glucose transporter protein deficiency	Paired CSF and blood glucose levels	Extremely rare
Pyridoxine dependency and deficiency	Trial of oral or intravenous vitamin B <sub>6</sub> (pyridoxine)	Consider in neonates and younger children with intractable seizures

other genetic syndromes in whom seizures are prominent and which can now be diagnosed with molecular DNA techniques. These include fragile X syndrome, Wolf-Hirschhorn syndrome, Angelman syndrome, Miller-Dieker syndrome, Smith-Magenis syndrome, Pallister-Killian syndrome and Rett syndrome. There are now a number of disorders of cortical malformation associated with epilepsy caused by specific gene mutations.<sup>107-109</sup> These include X-linked periventricular nodular heterotopia (FLN1 gene), lissencephaly-pachygyria and subcortical band heterotopia (LIS1 or DCX genes), lissencephaly with cerebellar hypoplasia (RELN gene), X-linked lissencephaly (ARX gene) and various patterns of polymicrogyria. Finally, mutations have been described in a number of ion channel genes, mostly giving rise to rare autosomal dominant epilepsies. Diagnostic testing is currently only available for most of these on an ad hoc basis. However, mutations on the sodium channel SCN1A have been described in families and sporadic cases with a number of epilepsy phenotypes, including generalized epilepsy with febrile seizures plus (GEFS+) and Dravet syndrome. Commercial diagnostic testing is becoming available.

## CLASSIFICATION

Classification profoundly affects our approach to medical disorders. In the past it was common to confuse classification of epileptic seizure types (i.e. symptoms) with types of epilepsy (i.e. syndromes and diseases). A major advance in the last few decades has been the widespread acceptance of classification schemes for both epileptic seizures and epilepsy syndromes proposed by the International League Against Epilepsy (ILAE). Until recently the classifications of seizures and of syndromes used worldwide were those proposed by the ILAE in 1981 and 1989 respectively.<sup>110,111</sup>

The 1981 classification divided seizures according to whether on clinical and EEG grounds they appeared to begin in a localized group of cortical neurones in one cerebral hemisphere (partial, focal or localization-related seizures) or whether both cerebral hemispheres appeared

to be involved from the start (generalized seizures). The list of generalized epileptic seizures was similar, though not identical, to that in the new system discussed later. Partial epileptic seizures were divided into simple partial (implying no impairment of consciousness), complex partial (implying impairment of consciousness as assessed by the children's reduced reactivity to external stimuli and amnesia for the event) and partial evolving into generalized tonic-clonic seizures. The occurrence of various symptoms (motor, somatosensory, special-sensory symptoms, autonomic and psychic) was the basis for further subdivision.

The 1989 classification of 'epilepsies and epileptic syndromes' introduced a new concept, which has gained widespread acceptance, namely that of epileptic syndromes. This was in recognition of the fact that the etiology, pathogenesis and clinical features were established for very few epileptic conditions and that it was therefore inappropriate to consider them as diseases. An epileptic syndrome is defined by the non-fortuitous clustering of various features of which the most useful are the type(s) of epileptic seizure, EEG features and age of onset. The two main components of the classification were: (i) the division of epilepsies and epileptic syndromes into those with generalized seizures (generalized epilepsies and syndromes) and those with partial seizures (partial epilepsies and syndromes) and (ii) the division of both generalized and partial epilepsies and syndromes according to whether the cause was unknown and there was no suggestion of an underlying cause other than a possible hereditary predisposition (idiopathic epilepsies), whether the cause was unknown but an underlying cause was suspected (cryptogenic epilepsies) or whether the epilepsy occurred as a consequence of a known disorder of the CNS (symptomatic epilepsy).

In 2001 the ILAE published proposals for a 'diagnostic scheme' composed of five axes:<sup>112,113</sup>

1. a glossary of terms used in epileptology;
2. a list of epileptic seizure types;
3. a list of epilepsy syndromes;
4. an etiological classification;

5. a classification of impairments arising as a consequence of the condition.
  - The terms 'partial' and 'localization-related' are abandoned in favor of 'focal'.
  - The division of focal seizures into simple and complex is abandoned, partly because of conceptual difficulties with the notion of consciousness and the relative lack of importance of this feature anyhow. A new term 'dyscognitive seizure' has been introduced. This is a seizure in which disturbances of cognition are prominent.
  - The term 'cryptogenic', which was considered confusing, is abandoned and is replaced by 'probably symptomatic'. A number of new terms are introduced. These include:
    - i. Epileptic disease. This is a pathological condition with a single specific, well-defined etiology, e.g. tuberous sclerosis.
    - ii. Epileptic encephalopathy. This is a condition in which the epileptiform abnormalities themselves are considered to cause a progressive disturbance in cerebral function.
    - iii. Benign epilepsy syndrome. This is a syndrome in which seizures are easily treated, or require no treatment, and remit without sequelae.

## Epileptic seizures

Ax12 of the ILAE proposals classifies seizures into self-limited and continuous seizure types (status epilepticus). Each of these is then subdivided into generalized and focal seizures, whose meaning is unchanged from before.

### Generalized, self-limited seizures<sup>112,113</sup>

*Generalized tonic-clonic seizures* (GTCS) involve an initial, bilaterally symmetrical, sustained contraction of the muscles (tonic phase) followed by bilateral repetitive, rhythmical contractions of the limbs (clonic phase). There is usually a phase of postictal drowsiness, of variable duration. During GTCS, manifestations such as tongue biting, cyanosis of the lips and incontinence are frequent. However, their usefulness in distinguishing between epileptic and non-epileptic seizures has been overemphasized.

*Tonic seizures* are characterized by sustained muscle contractions lasting a few seconds to minutes. They may involve the whole, or greater part, of the body or be confined to particular parts of the body. For example, tonic seizures may be manifested by opisthotonus or by a subtle elevation of the eyebrows.

*Clonic seizures* are manifested by rhythmical contractions of the limbs. An alternative term is rhythmic myoclonus.

*Myoclonic seizures* are characterized by sudden, brief (<100 ms), involuntary, single or multiple contraction(s) of muscle(s) or muscle groups. They may be massive, involving axial and proximal limb muscles, or subtle and fragmentary involving distal muscles. Facial muscles, such as the eyelids, may be involved. A number of special types of myoclonic seizure are described. These include *myoclonic absence seizures* (characterized by a typical absence seizure with rhythmical myoclonus usually involving the head and proximal muscle of the upper limbs); *eyelid myoclonia* (characterized by rhythmical myoclonia of the eyelids sometimes accompanied by a brief typical absence seizure) and *myoclonic atonic seizures* (consisting of a brief jerk followed by a diffuse loss of tone). *Negative myoclonic seizures* involve an interruption of tonic muscular activity for < 500 ms without any preceding myoclonus.

*Atonic seizures* are characterized by a sudden diminution of muscle tone lasting a second or longer, and involving the head, trunk, jaw or limb musculature.

An *astatic seizure*, also called a *drop attack*, is one in which there is a loss of erect posture resulting from an atonic, myoclonic or tonic mechanism.

*Epileptic spasms* (previously called infantile spasms) consist of a sudden flexion, extension or mixed extension-flexion of, predominantly proximal and truncal, muscles which is more sustained than myoclonus but briefer than a tonic seizure (approx. 1 s). They frequently occur in

clusters and it is now recognized that their occurrence is not limited to infancy or to West syndrome.

*Absence seizures* are characterized clinically by a brief impairment of consciousness. In *typical absence seizures* this is of abrupt onset and cessation with no postictal symptoms. In *atypical absence seizures* the onset and cessation may be less clearly defined, with the person appearing to drift into and out of the seizure. Typical absence seizures are accompanied, on the EEG, by generalized 3-Hz spike-wave discharges. Atypical absence seizures are usually accompanied by generalized spike-wave discharges at frequencies under 2.5 Hz. The depth of impairment of consciousness during absences varies. Unless mild, automatisms (defined as more or less coordinated, repetitive, motor activity usually occurring when cognition is impaired and for which the subject is usually amnesic afterwards) are frequent. They are usually relatively simple, for example lip smacking and fumbling with hands. Mild clonic, myoclonic and atonic phenomena may also occur during absences.

### Focal, self-limited seizure<sup>112,113</sup>

*Focal motor seizures* involve muscle activity in any form, with either an increase or decrease in muscle contraction. Subtypes include:

- *Focal motor seizures with elementary clonic motor signs*. The term 'elementary' implies that a single type of contraction of a muscle or group of muscles is involved; 'clonic' implies regular repetitive contractions. Such seizures often imply involvement of the primary motor area of the frontal lobe and may include a Jacksonian march with spread of clonic movements through contiguous body parts.
- *Focal motor seizures with asymmetrical tonic motor signs*. These seizures are characterized by an asymmetrical, sustained increase in muscle contractions, causing, for example, the child to adopt a 'fencing' posture. Such seizures are characteristic of those involving the supplementary motor areas of the frontal lobes although they can arise from other frontal lobe regions and from extrafrontal lobe sites.
- *With typical (temporal lobe) automatisms* as occurs in mesial temporal lobe seizures (described later).
- *With hyperkinetic automatisms* (such as pedalling, thrashing and rocking movements). Such seizures usually imply a frontal lobe origin.
- Rarer seizure types include *focal negative myoclonus* and *seizures with inhibitory motor signs* (implying a loss of muscle contraction as in motor arrest).

*Focal sensory seizures* are characterized by a perceptual experience not caused by appropriate stimuli in the external world. Subtypes include:

- *Focal sensory seizures with elementary sensory symptoms*. Here the term 'elementary' is used to imply a single, unformed phenomenon involving one primary sensory modality, e.g. somatosensory (parietal lobe seizures), visual (occipital lobe seizures), auditory, olfactory, gustatory, epigastric or cephalic.
- *With experiential sensory symptoms*. By this it is meant affective symptoms (fear, depression, anger, etc.), distortions of reality (déjà vu, jamais vu), feelings of depersonalization and formed illusionary or hallucinatory events. These are characteristic of seizures involving the junction of the temporal, parietal and occipital lobes.

*Gelastic seizures* are characterized by ictal laughter or giggling, usually without an appropriate affective tone. Such seizures often involve the hypothalamus.

*Hemiclonic seizures* are characterized by rhythmical clonic jerking involving one side of the body.

*Secondary, generalized seizures* are seizures whose onset is focal (e.g. motor or sensory) and then becomes generalized, usually as a tonic-clonic seizure.

The term *aura*, which had recently fallen from use, has now been defined as a subjective ictal phenomenon that, in a given child, may

precede an observable seizure; if it occurs alone, it constitutes a sensory seizure.

*Autonomic seizures* are characterized by altered autonomic function (objective or subjective) of any type (cardiovascular, pupillary, gastrointestinal, sudomotor, vasomotor and thermoregularity) at seizure onset or in which all manifestations are consistent with altered autonomic function.

### **Continuous seizure types (status epilepticus)**

Status epilepticus is defined by the ILAE as 'a seizure which shows no clinical signs of arresting after a duration encompassing the great majority of seizures of that type in most children or recurrent seizures without resumption of baseline central nervous system function, interictally'.<sup>112</sup> However, operationally it is usually defined as 'recurrent epileptic seizures continuing for more than 30 minutes without full recovery of consciousness before the next seizure begins, or continuous clinical and/or electrical seizure activity lasting for more than 30 minutes whether or not consciousness is impaired'.<sup>114</sup> For each type of epileptic seizure it is possible to define a corresponding type of status epilepticus:

- Generalized status epilepticus:  
generalized tonic-clonic status epilepticus;  
clonic status epilepticus;  
absence status epilepticus;  
tonic status epilepticus;  
myoclonic status epilepticus.
- Focal status epilepticus:  
epilepsia partialis continua (of Kozhevnikov);  
aura continua;  
limbic status epilepticus (psychomotor status);  
hemiconvulsive status with hemiparesis.

Some authorities recognize continuous spike and wave during slow sleep and hypsarrhythmia as special forms of 'electrical status'.<sup>115</sup>

A pragmatic clinical classification defines two main groups, convulsive and nonconvulsive status epilepticus. The former includes generalized tonic-clonic, clonic, tonic and myoclonic status epilepticus, epilepsia partialis continua and hemiconvulsive status with hemiparesis as convulsive status epilepticus and the others as nonconvulsive status epilepticus. Status epilepticus can also be defined according to etiology:

- Febrile status epilepticus – essentially a febrile convulsion lasting over 30 minutes. This is the commonest cause in children aged 1–3 years.
- Idiopathic status epilepticus – status epilepticus occurring without evidence of any previous CNS dysfunction (except possible previous seizures), and in the absence of an acute CNS or systemic disorder.
- Remote symptomatic – status epilepticus occurring in the context of a child with pre-existing static or progressive brain damage or dysfunction.
- Acute symptomatic – status epilepticus occurring during the course of an acute brain disorder caused by, for example, infection, trauma, hypoxic–ischemic insults, stroke, intoxication, metabolic and electrolyte disturbances, tumor and drugs, including antiepileptic drug withdrawal.

The clinical features of the different types of status epilepticus can generally be deduced from their names. However, it is worth noting that the clinical manifestations of both convulsive and nonconvulsive forms often become subtle as the seizure progresses. Hence, late in generalized tonic-clonic status, clonic movements may consist of barely perceptible stiffening of the limbs, while long lasting tonic status may mainly be manifested with hypoventilation, salivation and cyanosis. Nonconvulsive status may present with a child who is confused or is performing less well than is usual.

The effects and treatment of status epilepticus are considered elsewhere in this book.

### **Epilepsies and epilepsy syndromes**

The following summarizes the principal features of epilepsies and epilepsy syndromes currently recognized by the ILAE. More detailed accounts are given elsewhere.<sup>116–118</sup>

#### **Syndromes with onset in the neonatal period**

The incidence of seizures in the neonatal period is higher than at any time. Neonatal seizures can be classified as:

- Focal clonic – repetitive, rhythmic, unifocal or multifocal contractions of muscle groups of the limbs, face or trunk.
- Focal tonic – sustained posturing of a single limb or asymmetrical posturing of the trunk or sustained eye deviation.
- Myoclonic – generalized, focal or fragmentary arrhythmic shock-like contractions of muscle groups often provoked by stimulation.
- Generalized tonic – sustained symmetrical posturing of limbs, trunk and neck.
- Subtle seizures (often called motor automatisms) – these include random, roving eye movements, sucking, chewing and tongue protrusions and rowing, swimming and peddling movements of the limbs.

There is considerable debate as to whether all of these seizure types are epileptic in origin.<sup>119</sup> Clonic, focal tonic, generalized myoclonic and some subtle seizures are usually accompanied by ictal EEG discharges, are not usually provoked by stimuli and cannot be terminated by restraint or repositioning. They are probably epileptic in origin. Generalized tonic, focal and fragmentary myoclonic, and some subtle seizures, are usually not accompanied by ictal EEG discharges, can often be provoked by stimulation and terminated by restraint and repositioning. Many are probably not epileptic in origin, but may arise due to loss of cortical inhibition on lower centers.

The interictal EEG is of limited value in the investigation of neonatal seizures. Sharp waves, and even spikes, may be normal features and are not regarded as 'epileptiform abnormalities' as in older children. They are unlikely to be of significance, unless markedly asymmetrical in distribution. Asymmetries and absence of normal elements appropriate for the gestational age are of more help, but are indicators of brain dysfunction rather than specifically of seizure activity. Because neonatal seizures are often very frequent, ictal recordings are often obtained. Ictal discharges take many different forms but generally comprise combinations of repetitive sharp waves or spikes and abnormal paroxysmal rhythms. Discharges are often highly localized or may be confined to one hemisphere. They frequently move during the same recording. Generalized discharges are rare. Neonatal seizures are often unaccompanied by EEG discharges; conversely 'ictal' EEG discharges are frequently unaccompanied by clinical seizures. The clinical significance of such events is unclear.

A majority of neonatal seizures are symptomatic arising as a consequence of pre-, peri- or postnatal insults to the brain, including:

- Hypoxic-ischemic insults (including intrapartum hypoxia).
- Infection – including congenital infections, meningitis and encephalitis.
- Hemorrhage – including intraventricular, intracerebral, subdural and subarachnoid.
- Infarction.
- Malformations and maldevelopments of the brain.
- Metabolic problems including hypoglycemia, hypocalcemia, hypomagnesemia and inborn errors of metabolism.

The prognosis for neonatal seizures is heavily dependent on their etiology. It remains controversial as to whether the seizures themselves are damaging. This has led to uncertainty as to how aggressively they should be treated. Many clinicians only treat clinical seizures accompanied by ictal EEG changes (or if no ictal EEG is available, clinical seizures likely to be accompanied by ictal EEG changes).

Two specific symptomatic or probably symptomatic epilepsy syndromes of the neonatal period are described. These are *early myoclonic encephalopathy* and *Ohtahara syndrome*. Both usually have their onset within the neonatal period or first few months of life and are associated

with an identical abnormal EEG pattern known as suppression-burst. Early myoclonic encephalopathy is characterized by the occurrence of frequent, refractory generalized, focal or fragmentary myoclonia, focal clonic seizures and epileptic spasms. There is a high frequency of familial cases and the syndrome is often a manifestation of an inborn error of metabolism, especially nonketotic hyperglycinemia. It is highly resistant to treatment, carries a high mortality and survivors are nearly all severely retarded. Ohtahara syndrome is characterized by frequent tonic spasms. The etiology is heterogeneous but structural brain abnormalities are common. It often evolves to West syndrome. Seizures are highly resistant to treatment and again, there is an appreciable mortality with survivors nearly always being severely retarded.

Not all seizures in the neonatal period are a manifestation of a severe underlying problem. Two benign syndromes of neonatal seizure have been described. *Benign familial neonatal seizures* is an autosomal dominant epilepsy syndrome caused by mutations on voltage-gated potassium channels (KCNQ2 and KCNQ3).<sup>61,62,120</sup> The seizures occur in babies, who are otherwise well, and who remain well. They usually begin on the second or third day of life, but can be delayed up to the third month. A variety of seizure types have been described, but most involve an initial tonic component followed by autonomic changes (especially apnea and heart rate changes) and clonic components. Seizures are often initially frequent, but usually abate within a few days or weeks. The interictal EEG is usually normal. The ictal EEG usually shows generalized flattening, often followed by localized or generalized spikes or slow waves. There is no consensus regarding treatment, which is probably not necessary. Although the outlook is good, there is a significantly higher incidence of febrile and nonfebrile seizures in later childhood. *Benign idiopathic neonatal seizures* ('fifth day fits') is a nonfamilial condition occurring in otherwise normal babies.<sup>120</sup> Epidemiological data suggest clustering of cases, with at times epidemics, leading to the hypothesis of an infective etiology. Seizures, often frequent and prolonged, begin between days 1 and 7 of life and are mainly focal clonic in type, often with apnea. Drowsiness and hypotonia are common during the evolution of the disorder. A variety of interictal EEG patterns have been described. Ictal EEGs show rhythmic spikes or slow waves localized to various locations, particularly the rolandic regions. Generalized discharges also occur. As with benign familial neonatal seizures, antiepileptic drug treatment may not be required. The duration of active seizures is short, usually under a day. The long-term outlook is generally considered good, although detailed prospective studies are lacking.

### Syndromes with onset in infancy and early childhood

This period is marked by a high incidence of symptomatic and probably symptomatic epilepsies. Nevertheless, benign syndromes do occur, and the most common is that of febrile seizures. A notable feature of this period is the occurrence of the epileptic encephalopathies. These are conditions in which intense epileptiform activity appears to cause or contribute to neurodevelopmental problems.

Benign epilepsies of infancy are rare. The best known is *benign myoclonic epilepsy of infancy*.<sup>121</sup> This is an idiopathic, generalized epilepsy with onset between 4 months and 3 years. The characteristic seizures (indeed the only seizure type considered compatible with the diagnosis) are myoclonic jerks, mainly of the upper part of the body. They can be single or repeated, subtle, for example causing only head nods, or massive, causing falls. Also, in a minority of subjects, they may be precipitated by acoustic and tactile stimuli. Seizures can occur at any time while awake or asleep but often cluster when the infant is tired or on awakening. The seizures are accompanied on the EEG by a generalized discharge of spike or polyspike and waves. The interictal EEG, while awake, is usually normal, but sleep leads to a dramatic activation of spike or polyspike and wave discharges. As expected in an idiopathic epilepsy, neurodevelopmental progress prior to seizure onset is normal and there is often a family history of seizure disorders. Benign myoclonic epilepsy of infancy usually responds well to sodium valproate; treatment is generally recommended and is said in uncontrolled studies to improve prognosis. The period of active seizures probably lasts for up to 3 years. Some children

later develop other generalized epilepsies. Although considered a benign condition, around 15% have later learning difficulties.

Benign focal epilepsies in infancy are rare. *Benign infantile seizures (familial and nonfamilial)* occur in otherwise normal infants, with no identifiable predisposing factor, other than, in familial cases, a positive family history. Onset is from 3 to 20 months (usually 4–7 months if familial). Seizures are focal, with rare secondary generalization and often occur in clusters. Interictal EEG is usually normal. The familial form is autosomal dominant and links to chromosomes 2, 16 and 19 are described. *Benign familial neonatal-infantile seizures* is a similar autosomal dominant disorder presenting from day 2 up to 7 months of age. It is caused by mutations in genes for the sodium channel SCN2A.<sup>122</sup> The prognosis for these epilepsies is good. However, a subgroup of benign familial infantile seizures later develop paroxysmal choreoathetosis.<sup>123</sup>

*West syndrome* (with an incidence of 1.6–4.3 per 10 000 live births) is the best known epilepsy syndrome of infancy. It consists of a triad of epileptic spasms (this term is now preferred to infantile spasms and all other synonyms), hypsarrhythmia and psychomotor regression. Its onset is nearly always within the first year of life, and typically between 3 and 7 months of age.

Epileptic spasms involve a contraction of the axial muscles causing flexion, extension or both. They may be symmetrical or asymmetrical. The latter is a feature of focal brain lesions. Spasms may be single, but more typically occur in clusters and may occur at any time. However, they are particularly likely to occur when drowsy and on arousal and are rare in sleep. Spasms, particularly at onset, may be subtle, causing only brief head nods. Others are massive and cause distress. Other seizure types may precede, accompany or follow spasms. Of particular importance are spasms preceded by focal seizures, as this may indicate an operable lesion.

Typical hypsarrhythmia is defined as a more or less continuously abnormal EEG with high amplitude, irregular and asymmetrical slow wave activity across all leads with random sharp waves and spikes producing a chaotic pattern (Fig. 22.21). Spasms are often accompanied by electrodecremental responses in which the EEG briefly assumes a more normal appearance. Typical hypsarrhythmia occurs in under half of all cases of West syndrome. Modified forms include cases with some preservation of normal background activity, cases with synchronized bursts of generalized spike and wave activity and cases with significant asymmetries. Other EEG patterns which may occur include constant spike foci and burst-suppression. Hypsarrhythmia may be absent during awake recordings, but present in slow wave sleep.

Psychomotor stagnation and regression is extremely frequent, but not constant, in West syndrome. It often precedes the onset of spasms. Particularly prominent is loss, mostly visual, of interest in the environment.

An underlying cause for West syndrome can be identified in 85–90% of cases. Causes include:

- Neurocutaneous syndromes (tuberous sclerosis is the commonest single cause).
- Brain malformations (such as Aicardi syndrome, agyria-pachygyria, laminar heterotopia, hemimegalencephaly and other migrational disorders).
- Chromosomal abnormalities, including Down syndrome.
- Neurometabolic and degenerative diseases, including aminoacidurias, nonketotic hyperglycinemia, organicacidurias, urea cycle defects, mitochondrial disorders, CDG (carbohydrate-deficient glycoprotein) syndrome, pyridoxine dependency, biotinidase deficiency and PEHO (progressive encephalopathy with edema, hypsarrhythmia and optic atrophy) syndrome.
- Pre-, peri- and postnatal destructive lesions of the brain whether due to infection, hypoxic-ischemic insults, hypoglycemia, trauma or hemorrhage.
- Brain tumors.

A number of X-linked conditions causing West syndrome have been described.

The use of the terms 'cryptogenic' and 'idiopathic' are somewhat confusing when applied to West syndrome. Traditionally the former was used if no cause could be found, particularly if development prior to onset of spasms was normal. No idiopathic category was recognized. However, some children with West syndrome of unknown cause are normal prior to onset of spasms, but have spasms (accompanied by typical hypsarrhythmia) for a short period during which development is relatively unaffected. Most authorities now recognize these as true idiopathic cases.<sup>124</sup>

The treatment of infantile spasms is controversial with the debate centered on whether vigabatrin or hormonal treatment should be used first line and the type, dosage and duration of hormonal treatment.<sup>125,126</sup> The efficacy of vigabatrin in treating infantile spasms was first reported in the early 1990s.<sup>127</sup> It has been shown to be more efficacious than placebo<sup>128</sup> and spasms complicating tuberous sclerosis respond much better to vigabatrin than to hormonal treatment. A recent multicenter, randomized controlled trial (UKISS) compared vigabatrin (maximum dose 150 mg/kg/day) with either prednisolone (maximum dose 60 mg/day) or tetracosactide depot (maximum dose 60 IU on alternate days) in children with infantile spasms, except if due to tuberous sclerosis.<sup>129,130</sup> Freedom from spasms on days 13 and 14 was more likely with hormonal treatment (73%) than with vigabatrin (54%). However, at 14 months of age absence of spasms was similar (75% in the hormone group versus 76% in the vigabatrin group). Moreover, development (as assessed by the Vineland Adaptive Behavior Scales (VABS) was similar, although in the subgroup of those with no identified etiology for the spasms there was a significant increase in mean VABS score in those treated hormonally (mean 88.2) compared to those treated with vigabatrin (mean 78.9).

The clinician must make a choice between drugs of similar efficacy but completely different unwanted effects. Whether the evidence suggesting improved adaptive behavior in a subgroup of children is sufficient justification to recommend hormonal treatment over vigabatrin is unclear. The unwanted effects of hormonal treatment are more or less predictable, detectable and reversible but occasionally fatal, while the visual field defects caused by vigabatrin are unpredictable (but probably develop in up to one third) and, in infancy and early childhood, undetectable, but certainly not fatal.

When a response occurs to vigabatrin it is apparent within days. It is usually started at relatively modest doses of around 50 mg/kg/day with the dose increased in nonresponders every few days to around 180 mg/kg/day before concluding that it has been ineffective. It is usually possible to establish efficacy within a period of 2–3 weeks. Significant drowsiness is likely. Subjects who fail to respond to vigabatrin or who relapse often respond to subsequent hormonal treatment.

There are a multiplicity of studies comparing different hormonal regimens for the treatment of infantile spasms. A review concluded that:<sup>131</sup>

- Cessation or improvement in spasms occurs in 50–75% of subjects.
- The effect is apparent within a couple of weeks.
- Studies suggest either that prednisolone and ACTH are equally effective or that ACTH is more effective.
- Subjects who fail to respond to ACTH or prednisolone may subsequently respond to the other agent.
- There is no clear evidence that larger doses (150 U/m<sup>2</sup>/day) of ACTH are more effective than lower doses (20–30 U/day).
- Longer treatment periods do not usually improve remission rates.

UKISS used oral prednisolone for 2 weeks, starting at 10 mg four times a day and increasing, if necessary, to 20 mg three times a day after a week, subsequently, weaning it off over 15 days. Tetracosactrin was given intramuscularly for 2 weeks starting at 40 IU on alternative days, and increasing, if necessary, to 60 IU on alternative days after a week. A weaning dose of prednisolone was then substituted. Before starting hormonal treatment, infection should be excluded. Frequent monitoring of blood pressure, urine (for glycosuria) and serum electrolytes is important. Hypertensive children should be evaluated for cardiomyopathy. Hypertension and glycosuria may respond to a reduction in dose. Some authorities recommend tapering ACTH and prednisolone over a

1-week period, even when used for only short periods. If high dose and/or prolonged treatment regimens are used longer tapering courses are necessary; evaluation of the hypothalamic–pituitary axis at the end of therapy is advocated by some.

Infantile spasms complicating tuberous sclerosis respond much better to vigabatrin than to hormonal treatment.<sup>132</sup> Otherwise, the response rate is better in those in whom no underlying cause can be found. It is not clear whether it is appropriate to use different first line agents in the treatment of cryptogenic and symptomatic spasms.

Many other agents have been suggested for the treatment of spasms, whether as initial treatment or as add-on therapy. These include: benzodiazepines, especially nitrazepam; sodium valproate (used in doses considerably higher than usual); pyridoxine; topiramate; lamotrigine; zonisamide; and immunoglobulins.

A small, but important, group of children with focal brain lesions develop West syndrome. These may respond best to drugs like carbamazepine. Nonresponders may be candidates for early resective surgery. Suggestive features are: focal neurological signs; focal epileptic seizures, prior to the onset of or concurrent with epileptic spasms; focal onset of spasms or asymmetrical spasms; asymmetrical hypsarrhythmia or fixed EEG foci. All children with West syndrome require early evaluation with structural brain imaging, preferably MRI. Video-EEG may be necessary to detect focal onset of spasms or asymmetrical spasms.

The overall prognosis for West syndrome is poor and it has not been established whether drug treatment has any impact on the ultimate outcome. Spasms usually remit in infancy or early childhood, but may continue. However, 50–75% of children develop other forms of epilepsy, particularly the Lennox–Gastaut syndrome. From 70% to 90% of infants with West syndrome are mentally retarded and a significant minority have cerebral palsy and/or neuropsychiatric disorders, including autism.<sup>131</sup> West syndrome carries an increased mortality of perhaps around 5%. The main determinant of prognosis is etiology. Those with cryptogenic, and especially idiopathic, spasms, have the best prognosis, both in terms of becoming seizure free and in developing normally. However, symptomatic spasms complicating Down syndrome and neurofibromatosis are said to carry a better prognosis. Other good prognostic factors include normal neurodevelopment prior to onset of spasms, older age at onset and short duration of spasms. Early effective treatment is generally felt likely to improve outcome and has been shown to do so in Down syndrome.<sup>133</sup> However, this effect was not apparent in UKISS.

*Severe myoclonic epilepsy in infancy (Dravet syndrome)* has only been recognized for the last two decades but is among the most distinctive of the severe epilepsies occurring in infants and young children.<sup>134</sup> The key features for its recognition are the occurrence of febrile, or afebrile, clonic, or tonic-clonic, seizures, often unilateral and sometimes prolonged occurring in the first year of life in an otherwise normal infant. Initial development continues to be normal. However, somewhere between the second and fourth years of life, other seizure types occur, notably myoclonic seizures, atypical absences, absence status and focal seizures. This is accompanied by psychomotor delay, with nearly all children eventually being severely retarded. This justifies its inclusion within the epileptic encephalopathies. Ataxia, mild pyramidal signs and behavioral problems are also common. The interictal EEG is initially normal, except for early photosensitivity in a significant minority of children. With the onset of the polymorphous seizures in the second year of life, spike, polyspike and spike and wave discharges occur. The background may remain normal or show progressive slowing. Dravet syndrome is commonly associated with mutations on a sodium channel gene (SCN1A). However, similar mutations are also associated with other epilepsy phenotypes<sup>135</sup> and also with post-pertussis vaccine encephalopathy.<sup>136</sup> It is postulated that the Dravet phenotype results from the cumulative effects or interactions of a few or several genes of which SCN1A is but one. The syndrome is highly resistant to treatment. Given the combination of focal and generalized seizures types, it is probably most appropriate to use antiepileptic drugs with a broad spectrum of activity, such as sodium valproate, topiramate and levetiracetam and

to avoid drugs such as carbamazepine which may exacerbate generalized seizures. Lamotrigine may also exacerbate seizures.<sup>137</sup> Efficacy of stiripentol when used with sodium valproate and clobazam was shown in a double blind trial.<sup>138</sup>

Rarer and less well-characterized severe epilepsies occurring in infancy and early childhood include *migrating partial seizures of infancy*, *myoclonic status in nonprogressive encephalopathies* and *hemiconvulsion-hemiplegia syndrome*.<sup>139</sup> The first of these is characterized by an onset at around 3 months of age of intractable and escalating focal seizures (usually focal motor), which characteristically involve one area of the body before shifting to another. Myoclonic status in nonprogressive encephalopathies is characterized by repeated episodes of myoclonic status epilepticus occurring in children with nonprogressive 'static' encephalopathies, including cerebral palsy, Angelman syndrome and Prader-Willi syndrome. Hemiconvulsion-hemiplegia syndrome (HH syndrome) has been long recognized, but appears to be declining in frequency. Its cardinal features are the occurrence, in an otherwise normal child, of a prolonged unilateral, usually clonic, febrile seizure, either in the course of a trivial infection or else symptomatic of a severe acute brain disorder such as meningitis, followed by atrophy of one cerebral hemisphere and hemiplegia. Epilepsy supervenes after a variable period. Both focal and generalized seizures may occur. Prevention with rapid termination of prolonged febrile seizures is important and may help explain its decline in frequency.

### Syndromes with onset in mid- and late childhood and adolescence

This age group is associated with a decline in the incidence of epilepsy and by a number of relatively common and well-characterized epilepsy syndromes, which are almost certainly genetic in origin and many of which carry an excellent prognosis. These can be conveniently considered under the categories of the idiopathic focal and generalized epilepsies of childhood and adolescence. Symptomatic and probably symptomatic epilepsies are also important in this age group. They include focal epilepsies, most notably mesial temporal lobe epilepsy, and a number of epileptic encephalopathies such as the Lennox-Gastaut syndrome and the Landau-Kleffner syndrome.

**The idiopathic generalized epilepsies.**<sup>140</sup> These are characterized by:

- Occurrence in otherwise normal children and adolescents.
- Strong family history of epilepsy, including, but not restricted to, idiopathic epilepsies.
- A preceding history of febrile convulsions in many subjects.
- The occurrence in various combinations of three seizure types: generalized tonic-clonic seizures; typical absence seizures; and myoclonic seizures.
- EEGs in which the background is generally normal with paroxysmal regular or irregular spike or polyspike and wave abnormalities at 3 Hz or greater.

The three best-characterized, idiopathic generalized epilepsies are childhood absence epilepsy, juvenile absence epilepsy and juvenile myoclonic epilepsy.

*Childhood and juvenile absence epilepsies* are both characterized by the occurrence of typical absence seizures. In both these are relatively prolonged, typically 10–20 seconds, with severe impairment of consciousness such that automatisms are common. Other features during the absences such as eyelid blinking, mild clonic movements around the mouth and head nods may occur but are not prominent. In childhood absence epilepsy, absences are very frequent, occurring many times a day – hundreds may be recorded on video-EEG. In juvenile absence epilepsy they are less frequent, occurring at most a few times a day. Except for febrile convulsions, other seizure types occur only very rarely in childhood absence epilepsy. Occasional myoclonic jerks may occur in juvenile absence epilepsy and up to 80% of subjects with juvenile absence epilepsy have, or develop, generalized tonic-clonic seizures, which are usually infrequent. Many authorities consider that photosensitivity is not compatible with the diagnosis of childhood absence epilepsy, and possibly also juvenile absence epilepsy. Childhood absence epilepsy usually has

its onset between 4 and 8 years and generally remits by about the age of 12. Occasional children (no more than 10%) will develop generalized tonic-clonic seizures in their teenage years or adult life. Juvenile absence epilepsy usually has its onset between 7 and 16 years and is usually long lasting with susceptibility to seizures continuing into adult life.

The EEG in childhood and juvenile absence epilepsies is similar and is characterized by regular generalized spike and wave discharges at around 3 Hz (Fig. 22.19). The discharges are increased during sleep and on awakening and are provoked by hyperventilation.

*Juvenile myoclonic epilepsy* is characterized by a triad of seizure types. Typical absences occur in about one third of children, usually in late childhood or early adolescence. They are usually brief (a few seconds), mild and unaccompanied by automatisms. However, if they start in younger children they may resemble those of childhood absence epilepsy. Myoclonic seizures occur in all individuals, usually starting in early to mid adolescence. They may be massive (causing falls), or confined to the limbs, or extremities. They may be single or multiple and rhythmic. They usually cluster in the period shortly after awakening with a second cluster toward the end of the day. They are often not reported spontaneously, as the child considers them as a normal feature of everyday life. Enquiries should be made as to whether the child is considered 'clumsy' in the morning or has the 'shakes' with a tendency to spill drinks. Generalized tonic-clonic seizures occur in nearly all untreated children, usually a few years after the onset of myoclonic jerks. They usually cluster in the morning and may be heralded by a shower of myoclonic jerks or absences, sometimes leading to an erroneous diagnosis of secondary generalized tonic-clonic seizures. Photosensitivity, both clinical and on EEG, is common. The EEG in juvenile myoclonic epilepsy is characterized by irregular discharges of fast spike, or more often polyspike and wave (Fig. 22.19). Myoclonic seizures are usually accompanied by brief polyspike or polyspike and wave discharges. Although the background EEG is usually normal, focal abnormalities occur in a minority. These have the appearance of abortive generalized discharges and vary in location.

*Epilepsy with generalized tonic-clonic seizures only* usually begins in adolescence or young adult life. It is characterized by generalized tonic-clonic seizures only. These often occur exclusively, or predominantly, on awakening (hence the old name 'epilepsy with grand mal on awakening'). It should be noted that generalized tonic-clonic seizures, occurring predominantly on waking, occur in a number of epilepsy syndromes, including juvenile myoclonic epilepsy. It is the lack of other seizure types which distinguishes the syndrome.

The ILAE diagnostic scheme suggests inclusion of two syndromes, *epilepsy with myoclonic astatic seizures and epilepsy with myoclonic absences*, which were previously usually considered amongst the cryptogenic or symptomatic generalized epilepsies, within the idiopathic generalized epilepsies. The former (also known as Doose syndrome) usually has its onset within the first 5 years of life.<sup>141</sup> The defining seizure types are atonic and myoclonic, which are often combined (myoatonic seizure) and are often manifested as drop attacks. Episodes of nonconvulsive status epilepticus are common. The characteristic EEG feature is spike or polyspike and wave discharges, often with photosensitivity. The prognosis is variable. Many children continue to develop normally and seizures eventually remit. However, others, especially those with repeated episodes of nonconvulsive status epilepticus, show cognitive decline. In epilepsy with myoclonic absences, the characteristic seizures are typical absences, accompanied by marked rhythmical myoclonia, mainly affecting the upper limbs and head.<sup>142</sup> These seizures can occur in otherwise normal children, but many have pre-existing neurodevelopmental problems. In children who do not, such problems often supervene. The EEG is very similar to that seen in childhood absence epilepsy. However, video-EEG or an EMG lead applied over the deltoids will reveal myoclonus accompanying each spike-wave discharge.

There are many children with epilepsy with features suggestive of an idiopathic generalized epilepsy who do not fit within the above syndromes. In recent years a number of other syndromes have been suggested and are more or less well characterized. In *eyelid myoclonia with absences* (*Jeavons syndrome*) the characteristic seizure consists of

brief episodes of marked jerking of the eyelids usually accompanied by upward deviation of the eyes. These usually start in childhood, are often very frequent, and may be misdiagnosed as tics. On EEG, the seizures occur on eye closure and are associated with generalized polyspike and wave discharges (Fig. 22.19). All children are photosensitive and there is continued debate about the role of self-induction of the seizures. Despite the name, absences are usually inconspicuous. The condition usually continues into adult life and generalized tonic-clonic seizures commonly develop. *Perioral myoclonia with absences* is a syndrome in which typical absences are accompanied by marked rhythmical myoclonia of the perioral and/or jaw muscles. Episodes of absence status appear to be common as are generalized tonic-clonic seizures. The most recently described epilepsy to be placed by the ILAE with the idiopathic generalized epilepsies is *generalized epilepsy with febrile seizures plus (GEFS+)*.<sup>143</sup> This is an autosomal dominant condition in which different family members have variable phenotypes including febrile seizures only, febrile seizures with other, mainly generalized, seizure types, and myoclonic-astatic seizures. It is associated with a number of sodium ion channel mutations (SCN1A, SCN1B and SCN2A) and mutations on a GABA<sub>A</sub> receptor gene.

The idiopathic generalized epilepsies usually show an excellent response to sodium valproate, lamotrigine, topiramate and levetiracetam. However, lamotrigine may aggravate myoclonic jerks. Ethosuximide is a useful drug for childhood absence epilepsy, but is considered to be ineffective against generalized tonic-clonic seizures. Combined therapy, with two, or even all three, of these agents, is occasionally useful in refractory cases. Benzodiazepines, including clobazam and clonazepam, are also useful, particularly against myoclonic seizures. Sodium valproate, levetiracetam and lamotrigine are active against photosensitive seizures. Carbamazepine, vigabatrin, tiagabine and probably also phenytoin are generally ineffective and may exacerbate existing seizures and precipitate new seizure types: their use is contraindicated except in exceptional circumstances.<sup>144</sup>

**The idiopathic focal epilepsies.**<sup>145</sup> These are characterized by:

- Normal preceding neurodevelopment.
- A strong family history of epilepsy including, but not restricted to, idiopathic epilepsies.
- A strong history of preceding febrile seizures.
- Stereotyped seizures reflecting the site of ictal onset and spread.
- EEGs in which the background is normal but in which highly characteristic interictal focal spike and wave abnormalities are frequent.

*Benign childhood epilepsy with centrotemporal spikes* (commonly called *rolandic epilepsy* or *BECTS*) is the commonest of these epilepsies, and indeed may account for around 20% of all new onset epilepsies in young school-age children who are otherwise normal. The seizures have their onset in the lower rolandic cortex representing the face and oropharynx. Seizure onset peaks between 7 and 10 years. Seizures occur in sleep in only around 70% of children, in both sleep and awake in 15%, and while awake only in 15%. Seizures during sleep often occur shortly after falling asleep or shortly prior to awakening. The seizures are most characteristically unaccompanied by any impairment of consciousness (simple focal in the old terminology), but those during sleep may evolve (often rapidly) with disturbance of awareness and reactivity (complex focal) and/or secondary generalized tonic-clonic or hemiclonic convulsions. BECTS should always be considered in a child, of appropriate age, who presents with nocturnal generalized seizures. The seizures usually begin with somatosensory symptoms in and around the mouth. The child often complains of paresthesiae, numbness, 'heaviness' or 'thickness' of the lips, gums, inner cheek and tongue. This is often followed by clonic jerking of the perioral muscles, lips and tongue. Salivation is often prominent. Speech arrest may be due to either laryngeal involvement, or to involvement of nearby speech areas. Seizures usually last only a few seconds to a few minutes but status epilepticus has been described. Total seizure count is usually low; many children have a single seizure only. However, some children have numerous seizures, sometimes with more than one in a single night. The EEG is highly characteristic with

interictal sharp and slow wave complexes in the left and/or right central and/or mid temporal region (Fig. 22.20). They may be unilateral or bilaterally synchronous or asynchronous. They are strongly activated by sleep. Similar abnormalities occur in a minority of children in other brain regions. BECTS has an excellent prognosis. It usually remits within 1–2 years of onset and certainly before mid adolescence. It is exceptional for seizures to occur in adult life.

The second most common benign partial epilepsy of childhood is *Panayiotopoulos syndrome* (*early-onset benign childhood occipital epilepsy*).<sup>146,147</sup> It is encountered two to three times less frequently than BECTS. It predominantly affects younger children aged 3–6 years old. Seizures manifest with autonomic symptoms, particularly nausea, retching and vomiting. Often the seizure onset is inconspicuous with the child simply appearing unwell, pale, quiet or irritable. They may complain of feeling sick. Other autonomic manifestations include pallor, pupillary, cardiorespiratory and probably thermoregulatory changes. As the seizure progresses, there is frequently deviation of the eyes and head and impairment of consciousness. Unresponsiveness may be accompanied by marked loss of postural tone. The terms 'ictal syncope' or 'syncopal-like episodes' has been suggested for this. Around half of the seizures end in secondary generalization. Two-thirds of seizures start in sleep. An important and unusual feature in Panayiotopoulos syndrome is that around half of all seizures last for more than half an hour (sometimes for many hours) constituting autonomic status epilepticus. During such episodes the child's conscious level fluctuates and there is often intermittent retching and vomiting and eye and head deviation. The status may terminate with a hemiclonic convulsion or a generalized tonic-clonic seizure. Status in Panayiotopoulos syndrome is frequently not recognized as being epileptic in nature, but may lead to admission to an intensive care unit, with a suspected grave cerebral insult.

The interictal EEG usually reveals abnormalities similar to those seen in BECTS – sharp and slow waves or spikes – but predominating in the occipital regions (Fig. 22.20). As a consequence, Panayiotopoulos syndrome has been classified as an occipital epilepsy. However, this may not be appropriate given the frequency of extraoccipital EEG abnormalities and the predominantly autonomic seizure manifestations. Panayiotopoulos syndrome is among the most benign of all epilepsies. Total seizure count is usually low; many children have only a single seizure and seizures generally remit within 1–2 years of onset.

*Late-onset childhood occipital epilepsy* (*Gastaut type* or *CEOP*) begins predominantly in mid-late childhood with a peak age of onset around the age of 7–9 years. It is characterized by relatively frequent, usually brief, visual seizures occurring while awake. These occur in full consciousness and are mainly manifested by elementary visual hallucinations of, for example, colored balls (Fig. 22.23). By contrast, in migraine, visual hallucinations are usually black and white and jagged or sharp in outline.<sup>148</sup> Less commonly, visual hallucinations in CEOP are complex, e.g. of figures. Visual illusions, such as micropsia, visual field defects and episodes of ictal blindness also occur. Headache, often hemicranial, is common either ictally or postictally and misdiagnosis as migraine is common. The EEG is characterized by occipital paroxysms, which are runs of high-amplitude spike-waves or sharp waves, occurring in the posterior regions. Prognosis is less clear than with either BECTS or Panayiotopoulos syndrome – many individuals continue to have seizures in adolescence and adult life and some develop occasional generalized tonic-clonic seizures.

A third idiopathic occipital epilepsy syndrome in children – *idiopathic photosensitive occipital lobe epilepsy* – is discussed with reflex epilepsies.

A number of other epilepsy syndromes with certain similarities to BECTS and Panayiotopoulos syndrome have been proposed but are less well characterized. These include *benign childhood seizures with affective symptomatology*, *benign partial seizures in adolescence*, *benign childhood epilepsy with parietal spikes and frequent giant somatosensory evoked potentials*, *benign childhood focal seizures associated with frontal or midline spikes*, *benign focal epilepsy with central and vertex spikes and waves during sleep* and *benign focal seizures of adolescence*. These demonstrate that there are

Fig. 22.23 Patient's illustrations of visual hallucinations in childhood occipital epilepsy (Gastaut type).

many children who have features suggestive of benign focal epilepsy, but whose electroclinical features do not fit within existing syndromes.

In recent years, a number of idiopathic focal epilepsies, inherited in an autosomal dominant manner, have been described. The best characterized is *autosomal dominant nocturnal frontal lobe epilepsy*. This usually begins in childhood, but has an exceptionally wide age range of onset. The seizures are characteristically brief and occur during light sleep. They may be repeated many times per night. Motor symptoms predominate. A grunt, groan, or more complex vocalization, often heralds the seizure, followed by hyperkinetic motor behaviors (e.g. thrashing, thrusting and rocking movements) or tonic or dystonic posturing, sometimes with clonic components. The occurrence of dystonic features gave rise to the designation 'nocturnal paroxysmal dystonia', which was previously considered non-epileptic. The EEG is frequently normal, even during attacks. A minority show focal frontal interictal and ictal abnormalities. Neuroimaging is normal. The condition appears to be life-long. A good response to carbamazepine is seen in some, but not all, children. Other autosomal dominant focal epilepsies include *familial temporal lobe epilepsy* and *familial focal epilepsy with variable foci*.<sup>149,150</sup>

In children with benign focal seizures who have few seizures, particularly if seizures cause little distress, and in whom remission is expected (i.e. BECTS and Panayiotopoulos syndrome), it is reasonable not to treat with antiepileptic drugs and to await spontaneous remission. When treatment is given, it is important to ensure that the unwanted effects are not more troublesome than the seizures. Occasionally the idiopathic focal epilepsies can be made more severe with antiepileptic drug treatment. This is particularly described with carbamazepine.<sup>151</sup>

**Symptomatic and probably symptomatic focal epilepsies.** These epilepsies are mainly defined by their site of origin and, to a lesser extent, by their etiology. A broad distinction is made according to whether the site of origin is in the limbic system or in the neocortex (including the lateral

temporal lobes). Of the limbic epilepsies mesial temporal lobe epilepsy is the most important. Neocortical epilepsy syndromes include Rasmussen syndrome.

*Mesial temporal lobe epilepsy with hippocampal sclerosis* (often referred to simply as *mesial temporal lobe epilepsy*) is of considerable importance because it is the single largest cause of refractory epilepsy in adults and the commonest reason for undertaking epilepsy surgery. Mesial temporal sclerosis consists of severe loss of specific neurones in the hippocampus along with synaptic reorganizations. This probably results from a previous cerebral injury rather than as a consequence of repeated seizures and, at least in adults undergoing epilepsy surgery, is strongly associated with prolonged febrile convulsions in early childhood. It is not established whether these are the cause of mesial temporal sclerosis, or another manifestation of it. Genetic factors are also important and there is an increased incidence of various seizure disorders in the families of subjects with mesial temporal lobe epilepsy.

The following represents the sequence typical in mesial temporal lobe epilepsy, although there is considerable variation:

- Complicated febrile convulsion(s) in infancy/early childhood.
- Later onset of habitual seizures, usually in childhood, which characteristically respond well to initial treatment.
- Return of habitual seizures in adolescence/early adult life, which often become refractory to treatment.

The habitual seizures of mesial temporal lobe epilepsy often begin with an aura, manifestations of which may include autonomic features such as a rising sensation in the epigastrium, psychic features such as fear, déjà vu and feelings of depersonalization, visual illusions such as micropsia and macropsia and olfactory hallucinations such as unpleasant smells. Formed visual and auditory hallucinations are said not to occur. Many seizures do not progress beyond the aura. In the old terminology they were classed as simple focal seizures. However, they

often progress such that there is impaired cognition, perception, attention and memory (dyscognitive seizure or 'complex partial' in the old terminology). Motor manifestations are often prominent and include motor arrest, oro-alimentary and manual automatisms and lateralized motor manifestations such as forced head and eye deviation and tonic or dystonic posturing. Language disturbances also occur. Secondary generalization is often not a prominent feature. The postictal period is typically characterized by a variable period of confusion, disorientation, language disturbances and either relaxation or automated semipurposive movements. Contralateral Todd paresis may occur. More details on the lateralizing features of mesial temporal lobe seizures are to be found elsewhere.<sup>152,153</sup>

The characteristic interictal EEG abnormality is anterior temporal sharp waves, spikes and slow waves (Fig. 22.20). These are quite frequently bilateral, even in children in whom habitual seizures are unilateral. In younger children, bilateral synchronous spike-wave discharges may occur. A repeatedly normal, interictal EEG is common. MRI has revolutionized the detection of hippocampal sclerosis. Thin coronal slices orthogonal to the long axis of the temporal lobes usually reveal hippocampal atrophy, temporal horn dilation (both best appreciated on T1-weighted sections) and, on T2-weighted images, high signal in the hippocampus (Fig. 22.22).

The drug of choice for mesial temporal lobe epilepsy is carbamazepine. Initial response is usually good, but may not be maintained. There is currently no information about what percentage of children gain permanent seizure remission and how many develop refractory epilepsy. When carbamazepine fails, other drugs active against partial seizures should be tried. However, surgery offers the prospect of 'cure' in around 80% of children and should not be unduly delayed through a desire to exhaust all medical options.

Mesial temporal lobe epilepsy can also be caused by cortical dysplasias, tumors (particularly dysembryoplastic neuroepithelial tumors), hamartomas and chronic encephalitis and other destructive lesions.

The *neocortical epilepsies* are a heterogeneous group of epilepsies arising from the frontal lobes, lateral temporal lobes, parietal and occipital lobes. *Lateral (neocortical) temporal lobe epilepsy* is uncommon. Compared to mesial temporal lobe epilepsy, seizures are more likely to give rise to auditory, vertiginous and complex visual hallucinations and less likely to give rise to motor manifestations.

*Frontal lobe epilepsies* are relatively common and probably underrecognized. They pose particular diagnostic problems. Three main seizure types have been described:

- Focal clonic seizures. These characteristically occur in clear consciousness and involve localized rhythmical jerking of a limb. A Jacksonian march, consisting of sequential involvement of contiguous areas of the body in a focal motor seizure, may be seen. Such activity implies seizure activity in the primary motor area.
- Focal motor seizures with asymmetrical tonic motor seizures (asymmetrical tonic seizures, supplementary motor seizures). These are characterized by the assumption, usually suddenly, of fixed and abnormal postures, the most classical being the so-called 'fencing posture'. Motor manifestations are often preceded by somatosensory sensations of numbness and tingling. Other ictal features are speech arrest or forced vocalizations and secondary generalization. Asymmetrical tonic seizures are characteristic of seizures arising in the supplementary motor area of the frontal lobes.
- Focal motor seizures with hyperkinetic automatisms (frontal lobe complex partial seizures, hypermotor seizures). These seizures occur in association with impaired cognition and are characterized by complex motor automatisms. Frenetic, agitated, and sometimes sexual, behavior is often seen, along with vocalizations, ranging from humming to the shouting of obscenities. Such seizures can originate from many areas of the frontal lobes.

The reader requiring fuller descriptions is referred elsewhere.<sup>154</sup> Frontal lobe epilepsies are often characterized by frequent, mainly nocturnal, seizures, with little if any postictal drowsiness. The interictal and even

ictal EEG is often normal, reflecting the fact that large areas of the mesial and inferior frontal lobes are not directly accessible by scalp EEG. They are often confused with psychogenic seizures, which, however, rarely occur while the child is asleep and usually last longer.

*Occipital lobe epilepsies* are relatively uncommon. Characteristic ictal features include elementary and sometimes complex visual hallucinations. The most common are hallucinations of colored spots or geometric forms similar to those described for late-onset childhood occipital epilepsy (Gastaut type). Ictal blindness may also occur. Other features are a variety of abnormal eye movements such as tonic deviation, nystagmoid movements, forced blinking and eyelid flutter. Many different patterns of spread can occur, giving rise to features more typical of temporal or frontal lobe seizures. The interictal and ictal EEG is generally useful in the diagnosis of occipital epilepsies. However, occasionally discharges confined to mesial or inferior aspects of the occipital lobes may be undetected by scalp EEG and the propensity of seizures to spread may impede localization. The range of pathologies causing occipital lobe epilepsy is similar to that of other neocortical epilepsies. However, in addition, a syndrome of *occipital lobe epilepsy with bilateral occipital calcifications and celiac disease* has been described.<sup>155</sup> The relationship between occipital lobe epilepsies and migraine has also aroused much debate. Occipital epilepsy and migraine are often confused because both are characterized by visual hallucinations and by headache, often hemispheric. In addition, it is possible that occipital (and other) epilepsies may occasionally trigger migraine attacks. Whether epileptic seizures are ever caused by migraine remains to be established.

*Parietal lobe epilepsy* is rare. Ictal manifestations include somatosensory symptoms, particularly unilateral paresthesiae and pain (including abdominal pain), speech problems, dyspraxias and agnosias. Many parietal lobe seizures are 'silent' unless they spread. Interictal and even ictal EEG is often unhelpful.

*Rasmussen syndrome* (often called *Rasmussen encephalitis*)<sup>156</sup> is a symptomatic, neocortical epilepsy syndrome of unknown cause, characterized pathologically by so-called 'chronic encephalitis'. Its onset is usually between 1 and 15 years and may present either with focal seizures, which quickly become more and more frequent, or as status epilepticus, which is usually focal in nature. The most characteristic seizure type is focal motor seizures, often highly localized, for example to an extremity of one limb or around the mouth. However, impaired cognition during seizures is not uncommon, particularly as the condition progresses. *Epilepsia partialis continua* is seen at some time in the disease in the majority of children. The disease is nearly always strictly unilateral at onset, but 'spread' to the other hemisphere can occur with time. A hallmark of the disease is progressive cerebral atrophy, usually confined to one hemisphere, at least initially. This is accompanied by a progressive hemiparesis whose onset can occur within weeks of the onset of clinical seizures or be delayed for years. It is accompanied by cognitive decline. Interictal EEG may show progressive background slowing of the involved hemisphere. Ictal EEG is often lateralizing but rarely localizing. Structural imaging early in the disease may show focal high signal on T2-weighted images, particularly in the cerebral cortex. Later atrophic changes are seen.

The management of Rasmussen syndrome should involve early referral to an epilepsy surgery center, since early hemispherectomy is considered by many to be the treatment of choice. Localized resections are generally ineffective. Medical therapy with conventional antiepileptic drugs is nearly always unsuccessful in the long term, although short term control of seizure may be achieved. Immunotherapy with either steroid medication or intravenous immunoglobulin may be of benefit in some children and may avoid the need for hemispherectomy.

**Epileptic encephalopathies.** The best known epileptic encephalopathy of childhood is *Lennox-Gastaut syndrome*. However, there is considerable variation in how this syndrome is defined. At one extreme it has been used to designate virtually any seizure disorder in childhood characterized by drug-resistant seizures and impaired mental abilities. Alternatively, as here, it is used to designate a narrowly defined

symptomatic, or probably symptomatic, generalized epilepsy. Its onset is usually between 3 and 5 years of age; onset after 10 years of age is exceptional. The defining features are:

- The occurrence of mixed generalized seizure types of which tonic, atonic and atypical absences are the most prominent.
- Interictal EEG patterns with generalized slow spike and wave discharges and, in sleep, bursts of fast rhythms at 10–12 Hz (Fig. 22.21).
- Psychomotor delay.

Lennox–Gastaut syndrome has multiple causes, similar to those of West syndrome, from which it sometimes evolves. Indeed virtually any cortical brain pathology, whether focal or generalized, can cause it. True idiopathic cases are not generally recognized, children in whom no cause can be found being classified as probably symptomatic.

The characteristic seizures of Lennox–Gastaut syndrome can be present from the start. Alternatively, they may be preceded by other seizure types, including focal seizures. Seizures tend to be frequent, occurring many times a day, and tonic and atonic seizures often cause falls ('drop attacks'). During sleep, tonic seizures are particularly characteristic and are associated with 10–12 Hz fast rhythms. Episodes of nonconvulsive status epilepticus are common. Virtually any other seizure type can occur, including (according to many, but not all authorities), focal seizures. However, myoclonic seizures are not usually prominent. Their occurrence, especially if associated with EEG patterns other than slow spike and wave, should make one consider other severe epilepsies, such as severe myoclonic epilepsy in infancy. However, a myoclonic variant of the Lennox–Gastaut syndrome is recognized. Occasionally, children and adolescents with apparently idiopathic epilepsies develop features of the Lennox–Gastaut syndrome.<sup>157,158</sup> In some cases this may be drug induced.

Mental retardation is often pre-existing. However, the onset of the syndrome is nearly always accompanied by a slowing in development or even apparent regression. This is not of the relentless nature seen in neurodegenerative conditions. It often appears to mirror seizure control, with improvement occurring during quiescent periods. However, a majority of children eventually become mentally retarded, and this is often severe. Behavioral problems, including autistic behaviors, may coexist. A small number of children with otherwise typical Lennox–Gastaut syndrome develop normally.

Lennox–Gastaut syndrome is highly resistant to therapy. There are many different recommendations but in general it is best to use broad-spectrum agents such as sodium valproate, lamotrigine, topiramate, levetiracetam and zonisamide rather than narrower spectrum agents such as carbamazepine and vigabatrin. However, there is no doubt that the latter have benefited individual children. Other drugs, usually used as concomitant therapy, which may be useful, include the benzodiazepines, ethosuximide and acetazolamide. Controlled trials have demonstrated efficacy of lamotrigine, topiramate and felbamate in the Lennox–Gastaut syndrome.<sup>159–162</sup> Monotherapy should always be attempted, but many children do best on two, or occasionally three, drugs. Polytherapy carries significant risks of making seizures worse, particularly if they induce drowsiness. In children with Lennox–Gastaut syndrome it is important to define a realistic aim for drug therapy. This will involve accepting that complete seizure control is unlikely and that maximizing function and quality of life is of more importance. The natural history of the disorder is marked by fluctuations in the activity of seizures. This must be recognized when making decisions regarding drug treatment.

Other treatments, which may be helpful in Lennox–Gastaut syndrome, include the ketogenic diet, steroids, intravenous immunoglobulins and surgery. Except on very rare occasions when a focal or strictly hemispheric lesion gives rise to Lennox–Gastaut syndrome, resective surgery is not an option. However, corpus callostomy may be helpful if atonic drop attacks are a major problem. Vagal nerve stimulation may also be useful.<sup>163</sup>

The overall prognosis for Lennox–Gastaut syndrome is poor. A small number of previously normal subjects, particularly those whose condition is of later onset and who have the condition for only a short period

of time, have a favorable outlook. The remainder continue to have seizures for many years. These may continue to show the characteristics of the Lennox–Gastaut syndrome or there may be an evolution into other types of epilepsy.

*The Landau–Kleffner syndrome and epilepsy with continuous spike-waves during slow-wave sleep* are closely related epilepsy syndromes. The EEG pattern of continuous spikes and waves during slow sleep (CSWS) consists of bilateral generalized spike and wave discharges present for at least 85% of slow-wave sleep. This pattern is occasionally encountered in the course of a number of epilepsies. For example, it is described in children with benign childhood epilepsy with centrotemporal spikes in whom it may be associated with a decline in cognitive performance. It has also been described as a separate, and rather poorly defined, syndrome (epilepsy with continuous spike-waves during slow-wave sleep). Finally it is very common in the Landau–Kleffner syndrome. The latter is an epilepsy syndrome occurring in previously normal children, usually between 3 and 8 years of age, but occasionally younger, who develop an aphasia, which initially is mainly receptive, but often becomes global. Deafness is frequently suspected. Many children become totally mute and may fail to understand environmental noises. A notable feature of the syndrome is severe behavioral problems. Epileptic seizures are usually relatively infrequent and may be totally absent. They can be of various types. The awake EEG may be normal or else show focal, hemispheric or generalized spike-wave abnormalities. The sleep EEG often, but not invariably, shows CSWS. Sophisticated EEG techniques often indicate that the EEG abnormality is maximal in one or other posterior temporal electrodes. MRI is nearly always normal but PET and SPECT often show localized or hemispheric metabolic and perfusion abnormalities. All children with suspected Landau–Kleffner syndrome and/or CSWS require detailed neuropsychological evaluation.

Seizure control in these syndromes may not be difficult and may lead to improved language function. However, the syndrome frequently fails to respond to conventional antiepileptic drug medication. Most authorities appear to treat initially with sodium valproate. However, if an inadequate response is obtained, hormonal treatment (steroids or ACTH) is indicated and the response may be dramatic. Unfortunately relapses are common. The technique of multiple subpial transection has been pioneered for the treatment of Landau–Kleffner and appears to improve the outlook.<sup>164</sup> It is based on the functional organization of the cerebral cortex vertically but with the connections involved in the spread of seizures being arranged horizontally. The horizontal connections are disrupted by making multiple cuts perpendicular to the cortical surface while preserving the vertically orientated fibers. Eventually Landau–Kleffner syndrome remits. This can occur after only a few weeks or after many years. The long-term outlook in Landau–Kleffner syndrome reflects the duration of the condition;<sup>165</sup> most subjects have permanent language problems unless the stage of active disease was very short.

The widespread recognition of the Landau–Kleffner syndrome has led to renewed interest in the cognitive effect of seizures in other epilepsies.<sup>166</sup> It is now increasingly accepted that specific cognitive and/or behavioral disturbances may have an epileptic basis even when overt seizures are infrequent or absent. Recognition can be a major problem. Clues include fluctuations, sometimes abrupt, in aspects such as mood, attention, memory and performance. Sophisticated EEG techniques coupled with neuropsychological evaluation are necessary to investigate such 'cognitive seizures'. The role of antiepileptic drug treatment is uncertain, but a trial of therapy is probably justified if there is reasonable evidence that cognitive problems are the result of epileptic activity. However, the possibility of inducing cognitive problems with antiepileptic drugs must constantly be borne in mind.

**Reflex epilepsies.** Reflex seizures are seizures precipitated by sensory stimuli. The stimulus may be simple such as flashes of light, touch or unexpected loud noises, or complex such as colored pictures, eating, etc. Most stimuli inducing reflex seizures are extrinsic. However, intrinsic stimuli such as proprioception can occasionally induce seizures. The 2001 ILAE definition precludes seizures provoked by higher brain functions, such as cognition and specific emotions. However, these have

conventionally been considered with reflex seizures. The range of stimuli which have been linked to seizure provocation is wide and the clinician should be alert to the possibility of reflex seizures even if the stimulus seems bizarre and novel. Seizures precipitated by fever, alcohol, drugs and trauma are not considered to be reflex seizures. Reflex seizures occur in many epilepsy syndromes.

Light-induced seizures (photosensitive seizures) are by far the most common reflex seizures. Photosensitivity is a genetically determined trait. It can be assessed in the EEG laboratory by the response to intermittent photic stimulation (IPS). Normally IPS induces so-called 'photic following responses' which must not be interpreted as indicating photosensitivity. A number of abnormalities, both focal (nearly always occipital) and generalized, can be evoked by IPS in susceptible subjects and these may be associated with clinical photosensitivity. Of most significance is generalized spike and wave activity or multiple spikes, which continue for at least 100 ms after the train of flashes ends (Fig. 22.19). Light-induced seizures are most commonly generalized, particularly generalized tonic-clonic seizures, absences and myoclonic jerks. However, partial seizures, often but not exclusively with features suggesting occipital lobe onset, are increasingly recognized. Among the important clinical precipitants of light-induced seizures are television, video-games, VDU screens (which nevertheless are much less provocative than TV screens), discotheques (particularly stroboscopic lights), and natural flickering light, for example caused by light shining through trees or fences or reflected off water. Some people with light-induced seizures are also sensitive to specific patterns such as striped wallpaper and certain patterns on clothing. Very rarely pattern sensitivity can occur without photosensitivity. Some subjects who are photosensitive can, and habitually do, self-induce seizures. This may be achieved by waving the outstretched hand in front of the eyes, viewing provocative patterns, or watching TV sets extremely close up.

Light-induced seizures are particularly common in idiopathic generalized epilepsies. They occur in more than a third of children with juvenile myoclonic epilepsy and are universal in eyelid myoclonia with absences. Photosensitivity is also common in epilepsy with myoclonic-astatic seizures. In addition, many children with idiopathic generalized epilepsies, who have typical absence seizures, and do not fit within the patterns of currently recognized syndromes, have light-induced seizures. Their prognosis, in terms of remission of seizures, is much poorer than children with childhood absence epilepsy. Significant numbers of children and adults have focal seizures provoked by photic factors. *Idiopathic photosensitive occipital lobe epilepsy* is an epilepsy syndrome beginning in late childhood and adolescence. It is characterized by focal seizures with symptomatology suggesting occipital lobe onset (elementary visual symptoms, head and eye deviation, headache), often with secondary generalization. Seizures are provoked by visual stimuli and the interictal EEG shows occipital spike and waves and generalized or occipital photoparoxysmal responses on IPS.

Light-induced seizures are also characteristic of a number of symptomatic epilepsies and epileptic encephalopathies, including severe myoclonic epilepsy of infancy, Unverricht-Lundborg disease and Lafora disease.

Some subjects with photosensitive seizures may be able to avoid the provoking factor. Most, however, will require antiepileptic drug treatment. Sodium valproate is the 'standard' antiepileptic drug for photosensitivity. There is good evidence that levetiracetam, and to a lesser extent lamotrigine, are also effective. Other measures depend on the fact that photically induced seizures are more likely, the larger the area of retina stimulated. Hence TV should be watched from the maximum comfortable viewing distance and a remote control should be used to change channels. Fully covering one eye, or a light-polarizing screen or spectacles may be advised if the child cannot watch a TV or computer screen safely otherwise. Covering one eye may also be useful if the subject is caught unawares, for example at a disco if a strobe is suddenly used. TV should also be watched in a well-lit room. Factors such as fatigue and sleep deprivation are likely to also play a role and therefore photosensitive subjects should be advised to avoid watching TV or playing video-games for prolonged periods and if tired.

*Primary reading epilepsy* is a rare, probably genetically determined, epilepsy, which usually starts in late childhood and adolescence and is characterized mainly by jaw jerks, sometimes with spread, occurring while reading. Seizures may also be provoked by speaking. Interictal EEG is usually normal; an ictal recording is often easy to obtain.

Seizures evoked by unexpected auditory or somatosensory stimuli are most often encountered in children with symptomatic generalized epilepsies, who usually also have spontaneous seizures. They are sometimes seen in children with Down syndrome. Occasionally all seizures may be provoked by startle (*startle epilepsy*). The seizures are usually tonic but may be atonic or myoclonic. Obtaining an ictal EEG can be very helpful. Clonazepam is probably the most effective drug.

**Seizures not necessarily requiring a diagnosis of epilepsy.** This inelegant term is used to designate conditions in which recurrent epileptic seizures may occur (the usual pragmatic definition of an epilepsy), but in whom the term 'epilepsy' is, for a variety of reasons, inappropriate. The most important example is febrile seizures (the term 'febrile convulsions' is discouraged), which is distinguished from epilepsy principally to remove the stigma associated with epilepsy when describing a generally benign condition. A similar argument could be made for benign childhood epilepsy with centrottemporal spikes and Panayiotopoulos syndrome, which are equally self-limiting.

*Febrile seizures* are usually defined as epileptic seizures precipitated by fever (usually defined as above 38°C), not due to an intracranial infection or other definable CNS cause and not preceded by afebrile seizures. They are the most common form of epileptic disorder and affect about 3% of children. They generally occur between 6 months and 4 years of age, although younger and older children may be affected.<sup>167</sup> Prevalence in boys is slightly higher than in girls. Most febrile seizures are generalized tonic-clonic (or purely clonic) seizures. Focal and atonic febrile seizures also occur. A simple febrile seizure is generalized, lasts under 15 min and is not repeated during the same illness. Complex febrile seizures are focal and/or last over 15 minutes and/or recur during the same febrile illness. The focal nature of a febrile seizure may be revealed by a Todd paresis. Febrile status epilepticus is defined as lasting over 30 minutes. Approximately 6% of febrile seizures are prolonged, with 80% of these being the initial seizure.

Genetic factors are important in the etiology of febrile seizures.<sup>168</sup> Children of parents who had febrile seizures have a risk 4 times that of the general population and siblings of probands have a risk 3.5 times that of the general population. There is a high concordance in monozygotic twins. Polygenic inheritance, or autosomal dominant inheritance with reduced penetrance, are considered the most likely modes of inheritance. Although the usual definition of febrile seizures precludes children with known brain disorders, epidemiological studies have shown an increased risk of febrile seizures in children whose developmental milestones are slow (but not necessarily outwith the normal range). All infections which cause fever may be associated with febrile seizures, but some infections are more prominent. Roseola infantum (human herpes virus 6) and shigella dysentery are said to be associated with a particularly high risk of febrile seizures. Vaccinations, especially diphtheria, tetanus and pertussis (DTP) and against measles, may also be associated.<sup>169</sup> A rapid rise in the temperature is said to be important although data to prove this are lacking. However, it is certainly the case that febrile seizures often arise early in the course of the illness; it is often the first indication that the child is unwell.

The clinical skill in managing a child presenting with a suspected febrile seizure involves confirming that the event was probably epileptic, since a number of non-epileptic disorders (syncopes occurring during febrile illnesses, delirium and rigors) are commonly misdiagnosed as febrile seizures. It is important to exclude serious infections (particularly meningitis and encephalitis) in which both fever and seizures may occur. The evaluation must include a detailed history and examination. It is particularly important to obtain a detailed description of the attack and the circumstances in which it took place. Many children, when first seen, will have recovered and will be fully conscious. Febrile seizures are rare under 6 months of age and in this age group

examination of the CSF is almost mandatory. Between 6 and 18 months febrile seizures are common but meningitis can present in this age group without meningism. Many authorities advocate lumbar puncture in all children in this age group presenting with a first febrile seizure;<sup>168</sup> meningitis often occurs in children with coexisting respiratory tract infections, including otitis media. However, the value of this approach has been questioned.<sup>170</sup> Beyond 18 months of age lumbar puncture can be avoided if there is no meningism and a clear focus of infection is found. Investigations, other than those looking for sources of infection, are generally not required. Children whose conscious level is impaired when first seen should be assessed along standard lines. The risk of inducing brain herniation is such that lumbar puncture should be delayed unless the subject is localizing pain, has no focal neurological signs and no papilloedema. Recovery time following febrile seizures is generally shorter than for other seizures. The median time to full recovery following febrile seizures in a recent study was 18 minutes, compared with 1.35, 1.25 and 4.57 hours following idiopathic, remote symptomatic and acute symptomatic seizures respectively.<sup>171</sup> Apart from etiology, the only other factor which significantly affected (delayed) recovery was administration of 'rescue' medication. It is recommended that a child who has not fully recovered within an hour of a suspected epileptic seizure should be investigated and managed on the assumption that the seizure was acute symptomatic. Children are often admitted to hospital following their first febrile seizure. However, admission is not always necessary.<sup>170</sup> A reasonable alternative is for the child to be observed for several hours. If the child has fully recovered and a source of infection has been identified, s/he can be discharged, with advice given to the parents. Children with complex febrile seizures probably all warrant admission.

The overall prognosis for febrile seizures is excellent.<sup>172</sup> However, around one third will have at least one recurrence and 9% of children will have over three febrile seizures. The majority of recurrences occur within the year following the first seizure. Recurrences are more likely if the seizure has been complex, if there is a family history of febrile or nonfebrile seizures and if the initiating temperature for the seizure was relatively low. Meta-analyses have failed to show any benefit of continuous antiepileptic drug medication in preventing febrile convulsions and there is now almost universal agreement that it is not indicated.<sup>172,173</sup> The parents of children who have had febrile convulsions are generally given antipyretic advice, although this on its own offers poor protection from recurrences. Removal of excessive clothes and blankets is recommended. Occasionally tepid sponging may be useful, but cold baths and fans played directly onto the child should be avoided as they may increase core temperature. Antipyretic agents such as paracetamol and ibuprofen should be given. Intermittent prophylactic therapy with oral or rectal benzodiazepines has been advocated but is rarely used. Most authorities consider the most appropriate management is for the parents to have clear first aid instructions and advice as to when to call for emergency help. Depending on circumstances, it may be appropriate for the family to have a supply of either rectal diazepam or midazolam to be used nasally or buccally for prolonged seizures.<sup>174-176</sup> An important aspect of management is reassurance of the parents, who almost certainly will have been greatly traumatized by the event.

The risk of developing epilepsy in children who have had febrile seizures is increased compared to that of the general population. The risk is 2% at 5 years, 4.5% at 10 years, 5.5% at 15 years and 7% at 25 years.<sup>177</sup> The risk is greater if the febrile seizures started under the age of 1 year, in the presence of any preceding neurodevelopmental problem, if there is a family history of epilepsy and if the febrile seizures have been complex. Generalized epilepsies tend to follow when there is a family history of nonfebrile seizures and a large number of simple febrile seizures. Focal epilepsies are more common if there have been prolonged lateralized seizures. Although it is clear that the overall prognosis for children who have had febrile seizures, even if complex, is excellent, clinicians should avoid overoptimism. They should be particularly wary in cases where prolonged, often asymmetrical, febrile seizures have occurred in association with relatively mild febrile illnesses since this may be the herald of Dravet syndrome. In addition, the majority of children who

subsequently develop refractory mesial temporal lobe epilepsy have had prolonged, often lateralized febrile seizures. The intellectual and behavioral outcome of febrile seizures is excellent.<sup>178</sup>

The EEG has very little role to play in the management of febrile seizures. Within a week of the attack a variety of nonspecific abnormalities may be seen. In addition, various generalized or focal epileptiform abnormalities occur in the EEG of children who have had febrile seizures but are of poor prognostic significance.

*Post-traumatic seizures* are classified as early (occurring within a week of the trauma) and late. The former include immediate seizures, which occur within 24 hours of the injury. Only recurrent, late, post-traumatic seizures are considered a manifestation of epilepsy. Immediate and early post-traumatic seizures are much more common in children than in adults. They occur in up to 5% of all children and are usually focal, but can be generalized. In up to one fifth of cases they take the form of status epilepticus. Following severe head injuries the risk may be as high as 35%.<sup>179,180</sup> Late, post-traumatic seizures can occur at any time following the trauma but usually within 2 years. They are less common in children than in adults. In a large population-based study they occurred in 7.4% of children following head injury.<sup>179</sup> The risk is determined by the severity and type of head injury. There is no increased risk following mild closed head injuries. The risk is increased by early post-traumatic seizures, intracranial bleeding and depressed skull fracture. Both focal and generalized seizures can occur. Prophylactic anti-epileptic drugs probably do not decrease the risk of developing late post-traumatic seizures and are not indicated.<sup>181</sup> Phenytoin is generally used in the acute situation for treatment and prevention of early post-traumatic seizures.

Seizures can occur as a complication of a large number of disturbances in body homeostasis. Generally these only occur while the disturbance persists and hence a diagnosis of epilepsy is inappropriate. They include seizures occurring during hyponatremia, hypocalcemia and hypomagnesemia. Seizures may also be a feature of uremia, the treatment of renal failure with dialysis and during renal transplant rejection. Epileptic seizures are a well-known feature of hypoglycemia; they may also occur during hyperglycemic comas in diabetic children. Epileptic seizures are also an occasional occurrence in individuals with a variety of endocrine disorders.

There are many children and adults who have only a single seizure during their lifetime, or else a cluster of seizures over a short period of time with no further seizures, or else very occasional seizures with long periods between seizures. These individuals do not warrant a diagnosis of epilepsy. They probably represent a heterogeneous group, with the milder forms of different types of epilepsy. Seizures are liable to occur during periods of emotional or physical stress such as at exam times, when sleep deprived, or when drinking unaccustomed alcohol.

## DISEASES FREQUENTLY ASSOCIATED WITH EPILEPSY

Epileptic seizures occur in children with a huge range of different diseases and the manifestations of the seizures often show disease-specific characteristics. The following is a survey of some of the clinically relevant features of epileptic seizures as they manifest in diseases encountered in childhood. Comprehensive descriptions of many of these disorders are given elsewhere in this text.

### The progressive myoclonic epilepsies<sup>182</sup>

Most pediatricians find the concept of the progressive myoclonic epilepsies a difficult one. Nevertheless they often undertake extensive neuro-metabolic investigations. These are to a large extent designed to detect the progressive myoclonic epilepsies. The conditions included are so rare that most pediatricians might see only one or two cases throughout their career. Their key characteristics are:

- An epilepsy characterized by myoclonic and other seizure types, including generalized tonic-clonic seizures. The seizures are often precipitated by factors such as touch, action or intention.

- Neurological problems, usually including cerebellar signs, and often progressive.
- Mental deterioration, of varying degrees, but often eventually leading to dementia.

These features typify the 'core group' of progressive myoclonic epilepsies. In other progressive myoclonic epilepsies atypical features are present while in some other progressive epilepsies, myoclonic seizures occur but are overshadowed by other manifestations. In the latter group the epilepsy is almost an incidental problem and its characterization is of limited value in recognizing the disorder. Included are: nonketotic hyperglycinemia; D-glycemic aciduria; Menke disease; Krabbe disease; Tay–Sachs disease; Sandhoff disease; and Niemann–Pick C disease.

The core conditions included in the progressive myoclonus epilepsies are:

- Lafora disease;
- Unverricht–Lundborg disease;
- sialidosis (types I and II);
- Gaucher disease (type III);
- neuroaxonal dystrophy;
- myoclonic epilepsy with ragged red fibers (MERRF);
- dentatorubropallidolusian atrophy.

*Lafora disease* is an autosomal recessive disorder, common in the Mediterranean. Mutations on two genes (EPM2A and NHLRC1) have been shown to be responsible for most cases and there is evidence of the involvement of a third gene.<sup>183</sup> It usually presents between 6 and 19 years of age. Two features of the epilepsy are distinctive: (i) the precipitation of myoclonia by action and intention; and (ii) the occurrence of partial seizures with elementary visual phenomena. Mental and neurological decline with pyramidal, extrapyramidal and cerebellar signs appear, leading to early death. Diagnosis by molecular genetics may be possible but identification of so-called Lafora bodies on biopsy, particularly of apocrine sweat glands, may still be required. No specific treatment is available.

*Unverricht–Lundborg disease* (Baltic myoclonus/Mediterranean myoclonus) is an autosomal recessive disorder caused by a disease causing mutation in the CSTB gene on chromosome 21.<sup>184</sup> The age of onset is similar to that of Lafora disease. The distinctive features of the epilepsy are the precipitation of myoclonic seizures by maintenance of posture or intended movements and photosensitivity. Neurological and mental decline is usually very slow and prolonged survival is expected. Valproate is the treatment of choice; phenytoin is contraindicated as it appears to increase the rate of deterioration.

The *sialidoses* and *Gaucher disease type III* are lysosomal storage disorders caused by deficiencies of alpha neuraminidase and beta-glucocerebrosidase respectively. They present in childhood or adolescence with features of a myoclonic epilepsy and variable evidence of visceral storage and dysmorphism. Cherry red spots may be seen. Gaucher disease type III is characterized by horizontal ophthalmoplegia.

The extremely rare juvenile form of *neuroaxonal dystrophy* causes a progressive myoclonic epilepsy in late childhood or adolescence often with retinal degeneration. The pathological hallmark is the demonstration of axonal spheroids on rectal or skin biopsy.

Epileptic seizures occur in a number of mitochondrial disorders. However, the most characteristic is *MERRF* in which myoclonic epilepsy is associated with cerebellar signs, myopathy and often with other features seen in mitochondrial disorders. **Ragged red fibers** may be seen on muscle biopsy, but it can also be diagnosed on the basis of mitochondrial DNA mutations.

*Dentatorubropallidolusian atrophy (DRPLA)* is an autosomal dominant disorder with anticipation due to a trinucleotide repeat on chromosome 12. It is mainly seen in adults from Japan but does occur in children and in non-Japanese. Features of progressive myoclonus epilepsy are combined with an extrapyramidal movement disorder and dementia. If the possibility of Huntington disease is being considered, think also of DRPLA.

Diseases in which features of progressive myoclonus epilepsy occur which are atypical or which are associated with other prominent manifestations include:

- the neuronal ceroid lipofuscinoses;
- poliodystrophies (Alper disease);
- childhood onset Huntington chorea (myoclonic variant);
- Hallervorden–Spatz disease;
- bipterin deficiency;
- other mitochondrial disorders including mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS).

Special mention should be made of the *neuronal ceroid lipofuscinoses*.<sup>185</sup> These disorders were previously diagnosed pathologically and are characterized by the accumulation of ceroid lipofuscin in neurones. All the common forms can now be diagnosed enzymatically or by molecular DNA analysis. Epilepsy occurs in all forms of the disorder, but is a particularly prominent and early feature of the late infantile form which may be mistaken for the Lennox–Gastaut syndrome.

### The neurocutaneous disorders

Many neurocutaneous disorders are associated with seizures (e.g. tuberous sclerosis, type I neurofibromatosis, Sturge–Weber syndrome, epidermal nevus syndrome, hypomelanosis of Ito and incontinentia pigmenti).

### Brain malformations and maldevelopments

One of the major impacts of MRI has been the realization that many epilepsies arise as a consequence of malformations and maldevelopments of the brain (Fig. 22.22). Together these causes probably outweigh perinatal problems in the causation of neurodevelopmental problems. Milder disorders may be silent. When overt they present with combinations of mental retardation, cerebral palsy and epilepsy.

A large number of conditions may be associated with abnormalities of cortical development (previously usually called neuronal migration disorders). These include: metabolic diseases such as peroxisomal disorders and Menke disease; chromosomal disorders including Edwards (trisomy 18), Patau (trisomy 13), Down (trisomy 21), Smith–Magenis (deletion 17p) and Wolf–Hirschhorn (deletion 4p) syndromes; neuromuscular diseases including some forms of congenital muscular dystrophy and myotonic dystrophy; neurocutaneous syndromes; multiple congenital anomaly syndromes and infective and toxic causes. Among the latter prenatal cytomegalovirus infection and fetal alcohol syndrome merit special mention.

Heterotopias, including periventricular, subcortical and laminar (or band) heterotopias; agyria-pachygyria, including lissencephaly types I and II and focal pachygyria; polymicrogyria; schizencephaly and hemimegalencephaly are migrational disorders and are often highly epileptogenic, giving rise to focal or generalized seizure disorders, including epileptic spasms. Agenesis of the corpus callosum is also commonly associated with seizures. Aicardi syndrome is an X-linked dominant disorder almost confined to females. The brain abnormality is complex with agenesis of the corpus callosum (in most but not all cases), periventricular heterotopias, variable dysplasias of the cortex and ependymal cysts. Choroidal lacunae, often with coloboma of the optic discs, are a characteristic feature. Severe mental retardation and epileptic spasms are characteristic.

*Cortical microdysgenesis* implies a postmigrational defect in cortical organization. It comprises minor malarrangements and malorientations of cells within the cortex and is postulated to be a substrate for seizures in some children. It is not diagnosable in life.

The epilepsy complicating cerebral maldevelopments and malformations is for the most part treated along standard lines. Children with focal cortical malformations may be candidates for resective surgery. Hemimegalencephaly, a cause of catastrophic epilepsy in infancy, may be treated by hemispherectomy.

### Brain tumors

Brain tumors are an uncommon, but important and potentially curable, causes of epilepsy in children. Slow growing tumors of the cerebral

hemispheres, such as low-grade astrocytomas, oligodendrogliomas, gangliogliomas and gangliocytomas are more likely to present with seizures than are malignant tumors. Diagnosis may be delayed for many years. Seizures are mainly focal, but generalized seizures, with generalized EEG abnormalities, are well recognized. Intellectual ability and neurological examination is often normal. Treatment may be expectant if seizures are controlled by antiepileptic drugs and no tumor growth is observed on serial brain scans. However, surgery often offers a good hope of cure. Gelastic seizures, which often begin in infancy or early childhood, are characterized by laughter, usually without an appropriate affect. They are strongly suggestive of tumors of the floor of the third ventricle, especially hypothalamic hamartomas. Unfortunately these tumors are not easily resected, although there have been encouraging recent reports. Intractable epilepsy, mental retardation, behavioral problems and endocrine problems are frequent. Dysembryoplastic neuroepithelial tumors (DNET) are benign supratentorial tumors which are often located deep in the temporal or frontal lobes and are often associated with intractable focal seizures (Fig. 22.22). Treatment is usually by resection. Recently, angiocentric neuroepithelial tumors (ANET) have been described as a new tumour type associated with childhood seizures.<sup>186</sup> Treatment for brain tumors with surgery and radiotherapy may also give rise to epilepsy.

Although most brain tumors will be apparent on CT, especially if contrast is used, some may be missed. MRI is superior and is the imaging method of choice.

### Cavernous angiomas

These are thin-walled clusters of dilated blood vessels whose commonest manifestation is focal epilepsy, often intractable. They may be revealed on CT by areas of calcification. MRI is superior. They are often not apparent on angiograms. Minor bleeding is common; major bleeds are uncommon but occur. Some progressively enlarge and act as space-occupying lesions. Treatment is surgical if the lesion is accessible. Radiotherapy is an alternative.

### Genetic or presumed genetic disorders

Numerous chromosomal and other genetic disorders feature seizures as a prominent or occasional manifestation. Some have already been mentioned.

*Angelman syndrome* is complicated by epilepsy in up to 90% of children. The characteristic jerky movements of the upper limbs and trunk which gave rise to the eponymous name 'happy puppet syndrome' (a term which may cause parents distress) are caused by a unique form of cortical myoclonus which is reported to respond to piracetam. Epileptic seizures can start at any time from childhood to young adult life, but usually begin in infancy and early childhood. Epileptic spasms are rare. Seizure types include generalized tonic-clonic seizures, clonic seizures, myoclonic seizures, atypical absences and focal seizures, possibly with occipital lobe onset.<sup>187</sup> It may present as West or Lennox-Gastaut syndrome. Episodes of nonconvulsive status epilepticus or myoclonic status epilepticus are relatively common and may be recurrent. They are particularly troublesome in early to mid childhood. The severity of the epilepsy often appears to subside in later childhood. A more or less characteristic interictal EEG with high amplitude posterior slow waves with or without spikes has been described but is not always present. Most authorities favor treatment with broad-spectrum antiepileptic drugs or drugs useful against generalized seizures such as sodium valproate, lamotrigine and ethosuximide. Benzodiazepines are useful against episodes of status. Carbamazepine may cause myoclonic and absence seizures.

*Rett syndrome* is an X-linked dominant mental retardation disorder due to mutations on the MECP2 gene. Epileptic seizures are particularly associated with the third or 'pseudostationary' period of the disease, from about 2 to 10 years of age. Atypical absences are particularly prominent but partial and generalized tonic-clonic seizures also occur. Hyperventilation is a particularly striking feature of the condition. It may provoke atypical absences but many of the phenomena associated

with the hyperventilation are probably non-epileptic; certainly the response to antiepileptic drugs is poor. Seizures often show spontaneous improvement or even resolution in later childhood or adolescence. Atypical forms of Rett syndrome may present with epileptic seizures including epileptic spasms.<sup>188</sup>

*Fragile X syndrome* is associated with epilepsy in about a fifth of affected boys. The epilepsy is usually mild with relatively infrequent seizures and a tendency for remission in the teenage years. Both focal and generalized seizures are described. The EEG often shows paroxysmal abnormalities similar to those seen in benign childhood epilepsy with centrotemporal spikes.

*PEHO (progressive encephalopathy with edema, hypsarrhythmia and optic atrophy) syndrome* is a rare, probably autosomal recessive, disorder presenting in early life with drug-resistant epileptic spasms, retardation, hypotonia, blindness and optic atrophy. The children are generally almost immobile and have characteristic peripheral edema. Progressive microcephaly and marked cerebellar atrophy are other features. A PEHO-like syndrome, lacking the neuroradiological features and optic atrophy, is also described.

*Ring chromosome 20* is now recognized as causing a characteristic epilepsy, often with normal development prior to onset of seizures followed by learning difficulties. These include focal and secondary generalized seizures, seizures with frontal lobe semiology and episodes of nonconvulsive status epilepticus.<sup>106</sup>

### Metabolic disorders<sup>189</sup>

Virtually all the metabolic disorders which occur in childhood are associated with seizures. However, these are rarely the major feature and certainly the characteristics of the epilepsy are rarely of significance in establishing the correct diagnosis. Important exceptions to this are:

- *Nonketotic hyperglycinemia* in which early myoclonic seizures and Ohtahara syndrome are characteristic. Diagnosis is made by demonstrating a raised absolute or relative (to blood and urine) CSF glycine level.
- *Vitamin responsive seizures – pyridoxine (vitamin B<sub>6</sub>) dependent seizures* have been recognized for many years.<sup>190</sup> They typically begin in the neonatal period or infancy, but may begin prenatally (revealed by hiccups) or up to early childhood. Any seizure type, including epileptic spasms, may occur and frequently become intractable. They respond poorly to conventional antiepileptic drugs. Usually a dramatic cessation of seizures occurs on the intravenous administration of pyridoxine (doses of 40–300 mg). However, this may cause profound apnea and some authorities suggest giving a trial of oral pyridoxine. The condition is autosomal recessive but its cause remains elusive. Recently, children have been described with early onset seizures, often with encephalopathic features, who fail to respond to pyridoxine but respond to either pyridoxal phosphate or folic acid. It is now recommended that trials of these vitamins are given early to neonates and infants with intractable seizures. Diagnosis may be aided by CSF neurotransmitter studies.
- *Biotinidase deficiency.* This autosomal recessive disorder can present in the neonatal period, or beyond, with isolated seizures or seizures in association with skin rashes, alopecia, ataxia and various other neurological abnormalities. It can be detected by the production of a characteristic organic aciduria but more reliable and widely available is testing for deficiency of biotinidase in the blood. Seizures respond to biotin replacement.
- *Glucose transporter deficiency* presents with seizures in infancy and is associated with a deficiency in the transport of glucose across the blood-brain barrier. It is detected by an abnormally low CSF : blood glucose ratio (<0.45) (preferably tested for after a 4-hour fast) and responds to the ketogenic diet.

### Cerebral palsy<sup>191</sup>

Cerebral palsy is not a disease, but a collection of conditions characterized by abnormalities of movement and posture, caused by nonprogressive disorders of the developing brain. Epilepsy has been estimated

to occur in 10–40% of cases, but its likelihood depends on the type of cerebral palsy. Cerebral palsy involving damage to the cerebral cortex has a high risk for the development of epilepsy. Hence spastic hemiplegic and quadriplegic cerebral palsy are often accompanied by seizures, while these are rarer in spastic diplegic, dyskinetic and ataxic forms of cerebral palsy. Some studies suggest that nearly all children with spastic quadriplegic cerebral palsy develop epilepsy. Various types of seizure may occur. However, in hemiplegic cerebral palsy, focal motor seizures, often with a Jacksonian march, and secondary generalized tonic-clonic seizures are characteristic. In quadriplegic cerebral palsy generalized seizures (both primarily and secondarily generalized) predominate. Some such children develop epileptic encephalopathies, such as the Lennox–Gastaut syndrome. Startle seizures are relatively common in children with severe forms of cerebral palsy.

## MANAGEMENT OF CHILDHOOD EPILEPSY

### General principles

In the UK the National Institute for Health and Clinical Excellence (NICE) ([www.nice.org.uk](http://www.nice.org.uk)) and the Scottish Intercollegiate Guidelines Network (SIGN) ([www.sign.ac.uk](http://www.sign.ac.uk)) provide detailed advice on the diagnosis and management of epilepsy in children.

Education is the cornerstone to the management of children with any form of seizure disorder. Children, and more especially the families of children, who have had a first epileptic seizure, particularly if convulsive, will almost certainly have been extremely frightened. Initial reassurance should allay the fear that seizures are likely to be life threatening and/or cause brain damage. However, it is wrong to trivialize what has occurred. It is also a mistake to suggest that the attack is unlikely to ever happen again. This is a reasonable hope but is an unreasonable expectation. Education should cover the following points:

- An explanation of the terms 'epileptic seizure' and 'epilepsy'. This should stress the multiplicity of conditions covered by the latter and the huge range in their 'seriousness'.
- A specific explanation as to what type of seizure disorder the child has or may have.
- The impact this is likely to have on the child's future. A frank acknowledgment of uncertainties, which are often considerable, is appropriate.
- Treatment options available.
- 'First aid' measures to be taken in the event of further seizures, including detailed advice as to when medical help should be summoned.
- An exploration of the role of possible precipitants and measures which might be taken to reduce the risk of recurrence.
- Sensible restrictions which should be considered to ensure the child's safety and restrictions which are not required.
- What to tell other people, including the child's school.

The clinician should also explore the family's own beliefs about seizures and epilepsy. Highly prejudicial attitudes are surprisingly common and may require to be challenged directly.

Written and video information is usually greatly appreciated and all clinicians involved in treating a child with epilepsy should have access to a range of suitable material. Charities and self-help societies produce high-quality material, which is usually free or obtainable at nominal expense. Guiding families to useful websites is increasingly important as is the need for clinicians to counteract misleading Internet information.

A number of factors are likely to lower the seizure threshold in anyone with a seizure disorder. Knowledge of these is relevant to all children with epilepsies, although they operate most powerfully in the idiopathic generalized epilepsies. They include fatigue, sleep deprivation, emotional stress and anxiety, excitement, hunger and alcohol.

Undue restrictions are often imposed on children with epilepsy.<sup>192</sup> These have the potential to lead to overdependence in later life. The principal dangers are from drowning and falls. A child with continuing seizures (this might reasonably be defined as a daytime seizure within the last year) should be closely supervised during swimming

by a responsible adult capable of rescuing the child if a seizure occurs in the water. A 'buddy system' helps supervision. Similarly baths for younger children should be supervised and showers encouraged for older children. Climbing, unless protected, is ill-advised. Cycling on busy roads should be avoided if seizures are active. Otherwise cycling with a helmet poses few additional dangers. Most other sports and leisure activities should be encouraged unless there is clear evidence of an increased risk. Detailed advice about individual sports can be obtained from the websites of Epilepsy Action ([www.epilepsy.org.uk](http://www.epilepsy.org.uk)) and the National Society for Epilepsy ([www.epilepsynse.org.uk](http://www.epilepsynse.org.uk)).

Teenagers with epilepsy should be given the opportunity to discuss issues regarding sex, genetic implications, fertility, contraception and teratogenicity. The same websites provide up to date information regarding driving and employment issues in the UK.

Finally the clinician should be aware that most parents who have lost a child with epilepsy report that they would have wished to know about the increased mortality of children with epilepsy.

### Nondrug treatment and intermittent drug treatment

Although antiepileptic drugs play an important part in the management of children with seizure disorders, there are many children in whom regular antiepileptic drug treatment is not or may not be required. This includes:

- Children who have had a single seizure or who only have infrequent seizures.
- Children whose seizures have occurred in the context of a temporary state, for example during a period of hyper- or hyponatremia, or immediately after a head injury; acute treatment with antiepileptic drugs may be required but these should be withdrawn quickly.
- Children with febrile seizures.
- Children whose seizures are all provoked by a stimulus which can reasonably be avoided.
- Children with certain benign focal epilepsies characterized by infrequent seizures, often at night, causing minimal disturbance and with a high probability of remission. This includes many children with benign childhood epilepsy with centrotemporal spikes and Panayiotopoulos syndrome.

Consideration should be given as to whether, as part of an overall regimen to be followed if seizures occur, an antiepileptic agent should be provided for intermittent use in the event of prolonged convulsive seizures. Diazepam administered rectally has until recently been most often used. Midazolam administered buccally, sublingually or nasally is an alternative and a clinical trial found buccal midazolam to be superior to rectal diazepam.<sup>176</sup> Convulsive seizures generally last less than 2 minutes and it is therefore appropriate to recommend administering the drug either if the seizure lasts longer than usual or after 2 minutes.

### Antiepileptic drug treatment

There are a large number of antiepileptic drugs available to treat seizures in children. Before prescribing an antiepileptic drug the prescriber needs to consider:

- its efficacy in the particular type of epilepsy;
- potential adverse effects;
- possible interactions with other drugs, including other antiepileptic drugs and the contraceptive pill;
- route of elimination (essential knowledge if prescribing to children with renal or hepatic impairment);
- its ease of use (related to formulations available, dosing frequency and need for monitoring of levels and other parameters).

Much of our knowledge concerning the efficacy of antiepileptic drugs in humans is derived from clinical observation. The older agents were introduced at a time when classification mainly consisted of a division into grand mal and petit mal seizures. All the new drugs were introduced into clinical practice following trials mainly in adults with focal seizures. These were designed to obtain licensing approval for the drugs

rather than to help guide clinical practice. Some antiepileptic drugs have a wide spectrum of action across both generalized and focal epilepsies. These include sodium valproate, lamotrigine, topiramate, levetiracetam and zonisamide. Phenobarbital is also broad spectrum but may exacerbate absences. Other drugs, notably carbamazepine, vigabatrin, gabapentin, tiagabine and probably also pregabalin and, to a lesser extent, phenytoin are narrow spectrum agents with efficacy principally against focal epilepsies; they may exacerbate generalized epilepsies. However, vigabatrin has unique activity against epileptic spasms and all seizure types in tuberous sclerosis. Ethosuximide is active against absences and to a lesser extent atonic and myoclonic seizures. Piracetam is mainly used for cortical myoclonus, for example in Angelman syndrome. The benzodiazepines and acetazolamide are usually used as adjunctive agents in children with refractory focal and generalized epilepsies. Clonazepam may be particularly useful against myoclonic seizures. Historically, nitrazepam has tended to be used for treating epileptic spasms.

All antiepileptic drugs have potentially serious adverse effects. These are reviewed in detail elsewhere.<sup>193</sup> Here, only those adverse effects seen commonly or which are likely to influence prescribing habits are discussed.

All antiepileptic drugs are psychoactive and all have the potential to cause unwanted CNS effects such as drowsiness, sedation, dizziness and ataxia. However, such effects are more likely, even with standard dose regimens, with carbamazepine, phenytoin, phenobarbital, topiramate and the benzodiazepines than with sodium valproate and lamotrigine. Both phenobarbital and phenytoin are considered to impair cognitive function (impaired concentration, decreased motor speed and memory problems) even at normal dosages. Behavioral adverse effects, including hyperactivity and aggression, have been particularly reported with phenobarbital and vigabatrin, one reason for the sharp decline in phenobarbital usage in developed countries. Overall studies on the effects of other agents have been reassuring<sup>194</sup> but the clinician must always be alert to the potential deleterious effect on cognitive function of antiepileptic drugs in individual children. Many antiepileptic drugs, but notably sodium valproate, lamotrigine and ethosuximide, cause gastrointestinal upsets, particularly pain, nausea and vomiting. Hypersensitivity reactions, particularly rash, generally occur within a few weeks of starting the drug, but may occasionally be delayed. There is in particular a problem with lamotrigine, which has been associated with a widespread erythematous rash and Stevens–Johnson syndrome. If this occurs, the drug must be immediately discontinued. The risk of it occurring can be substantially reduced by slow titration, particularly in children also on sodium valproate. Rash is also regularly encountered with carbamazepine, oxcarbazepine, phenytoin, phenobarbital and zonisamide.

A few drugs have more or less unique adverse effects. These include: hair thinning and loss, weight gain and tremor with sodium valproate; appetite suppression and weight loss with topiramate and zonisamide; renal calculi with topiramate, zonisamide and acetazolamide; anhidrosis and hyperthermia with zonisamide and topiramate; and constriction of the visual fields with vigabatrin. The latter appears to be common and irreversible. Because of it, vigabatrin should only be used to treat epileptic spasms, seizures in tuberous sclerosis and those children in whom other options have been exhausted. In those treated and who have a mental age of over 7 years detailed assessment of visual fields every 6–12 months is recommended.<sup>195</sup> Carbamazepine and oxcarbazepine can both cause hyponatremia, although this is rarely severe.

Of the rare, potentially fatal adverse effects of antiepileptic drugs, particular attention has been paid to blood dyscrasias with phenobarbital, phenytoin, carbamazepine and ethosuximide, and to severe hepatic toxicity with sodium valproate. The origin of the latter is poorly understood. It is especially common in infants with developmental delay treated with multiple antiepileptic drugs. An underlying metabolic disorder may be implicated and the drug should be avoided where such conditions seem likely. It is unrelated to the mild hyperammonemia seen in many subjects treated with the drug and cannot be predicted by blood tests taken prior to or after starting the drug.

Long-term cumulative adverse effects do not occur with the commonly prescribed agents but phenobarbital and phenytoin can cause connective tissue disorders and metabolic bone disease with the latter also being associated with a cerebellar syndrome, intellectual blunting, coarsening of the facies, gum hypertrophy (partially avoidable with good oral hygiene) and hirsutism.

Many of the commonly prescribed antiepileptic drugs interact with other antiepileptic drugs and with non-antiepileptic drugs. Many interactions are rarely of clinical importance. In general, interactions between antiepileptic drugs either lower the effective concentration of one or both of the drugs increasing the risk of seizures or raise the plasma level of one of the drugs (or a metabolite) increasing the risk of toxicity. These effects can occur at the time of drug withdrawal as well as when a new drug is introduced. At such times, the clinician must carefully evaluate whether adjustments to the dosages of concomitantly prescribed antiepileptic drugs are needed. Carbamazepine (and oxcarbazepine), phenytoin and phenobarbital are enzyme inducers and increase the metabolism of other drugs eliminated by the liver. The effect is of significance when one or other of these drugs are administered together and also when they are administered with sodium valproate, lamotrigine and topiramate. Carbamazepine also causes significant autoinduction and hence carbamazepine levels often fall after a few weeks treatment. Enzyme inducers may also cause significant interactions with other prescribed drugs; most notably they decrease the effectiveness of the oral contraceptive pill.

Sodium valproate inhibits the hepatic metabolism of many antiepileptic drugs. In most cases this is of little significance. However, it causes an effective doubling of the half-life of lamotrigine. Clinically significant increases in the plasma levels of phenobarbital may also occur.

Phenytoin is a difficult drug to use for a number of reasons. Besides being an enzyme inducer, it has zero order pharmacokinetics, which means that small changes to the dose can lead to marked changes in plasma levels. It is also extensively protein bound. This means that other protein-bound drugs may cause rises in the unbound fraction of the drug by displacing phenytoin.

Unexpected carbamazepine toxicity may arise as a consequence of inhibition of its metabolism by macrolide antibiotics such as erythromycin. It also occasionally occurs due to inhibition of the metabolism of its pharmacologically active epoxide residue by sodium valproate and lamotrigine.

Vigabatrin, gabapentin, tiagabine, piracetam and levetiracetam are relatively free of significant interactions.

Knowledge about the elimination of antiepileptic drugs is useful to the clinician both because it helps predict possible interactions and is essential when treating children with hepatic or renal impairment. Carbamazepine, phenytoin, sodium valproate, lamotrigine, ethosuximide, oxcarbazepine, the benzodiazepines and tiagabine are all exclusively or predominantly eliminated by hepatic metabolism. Vigabatrin, gabapentin, levetiracetam, pregabalin and acetazolamide are excreted unchanged by the kidneys. Phenobarbital, topiramate and zonisamide are eliminated both by hepatic metabolism and by the kidneys.<sup>196</sup>

Although there have been numerous trials, particularly of the newer antiepileptic drugs, many of these were conducted primarily for licensing purposes and have limited relevance to the clinician in helping to choose between available options. To a considerable extent the way in which clinicians use antiepileptic drugs is based upon the results of uncontrolled clinical studies, their own experience and the advice of trusted colleagues. [Table 22.11](#) details the author's practice aided by the published experience of respected experts.<sup>118,197,198</sup>

### Using antiepileptic drugs

The decision to initiate treatment with an antiepileptic drug should not be taken lightly. Treatment is likely to be prolonged and the risk of adverse effects is significant. Treatment should only be started after a diagnosis has been made. A therapeutic trial of an antiepileptic drug in children in order to confirm the diagnosis of epilepsy should be avoided. The risk of treating a child who does not have epilepsy with multiple antiepileptic

**Table 22.11** Suggested dosage regimens for antiepileptic drugs available in the UK. These are likely to vary from the manufacturers' published information. Many of these drugs are unlicensed or have restricted licences for use in children in the UK

Antiepileptic drug	Initial dose (mg/kg/day)	Usual maintenance dose (mg/kg/day)	Dosage interval	Comments
Carbamazepine	5	10–20; may be up to 30	bd	Liquid and chewtab preparations as well as tablets; slow release preparation has significant advantages
Sodium valproate	10	20–30; occasionally up to 40	bd	'Chrono' preparation has limited advantages
Phenytoin	<3 yr – 8 >3 yr – 5	As determined by response and levels	od or bd	Liquid, tablets and capsules available. Prescribe by brand to avoid bioavailability problems
Phenobarbital	5	5; occasionally up to 10	od	
Ethosuximide	10	30–40	bd	
Acetazolamide	5	0–1 yr – 10 >1 yr – 20–30	bd	
Clobazam	0.25	0.25–1.0; occasionally up to 2.0	bd	
Clonazepam	0.01	0.05; occasionally up to 0.3	bd or tds	
Nitrazepam	0.05	0.25–1.0	bd	
Vigabatrin	40	60–80; up to 180 in epileptic spasms	od or bd	Sachets of dissolvable powder available
Lamotrigine	Monotherapy – 0.5 With enzyme inducers – 1.0 With sodium valproate – 0.2	Monotherapy – 2–10; occasionally up to 15 5–15 1–5	od or bd bd od or bd	Dispersible tablets available
Gabapentin	15	30–90	tds	Only capsules available
Topiramate	1.0	4–10	bd	Sprinkle granules available
Tiagabine	0.1	0.3–1.5	tds	Only tablets available
Oxcarbazepine	20	50–90	bd	Only tablets available
Levetiracetam	10	20–40	bd	
Zonisamide	1	4–8; occasionally up to 12	bd	

drugs is high. Because of their high prevalence, children with seizure disorders are often treated by clinicians whose knowledge and experience of epilepsy is limited. In developed countries, it should be considered unacceptable to treat a child for epilepsy unless the clinician can recognize the common types of seizure disorders, has access to suitable investigational facilities, including EEG and MRI, and has a reasonable knowledge of the available treatments. All children with rare, atypical or unclassifiable seizure disorders, seizure disorders which require special investigational facilities (such as video-EEG) or treatments (such as steroids) or whose seizures continue despite initial treatment should be assessed by a clinician with a special expertise in the epilepsies.

All children should initially be started on monotherapy. Use of more than one drug increases the risk of adverse effects. Large studies of children with new-onset seizures have failed to show a convincing difference in efficacy between the standard antiepileptic drugs.<sup>199,200</sup> A systematic review concluded that there is no evidence to support the choice of sodium valproate compared to carbamazepine in generalized epilepsies.<sup>201</sup> However, this emphasizes the limitations of overreliance on such studies since there is compelling evidence that carbamazepine may aggravate some generalized epilepsies in which it should be considered contraindicated.<sup>144</sup> Most authorities consider that sodium valproate is the drug of first choice for generalized epilepsies (whether idiopathic or symptomatic). This was supported by a recent randomized controlled trial ('SANAD') comparing sodium valproate with lamotrigine and topiramate in both children and adults.<sup>202</sup> Some authorities recommend lamotrigine in teenage girls because of concerns about weight gain, decreased fertility and the teratogenicity of sodium valproate. However, lamotrigine also has significant adverse effects including teratogenicity.

The wide spectrum of activity shown by levetiracetam, its relative lack of significant adverse effects and its ease of use make it a very attractive choice. However, licencing considerations and the lack of safety data in pregnancy still need to be considered. Ethosuximide is an alternative for childhood absence epilepsy but is less well tolerated. Carbamazepine is generally considered the drug of first choice for most focal seizure disorders, including secondary generalized epilepsies. Some support for this practice was found in a systematic review comparing carbamazepine and sodium valproate monotherapy.<sup>201</sup> However, sodium valproate is a suitable alternative for the benign focal epilepsies of childhood. Recently a randomized controlled study of children and adults (SANAD) concluded that lamotrigine was superior to carbamazepine, lamotrigine, gabapentin, topiramate and possibly oxcarbazepine for focal seizures.<sup>203</sup> However, the numbers of children included appears to have been relatively small since the median age was  $38 \pm 18$  years and only 1.4% had idiopathic focal seizures. Moreover carbamazepine was superior to lamotrigine in terms of efficacy but caused more adverse effects leading to discontinuation. This may have reflected the rapid dose titration recommended for carbamazepine. Sodium valproate is usually the drug of choice for photosensitive seizures; levetiracetam and lamotrigine are alternatives. If it has not proved possible to distinguish focal from generalized seizures reliably it is sensible to treat with a broad spectrum agent such as sodium valproate to avoid the possibility of exacerbating generalized seizures.

When initiating treatment, it is generally advisable to start with modest doses and to build up the dose as required. This reduces the risk of adverse CNS and gastrointestinal unwanted effects. Although many clinicians aim to achieve a 'target dose', seizure control may be

achieved at remarkably low doses in some children. The manufacturers of some drugs recommend measurement of various blood parameters prior to initiating, and during, therapy in order to avoid/detect early adverse effects. However, there is no evidence that this is effective and is rarely necessary.<sup>204</sup> Similarly blood monitoring of antiepileptic drug levels, although widely available, is usually unhelpful. The so-called target ranges for individual drugs are defined according to the levels at which a majority of responders to the drug achieved seizure control. Significant numbers of children will respond at lower or higher levels and unwanted effects may occur at levels within the therapeutic range, or may not occur despite levels being considerably above the range. Most epileptologists rarely perform antiepileptic drug levels, relying instead on careful clinical monitoring of wanted and unwanted effects. Exceptions to this are:

- with phenytoin, whose complex pharmacokinetics means that level monitoring can often be helpful;
- in children in whom detection of unwanted effects may be difficult. This is particularly the case in those with severe learning difficulties;
- as a check on compliance.

The limitations of blood levels should be appreciated. For drugs such as phenytoin, in which there is significant binding to plasma proteins, it is the free drug which is of importance both in terms of efficacy and safety. Measurement of the total plasma concentration may be misleading in circumstances in which there is altered protein binding. Saliva levels, though not widely available, may be more relevant.

A majority of children treated with antiepileptic drugs will become seizure free and most should be subsequently withdrawn from antiepileptic medication. However, the maxim of withdrawing treatment after two seizure-free years is an oversimplification.<sup>205</sup> The best predictor of relapse is the epilepsy syndrome. Relapse is rare in benign childhood epilepsy with centrottemporal spikes and benign childhood occipital epilepsy (Panayiotopoulos type) and almost certain in juvenile myoclonic epilepsy. Relapse rates are intermediate for other commonly encountered syndromes. Other predictors, all imperfect, of the likelihood of relapse are age (greater risk with onset of seizures in infancy or very early childhood), symptomatic etiology, EEG abnormalities (photosensitivity appears to be strongly correlated with relapse) and severity of epilepsy prior to control being achieved.<sup>206</sup> The decision as to whether antiepileptic drugs should be withdrawn needs to be an individual one based on a detailed analysis with the child and family which takes into account the likely consequences should a relapse occur. For all children with epilepsies in whom there is a good prospect for successful withdrawal (benign focal epilepsies, childhood and to a lesser extent juvenile absence epilepsy) withdrawal should be attempted after two seizure-free years, or even earlier.<sup>207</sup> Persisting EEG abnormalities, except in the idiopathic generalized epilepsies and if there is photosensitivity, should not unduly influence this decision. For children with epilepsies which have proved difficult to control a longer period free of seizures (perhaps 2–5 years) is advisable. It is probably not justified in recommending drug withdrawal in juvenile myoclonic epilepsy or photosensitive epilepsies in children who remain highly photosensitive on EEG testing.

Children who have been on benzodiazepines and barbiturates for anything other than brief periods are usually withdrawn very slowly over many months or even years as the risk of withdrawal seizure is considered high, although this has recently been questioned.<sup>208</sup> Other drugs are usually withdrawn over short periods such as 1–2 months. The evidence base for these recommendations is poor.<sup>209</sup> Detailed instructions as to what measures to take should a seizure occur during withdrawal should always be given. Some families appreciate being provided with an agent such as diazepam or midazolam for emergency use. However, they should be reassured that status epilepticus is extremely rare during antiepileptic drug withdrawal.<sup>206</sup> Overall the risk of relapse in children withdrawn from antiepileptic drugs is around 20% at 6 months, rising to 35% at 4 years.<sup>206</sup> Relapses usually occur within a year of withdrawal. If seizures recur dur-

ing or after withdrawal the drug should generally be restarted and the prospect of regaining control is very good but not assured.<sup>209–211</sup>

If the child fails to respond to an antiepileptic drug it is important to reconsider the diagnosis: misdiagnosis of epilepsy remains a major problem. Sometimes a child will have responded to a drug but intolerable unwanted effects cause it to be stopped. It is usually easy in this situation to choose a suitable alternative. If, however, seizures have not been controlled despite pushing the first drug to the limit of tolerability or to the maximum reasonable dose then a second drug should be tried as monotherapy. A study found that 42% of children who failed on initial monotherapy subsequently had a complete remission on other agents.<sup>212</sup> Different clinicians vary in how this is achieved. Some prefer to wean off the first drug as the new drug is being introduced. However, if some response has occurred this may lead to an increase in seizures. The alternative approach is to introduce the second drug while maintaining the child on the first drug. The dose of the first drug may need to be adjusted. When seizures have been controlled the first drug can be withdrawn. The difficulty with this approach is that there is often an understandable reluctance to alter things once seizures have been controlled. For generalized epilepsies, assuming that sodium valproate has been tried initially, appropriate second line choices are lamotrigine, topiramate and levetiracetam.<sup>213</sup> However, for childhood absence epilepsy ethosuximide would be an alternative. Moreover, in juvenile myoclonic epilepsy if absences and generalized tonic-clonic seizures are completely controlled but myoclonic jerks remain problematic a small dose of a benzodiazepine, such as clonazepam, is a suitable alternative. For focal epilepsies, assuming carbamazepine has been the first line drug, a large number of suitable second line agents, including sodium valproate, are now available and it is not possible to give a blanket recommendation. All the recently introduced drugs have been shown in double-blind, placebo-controlled trials to be efficacious against partial seizures. Moreover systematic reviews have concluded that gabapentin, lamotrigine, topiramate, levetiracetam and oxcarbazepine are effective at least in the short term as add-on treatment in children with drug-resistant focal epilepsies.<sup>214–219</sup> However, there are very few studies reported comparing them 'head-to-head'. When a child has failed to respond to two suitable major antiepileptic drugs pushed to their maximum dose, the chances of achieving complete seizure control rapidly diminishes. Many different strategies exist but a number of principles should be emphasized:<sup>220</sup>

- There is evidence that control is sometimes better with two and occasionally three antiepileptic agents. However, there is no evidence that four antiepileptic drugs are ever appropriate.
- If more than one drug is to be used the approach taken should be rational. Some combinations of drugs are more appropriate than others. For example when treating drug-resistant focal seizures it may be wise to use combinations of drugs with different modes of action. Moreover, drugs with similar adverse effects such as benzodiazepines and phenobarbital should be avoided.
- Polypharmacy has many potential problems: increased risk of adverse effects; risk of exacerbating seizures, particularly if drowsiness is a problem; risk of drug interactions causing all the drugs to be at subtherapeutic levels – drug levels may be helpful.
- The aim of therapy is to improve quality of life not necessarily to render the child totally seizure free.
- The diagnosis should be re-evaluated periodically. Pseudoseizures should be among the considerations.
- Compliance may need to be checked.
- If seizures are only being reported by one party the possibility of 'misreporting' by the carer to gain attention or benefits should be considered. Seizures are commonly reported in factitious and induced illness.
- A systematic approach should be adopted whereby each agent tried is given an adequate trial before deciding that it is ineffective.

In children with drug-resistant epilepsies thought should be given to trying less conventional medication such as short courses of steroids or ACTH and immunoglobulins. Anecdotal evidence suggests that these may be effective in individual children.

### *The ketogenic diet*<sup>221</sup>

Ketogenic diets have been used in the treatment of drug-resistant epilepsies for decades. It has not been established if they are particularly indicated for any particular seizure or epilepsy syndrome type and have been advocated for children with drug-resistant seizures of any type and from any cause. However, they should be avoided in children with mitochondrial diseases, particularly pyruvate carboxylase deficiency. A recent review concluded that approximately half of children will half their seizures, and about one third will have one tenth their baseline seizures.<sup>221</sup> The mechanism of action remains obscure. All ketogenic diets aim to induce ketosis by providing the child's caloric needs predominantly as ketogenic foods (fats). The classic (4:1) diet uses 4 g of fat to every 1 g of nonketogenic foods (protein and carbohydrate). The medium-chain triglyceride and the modified medium-chain triglyceride diets utilize medium-chain triglycerides, which are more ketogenic and hence allow a lower ratio of fats to other foods to be given. The diet is usually initiated by fasting in hospital with the aim of achieving and maintaining 3–4+ ketonuria. Acetazolamide and topiramate should be withdrawn first because severe acidosis may occur. Other antiepileptic drugs are usually continued, at least initially. A skilled dietitian is essential. Unwanted effects include hypoglycemia (usually only a problem when the diet is first initiated), hunger and thirst, weight problems, antiepileptic drug toxicity and renal stones. The diet must be kept strictly; even sugar-containing medicines can reduce its efficacy. Regular monitoring of growth and of blood electrolytes, liver function tests, lipids, proteins and full blood count is generally advocated. If successful, the diet is usually continued for at least 2 years. It should be stopped gradually.

The Atkin diet is reported to be effective in some children with refractory epilepsy.<sup>222</sup>

### *The vagal nerve stimulator*

This is a relatively new technique involving intermittent stimulation of the left vagus nerve in the neck. A pulse generator is implanted subcutaneously in the upper chest. Leads convey electrical impulses from it to the vagus nerve and are then transmitted up the nerve to the nucleus solitarius. The antiepileptic action of vagal nerve stimulation is poorly understood, but presumably relies on projections from the nucleus solitarius to cortical and subcortical structures. The generator is programmed using a PC and 'wand' to give chronic intermittent stimulation. A systematic review concluded that vagal nerve stimulation appears to be an effective and well-tolerated treatment for focal seizures.<sup>223</sup> There is currently no clear indication as to which children with refractory epilepsy should be offered this treatment. There is as yet no large randomized study reported from children but a median reduction in seizures of up to 43% has been reported in a small group with epileptic encephalopathies.<sup>224</sup> Very few children become seizure free. Efficacy appears to improve with time.

### *Epilepsy surgery*

A significant minority of children with medically refractory epilepsy can benefit from surgery both in terms of improved seizure control and overall quality of life. All children with seizures continuing, despite medical treatment, should be evaluated in a center with the facilities and expertise to assess their suitability for surgical treatment. Epilepsy surgery can be resective or functional. The former involves removing epileptogenic tissue, aiming to 'cure' the epilepsy. The latter modifies brain function in order to interrupt the transmission of epileptic discharges. Its aim is to improve seizure control, to modify seizure type or to minimize the deleterious effects seizures can have on cerebral function.

The evaluation and selection of children for any type of epilepsy surgery is multidisciplinary, involving pediatric neurologists, neurophysiologists, neuropsychologists, neuroradiologists, nuclear medicine physicians and child psychiatrists as well as the neurosurgeon. Severe learning difficulties and behavioral problems are relative, but not absolute, contraindications to surgery.

A prerequisite of resective surgery is that seizures are focal in origin or arise from one cerebral hemisphere. Identification of the seizure

focus involves integration of multiple sources of data. In all cases this involves:

- A detailed clinical assessment. Seizure sociology along with the findings on neurological examination may give useful information regarding seizure localization.
- Detailed scalp EEG studies. These will include interictal and ictal recordings with recordings during awake and sleep. Video-EEG is essential and it is usual to try to capture a number of the child's habitual seizures.
- High quality structural imaging with MRI; the prospects for surgery are considerably enhanced if a structural lesion can be identified.
- Neuropsychological evaluation. This may provide further useful information on the likely lateralization and even localization of the epileptic focus. In addition it seeks to identify cerebral dominance for speech and to give a baseline of the child's cognitive abilities.

If the data from these studies are congruent it is often possible to proceed to surgery without further investigations. However, if the site of the epileptic focus is still unclear further investigations are carried out. These may include:

- semi-invasive EEG studies (foramen ovale or sphenoidal electrodes);
- functional neuroimaging usually with ictal SPECT or interictal PET;
- invasive EEG studies using subdural grids of electrodes or depth electrodes.

In older children and teenagers undergoing resective surgery it is usual to establish the dominant hemisphere for language and memory. Traditionally this has been by the invasive carotid amytal test. Increasingly functional MRI and magnetencephalography are being used. Resecting a temporal lobe in which memory resides would result in a dense amnesia.

The majority of resections in both adults and children are of the temporal lobe. However, whereas in adults mesial temporal sclerosis is the predominant pathology, in children, tumors, cortical dysplasias and other focal pathologies are also relatively common.<sup>225</sup> In the Maudsley series of 41 children 15 years or younger 80% became seizure free. There was no mortality and series morbidity occurred in only 1–2%.<sup>225</sup> Extratemporal resections are less commonly performed and the outcome poorer with seizure free rates of well under 50%.<sup>226</sup>

Hemispherectomies and multilobar resections are performed considerably more often in children than in adults. They are indicated for some of the catastrophic epilepsies of infancy such as Sturge–Weber syndrome and hemimegalencephaly. Hemispherectomy is the treatment of choice in Rasmussen disease and has been used to treat severe epilepsies due to extensive unilateral infarctions. It is generally reserved for people with already established hemiplegias. Depending on the underlying pathology, up to 70–80% of children become seizure free.<sup>227</sup>

Functional procedures include callosotomy, stereotactic lesioning (e.g. with the gamma knife) and multiple subpial resection. The indications for callosotomy are still disputed. However, it is generally reserved for children with seizures presumed to be of focal onset but in whom rapid bilateral synchrony occurs. It seems to be most effective against atonic drop attacks. Few children become seizure free, but in many the seizures postoperatively are less disabling. Significant neuropsychological deficits may occur, particularly if the posterior part of the corpus callosum is divided. Multiple subpial transection involves sectioning horizontal cortical fibers thought to be responsible for seizure propagation, leaving vertically orientated fibers, responsible for normal function, intact. It has mainly been used in the Landau–Kleffner syndrome.

## STATUS EPILEPTICUS

This is conventionally defined as an epileptic seizure lasting for more than 30 minutes or frequent seizures for the same period without recovery of consciousness between seizures. Convulsive status epilepticus (CSE) in childhood is a life-threatening condition with serious risk of neurological sequelae<sup>228–230</sup> and constitutes a medical emergency. Although the outcome from an episode of CSE is mainly determined by its cause, the duration of CSE is also important. In addition, the longer the duration

of the status, the more difficult it is to terminate.<sup>230,231</sup> Treatment of convulsive seizures lasting more than 5 minutes is recommended in order to prevent the development of CSE.

Data from epidemiological studies suggest that 4–8 children per 1000 have an episode of CSE before the age of 15 years<sup>232</sup> and 17% of children with seizures present with CSE as their first unprovoked seizure.<sup>233</sup> CSE in children has a mortality of approximately 4%.<sup>234</sup> Neurological sequelae of CSE (epilepsy, motor deficits, learning difficulties and behavior problems) are age dependent, occurring in 6% of those over 3 years but in 29% of those under 1 year.<sup>233</sup> Important causes of CSE are febrile seizures and those with epilepsy in whom antiepileptic drug treatment is being modified. Idiopathic CSE is also relatively common.

An evidence-based approach to the prevention/treatment of CSE is shown in Figure 22.24.<sup>235</sup> Initial management should follow the ABC principle of resuscitation. Midazolam, used buccally, is more effective and as well tolerated as rectal diazepam<sup>176</sup> and is preferred by the carers. High flow oxygen should be given and the blood glucose measured by stick testing. It is important to emphasize that not all episodes of apparent status epilepticus are in fact epileptic. A brief history and clinical examination

should therefore be undertaken to confirm that the seizure activity is likely to be epileptic and not, for example, a drug-induced dystonic reaction, a tonic spasm due to raised ICP or a psychogenic (pseudo-epileptic) attack.

If the seizure does not rapidly respond to initial treatments, or if there is significant respiratory, cardiovascular or neurological compromise, the child should be intubated, artificially ventilated and treated in an intensive care setting. Monitoring of vital signs, including pulse, blood pressure and blood gases, is essential to ensure that a hypoxic-ischemic insult is not added to the direct effects of the status epilepticus. A small number of children will continue to convulse despite treatment with thiopental (refractory CSE). The most appropriate subsequent anti-convulsant management is unclear. Regimens using continuous intravenous agents such as midazolam<sup>236</sup> and inhalational anesthetic agents such as isoflurane<sup>237</sup> have been reported but are not fully evaluated.<sup>238</sup> During CSE, depletion of intracellular energy stores in muscle may lead to reduction in muscle activity. This may be misinterpreted as 'the seizure settling down', whereas the cerebral activity and damaging metabolic derangements are continuing. Careful examination, and EEG, if available, will help determine if there is ongoing seizure activity.

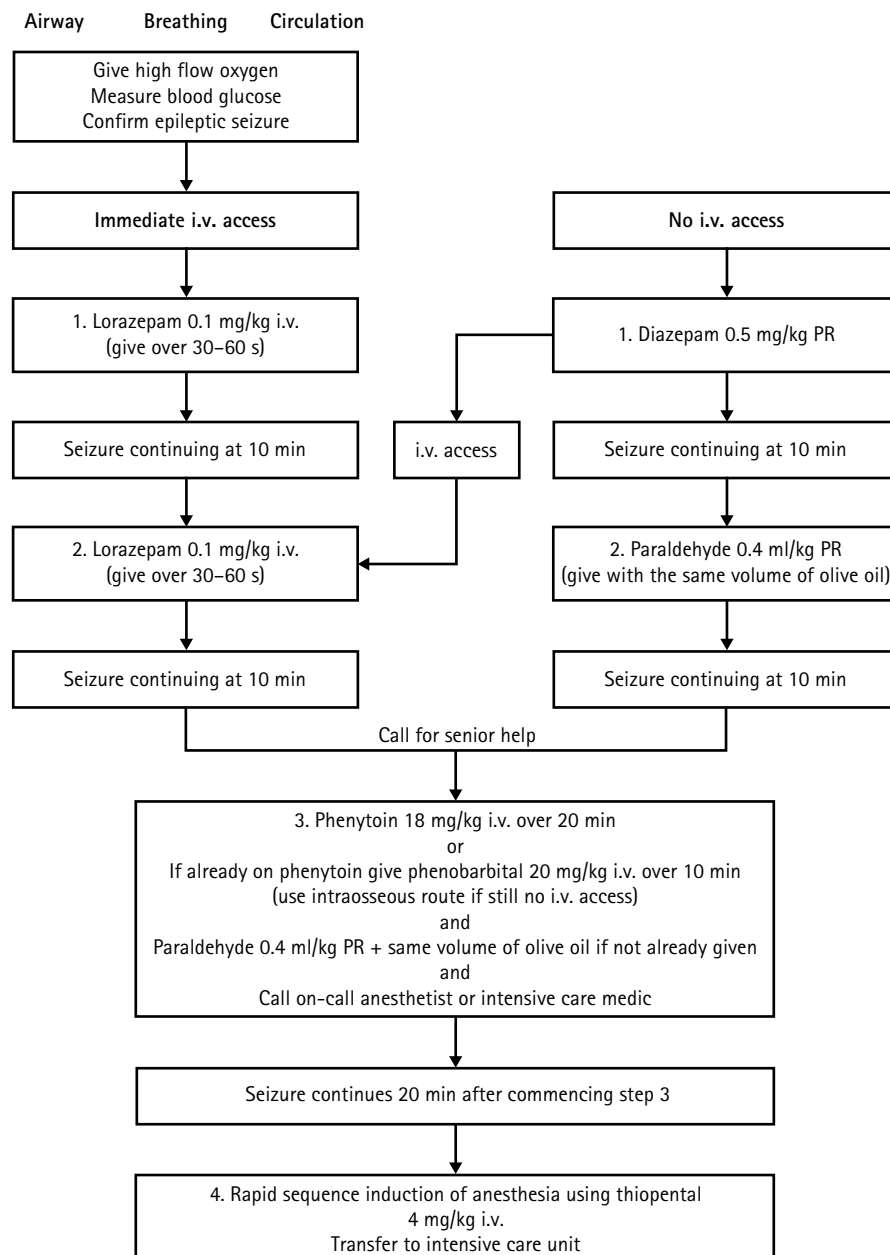

Fig. 22.24 British Paediatric Neurologist Association guidelines on the treatment of status epilepticus.

Impairment of consciousness following a seizure is common. This postictal impairment is easy to diagnose if the seizure has been witnessed, but may present difficulties if it has not. Although the coma score may be very low, supportive care is usually all that is required, provided steady improvement is documented. A cause for the seizure such as hypoglycemia or infection should be sought. Drug treatment with agents such as lorazepam and diazepam will greatly prolong the recovery period.

Nonconvulsive status epilepticus (NCSE) may present as a child with reduced conscious level. The child has continuous, or very frequent absence, atypical absence or complex partial seizures so that an enduring epileptic state is present. The child is unaware, or has severely impaired awareness, is ataxic, drooling and uncommunicative and may manifest minor jerks and myoclonus. This seizure state rarely happens as the first manifestation of epilepsy. It is usually seen as part of an epileptic encephalopathy such as the Lennox–Gastaut syndrome, but can occur in idiopathic epilepsies and may be provoked by inappropriate antiepileptic drug treatment, such as giving carbamazepine to children with absences. The parents or carers will often be aware of the cause of the impaired consciousness. An EEG will usually show continuous spike and wave activity. There is not the same degree of urgency in treating nonconvulsive as compared to convulsive status epilepticus. However, prolonged episodes of nonconvulsive status epilepticus have been linked to intellectual decline. Oral, rectal and intravenous benzodiazepines or steroids are often used. Occasionally benzodiazepines may provoke tonic status epilepticus.

In a child who has had seizures as part of their encephalopathy the possibility that subclinical or subtle seizures are continuing to impair consciousness should be considered. Such seizures may be difficult to detect and an EEG or continuous EEG monitoring may be required. The decision as to whether to treat an abnormal EEG without clear clinical seizure activity is a difficult one. In practice it is often possible to correlate EEG abnormalities with subtle seizure signs or physiological changes. Overtreatment of EEG abnormalities may prolong recovery of consciousness unnecessarily.

## NONEPILEPTIC PAROXYSMAL DISORDERS

The conditions described here are frequently misdiagnosed as epilepsy. Their recognition is important, not only to avoid this, but because they are important conditions in their own right, requiring investigation and explanation. Moreover, for many, specific and effective treatments exist. The reader who requires more information is referred to Stephenson unique text.<sup>239</sup>

### Syncope and anoxic seizures

A syncope or faint is a sudden loss of consciousness and postural tone caused by a cessation in the supply of energy substrates to the cerebral cortex. The latter is usually a result of hypoxia or reduced cerebral perfusion or a combination of both. An anoxic seizure is a non-epileptic seizure caused by syncope. In effect, it is a severe form of syncope. The clinical features consist of an initial loss of consciousness and postural tone (this phase may be brief) followed by tonic stiffening and/or clonic movements. If an EEG is recorded during an anoxic seizure it shows slowing, followed by flattening during the tonic phase, followed by the reappearance of slow waves, often coinciding with clonic jerks. No epileptiform abnormalities are seen. It should be noted that there are no unique features of syncopes and anoxic seizures that reliably distinguish them from epileptic seizures: eye rolling, tongue biting and urinary incontinence occur in both. Moreover, although many syncopes are short, both these and reflex anoxic seizures can be prolonged. Postictal drowsiness can follow epileptic seizures, syncopes and anoxic seizures. It is the circumstances in which syncopes and anoxic seizures occur which often allows them to be distinguished from epileptic seizures. However, in some cases definite distinction requires prolonged polygraphic recording.

The commonest forms of syncope are *simple faints* or *vasovagal syncopes*. The most important distinguishing feature is the circumstance of occurrence, which is often stereotyped for the individual. Common provoking factors are stress, emotion and upright posture, especially in confined spaces. Older children may recount initial symptoms of light-headedness, heat and graying of vision. Abdominal pain is also said to be common. During the attack the child is usually pale, limp and the pulse may be slow. Attacks may occur when supine. Clonic limb movements, sometimes asymmetrical, are common and postictal confusion may occur. There is often a family history of similarly affected relatives. Head-up tilt testing may help if the diagnosis remains in doubt. Vasovagal syncopes are considered to arise as a consequence of a vasodepressor mechanism, sometimes combined with vagally mediated cardio-inhibition. *Vagovagal syncopes* in which a reflex bradycardia or asystole follows vagal stimulation by swallowing or vomiting are more rare. Syncopes can also arise due to *orthostatic hypotension*, rare in children but more common in adolescence.

*Reflex anoxic seizures* (also known as *reflex asystolic syncope*) are a relatively common form of syncope in young children. The precipitant is usually a minor bump to the head provoking a vagally mediated cardiac asystole, which may last many seconds. Clinically the child simultaneously loses consciousness and becomes floppy and extremely pale (pallid syncope). Subsequent tonic stiffening and clonic movements are common. Although the heart quickly restarts the loss of consciousness may be prolonged. Reflex anoxic seizures should be distinguished from *breath-holding attacks* (*blue syncopes*, *prolonged expiratory apnea*). The pathophysiology of these relatively common attacks is still incompletely understood, but they are not behavioral in origin. They are provoked by fright, pain, anger or frustration. Crying is followed by the breath being held in expiration. Cyanosis and loss of consciousness follows. Although there may be a short period of limpness, characteristically tonic stiffening follows. Iron therapy, especially if there is iron deficiency, may be helpful.

Anoxic seizures, probably of all types, can exceptionally be followed by true epileptic seizures, usually with sustained generalized clonic jerking.<sup>240</sup>

All the syncopes discussed so far are benign, although attacks similar to breath-holding attacks occurring in some neurologically impaired children may not be so. Reassurance and explanation is all that is generally required. Simple faints wax and wane in their frequency, often being particularly troublesome in the teenage years. Most, but not all, infants with reflex anoxic seizures and breath-holding attacks eventually become free of the attacks in mid to late childhood. Specific treatment is not required although some advocate the use of atropine in reflex anoxic seizures. When very severe, these may also be helped by cardiac pacing.<sup>241</sup>

Some forms of syncope are less benign. Retarded children sometimes provoke 'drop-like attacks' by a *Valsalva maneuver*. Occasionally these have been fatal. *Gastroesophageal reflux* occasionally provokes apnea, sometimes followed by an anoxic seizure. The mechanism may be vagally mediated cardiac inhibition or laryngospasm and appears to be a feature of the awake state. Whether this is one cause of apparent life-threatening events and sudden infant death syndrome is controversial. Treatment is of the gastroesophageal reflux.

*Cardiac syncopes* are important and potentially life threatening.<sup>242</sup> Syncopes and anoxic seizures can be a manifestation of various cardiac arrhythmias and of structural heart disease. Particularly important to recognize are the *prolonged QT syndromes*. These ion channel disorders are characterized by anoxic seizures occurring during exercise and sleep. They are potentially fatal. In most but not all cases the corrected QT interval (QTc) is greater than 440 ms. If the clinical history is suggestive but the QT interval on a standard EEG is normal, prolonged ECG monitoring and exercise ECG is indicated.

*Cranio-cervical junction disorders* such as Chiari malformations may be associated with apneas and syncopes occurring during activities which increase intracranial pressure.

*Imposed suffocation* is a relatively common manifestation of *Munchausen syndrome by proxy*.<sup>243</sup> Attacks all begin in the presence of the perpetrator, usually the mother. Others may witness the conclusion of the attacks.

### Movement disorders and related conditions<sup>244</sup>

A large number of paroxysmal movement disorders occur in children and can be mistaken for epilepsy. The *episodic ataxias* are familial ion channel disorders.<sup>80,132,245,246</sup> Episodic ataxia provoked by factors such as startle or exercise often provides the clue to diagnosis and may be isolated or coexist with a variety of other problems, including epilepsy. They may respond to acetazolamide. Two types are distinguished. In type 1 (EA1) attacks last seconds or minutes and myokymia is present between attacks. It is associated with mutations on the potassium channel gene KCNA1. In type 2 (EA2) attacks are longer lasting and there may be associated cerebellar signs. It is associated with mutations on the calcium channel gene CACNA1A and is allelic with familial hemiplegic migraine and spinocerebellar atrophy type 6. A variety of conditions are described in which paroxysmal dystonia or dyskinesia or choreoathetosis occurs. The two best characterized conditions are *paroxysmal kinesigenic choreoathetosis* and *paroxysmal nonkinesigenic choreoathetosis*, both of which are autosomal dominant. The former is characterized by very frequent short episodes, unilateral or bilateral, of dystonia or choreoathetosis provoked by sudden movement. Although not an epilepsy, it frequently responds to antiepileptic drugs such as carbamazepine and phenytoin. The nonkinesigenic form is characterized by less frequent, longer attacks precipitated by stress, coffee or alcohol. It may respond to clonazepam. A third type – *paroxysmal exercise-induced dystonia* – is associated with dystonia coming on 10–15 minutes after exercise and lasting 5–30 minutes. It may respond to acetazolamide.

*Benign myoclonus of infancy* may be mistaken for epileptic spasms. The movements are more sustained than in true myoclonus and benign; non-epileptic infantile spasms and shuddering attacks are alternative names. It is unrelated to *benign neonatal sleep myoclonus* which is relatively common and frequently mistaken as epileptic. It is characterized by repetitive, usually rhythmic jerks of one or more limbs in sleep.

Various abnormal head movements are described. These include repetitive *head bobbing* and *banging*. The latter sometimes occurs in understimulated children. *Tics* are occasionally confused with seizures.

*Paroxysmal vertigo*, occurring in children between 1 and 5 years of age, and manifest as the child suddenly appearing distressed, pale and unsteady, sometimes with nystagmus, may be related to *benign paroxysmal torticollis of infancy*. In the latter repeated attacks of distress, vomiting and head tilt occur. In turn both conditions may be related to migraine.

*Benign paroxysmal tonic up-gaze of childhood* is usually seen in infancy and presents with prolonged episodes of sustained or episodic up-gaze. It may respond to L-DOPA. Learning difficulties are very common.

*Sandifer syndrome* refers to dyskinetic neck movements occurring in children with gastroesophageal reflux often in association with hiatus hernia.

*Drug-induced dystonic reactions*, including oculogyric crises, are seen with psychotropic drugs, particularly the phenothiazines and metoclopramide. Intravenous benzotropine or a benzodiazepine will abort attacks.

*Tetany* with carpopedal spasm and laryngospasm is a manifestation of hypocalcemia or hypomagnesemia, both of which can also cause epileptic seizures.

### Hyperekplexia

This is usually an autosomal dominant condition; less commonly it is recessive. It is caused by mutations in subunits of the glycine receptor. It is conventionally divided into major and minor forms. The latter is manifested by generalized hypertonia (which may lead to an erroneous diagnosis of cerebral palsy) and excessive startles to auditory, visual and somatosensory stimuli. In the major form there are, in addition, attacks of severe tonic stiffening with apnea. These can be

life-threatening. Excess startle can also be symptomatic of a number of other conditions.<sup>247</sup>

A useful diagnostic test is nose-tapping which causes an excessive and reproducible startle. Clonazepam and valproate are useful. In addition, the forced flexion maneuver consisting of sudden flexion of the head and limbs can be life saving during severe apneic attacks.

### Paroxysmal extreme pain disorder (previously called familial rectal pain syndrome)

This is a rare, usually autosomal dominant condition, which is probably manifest throughout life and is caused by mutations on genes coding for the sodium channel SCN9A.<sup>248</sup> It is characterized by discrete attacks with marked autonomic features. The most prominent of these is the sudden onset of excruciating pain that can be generalized or localized to sites such as the rectum, genitalia and face. Harlequin color changes may be conspicuous. Some attacks may be associated with severe apnea and asystole. The risk which these pose is unknown. Many attacks are unprovoked but triggers include startles, defecation, wiping of the nappy area, urination, eating and drinking. Carbamazepine is of some benefit.

### Sleep disorders

A number of different movement disorders related to sleep are described. These include benign neonatal sleep myoclonus, periodic movements of sleep, restless leg syndrome, jactatio capitis nocturna (repetitive head banging), hypnagogic jactitations (myoclonic jerks, usually of the legs, on falling asleep) and nocturnal myoclonus. These are all benign phenomena and except for restless leg syndrome, require reassurance only.

*Night terrors* are occasionally confused with frontal lobe seizures. They occur in infancy and early childhood and are associated with partial arousal from deep slow sleep. They usually occur early in the night and are manifested with the child screaming as if terrified. Although appearing awake, the child cannot be consoled and appears not to recognize his parents. There is no recollection next morning. *Nightmares* are a phenomenon of rapid eye movement sleep. *Sleepwalking* and *sleep talking* often occur together, usually in older children and adolescents who previously had night terrors. Again reassurance is all that is required along with advice about sensible safety precautions. *Hypnagogic hallucinations and illusions*, usually visual or auditory, occur in the transitions between wakefulness and sleep and are considered normal phenomena. *Restless leg syndrome* occasionally occurs in children. It usually responds to L-DOPA.

*Narcolepsy* is usually an autosomal dominant disorder which in its full form features:<sup>249</sup>

- excessive daytime sleepiness with frequent daytime naps;
- cataplexy, i.e. attacks of sudden loss of tone causing falls in full consciousness, often precipitated by laughter or excitement and misdiagnosed as epilepsy;<sup>250</sup>
- hypnagogic hallucinations;
- sleep paralysis manifested by attacks of inability to move or to move a limb occurring as the subject is wakening.

The disorder is probably underdiagnosed in childhood as it is usually manifested only as excessive daytime sleepiness with frequent daytime naps, the other features appearing in adolescence and adult life. However, its recognition is important as it can lead to school failure.

The diagnosis is essentially clinical. However, multiple sleep latency studies can offer confirmatory information. Subjects with narcolepsy have a short latency for entering rapid eye movement sleep and may pass straight into it from the awake state. In addition there is a very strong association with HLA-DQB1 0602, present in up to 98% of subjects. Recently narcolepsy has been shown to be associated with greatly reduced CSF levels of the neuropeptide hypocretin which is produced in the hypothalamus. This is likely to become the preferred diagnostic test. It is important to exclude nocturnal hypoventilation, a much commoner cause of daytime sleepiness than narcolepsy. The most important aspect of management of narcolepsy is ensuring that the family and school understand the nature of the condition and that the child has an appropriate period of night-time sleep (paradoxically night-time insomnia can be a problem), along with daytime naps. It is sensible to present the most important

educational material early in the day when the child is likely to be at its brightest. Amphetamines have traditionally been the main pharmacological agent used to treat excessive sleepiness in narcolepsy but modafinil is being increasingly preferred. Imipramine and clomipramine can be useful in cataplexy. More recently sodium oxybate has been shown to be particularly efficacious.<sup>251</sup> There is evidence that early treatment of narcolepsy/cataplexy with immunoglobulins may be disease modifying.<sup>252</sup>

### Psychological and psychiatric disorders

Many different psychological and psychiatric disturbances can present as paroxysmal episodes and are important in the differential diagnosis of epilepsy. *Masturbation* occurs at all ages and may be more or less obvious. In young girls it often involves adduction of the thighs and rhythmic hip flexion. The child is characteristically vacant, rigid and flushed. Other gratification phenomena are described and are manifested with stereotyped behaviors during which the child appears withdrawn. *Daydreams* are particularly prone to misinterpretation by school teachers. They occur when bored or fatigued and generally involve the child's attention gradually drifting away.

*Hyperventilation* is relatively common, especially in teenage girls. It provokes sensations of light-headedness, chest pain and paresthesiae. It may also be manifested with carpopedal spasm as in tetany. Hyperventilation is often a symptom of anxiety and may be helped by psychological intervention. Milder cases may be helped by rebreathing into a paper bag.

*Non-epileptic attack disorder (pseudoseizures)* occur in mid and late childhood and adolescence. Some are easily distinguished from epileptic seizures while in others the distinction may be extremely difficult. Pseudoseizures may mimic any type of epileptic seizure, including status epilepticus. There are no hard and fast rules whereby epileptic and pseudoseizures can be reliably separated. However, movements in the latter are usually thrashing and semipurposeful rather than rhythmic clonic jerks. In addition, in epileptic seizures the eyes nearly always open within seconds of the attack. Induction by suggestion can be very helpful. A major difficulty is in distinguishing frontal lobe seizures from pseudoseizures. Pseudoseizures are probably most common in children who also have epileptic seizures. However, they also occur in children who had epileptic seizures but whose seizures have stopped and in children who have never had an epileptic seizure, although a friend or relative may.

An ictal EEG recording which shows no epileptiform abnormalities is suggestive, but not conclusive, evidence of pseudoseizures; the ictal EEG is often normal during, for example, frontal lobe seizures and elementary focal seizures. Measurement of serum prolactin levels is occasionally useful, levels increasing after generalized tonic-clonic seizures and some focal seizures, but not usually after frontal lobe seizures or elementary focal seizures. It is crucial to have an accurate baseline measurement and to take the sample at the appropriate time after the start of the seizure.<sup>253</sup>

Confidently distinguishing between epileptic seizures and non-epileptic attack disorder may be impossible, even after extensive history taking and detailed investigations. However, if the latter seems more likely it is inappropriate to treat with antiepileptics in the hope that it might be. It must be accepted that even the best clinician will be mistaken from time to time. What is required is the honesty to review the diagnosis if the management offered fails. All children who have or are suspected of having non-epileptic attack disorder require the input of a child psychologist or psychiatrist. Often there is no serious underlying psychological or psychiatric problem and the prognosis is excellent. However, children who are, or have been, abused physically or sexually may present in this way.

Other conditions to consider in the differential diagnosis of paroxysmal disorders include the effects of *substance abuse*, *early-onset schizophrenia* with hallucinations and attacks of *rage* seen in older children and adolescents.

### Other neurological conditions

*Migraine* may be confused for epilepsy and vice versa. Some epileptic seizures, particularly of occipital lobe origin, superficially resemble migraine attacks. In addition, given that both conditions are relatively

common, it is not surprising that some children will be encountered with both conditions. Both migraine and some forms of epilepsy are regularly provoked by endogenous and exogenous factors. Therefore, it is likely that occasionally a migraine will provoke an epileptic seizure and vice versa. Exceptionally a severe migraine may result in an ischemic lesion, which acts as an epileptic focus.

*Alternating hemiplegia of childhood* is a rare disorder which begins within the first year of life, usually with brief tonic attacks, often unilateral with eye movement abnormalities, accompanied by general misery.<sup>254</sup> Shortly after attacks of alternating hemiplegia begin and are usually frequent. They may be provoked by various triggers. A striking feature is disappearance of the hemiplegia with sleep, often with its reappearance shortly after awakening. Although some response to flunarizine is reported, the condition is progressive with mental retardation and a variety of motor problems. Structural neuroimaging is normal.

## HEADACHE AND MIGRAINE

### HEADACHE

Headache is one of the most common health complaints in childhood. It is reported by children from infancy to adolescence and from all ethnic and socioeconomic backgrounds. The predisposition to headache, commonly, continues through adulthood.<sup>256</sup> Population-based studies of schoolchildren, between 5 and 15 years, showed that 66% suffered at least one episode of headache during a 1-year period and in 22% the headache was severe enough to interfere with normal activities.<sup>257</sup> The prevalence of headache increases steadily with age reaching around 90% at age 12–13 years.<sup>258</sup> The prevalence rate in preschool children is difficult to ascertain, but it is not unusual for parents of older children with migraine to describe attacks dating back to the first year of life. The prevalence rate of headache doubled from 13% to 26% between age 3 and 4 years in a population of an urban general practice in the UK<sup>259</sup> reaching a peak of 40–50% during the first year at school followed by a slight drop in the following 1–2 years.<sup>260</sup>

Headache is benign and infrequent in many children. At least 40% of schoolchildren, over the age of 11 years, use over-the-counter painkillers to treat their own headache.<sup>261,262</sup> and parents often treat their children's headaches inappropriately. A study of 100 caregivers showed that only 30% were able to determine the correct dose of paracetamol and to accurately measure the intended dose.<sup>263</sup> Advice may be sought from a wide variety of medical professionals (general practitioners, general pediatricians, pediatric neurologists, neurosurgeons, child psychiatrists, ENT surgeons and ophthalmologists) and from complementary therapists.

Headaches can be classified according to clinical presentation, duration of illness and frequency of attacks as acute, recurrent or chronic (Table 22.12).

### Acute headaches

Children often present with single or isolated attacks of headache which are commonly associated with other symptoms indicating an underlying focal or systemic illness. In one survey in 150 unselected children attending an accident and emergency department causes were classified as upper respiratory tract infections (57%), migraine without aura (18%), viral meningitis (9%), brain tumor (2.6%), ventriculo-peritoneal shunt dysfunction (2%), intracranial hemorrhage (1.3%), postictal headache (1.3%), post-concussion (1.3%) and undetermined causes (7%).<sup>264</sup> In a primary care setting febrile illnesses were also the main causes of acute headache in 634 children (56.8%).<sup>265</sup>

### Chronic headaches

Children usually present with at least 3 months history of constant headache or a headache with fluctuating intensity, but with no periods of complete recovery. Chronic headaches are rare in children, but brain tumors are the main concern to the parents and their pediatricians. Headache is rarely the only complaint and other symptoms may be more prominent.

Table 22.12 Main causes of headache in children and adolescents

<b>Acute headaches</b>
Viral illnesses: respiratory, gastrointestinal and flu-like illnesses
Bacterial infections: tonsillitis, pharyngitis, sinusitis, pneumonia
Intracranial infections: viral or bacterial meningitis, encephalitis
Intracranial bleeding
Head trauma
Others
<b>Recurrent headache</b>
Migraine: migraine without aura, migraine with aura, complicated migraine
Tension-type headache: episodic tension headache, chronic tension headache
Short-lasting unilateral headaches: cluster headache, neuralgias
Others
<b>Chronic headache</b>
Raised intracranial pressure: brain tumor, hydrocephalus, idiopathic intracranial hypertension
Hypertension
Substance induced: intoxication, medications
<b>Others</b>

## Recurrent headaches

Recurrent headaches are defined as those occurring over a period of at least 3 months. Idiopathic or primary headache is the most common and is separated by periods of complete normality. In a population-based study,<sup>257</sup> migraine (with or without aura) was the most common cause accounting for 77.2% of cases. Other causes were episodic and chronic tension headache in 11.7%, nonspecific headache in 9.7% and headache associated with illnesses such as asthma, hay fever, allergy and constipation in 1.5%. Similar causes, but with different proportions, are reported in children attending specialist clinics; 35% migraine (28% without aura, 5% with aura and 2% hemiplegic migraine), 38% tension headache (22% chronic and 16% episodic), 10% mixed migraine and tension headaches, 12% unclassified and 5% due to other causes or combination of causes.<sup>266</sup>

## Clinical classifications of recurrent headache

The 1988 International Headache Society's (IHS) classification of headache and facial pain and the revised second edition in 2004 are the most widely used and tested criteria particularly for migraine and tension headache.<sup>267,268</sup>

The classification and diagnostic clinical criteria suggest a disease continuum,<sup>269</sup> with features such as the pain quality, site of maximal intensity, severity and the number and nature of the associated symptoms during attacks determining the clinical diagnosis. Tension type headache is commonly mild to moderate in intensity, dull aching in nature, poorly localized or described as affecting the whole head. It is rarely associated with other sensory, vasomotor or gastrointestinal symptoms. Episodic tension-type headache with its infrequent attacks may represent the mild end of the headache spectrum while at the extreme end of the spectrum the pain during migraine attacks is more intense (moderate or severe), more localized (unilateral or frontal), throbbing or stabbing in character and is associated with a variable number of sensory, vasomotor or gastrointestinal symptoms. Migraine without aura can bear similarities to episodic tension type headache with some blurred borders separating the two conditions midway in the headache spectrum. Migraine with aura at the extreme end of the spectrum has a well-defined symptom constellation that may also include complicated attacks of migraine with dysphasia, hemiplegia or prolonged aura. The concept of the headache continuum encompassing all types of headache into one clinical spectrum has provoked wide interest, but is not universally accepted.<sup>270</sup>

## Evaluation of the child with recurrent headaches

A specific diagnosis can be made in the majority of patients on the basis of detailed clinical history and physical examination. Prospective headache diaries provide a reliable source of symptom reporting and also the distinction between several types of headache that may coexist in the same patient. Investigations are only needed occasionally.

## Clinical history of headache

Full clinical history is paramount although young children may find difficulties in describing pain and its characteristics (see Ch. 38, p. 1630). The child should be encouraged to use his/her own words and be assisted with visual images to describe certain ideas such as the severity of pain. Assessment of the headache should include the duration of symptoms, of individual attacks, their frequency and severity, the site of maximal intensity and the quality of pain. Possible trigger factors, warning signs and aura symptoms should be recorded. Associated clinical features such as anorexia, nausea, vomiting, light, noise or smell intolerance, pallor, visual disturbances, dizziness, confusion, abdominal pain and motor or sensory deficits should also be carefully assessed and recorded. Assessment should also be made of aggravating and relieving factors and the patients' own treatment strategies. It should also be determined if there are continuing sensory, motor or gastrointestinal symptoms between attacks of headache or a complete resolution of symptoms and a full return to normality. The complete clinical description of these features is best collected prospectively, by using a diary to record the events as they happen.<sup>271</sup>

## Physical examination

All patients should have a complete physical examination including the measurement of blood pressure. Neurological examination should be thorough and complete including measurement of the head circumference. Of particular importance is the detection of signs and symptoms of raised intracranial pressure (papilloedema, squints and pupillary abnormalities), cerebellar dysfunction (nystagmus, ataxia, intention tremor or torticollis), focal neurological deficits, brainstem disease and cranial nerve palsies.

## Investigations

Investigations are only needed in a minority of children with chronic or recurrent headache. Indications for neuroimaging, with CT or MRI are given in Table 22.13.<sup>266</sup>

Lumbar puncture and measurement of opening CSF pressure is indicated if infection or idiopathic intracranial hypertension is suspected.

## CHILDHOOD MIGRAINE

It is estimated that around 1 in 10 schoolchildren suffer from migraine. The prevalence rate is estimated at 1.3% in children between 3 and 5 years of age<sup>259</sup> and 3.4% at age 5 with a steady increase to 19.1% at 12 years of age. After the age of 12 the prevalence rate drops slightly to reach adult prevalence rates.<sup>257</sup> Boys and girls under the age of 12 years are almost equally affected with migraine, but in children older than 12 years migraine is commoner in girls than boys with a transition to adult rates of around 6% in males and 17% in females.

The etiology of migraine is not known, but it has a familial tendency. The risk for first degree relatives of patients is increased above

Table 22.13 Indications for neuroimaging in children with headache

1. Features of cerebellar dysfunction: ataxia; nystagmus; intention tremor
2. Features of increased intracranial pressure: papilloedema; night or early morning vomiting; large head
3. New focal or new neurological deficits including recent squint
4. Seizures, especially focal
5. Personality change
6. Deterioration of school work

general population levels: 1.9-fold for migraine without aura and 4-fold for migraine with aura, indicating that both genetic and environmental factors are probably involved.<sup>272</sup> The concordance rate for migraine without aura is higher in monozygotic (MZ) at 28% than in dizygotic (DZ) twins at 18%.<sup>273</sup> The concordance rates of migraine with aura are also higher in MZ (34%) than in DZ twin (12%).<sup>274</sup> Molecular genetic studies have, to date, identified at least one candidate region (19p13) and in patients with familial hemiplegic migraine the calcium channel gene CACNL4 has been implicated.<sup>275</sup> Mutations in this same gene have also been associated with familial episodic ataxia.

### Pathophysiology of migraine

Migraine attacks are triggered by specific physical or environmental factors in genetically predisposed individuals. The initiating steps may have neural, vascular, autonomic or biochemical origin. Regardless of the exact initiating factors, it seems that the principal pathway in migraine attacks involves the activation of the trigeminovascular system. The interactions between the cranial vascular system and the trigeminal nucleus are complex and interrelated. Stimulation of the trigeminal sensory nerves either naturally by specific trigger factors or experimentally by electrical impulses in laboratory animals may induce the release of vasoactive neuropeptides. The release of vasoactive neuropeptides (substance P, neurokinin A and calcitonin gene-related peptide) initiates a process of microvascular inflammation followed by vasodilation, mast cell degradation and plasma extravasation. Dihydroergotamine and sumatriptan as 5HT<sub>1B/D</sub> receptor agonists inhibit this process. As a result of the neurogenic inflammation, nociceptive impulses travel inferiorly to the trigeminal nucleus caudalis and superiorly to the thalamus and the cerebral cortex.<sup>276</sup> Diffuse projections from the locus ceruleus to the cerebral cortex may initiate a process of cortical oligemia that is better known as 'spreading depression of Leao' and may account for the aura symptoms that can occur independently of headache. Interaction of brainstem and afferent impulses from cranial blood vessels may lead to vasomotor changes and the characteristic throbbing headache.

### Clinical features and diagnostic criteria

The International Headache Society classifies migraine into two major forms; migraine without aura and migraine with aura. Other less common forms are also recognized. The majority of affected children (75–85%) suffer from migraine without aura although both major forms coexist.

Diagnostic criteria for childhood migraine and related disorders are given in Table 22.14.<sup>268</sup> Migraine headache is typically recurrent in nature with complete recovery between attacks. Stress and anxiety are the most commonly identified trigger factors. Only 10–15% of patients identify a food type (such as cheese, chocolates and caffeine-containing soft drinks) as a trigger factor. Aura symptoms, if present, precede the onset of headache and are commonly visual in nature (blurred vision, tunnel vision, blind spots (scotomata) or zigzag black and white lines in front of the eyes). Rarely the aura symptoms are sensory (tingling or numbness), motor (hemiplegia or speech disturbances), autonomic or nonspecific.

The headache starts as a mild pain that does not interfere with normal activities. It increases in intensity over 30–60 minutes to a moderate intensity that may stop some activities or proceed to a severe intensity that stops all activities. The pain is commonly described as throbbing, but some children may not be able to describe the type of pain, referring to it as 'just sore'. In the majority the site of maximal intensity is more likely to be frontal than unilateral.

During an attack the child is described by parents as pale, quiet and wanting to be left alone. Refusal of food and drink with nausea is common and vomiting may occur. Light, noise, strong smells and physical exercise may aggravate pain. Dizziness (unreal sensation of movement), abdominal pain, visual disturbances and sensory or motor deficits may also be associated, but to a lesser degree. Some patients describe unusual visual hallucination or distortion of images including micropsia (objects appearing small), macropsia (objects appearing very large)

Table 22.14 Diagnostic criteria

<b>IHS criteria for the diagnosis of migraine without aura</b>	
A.	At least five attacks fulfilling B–D
B.	Headache lasting 1–72 hours (untreated or unsuccessfully treated)
C.	Headache has at least two of the following characteristics: <ol style="list-style-type: none"> <li>1. Unilateral location (frontal and bitemporal locations are common in children)</li> <li>2. Pulsating quality</li> <li>3. Moderate or severe intensity (inhibits or prohibits daily activities)</li> <li>4. Aggravation by walking stairs or similar routine physical activity</li> </ol>
D.	During headache, at least one of the following: <ol style="list-style-type: none"> <li>1. Nausea and/or vomiting</li> <li>2. Photophobia or phonophobia (symptoms can be inferred from behavior)</li> </ol>
E.	No evidence of organic disease
<b>IHS criteria for the diagnosis of migraine with aura</b>	
A.	At least two attacks fulfilling B
B.	At least three of the following four characteristics: <ol style="list-style-type: none"> <li>1. One or more fully reversible aura symptoms indicating focal cerebral cortical and/or brain stem dysfunction</li> <li>2. At least one aura symptom develops gradually over more than 4 minutes, or two or more symptoms occur in succession</li> <li>3. No aura symptom lasts more than 60 minutes. If more than one aura is present, accepted duration is proportionally increased</li> <li>4. Headache follows aura with a free interval of less than 60 minutes (it may also begin before or simultaneously with the aura)</li> </ol>
C.	No evidence of organic disease
<b>Criteria for the diagnosis of abdominal migraine</b>	
A.	At least five attacks fulfilling criteria B–D
B.	Attacks of abdominal pain lasting 1–72 hours (untreated or unsuccessfully treated)
C.	Abdominal pain has all of the following characteristics: <ol style="list-style-type: none"> <li>1. Midline location, periumbilical or poorly localized</li> <li>2. Dull or 'just sore' quality</li> <li>3. Moderate or severe intensity</li> </ol>
D.	During abdominal pain at least two of the following <ol style="list-style-type: none"> <li>1. Anorexia</li> <li>2. Nausea</li> <li>3. Vomiting</li> <li>4. Pallor</li> </ol>
E.	Not attributed to another disorder
<b>Criteria for the diagnosis of cyclical vomiting syndrome</b>	
A.	At least five attacks fulfilling criteria B and C
B.	Episodic attacks stereotyped in the individual patient of intense nausea and vomiting lasting from 1 hour to 5 days
C.	Vomiting during attacks occurs at least 4 times/hour for at least 1 hour
D.	Symptom-free between attacks
<b>Not attributed to another disorder</b>	

or a combination of both: 'The Alice in Wonderland Syndrome'.<sup>277</sup> Sleep, rest and simple analgesics may relieve symptoms. Typical attacks lasts for at least 1 hour followed by gradual resolution.

The clinical features can be dominated by transient symptoms of cerebellar and brainstem dysfunction such as vertigo, ataxia, blurred vision, visual field defects, motor deficits, dysphasia and confusion. These features were attributed to vascular constriction in the territory of the basilar artery and hence described as *basilar migraine*.<sup>278</sup>

Some attacks of migraine are triggered by minor head injury and can be complicated by a disturbed level of consciousness commonly called

*confusional migraine*. They occur mainly in children and are commoner in boys than in girls. Features include an aura, followed by headache of variable severity and duration with drowsiness, irritability, agitation, disturbed speech, aggressive behavior and amnesia. Blurred vision, nausea and vomiting are common features and duration can vary from a few hours to several days.

Migraine attacks can be complicated by paralysis or paresis of the extraocular muscles, ptosis and pupillary dilation, but with no associated confusion or loss of consciousness. Such attacks are called *ophthalmoplegic migraine* and the eye features may not resolve for days or occasionally weeks after the resolution of headache. Some cases are indistinguishable from Tolosa–Hunt syndrome with MRI evidence of cavernous sinus dilation and changes consistent with local inflammation.

Attacks of migraine can be complicated by unilateral weakness, impaired speech or sensory loss. The neurological deficits are transient, fully reversible and may start before, with or after the onset of the headache. The neurological deficit may persist after cessation of headache. The disease can be sporadic or familial. In the latter case and when associated with episodic hemiplegia it is called *familial hemiplegic migraine* which has an autosomal dominant inheritance and may be associated with a deletion of the calcium channel gene CACNA 1A on 19p13.

## Treatment

The treatment of migraine includes reassurances to the child and the parents about the benign nature of the disorder and education on its natural course of remission and relapse. Satisfactory management may require more than one consultation in order to establish a good understanding of the condition and to address individual concerns. Children should be encouraged to identify their own trigger and relieving factors and explore their own treatment strategies. The judicious use of analgesics and other medications should be discussed early as many children and their parents use over-the-counter medications or have already received advice from their primary care physician.

## Management of acute attacks of migraine

In the majority an effective treatment of the acute attacks is the cornerstone of management and prophylaxis is not necessary. The treatment of acute attacks should start as early as possible after the onset of headache. Children should be allowed to rest and lie down in a quiet environment. Early administration of analgesics is commonly associated with good results.

Reviews of evidence-based treatment of migraine in children emphasize that only a few randomized trials are available. Paracetamol and ibuprofen continue to be the first line treatments.<sup>279,280</sup> The analgesic effects of paracetamol are probably mediated centrally with possible indirect action on spinal serotonin receptors. Ibuprofen is a nonsteroidal anti-inflammatory drug (NSAID) that inhibits the cyclo-oxygenase enzyme and hence prostaglandin synthesis. The analgesic effects of ibuprofen may also be mediated through independent spinal mechanisms (see Ch. 38, see p. 1632).

In children under 15 years of age, paracetamol in single doses of 15 mg/kg body weight and ibuprofen (10 mg/kg) were effective and well-tolerated in the treatment of migraine in a double-blind placebo-controlled trial.<sup>281</sup> Paracetamol had a more rapid onset than ibuprofen, but ibuprofen was twice as effective in aborting migraine within 2 hours. Aspirin is an effective analgesic, but its association with Reye syndrome has limited its use in children under the age of 15 years, especially in the presence of symptoms or signs of viral infection. Over-the-counter analgesics may contain combinations of drugs that have not been investigated in children. Occasionally a stronger analgesic such as codeine sulfate may be necessary.

Sumatriptan is a specific antimigraine medication with a good efficacy and safety record in adult patients. It is a selective agonist of 5 hydroxy-tryptamine (5-HT)<sub>1B/D</sub> receptors. It causes constriction of cerebral blood vessels and blocks nociceptive impulses. Sumatriptan is available by subcutaneous auto injection, oral tablets and as a nasal spray.

Nasal sumatriptan is shown to be effective in the treatment of acute migraine attacks. A large multicenter double-blind placebo-controlled

trial of 663 adolescents aged 12–17 years, using 5-, 10- and 20-mg doses, demonstrated that 10- and 20-mg doses were significantly better than placebo in alleviating symptoms after 1 hour and in complete resolution of symptoms after 2 hours.<sup>282</sup> A recent randomized trial of 83 children using nasal sumatriptan 10 mg for children under 40 kg of weight and 20 mg for those above 40 kg, showed similar results.<sup>283</sup> Bad taste was the most commonly reported side-effect.

Oral sumatriptan (doses between 50 and 100 mg) were not effective in children in a placebo-controlled crossover study of 23 children, aged 8–16 years.<sup>284</sup> An open study of subcutaneous injections of sumatriptan (0.06 mg/kg) in 50 children between 6 and 18 years of age showed only limited benefit.<sup>285</sup> Other triptans are available, but their efficacy in childhood is not known.

Metoclopramide or prochlorperazine may alleviate nausea and vomiting during migraine attacks, but there are no controlled trials of their use in children and concerns about extrapyramidal symptoms and dystonic reactions limit their use.

## Prevention of migraine

Nonpharmacological strategies for the prevention of migraine attacks should include avoidance of identified specific triggers. Dietary exclusion is only recommended in children with confirmed food triggers. Affected children should be encouraged to assume a healthy lifestyle with a regular pattern of sleep and meals and appropriate balance between rest and exercise. They should avoid spending excessive amounts of time on computer and video-games and be discouraged from smoking.

Pharmacological prophylactic treatment is not reliable and success is not always predictable. There is no consistent evidence for the efficacy and tolerability of any prophylactic agent. Therefore, treatment is only indicated if acute treatment is unsuccessful and migraine attacks are frequent (more than two attacks per month), prolonged and severe enough to interfere with school attendance and education. Prophylactic treatment should be continued for at least 6 weeks before considered ineffective and polytherapy should be avoided. Prophylactic treatment may be discontinued after 6 months, but can be restarted if necessary. Propranolol has been shown to reduce the frequency of migraine attacks in a double-blind placebo-controlled trial,<sup>286</sup> but the results were not confirmed in a similar trial.<sup>287</sup> In children over 7 years of age, propranolol may be given in a dose of 1–2 mg/kg/day in two divided doses. The mechanism of action is not clear, but may involve inhibition of the catecholamine-induced platelet aggregation and release of platelet serotonin. Side-effects may include hypoglycemia, hypotension, tiredness and mood changes.

Topiramate was shown in a large randomized, double-blind and placebo-controlled multicenter trial to provide significant reduction in the number of migraine days per month in children.<sup>288</sup> Doses between 2 and 3 mg/kg/day were reached after a period of 8 weeks' titration.

The evidence for efficacy of other medications (pizotifen, clonidine and valproate) is either inconsistent or based on studies in adults. Pizotifen was found to be effective in the treatment of abdominal migraine only,<sup>289</sup> but not in headache migraine.<sup>290</sup> Flunarizine, a cerebral calcium channel antagonist, may be effective at a dose of 5–10 mg per day,<sup>291</sup> but its use is associated with excessive side-effects such as drowsiness, depression and weight gain. Valproic acid is effective in adults, but has not been studied in children.<sup>292</sup> Amitriptyline was shown to be very effective in prevention of chronic headache, including migraine, in a large open observational study.<sup>293</sup> It may block the re-uptake of both serotonin and norepinephrine (noradrenaline) and its effect in migraine is independent of its antidepressant actions. A study of the efficacy of amitriptyline, (1.5 mg/kg/day) in the prevention of migraine in 19 children (6–12 years of age) has shown only a modest benefit.<sup>294</sup> Unlike in adults, it did not influence the duration of migraine attacks and drowsiness was the most common adverse effect.

## Prognosis

The natural course of migraine is that of remission and relapse, but with a tendency for permanent remission with increasing age. Remissions

of at least 1 year have been recorded in up to 58% of patients during periods of follow-up of at least 5 years.<sup>295</sup> Long term follow-up studies of 73 children with migraine showed that 34% became headache free after 6 years, 62% after 16 years and 40–47% after 22–40 years.<sup>256,296,297</sup>

### Alternating hemiplegia of childhood

Alternating hemiplegia of childhood (AHC) is a progressive disabling disorder of unknown etiology, but has long been considered as a form of 'complicated migraine'.<sup>298</sup> It presents in early infancy and has three distinct clinical phases.<sup>299</sup> During the first year of life (phase I) children show signs of delayed development, abnormal eye movement and episodes of dystonia. During the second year of life (phase II) alternate hemiplegic spells last between a few days to a few weeks. By the age of 5 years (phase III) fixed neurological deficits and variable degrees of disability, with developmental delay, spasticity and epilepsy are evident.

The diagnosis is usually based on the typical clinical course. CT and MRI are usually normal. Long term treatment with flunarizine results in reduced number and severity of hemiplegic spells, but it is unlikely to change the natural course of the disease. The relationship of AHC to migraine is based on its paroxysmal nature, the occurrence of headache during some attacks and the apparent high prevalence of migraine with aura among the relatives. However, the progressive nature of the disease and the permanent neurological and learning disabilities suggest that it is unrelated to migraine.

### Benign paroxysmal torticollis of infancy (BPTI)

BPTI is a benign disorder of early childhood characterized by self-limiting episodes of head tilt lasting a few hours to a few days. Attacks start during the first year of life, are sudden in onset and resolution and may alternate between sides.<sup>300</sup> BPTI has been linked to migraine and benign paroxysmal vertigo on clinical and epidemiological basis. The pathophysiology is unclear, but surface electromyography (sEMG) of the sternomastoid muscle during attacks shows dystonic changes.<sup>301</sup> The attacks start suddenly with the head held to one side and neck muscles on the side of the tilt, particularly the sternomastoid, are stiff and tense. During attacks the child may also have pallor, nausea, vomiting, ataxia and irritability. The diagnosis is based on the typical episodic clinical features.

Neuroimaging is indicated in order to exclude intracranial pathology. EEG may be indicated if epilepsy is suspected. A definite diagnosis should be followed by reassurance to parents about the benign nature of the condition. The majority of cases resolve by the age of 3 and almost all by the age of 5 years. No treatment is necessary.

### Benign paroxysmal vertigo

Benign paroxysmal vertigo (BPV) is characterized by recurrent episodes of an unreal sensation of movement of the child or his/her surrounding environment (vertigo). Each episode lasts for a few minutes, but occasionally may continue for hours or up to 2 days.

*Early onset BPV* is uncommon, but affects children between the age of 2 and 4 years. It is characterized by sudden episodes of pallor, screaming, unsteadiness, nystagmus, nausea and occasionally vomiting.<sup>302</sup> The child either sits or clings to his or her parent in fear. The attacks terminate spontaneously and the child returns to normal. There is no loss of consciousness and the child is aware and responsive during the event. Episodes of BPV decrease in frequency by age 5 years and may be replaced by episodes of headache typical of migraine.

*Late onset BPV* is common among schoolchildren<sup>303</sup> with a prevalence rate of 2.6%. Older children are able to describe the unreal sensation of movement. The attacks last for seconds to minutes with an average frequency of one attack per month and the only abnormal finding during attacks is horizontal nystagmus. Migraine is more common among children with BPV and among their first-degree relatives than in controls.<sup>303</sup>

The diagnosis is based on excluding underlying neurological causes, vestibular disorders, epilepsy, and the effects of medications and toxins by appropriate investigations. Treatment is often not needed, apart from

reassurance about the benign nature of the condition. Some children benefit from the antihistamine betahistine.<sup>304</sup>

### Abdominal migraine

Recurrent abdominal pain (RAP) is a common problem affecting around 8% of schoolchildren. Half the children with RAP (4%) have abdominal migraine<sup>305</sup> as defined by the clinical criteria in [Table 22.14](#). Abdominal migraine is characterized by recurrent episodes of a dull abdominal pain lasting between 1 and 72 hours. Between attacks the child is completely well. The clinical pattern of trigger factors, associated symptoms and relieving factors is similar to that of migraine headache in children. Attacks have been reported to start at any age from early infancy although the mean age of onset is around 7 years. At least one third of children continue to suffer attacks late into their teenage years and 70% have a current (52%) or past (18%) history of migraine.<sup>306</sup>

Management starts with confirmation of the diagnosis, reassurance to parents and identification and avoidance of trigger factors. Acute attacks should be treated with simple analgesics, rest, and fluid replacement and occasionally with anti-emetics. There is no published data on the use of specific anti-migraine agents such as sumatriptan. Drug prophylaxis has been evaluated in a randomized double-blind placebo-controlled trial of pizotifen and which has been shown to be effective.<sup>289</sup> Evidence for the value of other drugs such as propranolol and cyproheptadine is based on open trials.<sup>307</sup>

### Cyclical vomiting syndrome (CVS)

CVS is a disease mainly of early childhood and closely related to migraine. It presents with sudden episodes of anorexia, nausea, vomiting, lethargy and intolerance to light, noise and exercise. During attacks the child looks unwell, pale and miserable which can be severe enough to stop activities and may lead to dehydration if prolonged. The attacks last from a few hours to a few days and the child is completely well between attacks. It is estimated that around 2% of schoolchildren may have unexplained attacks of vomiting that fulfil the criteria for the diagnosis of CVS ([Table 22.14](#)).<sup>308</sup> The disease may begin during very early childhood and occasionally during the first year of life. With increasing age typical episodes are associated with headache that fulfils the criteria for the diagnosis of migraine. A follow-up study found a later diagnosis of migraine in 46% of cases compared to 12% in controls and 50% of children continued to suffer from attacks in adolescence and early adult life.<sup>309</sup> The treatment of acute attacks aims to stop vomiting and prevent dehydration. Early administration of oral or intravenous anti-emetic drugs such as ondansetron may abort attacks. Prophylactic treatment with erythromycin as a prokinetic agent may reduce the number and severity of attacks.

### TENSION-TYPE HEADACHE

Tension type headache (TTH) is common among children and adolescents who seek medical advice for headache. TTH is also known as psychogenic headache, muscle contraction headache or nonvascular headache. It can be classified as frequent, infrequent or chronic. The prevalence in the general childhood population is not known but in children with headache may be 1%.<sup>257</sup> However, it is common in children and adolescents attending accident and emergency departments, general practice and hospital clinics for headache as their chief complaint. Both male and females are equally affected and it is commoner in older children and adolescents. TTH is rare in children under the age of 6 years.

### Etiology and pathogenesis

The etiology is unknown, but there is evidence of a familial tendency, especially in chronic tension type headache (CTTH), and significant environmental influences. CTTH may evolve from episodic tension type headache (ETTH) or may start as chronic from the onset. It may be induced by chronic use of analgesics or high daily caffeine intake. Children with

CTTH have a higher than expected incidence of major life events such as chronic disease, family illnesses and bereavements.<sup>310</sup> Several initiating mechanisms have been suggested including muscle contraction, physical strain, anxiety and stress. No consistent biochemical or EMG changes have been found.

### Clinical features of TTH

The attack's duration is usually short, but is continuous in CTTH. The headache is typically described as pressure or tightening and mild to moderate in severity. It is bilateral in location and does not worsen with routine activities. It may be associated with photophobia or phonophobia, but not nausea or vomiting (Table 22.15).<sup>268</sup> The diagnosis is made on the basis of the typical clinical history and normal neurological examination and investigations are not needed in the majority of patients. The clinical features of ETTH can sometimes be indistinguishable from those of migraine without aura. In some patients both migraine without aura and ETTH coexist. The distinction between the two conditions is important in order to plan treatment and predict outcome.

### Management of TTH

Management of the child can be complex and multidisciplinary. The child and parents should be reassured of the absence of any sinister cause and offered general advice on healthy lifestyle. Children should be encouraged to adopt predictable patterns of sleep, regular meals, balanced diets, adequate exercise and rest. Successful management will require the co-operation of the children and their parents often with involvement, of schoolteachers, school nurses, and occasionally clinical psychologists. Attention should be paid to possible underlying chronic physical, psychological or emotional problems. The expertise of a clinical psychologist may also help in the management of acute headache attacks and in helping the child and the family to develop their own strategies in dealing with pain in general.

Simple analgesics are often effective and sufficient in ETTH, but are largely unsuccessful and should be discouraged in children with CTTH, as some may develop analgesia-induced headache.

Prophylactic therapy is occasionally needed to reduce distress caused by daily or almost daily attacks. Pain modulating agents such as amitriptyline in dosages between 10 and 50 mg per day (up to 1 mg/kg/day) was shown to be of value in an open trial.<sup>293</sup> The prognosis is variable and patients may run a course of remission and relapse.

## CLUSTER HEADACHE

Cluster headache is uncommon in children, but cases have been reported in children as young as 1 year of age.<sup>311</sup> In many adult patients the onset

of headache is before the age of 18 years and in some before the age of 10 years.<sup>312</sup> Episodic cluster headache is more common (affecting around 80% of patients) than the chronic form and more males are affected than females.

The cause of cluster headache is not known, but there is a strong familial tendency. The changes during attacks are consistent with neuronal, endocrine and vascular mechanisms involving trigeminovascular activation.<sup>313</sup>

The clinical features of cluster headaches during childhood are similar to those in adults with a tendency for the frequency and duration of cluster periods and the frequency of the individual headache episodes to increase with age. Headache attacks are short (up to 90 minutes) and have a well-defined periodicity. The pain is severe, sharp and reaches its peak intensity within 5–15 minutes and may provoke intense emotions and violent behavior. The pain is almost always unilateral with maximal intensity around the eye and can be associated with nausea and vomiting. Autonomic symptoms (nasal congestion, forehead sweating, conjunctival injection, meiosis, lacrimation and ptosis) are common and are almost always on the same side of the pain and resolve with the resolution of pain.

Atypical attacks (cluster headache-like disorders) have been reported in a small number of children. The headache is bilateral, the pain is not peri-orbital and children exhibit unusual motor behavior consisting of thrashing of limbs and irritability.<sup>314</sup> Early administration of high flow oxygen and subcutaneous injection or nasal administration of sumatriptan may relieve acute attacks. Short course of steroids (prednisolone or dexamethasone) can induce remission and verapamil, valproate, melatonin or topiramate may be given as prophylactic maintenance therapy.

## CHRONIC POST-TRAUMATIC HEADACHE (CPTH)

Episodes typically start within 2 weeks after head injury including minor trauma and continue for at least 8 weeks. The prevalence rate of CPTH in children is not known, but a follow-up study, 12–18 months after head injury, has shown that 29% of 138 children (mean age 9.2 years) suffered from recurrent headaches.<sup>315</sup>

The causes of CPTH are not fully understood, but the pathogenesis is likely to be complex and premorbid predisposition to headache and psychosocial factors may contribute.

The clinical features are those of idiopathic recurrent headaches (migraine and tension headache of childhood). Other symptoms of postconcussion syndrome may be present, but physical and neurological examinations are normal.<sup>316</sup> In children with typical presentation neuroimaging is not indicated.

Treatment includes reassurance and appropriate use of simple analgesics as required.

## HEADACHE DUE TO INTRACRANIAL DISORDERS

### Brain tumors

Headache is a common symptom of brain tumors and hence a common reason for referral to secondary care and neuroimaging. It has been reported in 62% of 3291 children with brain tumors,<sup>317</sup> and almost always associated with at least one other clinical feature such as ataxia, nystagmus, intention tremor, effortless vomiting, headache during sleep, focal neurological deficits, acquired squint, papilloedema, personality change or deteriorating schoolwork. However, headache may be the only initial presenting symptom in a minority (8–10%).<sup>318</sup> In a study of 600 children with migraine and 67 children with brain tumor, the most helpful distinguishing features in children with brain tumors were nocturnal headache and headache present on waking.<sup>319</sup> In a retrospective study of 74 children with brain tumors,<sup>320</sup> the mean duration of symptoms before diagnosis was 20 weeks. When headache is the only presenting symptom of brain tumor or raised intracranial pressure, it may have no specific features or may have features similar to those of migraine or tension-type headache leading to a delay in the diagnosis of

Table 22.15 Diagnostic criteria and clinical spectrum of tension type headache

	Infrequent ETTH	Frequent ETTH	CTTH
A: Frequency	< 12 days/year	12–180 days/year	> 180 days/year
B: Duration	30 minutes	7 days	Hours to continuous
C	At least three of the following:		
	1. Pressing/tightening quality		
	2. Mild to moderate severity		
	3. Bilateral location		
	4. Not aggravated by walking		
D	All of the following:		
	1. No nausea (anorexia may occur)		
	2. No photophobia or phonophobia		
E	Not attributed to any other disorder		

ETTH, episodic tension type headache; CTTH, chronic tension type headache.

**Table 22.16** Frequency of associated symptoms in children with brain tumors

Symptom	Headache < 4 months	Headache ≥ 4 months
Vomiting	87%	76%
Visual disturbances	53%	63%
Unsteadiness	49%	45%
Educational or behavioral problems	37%	45%
Disturbed sleep	26%	31%
Growth or endocrine problems	7%	21%
Seizures	7%	8%
None	0	0

the underlying cause. The frequency of associated symptom in 200 children with brain tumors were similar in children with short (<4 months) or long (at least 4 months) history of headache and in no child was the headache the only feature (Table 22.16).<sup>321</sup>

Brain tumors are rare in children with chronic headache and with normal physical and neurological examination. In a large study of 815 children with chronic headache (lasting over 3 months) the prevalence rate of brain tumor was 0.1% suggesting routine neuroimaging in this group of children is not needed.<sup>266</sup> However, neuroimaging is indicated in some children with significant signs and symptoms as shown in Table 22.13.

### Idiopathic intracranial hypertension (IIH)

IIH is a rare clinical syndrome of raised intracranial pressure and headache. It occurs in all ages, including infancy. No specific causes have been identified and the pathogenesis is unclear. Clinical features are those of raised intracranial pressure and headache is the most common symptom which is often located at the forehead and is worse on lying down or on awakening in the morning.<sup>322</sup> Other symptoms may include nausea, vomiting, visual disturbances (diplopia, visual loss, blurred vision and visual field defects), lethargy, dizziness and behavioral problems. There is no deterioration in the level of consciousness. On examination, papilledema is the most common sign occurring in the majority of patients followed by VIth cranial nerve palsy and defects of visual acuity.<sup>323</sup>

Ophthalmological examination is an essential part in the assessment and children often present during assessment of visual disturbance by opticians or ophthalmologists.

Neuroimaging with CT or MRI to exclude other causes of increased intracranial pressure is indicated and lumbar puncture shows CSF pressure above 200 mmH<sub>2</sub>O and a normal CSF analysis.

The criteria of the International Headache Society for the diagnosis of IIH are:<sup>268</sup>

1. cerebrospinal fluid (CSF) pressure above 200 mmH<sub>2</sub>O water in the recumbent position;
2. normal neurological examination except for papilledema, visual field defect, enlarging blind spot or VIth cranial nerve palsy;
3. normal CSF chemistry and white cell count;
4. no clinical or neuroimaging evidence of venous sinus thrombosis or mass lesion;
5. no metabolic, hormonal or toxic cause for the intracranial hypertension.

IIH is largely self-limiting, although permanent visual field loss and reduced visual acuity occurs in 13–27% of children,<sup>322</sup> hence the need for and early recognition and treatment followed by regular ophthalmological review. A number of treatment measures have been shown to be effective in reducing the intracranial pressure. Single or repeated lumbar puncture with CSF removal may be all that is required. Acetazolamide is useful but large doses may be required in combination with a loop diuretic. Steroids have not been properly evaluated but case reports suggest that the pressure drops within 24 hours. Surgical

options include lumboperitoneal or ventricular peritoneal shunt and optic nerve decompression.

### HEADACHE DUE TO SINUSITIS

Sinus diseases are unusual during early childhood, as paranasal sinuses are not fully developed before the age of 8 years. In affected children the headache is usually mild and its site of maximal intensity is related to the affected sinuses. The International Headache Society describes the headache of acute frontal sinusitis as 'located directly over the sinus and may radiate to the vertex or behind the eyes'. In maxillary sinusitis 'the headache is located over the antral area and may radiate to upper teeth or to the forehead'. In acute ethmoiditis 'the headache is located between and behind the eyes and may radiate to the temporal area'.<sup>268</sup> The headache of acute sinusitis is almost always associated with other features of upper airway disease: nasal congestion, discharge, sneeze and cough, making the diagnosis of acute sinusitis relatively easy.

Headache due to chronic sinusitis may be present with or without upper respiratory tract symptoms and should therefore be suspected as the cause of chronic headache in the presence of clinical features such as sleep disturbance, nasal discharge, nasal blockage and decreased sense of smell. Headache can be the only symptom of 'silent' sinus disease.

The diagnosis of chronic sinusitis should be confirmed with appropriate imaging. Medical treatment may include antihistamine decongestants, antibiotics and simple analgesia. Surgical treatment is rarely needed except in the presence of underlying predisposing factors or nasal polyps causing obstruction (see Ch. 32, see p. 1514).

## DISORDERS OF MOVEMENT

### EXTRAPYRAMIDAL DISORDERS, BASAL GANGLIA DISORDERS

Movement disorders (involuntary movements) accompany many diseases thought to originate from the basal ganglia. Some are among the most benign of neurological disorders but others are progressive. There are no clear figures concerning the incidence and prevalence of movement disorders. However, movement disorders are not uncommon.

The underlying causes include infections, metabolic disorders and neurotransmitter imbalance. However, the cause of many is unknown. The basal ganglia are particularly susceptible to hypoxia. This is seen in carbon monoxide poisoning, neonatal asphyxia and post cardiopulmonary bypass. Heavy metals also appear to have a special affinity for this part of the brain (e.g. copper deposition with Wilson disease, iron deposition in Hallervorden–Spatz disease and the dyskinesias of manganese, molybdenum and thallium poisoning). Metabolic diseases such as phenylketonuria, Leigh encephalopathy and glutaric aciduria may present with a predominant dyskinetic clinical picture.

### Anatomy of the basal ganglia

The extrapyramidal system in classic neurology consists of part of the cerebral cortex anterior to the motor strip and several masses of gray matter deep in the hemisphere white matter and the upper brainstem. The nomenclature has been rather confusing as words such as basal ganglia, striatum, corpus striatum, and lenticular nucleus are either synonyms or groupings of nuclei. The corpus striatum is the name given to the lentiform nucleus (i.e. the combined putamen and globus pallidus) and the caudate nucleus. It is more appropriate to think in terms of the caudate, putamen and globus pallidus in the cerebral hemisphere together with the substantia nigra in the upper brainstem and the subthalamic nucleus of Luys as constituting together the basal ganglia.

The basal ganglia can be regarded as a major motor computation center receiving information from the cortex about movements being planned together with information from the parietal cortex about body image and from vision. They receive input regarding the force, speed and direction of movement planned by the cerebellum together

with information on the position of the head and eyes from the labyrinth and information about body contact and visual information on the position of the body in space. The basal ganglia and extrapyramidal motor cortex inhibit certain primitive brainstem reflexes such as the asymmetrical tonic neck reflex, primitive walking and swimming reflexes and probably store more sophisticated patterns of movement.

### Biochemistry of the basal ganglia

The main interest in biochemistry of the basal ganglia stems from the discovery of the dopaminergic pathways from the substantia nigra, the effects of L-DOPA in parkinsonism and the study of the extrapyramidal side-effects of drugs like the phenothiazines.

Classic parkinsonism has three components – tremor, bradykinesia and rigidity – and although the symptoms and signs of basal ganglia disease will be discussed in more detail later (see below), it is necessary to consider some aspects to understand the role of dopamine and L-DOPA in normal basal ganglia function and in disease. The three components appear independently determined because the tremor may be made worse by L-DOPA but helped by surgery; the bradykinesia is helped by L-DOPA but surgery has no effect; the rigidity is helped by L-DOPA and surgery and is especially helped by anticholinergics. Current evidence suggests that cholinergic, serotonergic and gabanergic pathways are normally balanced (inhibited) by dopamine and that while dopamine is important in inhibiting rigidity, it is involved in the causation of the hyperkinetic dyskinesias. Rather confusingly, however, there are some children with dyskinesias involving too much movement who are helped by L-DOPA. In tardive dyskinesia and chorea there should be inherent dopamine excess or drugs that directly stimulate dopamine receptors could be responsible. Drugs which cause tardive dyskinesias, such as the phenothiazines, are known to have anticholinergic, anti-serotonergic and antihistaminergic effects and to leave dopamine unopposed. Drugs which reduce dopamine action, such as tetrabenazine, haloperidol and reserpine, will reduce the involuntary movements in chorea, but are more likely to induce a parkinsonian picture as a side-effect. Parkinsonism can be induced either by depleting the brain's production of dopamine, as occurs with reserpine and tetrabenazine when the dopamine receptors remain free, or alternatively it can be caused by blocking the dopamine receptors by such drugs as haloperidol when L-DOPA cannot reverse the parkinsonism so produced.

Some other drug effects are also important. Thus multiple tics may appear as a complication of chronic amphetamine use or chronic overdose by methylphenidate (Ritalin). Both of these drugs increase brain dopamine as well as having a noradrenergic effect. 5-Hydroxytryptophan has been given to patients with Lesch–Nyhan syndrome, and in this disorder, it appears to lessen self-mutilation. In the past, it has also been used in children with Down syndrome in the hope that it would improve muscle tone and motor performance, but it was found to produce marked rigidity and myoclonic jerks. Cholinergic drugs such as physostigmine will make parkinsonism worse, but will lessen choreiform movements. Together clinical anatomy, physiology, biochemistry and pharmacology help to explain the diverse clinical signs and symptoms which occur in disorders of the basal ganglia.

### Movement disorders: general considerations

Many neurological diseases have movement disorders as the main presentation or part of it. These movements are often misdiagnosed as epilepsy, behavioral disorder or tics.

A good eyewitness description is important. However, where possible, it is essential to observe the movements. Videotapes are an excellent way of achieving this especially when they are infrequent or episodic.

Movement disorders may present as more or less continuous abnormal movements or posture or these may fluctuate with time and in relation to emotional state and anxiety. In addition, they may present as paroxysmal episodes mimicking epileptic attacks. Movement disorders may be benign and transient such as benign myoclonus of infancy and dyskinesia after the withdrawal of benzodiazepines (especially intravenous midazolam), or phenytoin in the pediatric intensive care unit (Table 22.17).

Table 22.17 Transient movement disorders in childhood

Benign paroxysmal torticollis of infancy
Benign myoclonus of the newborn
Benign myoclonus of infancy
Jitteriness
Transient paroxysmal dystonia of infancy
Spasmus nutans

It is necessary to observe the child at rest, while sustaining postures, such as outstretching the limbs, during active movement, such as tying shoelaces, and, if possible, under stress. Although involuntary movements often present at rest, they are usually more pronounced with volitional execution of a motor task and may significantly disrupt the motor activities. Children often try to mask abnormal movements by combining them with a normal movement pattern. For example, children with chorea usually mask their abnormal movements by scratching the nose or forehead or by clenching the fingers together. The clinician should not be misled and should notice that these normal movements are not purposeful. Movement disorders are almost always absent during sleep. They are not associated with loss of consciousness and children have full recall of the episodes.

Sometimes, the involuntary movements are a mixture of several types such as choreoathetosis and myoclonic dystonia. The correct classification is often difficult and requires experience and skill. More clinical details will come later regarding specific types of movement disorder and associated conditions.

### Investigation of movement disorders

Identification of the movement disorder type should be attempted but is not always possible. Investigations are directed toward the suspected most likely diagnosis. Many diseases may cause more than one type of movement disorder. This includes tumors of the basal ganglia, which makes it reasonable to perform neuroimaging in all children with acquired movement disorder. On the other hand, a single type of movement disorder can be caused by many different diseases. Treatable conditions, such as Wilson disease, should be looked for early as more benefit is obtained with early treatment. Specific investigations for each movement disorder and related conditions will be dealt with in the relevant sections.

### Classification of movement disorders

Movement disorders (dyskinesias) can be classified in many ways (Table 22.18). An anatomical classification may conclude that lesions of the globus pallidus cause parkinsonism or a lack of movement,

Table 22.18 Classification of movement disorders

<b>Dyskinesias</b>
Hyperkinetic
Hypokinetic
Akinetic
<b>Anatomical</b>
Lesion of the putamen
Lesion of the caudate
Lesion of the globus pallidus
<b>Clinical presentation</b>
Acute
Progressive
Chronic
<b>Type of predominant movement</b>
Chorea/athetosis
Dystonia
Tremor
Tics

lesions of the putamen cause athetosis and lesions of the caudate cause chorea. However this is a gross oversimplification. Alternatively, they can be classified on the basis of clinical presentation, i.e. whether there is an acute dyskinesia, progressive dyskinesia or chronic nonprogressive dyskinesia. A third method is according to the predominant type of movement, i.e. chorea and choreoathetosis, dystonia and tremor. Also, movement disorders can be classified as hyperkinetic or hypokinetic.

### Hyperkinetic dyskinesias

These are typified by the choreas, hemiballismus, tics and orofacial dyskinesias. This group is most often associated with a reduction in muscle tone and the movements disappear in sleep, or if the child is totally relaxed and lying down. Symptomatically there is a close link between this group of disorders and cerebellar dysfunction, e.g. myoclonus can occur in both. In the hyperkinetic dyskinesias the child is restless, fidgety, cannot sit still, stamps his feet, grimaces, shakes his head, may get a constant urge to run, may grunt, make clucking noises and show respiratory irregularity. Difficulty keeping still is referred to as akathisia. The hyperkinetic dyskinesias tend to be associated with high levels of dopamine or noradrenergic substances.

### Hypokinetic dyskinesia

In the most severe cases there is akinesia and the child cannot initiate any movement even though not paralyzed. Less severe cases with bradykinesia are associated with difficulty in initiating movements, e.g. difficulty in running is characteristic. The most characteristic hypokinetic state is parkinsonism, which is classically associated with dopamine depletion.

## CHOREA AND ATHETOSIS

### Definition and general considerations

Chorea is rapid, repetitive, jerky movements affecting any part of the body. It may be unilateral or bilateral and affect the face and trunk as well as the limbs. The movements are neither rhythmic nor stereotyped and they migrate from side to side and limb to limb. True choreiform movements tend to be jerky, unpredictable and random and differ from tics in that they have no pattern of repetition, but the so-called convulsive tic with repeated wild flinging movements of the arms and lateral jerking of the head may resemble hemiballismus. Chorea may be incorporated into a voluntary movement. The sudden wild flinging of the arm or the head in chorea is made semipurposive by pretending to scratch the head or straighten the hair. The child may sit on the affected hand, or the tongue is held between the teeth to try to lessen the movements. Walking and feeding may become impossible due to the repeated jerks of the head and limbs together with involvement of the lips, tongue and palate.

True choreiform movements can be appreciated most easily by getting the child to stand still, arms outstretched when the jerks appear as a gross caricature of the milder constant readjusting movements seen in pure cerebellar disease, as if there was a total absence of damping, with wild overswings of correction. The head and upper limbs are affected more than the trunk and lower limbs, and total relaxation in the supine position lessens the movements as maintenance of posture and initiation of voluntary movement seems to be important in triggering them off. The face and bulbar muscles are involved when there are bilateral choreiform movements of the arms (a tic may be unilateral and have bulbar involvement). It must be remembered that low amplitude choreiform movement of the outstretched hands as a normal physiological variant is a frequent finding in boys of early primary school age.<sup>324</sup>

Athetosis literally means without posture, i.e. it is a posture that is constantly changing. It is a slow, writhing movement of the limbs that is frequently associated with chorea (choreoathetosis). Isolated athetosis is almost always due to perinatal asphyxia. Previously, kernicterus was the major cause. The movements in the athetoid child are slower than those in a child with pure chorea and they involve gradual changes in posture secondary to changes in muscle tone. The upper limbs appear to be constantly moving between the primitive extensor posture and the hemiplegic flexor posture. The fingers start in the hemiplegic position

with the hand closed across the adducted thumb and flexed at wrist and elbows. The fingers then extend and the arm extends, abducts and internally rotates into the extended (also called avoiding) position. Since the leg is extended in both postures, it remains in equinus and does not show the same movements as occur in the arms. Feeding, especially chewing, is difficult and speech is always affected. Walking may be possible, with a reeling gait and contortions of the trunk, yet surprisingly few falls result.

Athetosis of the hands, dilation of the alae nasae and fanning of the toes is often seen in normal infants at birth and may become very obvious after relatively mild asphyxia. Pathological athetosis rarely appears in the first year of life in brain damage syndromes. Dystonic extension appears at about 4 months of age and athetosis may not occur for a further 2 or 3 years. Grimacing, laughing, crying and inappropriate emotional responses can accompany the fluctuating muscle tone.

### Differential diagnosis

The conditions which present with chorea/choreoathetosis may be acute (Table 22.19), chronic and progressive (Table 22.20) or chronic and nonprogressive (Table 22.21). Some conditions are genetic (Table 22.22), systemic, metabolic, or secondary to infections and vascular diseases. Chorea might be the initial or most prominent symptom or may be present as an associated symptom.

Table 22.19 Acute-onset choreiform disease

Sydenham chorea
Toxic dystonic/chorea
Phenothiazines – chlorpromazine (Largactil), trifluoperazine (Stelazine), fluphenazine (Moditen), thioridazine (Melleril)
Phenytoin
Carbamazepine (tics and dystonia)
Maxolon
Prochlorperazine (Stemetil)
Lithium
Tricyclics – amitriptyline
Manganese poisoning
Thallium poisoning
Hydrogen sulfide
Fentanyl
Propofol
Serotonin reuptake inhibitors – paroxetine
Bethanechol
High estrogen contraceptive pill
Lamotrigine
Chorea gravidarum
Chorea and the contraceptive pill
Chorea and lupus erythematosus
Chorea and Henoch–Schönlein purpura
Hemolytic uremic syndrome
Hypoparathyroidism
Paroxysmal kinesigenic dystonia
DOPA-sensitive dystonia (Segawa)
Carbon monoxide poisoning
Following cardiac bypass surgery
Postdialysis dyskinesia
After burns – burns shakes
Metabolic diseases – Leigh disease
Familial paroxysmal choreoathetosis
Infections
Encephalitis lethargica
Toxoplasmic encephalitis
Coxsackie, echo and varicella encephalitis
<i>Haemophilus influenzae</i> B meningitis
AIDS encephalopathy
Neurosyphilis
Epidemic rubeola

Idiopathic torsion dystonia
DOPA-sensitive dystonia of Segawa
Metabolic
Wilson disease
Glutaric aciduria
Phenylketonuria
Leigh encephalopathy
Mitochondrial diseases (MELAS, MERRF)
Homocystinuria
Triosephosphate isomerase deficiency
Sulfite oxidase deficiency
Methylmalonic acidemia
Dihydropteridine reductase deficiency
Hexosaminidase A and B deficiency (onset 10 years with dystonia)
Lesch-Nyhan syndrome
Lysosomal enzyme disorders – G <sub>M1</sub> , G <sub>M2</sub> , Krabbe and metachromatic leukodystrophy
Fahr syndrome (basal ganglia calcification)
Hypoparathyroidism
Infectious origin
Subacute sclerosing panencephalitis
AIDS encephalopathy
Infantile bilateral striatal necrosis
Hallervorden-Spatz disease
Ataxia telangiectasia
Ataxia with ocular dyspraxia (Aicardi)
Pelizaeus-Merzbacher disease
Familial dystonic paraplegia
Paroxysmal dystonia with myoclonus
Paroxysmal sleep dystonia
Neuraxonal dystrophy
Parkinson disease
Hunt juvenile parkinsonism (striatonigral degeneration)
Hunt pallidocerebellar degeneration
Pilocytic astrocytomas

MELAS, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; MERRF, myoclonic epilepsy with ragged red fibers.

Table 22.21 Chronic nonprogressive disease (cerebral palsies)

Bilirubin encephalopathy
Hypoxic-ischemic encephalopathy
Autosomal recessive striatonigral dysplasia
Dystonia of prematurity

Table 22.22 Inherited choreas

Benign familial chorea	AD or AR
Dentatorubropallidoluysian atrophy (DRPL)	AD
Familial paroxysmal choreoathetosis	AD
Huntington chorea	AD
Neuroacanthocytosis	AD or AR
Pontocerebellar hypoplasia type 2	AR

AD, autosomal dominant; AR, autosomal recessive.

## Specific syndromes

### Genetic diseases

**Huntington chorea.** This dominantly inherited condition characteristically appears in adults around 30 years with dementia, rigidity and chorea as well as psychological and behavior changes. Ten percent of cases start in childhood and inheritance is usually from the father. It is therefore an imprinted disorder with spontaneous mutations being

very rare. It is a triple codon repeat disease: 35–90 repeats of trinucleotide CAG are diagnostic on chromosome 4p16.3. Diagnosis of suspected childhood cases is now possible. Presentation can be with seizures in 50% of cases, thus differing from the adult who presents with dementia or dystonia. However, up to 50% will present with dementia, manifested by a fall off in schoolwork before the rigidity, which is often asymmetrical. MRI scan shows selective atrophy of the head of the caudate nucleus.

**Benign familial (hereditary) chorea.** This is a rare dominantly inherited disorder. The onset is usually in early childhood. It starts with the child's first steps. Intelligence is usually normal. Chorea may associate with athetosis, hypotonia and tremor. The condition becomes less pronounced by adolescence and may disappear in some affected adults.

It is difficult to distinguish between this condition and other causes of chorea, especially familial paroxysmal chorea. The family history and the continuous, non-episodic chorea are important pointers. Treatment with anticonvulsants, chlorpromazine or haloperidol is beneficial in some.

**Hallervorden-Spatz syndrome.** The basal ganglia are very rich in iron. The reason for this is not known nor is it understood why the basal ganglia are so selectively vulnerable to heavy metal toxicity. Hallervorden-Spatz syndrome, a recessive condition, is associated with an increase in the amount of stainable iron. The globus pallidus and substantia nigra are affected with accumulation of iron pigments, a decrease in myelin and axonal swellings (spheroids). The clinical picture is not of parkinsonism but of spasticity with brisk reflexes, extensor plantar responses and increasing extrapyramidal rigidity of a hemiplegic dystonic type affecting all four limbs. When progression is very slow, the child may be thought to have cerebral palsy. Usually by the age of 10 years there is fixation of posture with varying degrees of choreoathetosis. Death usually occurs in the early twenties. There is no definitive diagnostic test, but as the condition progresses many children on MRI show an appearance of the basal ganglia which is typical and has been likened to a 'tiger's eye'. Genetically the syndrome appears to be heterogeneous.<sup>325</sup> Brain biopsy does not help unless one is fortunate enough to see circular inclusions known as spheroids. Iron metabolism, as judged by the measurement of serum iron, transferrins or iron absorption, is normal. No treatment is of any avail. The disease is rare and differentiation from metachromatic leukodystrophy, Alexander disease and Pelizaeus-Merzbacher disease can be clinically difficult. All may be misdiagnosed initially as cases of cerebral palsy.

**Paroxysmal choreoathetosis.** This is an odd condition with grimacing, choreiform movements and abnormal posturing, which occur in episodes. It may be difficult without a continuous 24-hour EEG recording to differentiate sporadic cases from epilepsies manifested with similar abnormal movements. The condition does not progress and is not associated with dementia. Onset may be as early as 6 months of age. Examination between episodes is normal, as is the EEG. It is dominantly inherited and no biochemical abnormality has been found. Sudden movement, or a particular movement, may precipitate bouts of choreoathetosis. The episode may be brief or may last several hours. Consciousness is usually maintained, even in paroxysmal choreoathetosis lasting hours or days. Paroxysmal choreoathetosis can also occur as a consequence of lesions to the basal ganglia, such as low grade astrocytomas. Dystonia or athetoid posturing precipitated by movement, i.e. paroxysmal kinesiogenic dystonia, may be very sensitive to carbamazepine.

Initial treatment is with anticonvulsants, particularly carbamazepine and phenytoin. If unsuccessful, prolonged episodes can be treated with anticholinergics such as benzatropine.

### Systemic diseases

**Sydenham chorea.** This is the most common acquired chorea in children. It is a cardinal feature of rheumatic fever and alone is enough for the diagnosis. The onset is usually 4 months after the initiating streptococcal infection.

The onset is usually insidious and diagnosis is often delayed. Chorea, hypotonia, dysarthria, restlessness and emotional lability are essential features. An early feature is an unexplained deterioration in

school work with the affected child being accused of 'messaging about'. Obsessive-compulsive behavior may be present.

On examination the child looks fidgety with migratory chorea of limbs and face. This may be unilateral initially but eventually becomes generalized in most. The child tries to mask the chorea with voluntary movements, which gives the appearance of restlessness.

Gradual improvement occurs over several months, and most young people recover completely. Rheumatic valvular heart disease develops in one third of untreated cases.

The diagnosis is essentially clinical. The differential diagnosis includes drug-induced chorea and systemic lupus erythematosus, making measurement of lupus antinuclear antibody titers worthwhile. Antistreptolysin O titer is usually back to normal or only slightly raised by the time of presentation.

All children with Sydenham chorea should be treated with high doses of penicillin for 10 days to eradicate active streptococcal infection and should continue with prophylactic penicillin until the age of 21. Pimozide usually controls the neurological symptoms without sedation. Alternatives are tetrabenazine, benzodiazepines, phenothiazines or haloperidol.

**Chorea gravidarum.** Chorea can complicate pregnancy. The likely explanation is that it may be the initial attack or recurrence of Sydenham chorea or lupus erythematosus triggered by the pregnancy.<sup>326</sup>

**Chorea associated with systemic lupus erythematosus and hyperthyroidism tumors.** Although chorea is a rare presentation of tumors compared with seizures or a slowly evolving paresis, cerebral hemisphere tumors may be associated with any types of movement disorder.

## DYSTONIA

### Definition

Dystonia is an abnormal posture caused by the simultaneous contraction of agonist and antagonist muscles.

### Differential diagnosis

Dystonia may be focal, affecting a single body part, segmental affecting contiguous parts, hemidystonia, affecting one side, or generalized, affecting both sides of the body. The differential diagnosis of dystonia is listed in Table 22.23; other conditions associated with abnormal postures are listed in Table 22.24.

### Specific syndromes

#### *Focal dystonias*

**Benign paroxysmal torticollis.** This is a self-limiting, benign condition that starts in the first year of life with repeated attacks of sickness, apparent discomfort and tilting of the head to one side and often associated with eye deviation to the same side. This may be repetitive. The affected side may change from one to another. Occasionally the trunk might incline to the same side and this may be associated with a degree of ipsilateral stiffness. Ataxia is not uncommon, especially later in the course of the disease. Shifting torticollis that occurs in attacks suggests the diagnosis. The combination of head tilt and nystagmus is termed spasmus nutans.

Although the initial presentation may suggest a posterior fossa tumor, the attacks rapidly subside leaving a normal child with no neurological abnormalities.

There is a well-recognized relation between this condition and migraine as with paroxysmal vertigo, and a family history of migraine may be relevant to the diagnosis.

**Dystonia associated with hiatus hernia: Sandifer syndrome.** Hiatus hernia may be associated with sudden spastic opisthotonic extension of the head, neck and sometimes of the upper part of the trunk. The head may move from side to side with the upper trunk bent to one side. All manner of bizarre posturing predominantly of the upper torso and arms may be seen. These bouts usually cease during sleep and may increase during, or shortly after, feeding. Vomiting and other symptoms of the hernia may be obvious or occult.

**Table 22.23** Differential diagnosis of dystonia in children

Spasticity
Neuromuscular conditions
Stiffman syndrome
Hysteria

The condition may be underdiagnosed or misdiagnosed as one of the idiopathic movement disorders leading to unnecessary treatment and intervention. The key is to consider the possibility and then treat the hernia and associated reflux as appropriate.

#### *Generalized dystonias*

Flexor dystonia is a feature of carbon monoxide poisoning, head injury and encephalitis. The affected child may lie curled up with marked flexor dystonia and complete akinesia. In less severe cases the child may be stooped, flexed at the elbows, knees and hips with the head bent forward. Classically, the arms are flexed and resist passive extension and the legs are flexed on the abdomen with the toes tending to claw. The asymmetrical tonic neck reflexes and progression reflexes are absent. It is not influenced by anxiety and does not disappear in sleep. Chorea and athetosis are not seen. L-DOPA will release the patient from the flexor rigidity.

Extensor dystonia occurs most commonly in children as the dystonic phase of cerebral palsy. It is not caused by a known neurotransmitter imbalance but may be seen as part of some of the very acute dystonic reactions described later as unwanted effects of certain neuroleptic drugs, in which case they are rapidly abolished by anticholinergics. Extensor dystonia corresponds to the physiological second stage of extension seen in normal child development between 6 weeks and 4 months after birth. In the abnormal or diseased state it is an obligatory exaggeration or caricature of this normal physiological developmental state. It is the hallmark of the cerebral palsies which follow kernicterus before choreoathetosis makes its appearance, of dystonia associated with prematurity or due to basal ganglia damage following perinatal asphyxia.

**Juvenile parkinsonism.** The clinical picture of tremor, bradykinesia and flexor rigidity has already been outlined. Parkinsonism is a form of dyskinesia rarely seen in children (Table 22.25).

Treatment of parkinsonism consists of L-DOPA combined with inhibition of the peripheral tissue breakdown by a specific carboxylase which increases the concentration of L-DOPA in the brain. This is often combined with an anticholinergic such as benztropine. Surgery does not have a place in most of the cases of childhood parkinsonism.

**Dopa-responsive dystonia.** Dopa-responsive dystonia (DRD) is also known as hereditary progressive dystonia with diurnal variation (HPD) and Segawa disease. The onset usually is between 2 and 9 years.

The striking feature of the disease is the fluctuation of dystonia in relation to the sleep-waking cycle. The child may be normal on waking, but after 30–60 minutes the dystonic movements start and increase with time. The response to low dose L-DOPA is dramatic, with restoration of normal mobility.

The initial presentation is with gait disturbance, difficulties walking and frequent falls. Dystonia usually affects one of the lower limbs and then spreads to others. Rarely it involves the truncal muscles.

Sometimes, the diurnal fluctuation might not be prominent, the family history may be absent and the response to L-DOPA may not be dramatic. It is essential to give the medication a full 3 months' trial. It is also very important to consider the diagnosis of a dopa-responsive dystonia in children with a symmetrical cerebral palsy where the investigations, including neuroimaging, are normal and there have been no antenatal/perinatal risk factors (such as prematurity in a child with a diplegia). It is particularly important to think of this possibility where the signs continue to evolve after the first 2 years or so, into later childhood.

In many children in this undoubtedly heterogeneous group, DRD is inherited as a dominant trait with low penetrance. The gene is mapped to chromosome 14 and codes for the enzyme GTP cyclohydrolase 1 which is involved in the synthesis of bipterin. Several different mutations are reported.

Treatment is with L-DOPA along with an inhibitor of peripheral catabolism. The required dose is usually small (50–250 mg/day). Considering the existence of atypical responses, higher doses up to (750 mg/day) may need to be tried. Table 22.26 shows other conditions which respond to L-DOPA. Some people have been treated now for 30 years or so with no reports of long term unwanted effects or signs of tolerance.

**Dystonia musculorum deformans.** Idiopathic torsion dystonia (ITD) is a severe dystonia that occurs in many of the diseases already described. The term is usually restricted, however, to unilateral torticollis exten-

sion of the leg, torsion of the trunk, extension and internal rotation of the arm (Fig. 22.25).

Although the condition can be seen in some cases of dyskinetic cerebral palsy and in some children with a relatively pure dyskinetic hemiplegia, there are two genetic forms, autosomal recessive and autosomal dominant. The former is more common in Ashkenazi Jews. A large proportion of the early onset dominant form have a coding sequence deletion in the GAG trinucleotide repeat in the DYT1 gene on chromosome 9q34. This offers a useful diagnostic test.<sup>327</sup> Treatment is with L-DOPA, anticholinergics and benzodiazepines (Table 22.27).

A group of children with onset of a paroxysmal dystonia, which is better in the mornings and worsens as the day wears on, has been described. Rest does not reduce the dystonia but rapid eye movement (REM) sleep results in alleviation for a short time. The condition may be associated with a severe generalized dystonia with brisk reflexes and extensor plantar responses and may progress to the point where the child cannot walk. The importance of this subgroup of dystonia musculorum

Fig. 22.25 Characteristic posture of the left lower limb in dystonia musculorum deformans. Mother and an uncle also suffered from the condition.

Table 22.27 Treatment of idiopathic torsion dystonia

Levodopa/carbidopa
Anticholinergics
Benzodiazepines (clonazepam, tetrabenazine)
Others (baclofen, carbamazepine)
Mixed treatments (e.g. anticholinergics + baclofen +/- pimozide and/or tetrabenazine and/or haloperidol)

deformans is that these children are extremely sensitive to L-DOPA and 25 or 50 mg of the drug together with a peripheral carboxylase inhibitor results in very dramatic improvement.

**Wilson disease.** This is an important cause of dystonia and is discussed in Chapter 26 (see p. 1125).

**Glutaric aciduria type 1.** In this condition, episodes of crying, cyanosis, pallor, lethargy and hypotonia may commence early in the first year of life. From about 5 months onwards an acute onset with tachypnea, acidosis and stiffness following a minor infection is common. There may be associated seizures, suggesting a diagnosis of febrile convulsions, or encephalitis, in the first instance. The episodes tend to be repeated and dystonia and choreoathetosis, if not present initially, gradually appear. The caudate and putamen show a loss of nerve cells and gliosis. Organic acid analysis shows raised glutaric and betahydroxyglutaric acid excretion in most, but not all cases. Serum L-carnitine is usually reduced. Glutaryl CoA dehydrogenase assay in fibroblasts gives the definitive diagnosis. Treatment with a low lysine and tryptophan diet has been tried without dramatic clinical improvement.

Choreoathetosis can also be a symptom of other metabolic disorders such as D-glyceric acidemia and sulfite oxidase deficiency, underlining the importance of a full metabolic screen with appropriate specialist advice in this group of disorders (see Ch. 26, p. 1062).

**Dystonia with basal ganglia calcification.** With the advent of modern imaging, basal ganglia calcification is a relatively common finding. There are many causes (Table 22.28) and the movement disorder may not be the initial or sole presentation.

**Symptomatic generalized dystonia.** Many diseases and disorders such as brain tumors, the effect of hypoxia, stroke, head injury and encephalitis may cause dystonia. The onset of dystonia may be during the acute illness or several years later.

### Drug-induced movement disorders

Drug-induced dyskinesias are usually idiosyncratic reactions or the result of toxicity and not related to the principal pharmacological action of the specific causative drug. Drug-induced dyskinesias are particularly likely with major tranquilizers (phenothiazines and butyrophenones) and the newer antipsychotic agents, which may cause parkinsonism, tardive dyskinesia and acute dystonic reactions, the latter presenting as opisthotonos and oculogyric crises. Treatment is with diphenylhydramine (2 mg/kg), tetrabenazine or anticholinergic agents. Metaclopramide can cause an identical clinical picture.

Opisthotonos, muscular rigidity and other extrapyramidal signs association with hypothermia, decreased consciousness and autonomic disturbance occur in the neuroleptic malignant syndrome precipitated by certain inhalational anesthetic agents.

Stimulants (e.g. methylphenidate) cause motor tics and chorea and are a cause of Tourette-like disorder (see below).

The selective serotonin reuptake inhibitors (SSRIs), used in pediatric practice for depression and obsessive-compulsive disorder, may produce

a hyperkinetic movement disorder with myoclonus and tremor as part of the serotoninergic toxic syndrome.

### MYOCLONUS

Myoclonus is a brief, sudden, involuntary, shock-like muscle contraction arising from the central nervous system. It is usually associated with co-contraction of agonist muscles. A distinction of practical clinical importance is epileptic versus non-epileptic myoclonus. Both types may be focal or generalized and repetitive or nonrepetitive. Further division into rhythmic myoclonus (of brainstem or spinal origin) and arrhythmic myoclonus (cortical or subcortical in origin and due to lack of inhibition) is useful clinically.<sup>328</sup>

Epileptic myoclonus occurs in many different epilepsies. It is a prominent feature of some idiopathic generalized epilepsies, e.g. juvenile myoclonic epilepsy, of the symptomatic and probably symptomatic encephalopathies of the infant and preschool child and is a prominent feature of the epilepsies associated with inherited metabolic disorders, e.g. mitochondrial disorders.

Benign myoclonus of early infancy very closely resembles infantile spasms but is non-epileptic. The infant is not encephalopathic and the EEG is normal.<sup>329</sup>

In benign neonatal sleep myoclonus focal or generalized myoclonic jerks occur in slow wave sleep. It is a common condition and myoclonus may be very frequent. Anticonvulsants are often prescribed inappropriately. Myoclonus does not occur in wakefulness and may be present for some months beyond the neonatal period into infancy. There may be a family history of the condition.<sup>330</sup>

Essential myoclonus is an extrapyramidal disorder of dominant inheritance and is nonprogressive. Myoclonus is worse on movement. EEG is normal, intellectual impairment absent and the condition is not progressive.

Myoclonus is a feature of a wide range of serious neurological disorders. Metabolic disorders in which myoclonus is a feature include aminoacidopathies (hyperglycinemia, phenylketonuria and maple syrup urine disease), sialidosis – cherry red spot myoclonus, Unverricht–Lundborg disease, mitochondrial cytopathies, the late infantile neuronal ceroid lipofuscinoses, Menke disease, sphingolipidoses and Wilson disease.

A curious form of upper limb myoclonus is seen in slow virus infections, including subacute sclerosing panencephalitis in which the myoclonus is 'hung up', i.e. sudden contraction of muscles followed by delayed relaxation.

Symptomatic myoclonus may occur in conditions characterized by brain malformations, such as Aicardi syndrome, tuberous sclerosis and Sturge–Weber syndrome.

When myoclonus is symptomatic it is never the only neurological symptom, but it may be the only symptom at presentation and for a time thereafter. Symptomatic myoclonus may arise from pathology at any level of the neuroaxis and is the result of hyperexcitability (or lack of suppression) of gray matter in the cortex, basal ganglia, brainstem

Table 22.28 Causes of basal ganglia calcification

Endocrine	Congenital and metabolic disease	Infection	Neoplasms
Hypoparathyroidism	Mitochondrial encephalopathies	Toxoplasmosis	Craniopharyngioma
Pseudohypoparathyroidism	Leigh's encephalopathy	Subacute sclerosing panencephalitis	Optic nerve glioma
Pseudopseudohypoparathyroidism	Hallervorden–Spatz disease	Cytomegalovirus infection	Radiotherapy
Hyperparathyroidism	Chronic methemoglobinemia	Congenital rubella	Methotrexate therapy for leukemia
Hypothyroidism	Carbon monoxide poisoning	AIDS	
	Lead poisoning		
	Systemic lupus		
	Cockayne syndrome		
	Down syndrome		
	Tuberous sclerosis		
	Neurofibromatosis		

and spinal cord. Cortical myoclonus, in which there is increased cortical excitability with giant sensory and action potentials, results from localized brain lesions, e.g. space-occupying lesions of the sensorimotor cortex, or, more frequently, is of multifocal origin following cerebral hypoxia.<sup>331</sup> In the latter situation, the myoclonus may be generalized or focal.

In celiac disease the syndrome of progressive myoclonic ataxia is seen. This is not responsive to a gluten-free diet and an auto-immune etiology has been suggested.

An autoimmune etiology has also been proposed in the opsoclonus-myoclonus (dancing eye) syndrome. This serious disorder presents in the infant or toddler with irritability, loss of skills, generalized myoclonus, ataxia and chaotic eye movements (opsoclonus). The condition has a postinfectious etiology in around 50% of cases but an association with neural crest tumors, particularly neuroblastomas is recognized. The pathophysiology involves binding of specific autoantibodies to the Purkinje cells of the cerebellum. Steroids and intravenous immunoglobulins are effective treatments but the course is often relapsing and half of those affected have persisting neurodevelopmental impairments.<sup>332</sup>

Spinal myoclonus is segmental or involves multiple spinal segments. Segmental myoclonus is usually symptomatic of a structural cord lesion.

Treatment of symptomatic, non-epileptic myoclonus is of the underlying cause. Piracetam, clonazepam and valproate may be helpful but pharmacological treatment of symptomatic myoclonus is often disappointing.

## TICS AND TOURETTE SYNDROME

Tics are involuntary, purposeless contractions of functionally related groups of skeletal muscles. They are brief, repetitive, stereotyped, non-rhythmic movements or vocalizations. Motor tics persist in sleep (which is unusual in movement disorders).

Transient tic disorder is common. Estimates vary from 5% to 25% of all children at some time in childhood.<sup>333</sup> Most people have some stereotyped movement that they pursue when tired, bored or stressed. A ride on a bus, a glance around a lecture or committee meeting will reveal an array of hair twiddlers, nail biters or pickers, finger drummers or foot tappers. Most people keep these idiosyncrasies throughout their lives, with periods in which the habit is more or less obvious. The adoption in some diagnostic classifications such as DSM-IV of a fixed time course in some of its definitions (Table 22.29) is therefore problematic.<sup>334</sup>

Those who have movements above the shoulders often get taken to doctors as they are less likely to be accepted in social settings. It is rare to be presented with a finger tapper, much more commonly a blinker. Many children with tics persisting for more than 1 year have Tourette syndrome, which is increasingly recognized as having great variation

in severity. Tourette syndrome is a chronic disorder characterized by multiple motor and at least one vocal tic waxing and waning but present for at least 1 year with onset most commonly between 4 and 11 years of age. It is no longer regarded as rare – the prevalence is 1:2000 and the male to female ratio 4:1.<sup>335</sup>

Simple tics presenting to doctors usually involve the face or shoulders – blinking, stretching facial muscles, head flicking, shoulder shrugging, etc. More complex tics include forced touching, sniffing or licking and there is a close association with obsessive-compulsive disorder (OCD). Premonitory sensory sensations preceding the tics are common. Tics can be voluntarily suppressed for a short time but this is distressing if continued. ‘Sensory tics’ can occur alone.

Simple vocal tics include grunting, throat clearing, coughing, barking and complex vocal tics include echolalia phrases. Coprolalia (obscene words), though well known, is rare, occurring in less than 10% of cases.

Although tics are the most common clinical manifestation of Tourette syndrome, it is often the associated psychopathology that produces most impairment. These include obsessive-compulsive disorder, attention-deficit-hyperactivity disorder (ADHD), depression, anxiety and specific learning difficulties, particularly dyscalculia. There is often a strong family history of tic disorder or psychopathology with OCD being particularly common.

As with most tic disorders people with Tourette syndrome have a life-long tendency to the disorder with good spells and bad spells and often an exacerbation during adolescence.

Treatment is multidisciplinary. It is important to support the family and the child in education. Occasionally behavioral treatments for tics and obsessive-compulsive symptoms may be helpful. Neuroleptics, sulphiride and haloperidol are highly effective. Trandine is useful for treatment of ADHD. Drug holidays are indicated and families must be warned about the rare but serious occurrence of tardive dyskinesia with chronic neuroleptic use.

A Tourette-like disorder with tics, but without the psychopathology of Tourette syndrome, may occur secondary to acquired brain injury, such as following head injuries. Pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS) is of interest in that in a significant number of children with Tourette syndrome group A streptococcal infection is associated with antibodies that cross-react with putaminal neurones. Some children in whom traditional pharmacotherapy treatment has failed have responded to steroids or immunomodifying therapy.<sup>336</sup>

## TREMOR

Tremor is a continuous rhythmic and involuntary movement disorder of a body part and results in alternating contractions of agonist and antagonistic muscles.

Table 22.29 DSM-IV criteria for tic disorders. (Adapted from APA<sup>334</sup>)

### Common criteria

The tics occur many times a day (usually in bouts) nearly every day

The disturbance causes marked distress or significant impairment in social, occupational or other important areas of functioning

Onset is before age 18 years

The disturbance is not due to the direct physiological effects of a substance or a general medical condition

### Tourette syndrome

Both multiple motor and one or more vocal tics have been present at some time during the illness, although not necessarily concurrently, throughout a period of more than 1 year, and during this period there was never a tic-free period of more than 3 consecutive months

### Chronic tic disorder

Single or multiple motor or vocal tics, but not both, have been present at some time during the illness throughout a period of more than 1 year, and during this period there was never a tic-free period of more than 3 consecutive months

### Transient tic disorder

Single or multiple motor and/or vocal tics for at least 4 weeks but not longer than 12 consecutive months

### Tic disorder not otherwise specified

Cases that do not meet the criteria for a specific tic disorder

A clinically useful classification is tremor at rest, tremor on maintenance of a posture (postural tremor) and action tremor, i.e. tremor occurring on performance of a voluntary activity. It must be noted that action tremor is not synonymous with the intention tremor of cerebellar disease. Intention tremor is one type of action tremor and is characterized by accentuation of tremor just before the target is reached on finger/nose testing. At its most extreme the oscillations in terminal intention tremor, as seen in Wilson disease, may be so violent that there is a risk of self-injury. A similar gross intention tremor can be seen after traumatic brain injury.

Resting tremor is not common in pediatric practice. Causes include Wilson disease, juvenile Parkinson disease and neuroleptic drugs.

Postural tremor is tested by asking the child to stand with arms outstretched or to hold arms abducted and flexed at the elbows, with the hands brought to the midline and the fingers of one hand almost, but not quite touching the fingers of the other hand. The commonest cause of postural tremor is physiological tremor.

Familial essential tremor is often of dominant inheritance and both postural and action tremor are present. While there is a danger of overdiagnosis of essential tremor (particular care is necessary if family history is negative), most high frequency low amplitude tremors are physiological. If an essential tremor is widespread, the legs may be involved, and titubation, producing head nodding, may be present. Shuddering attacks in infants are an early manifestation.<sup>337</sup> Essential tremor may worsen during childhood. Treatment should be considered if writing is seriously impaired. Propranolol and primidone may help but unwanted effects limit usefulness.

Symptomatic causes of tremor include traumatic brain injury (tremor may become evident in the first year post injury and subsides spontaneously in 50% of cases), juvenile Parkinson disease, severe malnutrition with cobalamin deficiency, Wilson disease, hepatic encephalopathy, as a drug side-effect (e.g. sodium valproate), in juvenile multiple sclerosis, galactosemia, hereditary and acquired ataxias, Hartnup disease, hereditary fructose intolerance, thalamic tumor, vascular accidents involving the thalamus and internal capsule, spinal muscular atrophies and occasionally in hereditary motor and sensory neuropathies. Treatment is of the underlying cause.

## NYSTAGMUS

Nystagmus is a tremor of the eyes, which may involve rhythmical conjugate oscillatory movement in any plane. It usually involves an initiating component and a fast correcting component. Clinically, different patterns of movement may be recognized. In pendular nystagmus the oscillations are slow in each direction with the eyes in a neutral position but on lateral gaze they may show a jerky quality. Jerk nystagmus indicates a slow phase in one direction followed by a fast corrective jerk in the other. It is the direction of the fast component that conventionally defines the direction of the nystagmus. When gaze is in the direction of the fast phase the intensity of the nystagmus increases.

Nystagmus should be differentiated from the roving eye movements of a blind child or one with significantly reduced acuity, particularly in the first 2 years of life. Opsoclonus involves very fast saccadic eye movement in all directions occurring in sudden bursts. It is associated with the dancing eye syndrome and its underlying causes, notably neuroblastoma. Ocular bobbing and dipping involve downward movement of the eyes with corrective movement to the mid-position. They indicate brainstem dysfunction often seen in comatose children. Oculomotor dyspraxia, commonly associated with ataxia telangiectasia, involves difficulty with horizontal saccadic eye movement. The eyes are often left behind the position of the head, later to be restituted with a characteristic flick of the head.

The most common cause of jerk nystagmus is gaze-evoked nystagmus reflecting dysfunction of the posterior fossa centers responsible for holding the eyes in an eccentric position. Vestibular nystagmus is also a jerk nystagmus resulting from involvement of the vestibular end-organ or its central pathways and nuclei.

Congenital nystagmus may be sensory, due to low acuity, or motor, due to a defect in the slow eye movement system. It is usually evident

from birth and dominant, recessive and X-linked inheritance is described. It is usually horizontal (even on upgaze) but may be vertical or rotary. Pendular nystagmus is almost never acquired. Congenital nystagmus is abolished by sleep and increased by attempts at fixation. Up to 8.0% of children may have associated head bobbing.

## ATAXIA

### Definition and types

Ataxia is incoordination of movement not due to weakness, involuntary movements or abnormal muscle tone and is the major clinical sign of cerebellar disease. Sensory ataxia results when there is impaired afferent input into the cerebellum via the spinocerebellar pathways.

The three types of ataxia resulting from cerebellar disease are gait, truncal and limb and each has anatomical localizing value. Gait and truncal ataxia are due to lesions of the vermis or brainstem cerebellar connections; limb ataxia results from ipsilateral cerebellar hemisphere lesions. The causes are summarized in Table 22.30.

### Examination

An infant is best examined on the parent's knee and encouraged to reach out with each hand. Intention tremor is distinctive, of maximum

Table 22.30 Selected causes of ataxia in childhood

<b>Progressive/inherited</b>
Friedreich ataxia
Ataxia telangiectasia
Spinocerebellar degeneration (SCA)/olivopontocerebellar ataxias

Angelman
Chiari malformation
Basilar impression

amplitude at the beginning and end of the range of movement and is irregular. Dysmetria is error in the estimation of the amplitude of movement.

In the older infant a delay in gaining independent walking, having cruised at a normal age, may be the first manifestation of gait ataxia. A child with truncal ataxia will not sit without supporting herself or is easily knocked off balance when sitting.

It is important when using the finger/nose test to ensure maximum range of movement, by ensuring that the child's arm is not held adducted against her trunk and that the child's arm is fully extended during finger/nose testing.

A child with gait ataxia stands and walks with feet widely apart and cannot place one foot directly in front of the other (tandem walking). This is best demonstrated to the child. Most 5-year-old children can tandem walk easily, when shown what to do by the examiner.

Rapid alternating movements (dysdiadochokinesis) are tested by rapid pronation and supination of the forearm.

Every ataxic child should have careful fundal examination for papilledema, plotting of head circumference and, in the infant, assessment of fontanel pressure, as posterior fossa space-occupying lesions often present with ataxia.

Other signs of cerebellar dysfunction commonly seen in ataxia are jerk nystagmus, hypotonia and diminished reflexes.

## Causes of ataxia

Ataxia is always of significance and requires full investigation. It is rare for a definitive diagnosis not to be made.

### Tumors

**Infratentorial tumors.** Infratentorial tumors often involve the cerebellar vermis producing gait ataxia. Any unsteady child with headache or sleepiness must be assumed to have a posterior fossa tumor. There may be no long tract signs. The commonest tumors are medulloblastoma/primitive neuroectodermal tumors, which produce obstructive hydrocephalus with headache, vomiting and ataxia. Cerebellar hemisphere astrocytomas do not usually produce obstructive hydrocephalus, are indolent, of good prognosis and produce ipsilateral ataxia. Diffuse astrocytomas also occur. Ependymomas produce fourth ventricle obstruction.

**Intrinsic brainstem tumors.** These present with gait and truncal ataxia, with cranial nerve dysfunction and long tract signs. Cranial nerve dysfunction is often evidenced by dysphagia, lower motor neurone facial palsy and gaze palsy or nystagmus. The duration of ataxia before diagnosis may be as short as a few weeks and a mistaken diagnosis of acute cerebellar ataxia may be made if specific signs, particularly lower motor neurone cranial nerve dysfunction, are not sought.

Cranial MRI is almost invariably abnormal though CT may be normal. Cranial MRI shows an intrinsic brainstem lesion, a cystic mass or an exophytic lesion. Histological diagnosis is difficult because of the site of tumor and danger of brainstem swelling with biopsy. Biopsy is now no longer usually performed in typical cases. Prognosis is generally poor, with death within 2 years, but a small number are long term survivors with only very slow progression.

### Acute ataxias

The commonest neurological causes of acute ataxia are infectious or postinfectious.

Acute cerebellar ataxia often follows a viral infection, commonly varicella. It is most common in children under the age of 4 years. It often presents with the child suddenly stopping walking. He may revert to crawling and ataxia may be difficult to demonstrate. The infant is not weak and reflexes are present, although they may be depressed. There is no cranial nerve involvement other than nystagmus (in 50% of cases). However, the child may be dysarthric. Differential diagnosis includes posterior fossa or brainstem tumor and if cranial MRI is available it should be done. CSF is usually normal. It is particularly important to note that CSF protein is normal early in the course of the condition. The importance of this finding is that CSF protein is usually elevated in

postinfectious polyneuropathy, which may present as gait ataxia. The child with acute postinfectious cerebellar ataxia is not encephalopathic and not distressed (pain is an important early feature of postinfectious polyneuropathy). Recovery is rapid (weeks) but occasionally takes months and in a very small number of children ataxia persists.

A rare type of postinfectious polyneuropathy is the Miller–Fisher syndrome, which presents with an acute cerebellar ataxia, ophthalmoplegia and areflexia but with no weakness. CSF protein is elevated and serum antibodies against ganglioside CQ1B may be found. Antibodies against this ganglioside recognize epitopes from *Campylobacter jejuni* indicating crossreactivity. Urgent MRI is indicated by the combination of ophthalmoplegia and ataxia. The cause of ataxia in the Miller–Fisher syndrome is unknown. Recovery is over weeks and is usually complete. Intravenous immunoglobulins may help as in postinfectious polyneuropathy.

Many metabolic disorders include ataxia in their clinical phenotype. In females with X-linked ornithine transcarbamylase deficiency, ataxia (which is often of acute onset) and vomiting occur during metabolic decompensation. Ammonia is elevated. Other metabolic disorders presenting with acute ataxia include mitochondrial cytopathies, maple syrup urine disease and Hartnup disease. Ataxia is a feature of Batten disease and metachromatic leukodystrophy. In these conditions ataxia is of subacute onset.

Distinguishing acute ataxia from acute labyrinthitis is difficult in a young child. The child with labyrinthitis is distressed, vomiting and does not have limb ataxia when encouraged to reach.

Acute ataxia as a result of poisoning or intoxication is caused by anticonvulsants (particularly carbamazepine and benzodiazepines), alcohol and thallium containing insecticides.

In nonconvulsive status epilepticus, and the symptomatic and probably symptomatic age-dependent epileptic encephalopathies ataxia, initially intermittent, may be the presenting feature with regression of speech and cognition.

### Inherited ataxias

The inherited ataxias are of recessive, dominant or X-linked inheritance and many are triplet repeat diseases. The commonest is Friedreich ataxia; the others are summarized in [Table 22.31](#).

### Friedreich ataxia and other spinocerebellar degenerations

This has a prevalence of 1:48 000 and is a progressive disorder with most children having very severe physical disability by adulthood although survival to the fifth or sixth decade is possible.

Friedreich ataxia is recessively inherited. The gene is mapped to 9q13 and codes for the protein frataxin, an 18-kb soluble mitochondrial protein with 210 amino acids. The GAA triplet repeat expansion produces frataxin deficiency with clinical severity related to the GAA expansion size. The protein function is unknown. Truncal ataxia is the first symptom, with onset as young as 2 years, followed by dysarthria, limb ataxia and evolving kyphoscoliosis. Findings include nystagmus, pes cavus, distal weakness, posterior column dysfunction, areflexia and extensor plantars.

All children require cardiological assessment and review. Hypertrophic cardiomyopathy and ECG abnormalities (T wave abnormalities and heart block) are found. Diabetes and impaired color vision also occur. Friedreich ataxia is relentlessly progressive and there is no specific medical treatment of proven benefit. However, much can be done to help the child and family by rehabilitative management ensuring access to education, independent mobility (often with a powered chair) and help with activities of daily living.

Diagnosis is by determining the number of GAA repeats in a child with progressive ataxia.

All of the inherited spinocerebellar ataxias have varying degrees of pyramidal and extrapyramidal involvement. There are 10 autosomal dominant hereditary ataxias (spinocerebellar ataxias, SCAs) separated by genotype. Most are triplet repeat diseases.<sup>338</sup>

Table 22.31 The spinocerebellar ataxias: genotypes and main clinical features. (After Morrison<sup>336</sup>)

Name	Gene locus	Autosomal inheritance	Triplet repeat	Anticipation	Chorea	Dementia	Sensory loss	Retinal degeneration
SCA-1	6p23	AD	CAG	P			+	
SCA-2	12q23	AD	CAG	P	+	+		
SCA-3/MJD	14q32.1	AD	CAG	P			+	
SCA-4	16q24	AD	?	?			+	
SCA-5	11cent	AD	?	M

ABLP	4q22-24	AR		-			+	+
SCA-8/ IOSCA	10q24	AR	?	-	+			+

All show cerebellar ataxia.

P, with paternal transmission; M, with maternal transmission.

?, Not yet identified.

IOSCA, infant onset spinocerebellar ataxia; MJD, Machado-Joseph disease.

AD, autosomal dominant; AR, autosomal recessive.

## Ataxia telangiectasia

The second commonest cause of progressive ataxia in childhood is ataxia telangiectasia which is discussed elsewhere in this chapter (see p. 839).

## Inherited vitamin E deficiency

Any chronic disorder causing intestinal fat malabsorption may result in vitamin E deficiency and hence features of spinocerebellar degeneration. Vitamin E deficiencies, due to abetalipoproteinemia and familial vitamin E deficiency, are recessive ataxias. The importance of the latter is that the phenotype is of Friedreich ataxia though cardiomyopathy is rare. In hereditary vitamin E deficiency the gene is located on 8q13 and codes for alpha tocopherol transfer protein. Large doses of vitamin E can halt progression and occasionally improve neurological function.

## NONPROGRESSIVE ATAXIAS AND ATAXIC CEREBRAL PALSY

Congenital nonprogressive ataxia is synonymous with ataxic cerebral palsy and many nonprogressive ataxias of early onset, particularly if associated with learning difficulties, are inherited. Even if there is a history of intrapartum asphyxia, attributing ataxic cerebral palsy to this cause is likely to be wrong and there may be recurrence in future children. Inheritance is usually recessive, occasionally dominant. All such children should undergo MRI scanning, which often shows congenital cerebellar abnormalities, such as vermian or generalized cerebellar hypoplasia.

In ataxic diplegia there are components of both ataxia and spastic cerebral palsy. The causes are similar to spastic diplegia and both are associated with prematurity. In addition it is a characteristic feature of 'neglected' hydrocephalus. Inherited forms of ataxic diplegia occur.

## SYNDROMES FEATURING ATAXIA

Children with Angelman syndrome have severe learning difficulties, a jerky ataxia (hence the former derogatory term 'happy puppet') and (usually) a submicroscopic deletion of maternally derived 15q11-q13.

Ataxia is found in Joubert syndrome, Dandy-Walker cyst and Chiari malformation but in these cases ataxia is but one feature of a complex syndrome. Other causes of ataxia are summarized in Table 22.30.

## THE CARBOHYDRATE-DEFICIENT GLYCOPROTEIN SYNDROMES

This group of disorders is dealt with in detail in Chapter 26. The diagnosis should be considered whenever ataxia is accompanied by a learning disability, epilepsy or dysmorphism. Transferrin isoelectric focusing is a useful diagnostic test but will not detect all cases.

## CEREBRAL PALSY

### DEFINITION

Cerebral palsy is a disorder of posture movement and tone due to a static encephalopathy acquired during brain growth in fetal life, infancy or early childhood. Though the brain disorder is unchanging, the effects are dynamic, as the brain matures, and the child's developmental capabilities extend.

### CLASSIFICATION AND EPIDEMIOLOGY

Cerebral palsy syndromes are classified according to the type of motor disorder and the topographical distribution of the condition.<sup>339,340</sup> Spasticity was the commonest motor impairment, reported to be present in 85% of a West Swedish series of 328 children,<sup>341</sup> or about 1:500 children. Dyskinetic cerebral palsy was found in 8.5% and simple ataxia in 6.5%. This means that dyskinetic cerebral palsy occurs in about 1:5000 children and simple ataxia in 1:6500 children. An average general practitioner (GP) in the UK has 25 babies born into the practice per year and the average health visitor (HV) has a caseload of up to 100 new babies per year. So those providing generic services see newly born children with spastic cerebral palsy quite infrequently – a GP once in 20 years and a HV once in 5 years. Only one GP in six and one HV in two will ever have a child patient with dyskinetic cerebral palsy throughout a whole working life. One GP in eight and one HV in three will ever look after a

child with simple ataxic cerebral palsy. The diagnosis of cerebral palsy is made by increasing suspicion over time; it is not easy for clinicians who have never seen the condition before.

Cerebral palsy can be classified by its taxonomic distribution. Thus hemiplegia describes cerebral palsy affecting one half of the body predominantly, the upper limb more than the lower limb, normally sparing the bulbar muscles. Quadriplegia, or tetraplegia affects all four limbs, upper limbs more than lower limbs. It is sometimes described as a double hemiplegia and is usually associated with a bulbar palsy. When all four limbs are affected, but the upper limbs are affected less than the legs, this is described as a diplegia. If the part of the body affected predominantly is the bulbar muscles, this is described as congenital suprabulbar paresis or Worster–Drought syndrome.<sup>342</sup> It is helpful to write about functional ability when communicating with colleagues. No two children with cerebral palsy are the same. In recent years improved motor function tools have become available which aid this approach.<sup>343–347</sup>

## ETIOLOGY OF CEREBRAL PALSY

Cerebral palsies may arise from genetic causes,<sup>348</sup> developmental brain anomalies, e.g. bilateral perisylvian polymicrogyria in some children with congenital suprabulbar paresis,<sup>349</sup> aqueduct stenosis and Arnold–Chiari malformation of the cerebellum in children with ataxic diplegia, or from a host of acquired causes including intrauterine infection. In a study of 276 term infants with moderate or severe newborn encephalopathy and 564 controls, birth defects were found in 27.5% of the former but only 4.3% of the latter.<sup>350</sup>

Spastic diplegia is the commonest form of cerebral palsy. The children have four-limb cerebral palsy, but the legs are more affected than the arms and bulbar involvement is relatively slight. A minority have ataxia also, mainly truncal (ataxic diplegia). Two thirds of children affected are preterm, but almost always appropriate for gestational age. The characteristic pathology is periventricular leukomalacia (PVL), which occurs when the periventricular structures are particularly vulnerable to hypoperfusion (26–36 weeks' gestation), usually in utero.<sup>351</sup> Birth hypoxia-ischemia is only recorded for a tenth of these children and is never the single risk factor.<sup>352</sup> The response of glial cells to cytokine release triggered by infection in fetus or mother is at least as important.<sup>353</sup> Periventricular venous infarction may coexist with intraventricular hemorrhage in these children, sometimes leading to striking asymmetries of neurological findings in later childhood. In term diplegic infants, with no history of hypoxia-ischemia, it is common to find periventricular myelin defects indicating early prenatal origin from the early third trimester.<sup>354</sup>

Hemiplegia is the commonest form of cerebral palsy in term infants and is second only to diplegia among preterms. The proportion of infants with hemiplegia born at term is about 80%.<sup>355</sup> Hemiplegia derives, usually, from prenatal circulatory disturbances during pregnancy, the commonest, affecting over a third, being periventricular leukomalacia (PVL) due to hypoperfusion of the brain early in the third trimester.<sup>356</sup> Cerebral maldevelopments and major cortical/subcortical lesions each account for about a sixth of cases. Though two thirds of children with hemiplegia have unilateral lesions (rare in other types of cerebral palsy), one third have bilateral lesions.<sup>357</sup> Conversely, children with unilateral lesions, even agenesis of a cerebral hemisphere, do not necessarily show a hemiplegia. The relationship between structural lesions demonstrated by imaging, and neurological function is complex, reflecting the brain's capacity for plasticity in response to dysgenesis or damage.<sup>358</sup>

Spastic quadriplegia (tetraplegia) is a severe form of four-limb cerebral palsy, arms more affected than legs, with bulbar palsy. All have severe or profound learning difficulties; up to 90% have epilepsy; bulbar palsy is often severe and about half have cortical blindness. Currently about a third to 40% are born preterm, including children who would not have survived in the past. Children with acquired spastic diplegia of prematurity almost always show evidence of PVL, whereas those with acquired spastic quadriplegia may show PVL, but more commonly

show full-term-type border zone infarcts, bilateral basal ganglia/thalamic lesions, subcortical leukomalacia and multicystic encephalomalacia.<sup>357</sup> Severe PVL is characteristic of children whose gestational age at birth is between 25 and 32 weeks, whereas term babies tend to have mild PVL. Diplegia (legs are more affected than the arms) should not be loosely confused with quadriplegia (arms more affected) in clinical notes or studies.

Dyskinetic cerebral palsy describes four-limb involvement and bulbar palsy, with fluctuating tone and involuntary movements. Magnetic resonance imaging has helped our understanding of acquired dyskinetic cerebral palsy. Acute near-total intrapartum hypoxia-ischemia for 10–20 minutes causes damage predominantly in the subcortical gray matter.

Affected children should be tested for evidence of congenital rubella, toxoplasmosis or cytomegalovirus (the Guthrie test blood spot taken at birth may be helpful) together with urine culture for rubella and cytomegalovirus, which may be excreted for 3–5 years. Serological tests for syphilis will have been part of the mother's antenatal care but this should be confirmed from the maternity records. Human immunodeficiency virus (HIV) has emerged as an important cause of cerebral palsy (particularly spastic CP) in recent years. This causes a low-grade chronic brain infection, which may not be evident on CT scan. The processes of brain development interact with, and partly overcome, the destructive effects of the encephalopathy so that the child appears to be developmentally delayed, but improving over the first 2 years. Signs of apparent cerebral palsy emerge, but the child may appear to progress up to a point, e.g. sitting and crawling, before regression sets in. Such children do not show signs of full AIDS with a sequence of major infections and bowel upsets. The first serious infection may be *Pneumocystis carinii* pneumonia. This is difficult to diagnose clinically though the chest X-ray is characteristic with a 'ground glass' appearance in the lung fields and a hypoplastic thymus. Opportunistic superinfection, with other organisms such as toxoplasma or cytomegalovirus, may occur and may cause an encephalopathy in their own right. The diagnosis is by detection of HIV antibody titers and characteristic CD4:CD8 lymphocyte counts (see Ch. 28).

Herpes simplex infection can be acquired from the genital tract during birth, leading to a destructive encephalopathy, one consequence of which is a spastic quadriplegia, usually with cortical blindness and epilepsy. The acronym 'TORCH screen' is an aide-mémoire although toxoplasma, rubella and cytomegalovirus cause intrauterine infection whereas herpes simplex virus causes brain damage in an acute, usually obvious, illness after birth. Perhaps the 'H' should now be for HIV.

One mechanism proposed for causing cerebral palsy is the effect of the vanishing twin.<sup>359,360</sup> The proposal is that twin-to-twin transfusion occurs in the first trimester in monochorionic twins through a vascular anastomosis. Following the death of one twin, thromboplastic-like material passes through the vascular connection into the survivor's circulation resulting in end organ damage (the embolic theory). Alternatively the survivor's blood may be shunted into the low-resistance vascular system of the dead fetus causing acute hypovolemia, ischemia and end-organ damage (the ischemic theory). A 'prevanishing twin' syndrome before sonographic detection of two gestational structures may be supported by chorionic villus sampling (CVS). Cytogenetic evidence for this syndrome has been found in 1:2000 singleton pregnancies undergoing CVS.<sup>361</sup> The combination of placental chimerism (rather than mosaicism) and unlike-sexed cell lines, including cells with a chromosome abnormality not found in the surviving fetus, is suggestive of twin-to-twin transfusion early in the first trimester in dichorionic twinning.

## PREVENTION OF CEREBRAL PALSY

Stanley et al<sup>362</sup> reviewed causal pathways to the cerebral palsies, a new etiological model and also possibilities for the prevention of the cerebral

palsies, i.e. social and medical factors. They quote Hill and Hill's<sup>363</sup> criteria suggesting a causal link should be:

- Strong: high relative risks or odds ratios.
- Consistent: cohorts from different geographic populations/time periods show the same patterns of causal associations.
- Specific: the disease occurs only following exposure to the putative cause and not to other exposures. The exposure is followed by one specific disease, rather than by many diseases.
- Time sequence: the putative cause precedes the outcome.
- Dose dependent, or with a biological gradient: the degree of association increases with increasing intensity of exposure.
- Biological plausibility: a biologically plausible mechanism for the causal association exists.
- Coherence of evidence: the proposed mechanism is consistent with current biological wisdom.

These, often called the Bradford Hill criteria, and the analytical methods to measure the associations, such as multivariate analyses, are largely based on *single and sufficient* or, less often, *multiple independent* causal models. Links between factors on a causal pathway operate in two ways:

1. Independent but their coincidence is necessary for the consequence, e.g. a Rh-ve mother has a Rh+ve partner hence the possibility of a Rh incompatible fetus.
2. Cascade: A causes, or predisposes, to B, which causes or predisposes to C, e.g. a multiple pregnancy predisposes to premature delivery and higher risk for intracerebral hemorrhage.

There are many interventions which could prevent cerebral palsy. These may be considered as follows:

- Proven: MMR vaccination, iodine supplementation in iodine-deficient areas, anti-D for RH-ve women, reducing risk of methylmercury exposure, transfer of the very preterm infant in utero to a tertiary center, reducing embryos transferred in infertility treatments to three or less, fencing swimming pools, home support for socially disadvantaged parents.
- Probable: early routine ultrasound, avoiding excessive alcohol intake in pregnancy, phototherapy for neonatal jaundice, vitamin K at birth to prevent brain hemorrhage, infant restraints in cars, child abuse prevention strategies, sudden infant death syndrome prevention strategies.
- Possible: mode of delivery for very preterm births including breech presentations, zinc, folate or fish oil to prevent intrauterine growth retardation (IUGR), methods of detecting IUGR, operative delivery for fetal distress, amnioinfusion for umbilical cord compression, rescue therapy for birth hypoxia-ischemia.
- Doubtful: electronic fetal monitoring for fetal distress – addition of fetal scalp sampling or ECG, bedrest for growth restriction, hospitalization for multiple pregnancies, multifetal pregnancy reduction for high order multiples, antenatal indometacin or thyrotropin-releasing hormone.

In spite of the proven or probable interventions available, the rate of cerebral palsy remains steady. Such interventions might not be enough. We may not understand all the steps in a complex causal pathway. There may be social factors, which influence people's decisions, which affect the outcome – access to a telephone, care of other children, independent transport, for instance. The balance between death and cerebral palsy may be irreducible. Even if it were possible to prevent the occurrence of cerebral palsy in children who entered labor as healthy, but who showed signs of intrauterine hypoxia-ischemia, to reduce by a quarter the 25% of cerebral palsy cases born preterm, and to prevent the 2% secondary to intrauterine infection, the total reduction in cerebral palsy cases would not exceed 20%. A preventative program might also increase survival rates of children with CP, thus offsetting any benefit.

## CLINICAL FEATURES

### Spastic diplegia

By the time diplegic children reach the age of 5 years or so they show spasticity in their legs more, or far more, than in their arms (Fig. 22.26).

Fig. 22.26 Diplegic gait. Internal rotation with hip adduction.

If the signs are restricted to the legs, investigation of the spinal cord for a paraplegia should be undertaken, even though there is known to be brain damage from intracerebral bleeding, ischemia, meningitis or other conditions in infancy. Such spinal lesions as diastematomyelia, neurenteric or dermoid cysts, myelodysplasia, neurofibromata or vascular infarction may be found. The signs in the diplegic child's arms vary from mild spasticity to manual dyspraxia or dyskinesia, which may have emerged when the child was 3 or 4 years old.

Premature infants in the special care baby unit commonly show neurological abnormalities or ambiguities, which are hard to assess. They may show increased or decreased tone. Episodes are observed which may be seizures. The need for parenteral or nasojunal feeding removes oral feeding behavior as an indicator of health. Ultrasound scans may show focal lesions of uncertain significance. Risk of cerebral palsy is known to be high for extremely low birth weight premature babies, though most premature babies grow up to be healthy children, free of neurological deficits. Parents and health professionals are bound to be concerned for each individual baby: 'is he/she going to be all right?' An explanation of attendant risk, in the light of neuroimaging findings, with regular review helps manage that uncertainty. Parents respect honesty.

*Dystonia of prematurity* is a form of extensor hypertonus emerging around 40 weeks' gestational age and reaching its peak by 4 months old. This causes much parental concern and makes affected children difficult to handle in the first 7 or 8 months. It is most marked when the infant is lying supine, with the neck extended, or when the child is suspended under the armpits. The arms become extended rigidly with internal rotation and fisting of the hands. The mouth may open widely, the legs become extended and stiff, the feet adopt an equinus posture with a spontaneous extension of the big toes and fanning of the other toes. Clonus is not seen. The back arches in extension, even opisthotonos, if the feet come in contact with a firm surface. When the head is turned to the side there is an obligatory asymmetrical neck reflex in the first few months. Attempting to position the child in a sitting position is unsuccessful, as the child remains stiff as a board. When the feet touch the floor, with the child suspended, rapid automatic walking is observed, with a degree of scissoring so that the feet tread on each other. The signs are most marked when the child is agitated, hungry, in discomfort or even at the beginning of feeding. However, when prone, especially when the neck is flexed, the child adopts a flexed posture. If a child has spastic cerebral palsy by this age, which is rare, posture does affect the degree of spasticity but turning the child into a prone position does not abolish spasticity or increased extensor tone.

Dystonia of prematurity, unless severe, resolves, spontaneously leaving no persistent motor signs. While it is present parents appreciate advice on handling and activities by a physiotherapist. In a small proportion of children the dystonia persists and may be a life-long condition. Prediction of outcome at 4–6 months is difficult. An explanation of probable outcome is helpful with physiotherapy advice. In children who turn out to have spastic cerebral palsy, the dystonia merges into spasticity, after a period of mixed rigidity and spasticity in the legs. The dystonia in the neck, trunk, arms and hands resolves leading to a spurt in development, especially hand function. Sitting is late, but is achieved. Spasticity may first be noted at the ankles where clonus can be elicited. It soon becomes evident in the hip adductors and the hamstrings. In some children the spasticity is not demonstrable at rest and is only observed during exertion.

### Spastic quadriplegia

The children with spastic quadriplegia have a high risk of associated learning disability and epilepsy (Fig. 22.27). They may be hypotonic in early infancy but spasticity emerges in the early months of life. There is a continuing need to find suitable positioning and seating. Gastrostomy feeding is often indicated. Standing frames give experience of upright position and promote stronger bone growth. Hydrotherapy is beneficial. Medication for spasticity in cerebral palsy is disappointing. It is rare for baclofen or diazepam to be beneficial in doses which are free of causing unacceptable levels of drowsiness or vomiting. Botulinum toxin, in experienced hands, has a place in prevention of fixed deformities.

### Ataxic cerebral palsy

In infancy, children who develop ataxic cerebral palsy show hypotonia and very delayed motor development (Fig. 22.28). Sitting is long delayed. Truncal ataxia predominates over limb dysmetria. Eventually they may cruise round furniture or walk with support for many months before walking independently. Even then they may be advised to use a walking aid. Hydrotherapy is much enjoyed by ataxic children.

### ATAXIC DIPLEGIA

Children who grow up to demonstrate signs of ataxic diplegia do not go through a dystonic phase. On the contrary, they show very low tone in the trunk and limbs until signs of spasticity evolve, usually distally in

Fig. 22.27 Four limb cerebral palsy.

Fig. 22.28 Ataxic 3-year-old child showing broad-based gait and elevated arms.

their legs. Motor development is markedly delayed, usually more by the ataxia than the spasticity.

### Autosomal recessive diplegia

Children who turn out to have genetic diplegias show normal tone in early infancy but begin to show signs of spasticity distally at about a year. It is important to remember that children who have a symmetrical diplegia or quadriplegia involving dystonia may have a dopa-responsive dystonia, especially where investigations are normal (see section on 'Movement disorders').

**Differential diagnosis.** At first it may be difficult to know whether the tightness at the ankles indicates Duchenne muscular dystrophy, meta-chromatic leukodystrophy or some other progressive disorder. These conditions have to be distinguished from hereditary spastic paraplegias, some of which are autosomal dominant though autosomal recessive forms also occur associated with loci mapping to chromosomes 8 (spg5), 15 (spg11) and 16 (spg7 which encodes for the protein paraplegin, apparently involved in mitochondrial function). In these disorders, which are of unknown pathogenesis, there is a progressive gait disturbance due to lower limb spasticity. They have hyperreflexia in their legs and extensor plantar responses. Ataxia, amyotrophy, neuropathy, extrapyramidal signs or pigmentation may be found also. In the dominant form there is an affected parent. In the recessive form more than one sibling is affected with or without parental consanguinity or there is an isolated patient with parental consanguinity.

### Hemiplegia

Children present in the second half of the first year of life when pincer grasp, individual finger movements, bimanual activities and manipulation of objects are seen to be asymmetrical (Fig. 22.29). At first it may be attributed to the unaffected side being unusually dominant, an inappropriate conclusion so early in life. However it is evident that the affected hand tends to be fistled and there is poverty of movement in this arm and hand. If the child is able to sit unsupported, the lateral guarding reaction when the child is pushed to that side is absent or much less than on the unaffected side. The forward parachute reaction is asymmetrical. Hemiplegic children are a little late to pull to stand, to cruise

Fig. 22.29 Spastic hemiplegia, right-sided – hyperpronated.

around furniture and to walk independently, but not to a marked degree unless there is a comorbid global learning disability. A striking feature is that the child tends to go up on the toes of the affected foot. When walking begins, the heel tends to remain off the ground. As children grow older it is helpful to examine their outdoor shoes when they have been using them for some weeks. It is evident that there is a marked asymmetry with excessive wear at the toe and little or no wear at the heel compared with the unaffected side. As years pass there comes to be a clear asymmetry of growth between the limbs on the affected and unaffected sides, most evident in the hands and feet, in distinction from the symmetrical findings in children with acquired hemiplegia in later childhood.

Children with hemiplegia may have associated sensory loss on the affected side of the body and may also have a partial or complete hemianopia. As they grow older, some develop dyskinetic movements on the affected side. It may also become clear that there are mild signs of spasticity and increased reflexes on the supposedly unaffected side so that the condition is a markedly asymmetrical form of spastic quadriplegia. About a third of hemiplegic children have seizures and these are the first presentation in some of them. A surprising proportion of hemiplegic children have sufficient associated learning difficulties or other disabilities to attend special schools. In Salford, Manchester, in 1988, of 110 children with cerebral palsy, 27 had a hemiplegia of whom 17 attended special schools.<sup>364</sup>

### Dyskinetic/dystonic cerebral palsy

Though pediatric neurologists with a regional practice will have a number of patients with dyskinetic/dystonic cerebral palsy, the condition arises infrequently in any local service, whether as a consequence of acute near-total intrapartum terminal hypoxia–ischemia or as an autosomal recessive disorder (Fig. 22.30). About 1:7000 children is affected. Only one in ten primary care physicians (general practitioners) will ever have such a child born into his or her practice in a working lifetime. Though families may expect their doctors to know about the condition, it is only through close liaison with therapy and specialist neurology services that knowledge and confidence will grow.

In infancy the children seem hypotonic with poor conjugate use of their eyes to follow people or objects. They have impassive facies, do not learn to speak, and have major feeding difficulties. Hand function is of little or no functional benefit. Dystonic posturing may make the child hard to handle. Commonly these children show emotional lability and

Fig. 22.30 A child with dyskinetic cerebral palsy, showing uncontrolled patterns of movement and flaccid trunk, while attempting to reach out.

they are easily distressed but cannot easily demonstrate their intelligence. The involuntary choreiform or athetoid movements do not appear until the second year or subsequently. Parents may be convinced of their child's intelligence yet the standardized developmental assessments of ability yield results suggesting very low function.

As these children grow up they need expert advice on seating, feeding and communication particularly.<sup>365</sup> Saddle seating may be more secure and more suitable than conventional seating. Gastrostomy feeding may be required, at least for a time. There are a number of Advisory Centers for Education around Britain to give advice on aids to communication for personal and educational purposes.<sup>366</sup> Expert advice on physiotherapy,<sup>367,368</sup> hydrotherapy,<sup>369</sup> and other forms of exercise should be sought. Medication may be considered, only to be rejected.<sup>370</sup> It is exceptional for a child to benefit from drug therapy. A conceptual framework for reviewing outcomes in developmental disabilities has been proposed<sup>371</sup> but more research is needed.<sup>372</sup> As school leaving age approaches, there should be a multidisciplinary approach to transition planning and a college with the appropriate expertise should be sought. Expert careers advice is invaluable and suitable recreational opportunities should be investigated. There is justified concern for the decline in adult rehabilitation services over the past 30 years.<sup>373–375</sup>

### Clinical progress

In early childhood the principal parental concern is to promote independent walking in children with diplegia or other forms of cerebral palsy. Facilitating hand function, feeding<sup>376–380</sup> and communication become increasingly important with time. Increasingly sophisticated technical options are available. However promotion of independence, recreation,<sup>380,381</sup> personal and social development is most important as preparation for adult life.<sup>382</sup>

### MULTIDISCIPLINARY TEAMS AND CHILD DEVELOPMENT CENTERS

For parents of children with cerebral palsy, the discovery of the many associated potential problems can be daunting. There may be a multiplicity of appointments with different medical specialists, including dietitians, therapists, specialist nurses, orthoptists, audiometricians,

medical social workers and diverse doctors. Coordination of investigation and treatment is best carried out through a child development team<sup>383</sup> based in a child development center<sup>384,385</sup> as recommended in the Court Report.<sup>386</sup> The nature of such teams and the facilities in these centers differ from place to place,<sup>387</sup> not least because of diversity of services from agencies other than health services. Making the services work in co-operation needs continuous attention as personnel and policies change frequently. These are among the keys to successful provision:

- good coordination of health, education and social services;
- clear lines of communication between primary care and specialist health services;
- shared single set of case notes for hospital and community health services;
- access to necessary expertise including seating, communication aids, orthotics, prosthetics, clinical psychology, dental services, feeding team;
- medical specialist services: vision, hearing, epilepsy service, orthopedics, psychiatry, genetics;
- close links with voluntary organizations;
- parental choice at all times;
- parent-held records;
- children's needs are paramount.

## ASSOCIATED HEALTH PROBLEMS IN CEREBRAL PALSY

*Feeding problems* due to bulbar palsy, handling and seating difficulties, involuntary movements or posture and tone problems are a common first presentation. The children are prone to oral hypersensitivity and to bite on whatever is put in their mouths. Parents can be taught to desensitize the child's mouth before feeds. The reverse may be the case and the child's mouth may need stimulation during feeds. There may be aspiration of food with consequent respiratory symptoms. When this is chronic, the chest develops an increased anteroposterior diameter. Gastroesophageal regurgitation may occur leading to postprandial dyspepsia (heartburn) and vomiting. These symptoms may provoke crying or reflex syncope. Food thickeners and barrier treatment such as Gaviscon can be used as well as an upright position after meals. They may drool saliva. If this is persistent, they may benefit from hyoscine skin patches behind the ear or between the scapulae or from oral glycopyrrolate. Surgery on salivary glands or salivary ducts is not very successful in the long term.

*Gastrostomy* will be considered for those children with an unsafe swallow or whose intake is insufficient for growth, reflected in a markedly delayed bone age. A multidisciplinary team makes the assessment and simpler management strategies will be tried first. Assessment for gastrostomy includes a videofluoroscopy, by an experienced radiologist, with the child's speech and language therapist in attendance. The procedure is seen as mutilating, so parents need careful preparation and support. Subsequent satisfaction is usually good, with less coughing and choking; medication can be given more reliably and feeding time is improved, allowing the parent to spend more time doing other things including play, and with other children.<sup>388</sup> A dietitian will advise on the content of gastrostomy feeds. A common practice is to give a slow overnight infusion of feed by syringe pump, to reduce the volume that has to be given in the day. The cost–benefit of tube feeding has been questioned by Strauss et al<sup>389</sup> who demonstrated an increased mortality risk in tube-fed children (relative risk 2.1, with no increased risk in the most severely disabled children, but a doubled risk in those with less severe disabilities with increased risk of aspiration of vomit), but the lesson may be in the selection process and the appropriate use of fundoplication. There is a need for prospective studies<sup>390</sup> including comparison of the available gastrostomy tubes.

When reflux and vomiting are troublesome and persistent, and this can become more of a problem after gastrostomy, as feeding volume increases, *fundoplication* is considered. This is a major procedure and requires postoperative high dependency backup till breathing is safe.

The procedure – wrapping part of the fundus of the stomach around the lower part of the esophagus – is not an exact science. Sometimes it turns out to be too tight and swallowing becomes difficult, as is burping air. Sometimes it turns out to be too slack and makes little difference. So re-operation may be required. When it works well it makes a great difference to reflux and vomiting. There is, however, a significant risk of complications with gastrostomy and fundoplication.<sup>391,392</sup>

*Constipation* is a risk in all children who are inactive and if this is allowed to persist there is a risk of acquired megacolon, a lot of colicky pain after meals and soiling with overflow. Sometimes constipation can build up when the child is unwell. Pushing frequent fluids is wise.

The mainstays of treatment are:

- adequate, frequent fluid intake including fresh fruit juice especially during fever;
- varied, stimulating diet;
- communicative mealtimes – social occasions not just 'feeding time';
- some pureed fruit and fiber in the diet but not too much as it packs the colon;
- exercise including hydrotherapy;
- relaxed but consistent toileting;
- lactulose as a stool softener morning and evening mixed with a cordial;
- Senokot syrup in the morning.

Prune juice and syrup of figs are effective but are used less than they used to be, probably because children don't like the tastes. There is a range of unstandardized herbal preparations of cascara, frangula, rhubarb, senna, aloes, colocynt and jalap which should be avoided in children because of their unpredictable laxative effects. Osmotic laxatives such as magnesium hydroxide (milk of/cream of magnesia) or magnesium sulfate (Epsom Salts, Andrews Liver Salts) can be used in older children.

Judicious short term use of sodium picosulfate can help clear the bowel but is not appropriate in very young children.

*Incontinence* is persistent for children with severe cerebral palsy. It is also a problem, alongside enuresis, for many less severely affected children for longer than is seen in most children. Toileting routines should be attempted when the child is ready developmentally. Extra consideration is needed for time taken to go to the toilet, transfer from a wheelchair in some, unfastening and fastening clothes, for balancing on the toilet, with help from a rail if needed, and for wiping, which may be difficult. While parents and care staff will help young children, this is not appropriate from the onset of puberty when a toilet that washes, then dries, the youngster's bottom is a more dignified solution. For those who are not capable of a continence program there needs to be a regular supply of nappies of appropriate size.

*Osteopenia*<sup>393</sup> is a risk in immobile children with cerebral palsy, with consequent increased risk of fractures. This is not due to abnormalities of vitamin D or parathyroid hormone.<sup>394</sup> While enabling children to spend part of each day in a standing frame and promoting physical activity, e.g. with hydrotherapy, is likely to promote improved bone density, use of bisphosphonates for 12–18 months has been shown to increase bone density by 20–40%, with no apparent adverse effects.

A third of the children have a *global learning disability*, which may be moderate or severe. It may be thought that this is also true of children with dyskinetic cerebral palsy because there is so little that they can do; their eye movements may be random and communication is extremely difficult. Beware – some of these children are very intelligent but remain 'locked in' until technological means are found to enable them to control speech synthesizers, computers, environmental control systems and other technology. In the past, many such children and adults have languished, completely inappropriately, in provision for people with profound and multiple disabilities. A third of children have patchy or *specific learning difficulty*. The commonest specific difficulties are in language and communication, in visual perception or in mathematical tasks and calculation. There has been little reliable research into the communication difficulties of children with cerebral palsy<sup>394–397</sup> and the subject has been referred to only briefly in standard texts. Yule

and Rutter<sup>395</sup> suggest that this is because few therapists work with children with physical disabilities. There is a substantial risk of hearing impairment in children with cerebral palsy, either from associated sensorineural loss or from secretory otitis media, which is very common in children with eustachian tube dysfunction in bulbar palsy. There has been a good deal of attention to communication before speech and to means of augmented communication (signing and symbol systems, information technology, speech synthesizers for instance) among practitioners. Doctors rely on advice from their speech and language therapy colleagues throughout. It is wise to beware early judgments on the communication potential of children with choreoathetoid (dyskinetic) cerebral palsy. So often they turn out to be much more capable than first thought. Perceptual difficulty may make it difficult for children to tell the time from a conventional clock, to understand maps and diagrams or to find their way about, including difficulty in avoiding obstacles with their wheelchairs.

*Hearing impairment* is very common in children with cerebral palsy, usually from fluctuating loss with secretory otitis media, but sometimes from sensorineural loss, or a combination of the two. Grommets can produce dramatic short term benefits but hearing aids may be the more effective long term solution, combined with expert learning support services.

*Visual impairment* is common in children with cerebral palsy, more than half of whom have visual problems for several reasons.<sup>398</sup> The condition causing the cerebral palsy such as congenital cytomegalovirus, toxoplasmosis or rubella may also have caused a cataract, colobomas or retinal lesions including pigmentary retinopathy. Retinopathy of prematurity is amenable to control by laser therapy or cryotherapy, but skilled ophthalmic examination of preterm infants' eyes has been available in recent years. The eyes may be too small (microphthalmia) or too big (buphthalmos or congenital glaucoma). The child may be shortsighted or longsighted. Cortical visual defects are common.

*Epilepsy* is common in children with cerebral palsy, affecting about a third overall.<sup>399</sup> Hadjipanayis et al<sup>400</sup> reported a prevalence of epilepsy of 41.8% in 323 patients with cerebral palsy in Athens, Greece. However the rate varies between studies, as the type of cerebral palsy in children in each study is different. The risk of epilepsy varies from rare, in pure ataxic cerebral palsy, to very high (up to 94% in some series but 71% would be more typical) in children with spastic quadriplegia and severe learning disability.<sup>400</sup> The prevalence of epilepsy in spastic or ataxic diplegia is 16–27%, but only 3% in encephalopathy of low birth weight (Little disease). In dystonic/dyskinetic cerebral palsy the prevalence is about a quarter and in hemiplegia between 30% and 50%.<sup>400</sup> Diagnosis of the condition is difficult enough in general<sup>401,402</sup> in children. This is more difficult in a child with cerebral palsy, who may have difficulty describing symptoms. It depends on careful observation and history taking while detection of side-effects requires constant vigilance: a child who lost her sitting balance (possible neurodegeneration?) got better when her phenytoin was stopped, another with a cachectic state (possible malignancy?) regained his weight when his carbamazepine was stopped. Vigabatrin may cause visual field defects which are difficult to detect in disabled children though there is a program to attempt to do this. Sodium valproate can lead to considerable weight gain. Always weigh costs versus benefits.

### Psychiatric aspects

The commonest psychiatric reactions to having cerebral palsy are anxiety, depression and/or withdrawal. Other features include attention deficit hyperactivity disorder, tantrums, social naivety, passivity and autistic spectrum disorders which Nordin and Gillberg<sup>403</sup> found in 10.5% of children with cerebral palsy. The implications of the differences in neurobiological findings between children with cerebral palsy and those with learning disability or autism are not understood. Concentrations of neuropeptides and neurotrophins are raised in the blood of newborn infants who subsequently go on to develop severe learning disability and/or autism, but not in children with cerebral palsy.<sup>404</sup> Conversely altered

secretion of androgens is a feature of children with cerebral palsy, but is not a feature of children with autism or learning disability.

### Sleeping difficulties

It is very common for children with cerebral palsy to be difficult to settle at night, or to wake up unduly frequently during the night. For those with four-limb involvement or with severe spasticity in the legs the lack of activity in the day does not leave them tired at night. They may benefit from melatonin, 2 mg half an hour before a bedtime routine. Some require a higher dose of 4 mg.<sup>405</sup> If this does not help, it is worth trying 6 mg daily for a month. Of the other night sedatives, among the most reliable is chloral hydrate elixir. Though it tastes strongly and needs to be mixed with a palatable disguise, it does not suppress dreaming sleep and can be omitted without causing withdrawal symptoms. Some children with cerebral palsy cannot turn in bed and become uncomfortable unless supplied with a sheepskin, a ripple mattress, special cushion or need to be turned in bed on a regular basis. Antihistamine analogs such as alimemazine tartrate (Vallergan) can help on a one-off basis, but they may have a paradoxical effect of exciting the child or provoking seizures.

## TREATMENTS FOR CEREBRAL PALSY

### Treatment of spasticity

Parents and carers may seek treatment for spasticity with expectations that exceed clinical possibilities. The most important starting point is an understanding of the limitations of all forms of treatment, alongside the usually moderate gains that can be made. A spastic diplegic gait will always be recognizable as such but improved function, efficiency and comfort are all worthwhile. A child will be well advised to walk a little, without rushing, in as good a gait as possible, rather than walk as far or as fast as possible. Unrealistic expectations will burden the child, as well as the physician, with a sense of failure.

Dynamic spastic tone can be modified by ankle-foot orthoses, serial casting with progressive dorsiflexion of the ankle, medication or surgical procedures. The balance to be struck is between useful relaxation on the one hand and undesirable weakness or constitutional side-effects on the other. Scoliosis may be contained by wearing bracing or jackets. Children with ataxic or dyskinetic cerebral palsy may feel more secure in Lycra splinting but this has little part to play for spasticity.

Fixed contractures may be released by orthopedic operations, but these must be carefully selected so that the child does not consequently suffer any deterioration in functional level.

The aims for the child are to relieve pain and discomfort, improve function, facilitate care and contain contractures.<sup>406</sup> The authors' approach to therapy is summarized in Table 22.32.

### Oral medication

*Baclofen* acts at the level of the neurones in the spinal cord, enhancing gamma-aminobutyric acid (GABA) activity as a GABA agonist, inhibiting some of the excess excitatory activity responsible for spastic tone. Dosage is built up gradually, according to effect and tolerance, to 2 mg/kg/day. Its effect will be global, rather than targeted, which may produce undesirable hypotonia of truncal muscles, adversely affecting sitting posture, for instance. It is essential that all treatments should be monitored in conjunction with physiotherapy assessments as well as the observations of the carers. This is very important for the child with four-limb spasticity in whom important side-effects may be overlooked, and who is especially susceptible to increasing polypharmacy. When there is doubt about benefit, then a planned withdrawal gradually (so as to avoid rebound spasticity, fits or hallucinations) will usually clarify its role.

Adverse effects on the child's alertness, diminished appetite, nausea or vomiting, and exacerbation of epilepsy should all be looked for. As for any treatment, there should be a general agreement between doctor and carer that only substantial, trouble free gains from treatment can justify its prolonged prescription.

Table 22.32 Schema for the treatment and management of cerebral palsy

Goals <sup>371</sup>	
1. Facilitating care	
2. Improving function	
3. Containing contractures	
4. Relieving pain and discomfort	
Spasticity	
Medication	Baclofen Tizanidine Benzodiazepines, esp. Valium Intramuscular – botulinum toxin
Surgery	Release of contractures, tendo-Achilles, hamstrings, hip adductors Scoliosis – spinal brace (operative fixation rarely?) Hip dislocation – <i>prevention</i> : adductor tenotomy/obturator neurectomy, derotation osteotomy – <i>correction</i> : open reduction, resection of head of femur (Girdlestone procedure) Upper limb – hand surgery? Reasons for (hygiene)
Neurosurgery	Intrathecal baclofen Dorsal rhizotomy
Physical and occupational therapy	Stretching, splinting, seating, standing, walking aids Home and school, aids and adaptations Advice on handling and posture
Pediatrician	Attention to associated conditions that will exacerbate spasticity: pain (e.g. ear infection, pressure area, reflux esophagitis, constipation, upper airways obstruction. Or compound it, as with sleep disorder, seizures, failure to thrive
Athetosis and dyskinetic cerebral palsy	Medication most difficult, consider L-DOPA Valium and possibly oral baclofen for dystonia For children with later acquired disorder consider biotin and pyridoxine Physical/occupational therapy as above (? Lycra suits) Pediatrician as above Orthopedic surgery as above Neurosurgery? stereotactic basal ganglia stimulation
Ataxia	Supportive therapy only – walking frames/Lycra suits?

*Dantrolene* acts on calcium channels, reducing the power of muscle contraction. Relaxation may be at the cost of reduced function. Side-effects also include nausea, vomiting and diarrhea. Hepatotoxicity has been reported.

*Tizanidine* is an  $\alpha_2$ -adrenergic agent, which modifies excitatory transmitter activity. It has not been fully appraised for spastic cerebral palsy, in spite of manufacturers' claims that it may have a better side-effect profile for some patients compared with baclofen.

*Tiagabine* has not been effective in recent experience.<sup>407</sup>

*Diazepam* can be a very effective muscle relaxant, but its use is limited by systemic side-effects of drowsiness. However this is not inevitable, and when spastic tone is distressing, it is worth a trial. It can be very helpful for instance in seeing a child through a painful episode such as a fracture. Rebound spasticity can be severe following a prolonged period in plaster. Baclofen can also give relief at such times. Botulinum toxin (see below) may have a similar role.

## Botulinum toxin

Botulinum toxin A (BTA) is a paralyzing agent derived from *Clostridium botulinum*. It causes muscle relaxation by chemically blocking acetylcholine release, with the loss of motor end plates. Its effect reverses over 3–6 months as affected nerve roots sprout forming new junctions. It is given intramuscularly, usually targeting lower limb muscle groups in spastic diplegic children. These include hip adductors, hamstrings, gastrocnemius and soleus, which all contribute to the classic crouched gait and scissoring typical of this group. Multiple site injections, selected after clinical and video assessment by a multidisciplinary team, are most effective. The team usually comprises at least a dedicated physiotherapist, an orthopedic surgeon and pediatric neurologist.

Three groups of patients may benefit: (i) ambulant children with a dynamic equinus throughout the gait cycle with knee flexion > 20 degrees or scissoring; (ii) children who are losing ability to get to standing or maintain standing; (iii) children of any functional category who are in pain or discomfort around the hip, or where adductor spasm seriously hampers care and hygiene.

The treatment is only effective for dynamic spasticity, especially in the young child, where therapeutic gains are greater and realistic aims to delay surgery beyond 8 years of age likely to be achieved by repeated injections. Toward adolescence many patients experience diminishing returns because of the added problems of growth. It is probably best considered as a possible treatment for windows of time in the child's life.<sup>408</sup> It must always be complemented by continuing physiotherapy and conventional containment of contractures, e.g. with orthoses.

The injections are painful, requiring sedation and local anesthetic cream for most children. Dose guidelines must be carefully followed, since it is a paralyzing agent. Systemic spread from an injection site can cause bladder incontinence, lethargy and laryngeal weakness temporarily in a few children, though in the main side-effects are not common.

## Orthopedic surgery

The consensus in orthopedic intervention is for multilevel surgery delayed until the age of 8–11 years for the release of contractures at tendo-Achilles (TA), hamstrings and hip adductors. The skill is as much in selecting the operation that is right for the child as in performing it. An ill-chosen isolated release of the TAs may bring the foot out of equinus, but put the child into a worsened crouch at the hips and knees, speeding their progression to wheelchair dependence. Hamstring release may weaken hip extension, worsening the crouch position at the hip.

Hip subluxation can be contained by timely release of psoas and adductor muscles. The adducting hip is the one at risk of dislocation, but in the windswept posture the opposite abducting hip can also develop an abduction contracture, hampering seating. Femoral osteotomy can realign the femoral head into the acetabulum, correcting a persisting fetal alignment that lends to dislocation. In more severe cases the acetabulum may be refashioned as well. In extreme cases the femoral head may be resected (the Castle procedure) but sitting balance, if present, is likely to be lost.

Scoliosis is most common in non-ambulant four-limb spasticity. Early attention to seating with scoliosis support inserts is important, as is standing time in a frame, use of bracing or molded jackets. Spinal fixation is a major operation which may be selected for some patients with a curve of > 40 degrees before the age of 15 years. However the general state of health of the child with respect to risks and likely change in quality of life postoperatively have all to be weighed thoughtfully.

## Neurosurgery

Intrathecal baclofen delivered at very low doses through a pump driven by an implanted battery may be very effective for children with four-limb spasticity. The implant is positioned subcutaneously or subfascially in the abdomen or loin. A fine tube leads intrathecally to the mid-to-lower thoracic level, and there is a reservoir of baclofen that is replenished at intervals by injection. Complications include infection and meningitis, CSF leaks and wound infection. The system itself can become displaced or disconnected.

It has been used less hitherto in the UK for ambulant patients than in the USA. However it does have the advantage of an effective preoperative assessment by injecting a test dose at lumbar puncture. The response is measurable in a few hours.

Selective dorsal rhizotomy is a neurosurgical procedure by which selected lower nerve roots in the lumbar sacral distribution are partially deafferented. This reduces spasticity permanently. It is thought to work by reducing the afferent stimulation of alpha motor neurones, which already lack inhibition from the dysfunctional or damaged corticospinal tracts. There can be bladder dysfunction as a complication and significant muscle weakness that impairs function. Functional improvement has not been demonstrated in all studies and therefore it is a form of treatment that is still being assessed.

## DISCLOSURE OF DIAGNOSIS OF CEREBRAL PALSY

As soon as it becomes clear that the child is developing signs of spastic diplegia or any other form of cerebral palsy, arrangements should be made for a senior doctor to discuss the findings with the parents. Guidelines on good practice have been published by the UK-based charity Scope<sup>409</sup> based on the recommendations of Cunningham et al<sup>410</sup> in relation to infants with Down syndrome, which is a life-long condition, diagnosable at birth. The reason for including this in the section on spastic diplegia is that there are many reasons for clinical uncertainty on the way to making this diagnosis. Yet there comes a time when it is possible to be reasonably confident. It is a way of describing how a child functions at present. In future it is possible for some children to grow out of this condition or other forms of cerebral palsy<sup>411</sup> so this, and other uncertainties, will be part of the discussion with parents. Important points are as follows:

- planned appointment as soon as feasible after diagnosis made;
- both parents present;
- with a relative, friend or professional (nurse, social worker, therapist) if parents wish;
- senior doctor with wide experience of developmental disabilities;
- trainee present if parents agree;
- quiet, comfortable room, free of interruption or disturbance;
- as much time available for discussion as parents find helpful;
- a full account of the condition and possible associated problems;
- details of further investigations or assessments;
- explanation of treatment plans and timetable;
- permission to notify the local education authority that the child may have special educational needs;
- information about help available from the social services department;
- details of local and national voluntary organizations who can help (photocopy the relevant pages of the Contact a Family Directory);
- write in the parent-held child health record;
- let parents have a copy of the clinic letter to the general practitioner;
- offer a home follow-up visit by a colleague to help the parents understand what they have been told;
- arrange a follow-up clinic visit and encourage parents to make a list of questions;
- assure parents of your willingness and that of your colleagues to help their child to find what he/she can do best and to make the most of that at each stage through childhood and adolescence;
- at all times show willingness to seek a second opinion.

## LIFE EXPECTANCY

The life expectancy of children and adults with cerebral palsy is reduced but this is explained, almost entirely, by those with four-limb involvement lacking independent movement and self-care abilities. Strauss and Shavelle<sup>412</sup> reported findings on 24 768 individuals aged 15 or over and receiving services in California between January 1980 and December 1995. This work was extended, in a study period from 1986 to 1995, to a Californian population of 45 292 individuals of all ages with cerebral

palsy.<sup>413</sup> Detection of other conditions was poorer in people with cerebral palsy, so that mortality from breast cancer was three times that of the general population. The risk of brain tumors was raised dramatically, especially in children (standardized mortality ratio = 24) indicating an increased risk in those diagnosed as having cerebral palsy. There was a range of life expectancy of over 40 years in the adult study, according to the functional level. Some with the least independent function had a life expectancy of only 11 years. Similar findings have been reported in North East and South East Thames Regions in Britain,<sup>414-416</sup> in British Columbia, Canada,<sup>417</sup> and in Western Australia.<sup>418</sup>

In South East Thames, 79% of children with severe learning disability and cerebral palsy survived to a mean age of 16 years. This is higher than in an earlier study in Rochester, Minnesota over the period 1950-1976.<sup>419</sup> In the Australian study, half the children with profound and multiple learning disability with cerebral palsy (DQ < 20) lived to adult life. Of those with a DQ of 20-34, 76% survived to adult life, while 92% of those with higher ability did so. Those who reached 25 years had good subsequent life expectancy. There was no evidence in this study that advances in medical care and improvement in community awareness had improved the survival of people with cerebral palsy. It is premature to judge the impact on life expectancy of gastrostomy feeding, food supplements and the involvement of speech and language therapists, dietitians and others in feeding teams, tracheostomies for those prone to respiratory failure and the contemporary range of antiepileptic drugs. There is evidence of improved quality of life but, as yet, not of significant change in length of life. Comparison between the survival data from Western Australia and California was made by examination of both databases by Shavelle et al<sup>420</sup> and the differences were found to be slight if severity of learning disability was controlled for. The apparent disparity in survival was not due to differences in care, but because the Australian population included a higher proportion of mildly affected people and a lower proportion of people with severe or profound learning disability. This is the first published controlled comparison of survival in cerebral palsy between countries.

The interaction between cerebral palsy and learning disability in life expectancy has been reported to be an increasing problem (from 0.7 to about 0.9/1000 live births over the decade studied by Nicholson and Alberman<sup>421</sup>). Learning disability is, in itself, a risk factor for early death, especially from respiratory disease, which is three times commoner than in the general population.<sup>422</sup> Whereas 83% of the whole population live to be 65 years old or more, fewer than 50% of 2000 with an IQ < 70 and known to services in two London districts did so in this 8-year study. The risk of death before 50 was 58 times higher than in the population of England and Wales. Early death was associated with cerebral palsy, incontinence, problems of mobility and residence in hospital. Nonetheless, for children and adolescents with cerebral palsy and learning disability we must plan for their survival into adult life and advocate their case for transition into suitable health services when they leave pediatric care. More recently Hutton and Pharoah<sup>423</sup> reported a new finding that severe visual disability and lack of information on hearing (probably as a surrogate for severe impairment) had a significant association with reduced survival.

## QUALITY OF LIFE AND COSTS OF CARING

In a review of 1365 published measures of quality of life only 5% were found to be applicable to children.<sup>424</sup> There are few published data on the views of children with disabilities on their quality of life and none of children with cerebral palsy and/or learning disability. Quality of life assessments of and by children with epilepsy have been reported.<sup>425</sup> Sociometric study of fifty-five 9- to 11-year-old children with hemiplegia in 54 mainstream schools has demonstrated increased risk of peer rejection, lack of friends and victimization.<sup>426</sup> As increasing inclusiveness is promoted for children with disabilities in mainstream schools there is a need to make provision for their social as well as physical and academic development. Fostering the social skills of children with disabilities may reduce the risk of social disadvantage.

The views of children with attention deficit hyperactive disorder (ADHD) concerning behavior disturbance, social competence and familial environment have been found to differ from those of their parents.<sup>427</sup> Children perceived themselves as equally competent and socially accepted as their peers, in contrast to their parents' ratings. Though parenting a preschool child with ADHD was found to be stressful it was not considered by parents or children to affect family functioning adversely. Parents of children with physical and/or learning disabilities have reported lower quality of life in all family members compared with parents of children without disabilities.<sup>428,429</sup> The substantial impact of severe disablement in a child on parental careers, family income and expenditure patterns has been demonstrated clearly in a study of nearly 500 children with disabilities and nearly 700 controls.<sup>430</sup> In that study, 67% of mothers of children with disabilities were unable to enter or keep paid employment after the birth of their child compared with 60–69% of mothers of children without disabilities who are able to do this.<sup>431–433</sup> In a study of time costs of caring for 16 children with severe disabilities, including cerebral palsy, compared with 31 children without disabilities, it was found that personal care time was significantly greater per waking hour throughout the day for the former.<sup>434</sup> Twelve of the 16 mothers of children with disabilities were not in paid employment. Twelve had little or no extended family support. Care needs did not decline with increasing age, preventing mothers working outside the home outwith school hours. (The same would be true of fathers when, as is now increasingly common, they act as main carers.) This is the only published study of time costs of caring for a child with a disability carried out entirely in the family home. Two previous studies were based on observation of institutional care<sup>435,436</sup> while that of Edebol-Tysk<sup>437</sup> was a study partly in an institution and partly at home.

Most parents do not regret the changed way of life consequent upon having a child with a disability but some find it a struggle. In a study of 110 children with cerebral palsy in Salford<sup>364</sup> 39% of the children attended mainstream schools. Of those attending special schools 22% had attended mainstream schools but the placement had broken down. Thirty-nine percent of those now in mainstream had been in a special school or nursery in the past. Of the children attending mainstream schools 88% were community ambulant compared with 17% in special schools. Two of the mainstream children were partially sighted compared with 11 who were partially sighted and 11 who were blind in special schools. Of the mainstream children 95% could feed themselves compared with 36% in special schools. Only 5% of those in mainstream school had current epilepsy compared with 52% of those in special schools. No mainstream child was bowel or bladder incontinent though help was needed for 17%/9% of the children for these functions. Fifty-three percent of the special school children were incontinent and an additional 18%/12% needed help for bladder or bowel function. Thus the children in special schools had more severe and complex disabilities than the mainstream children. Of the mainstream children 11% had a single parent compared with 35% of the special school children. Fifteen (14%) of these 110 children with cerebral palsy were on or had been on the child protection register compared with 1:500 in Salford children in general at that time. Four percent of mainstream children and 18% of special school children were in residential or foster care and two children had been adopted. In addition a further child had suffered a skull fracture, one had sustained extensive scalds in the bath, one had hypoxia–ischemiated as a result of having a large screw in his mouth and another had a sibling on the child protection register.

Knowing of the pressures experienced by families of children with disabilities should prompt services to go out of their way to be helpful, to be pre-emptive and to minimize the risks of dysfunction.<sup>438</sup>

## MEDICOLEGAL ASPECTS

Despite immense changes in obstetric and pediatric practice since William Little<sup>439</sup> ascribed cerebral palsy to perinatal causes, and a major decline in neonatal death rate, the incidence of these disorders has remained relatively unchanged in resource rich countries at about

2:1000 children for the last 40 years.<sup>440–442</sup> The incidence in resource limited countries has been reported to more than twice this.<sup>443</sup>

The widespread lay belief that cerebral palsy is likely to be the consequence of brain damage (intrapartum hypoxia–ischemia) during birth has led to extensive litigation. Yet intrapartum causes only account for a small minority (about 10%),<sup>444,445</sup> and most affected children have suffered an unforeseen disaster rather than lack of care.<sup>446</sup> In an Oxford study comparing the relationship between quality of intrapartum care for 34 children with cerebral palsy compared with 377 controls,<sup>447</sup> only 2.9% of the cerebral palsy cases were considered to have experienced suboptimal care in labor compared with 14.5% of controls. None of the cerebral palsy cases had received suboptimal quality of care in response to fetal distress compared with 1.4% of controls. A change in practice toward no-fault compensation and a care package for children with cerebral palsy has been proposed. This would have the advantage of relative speed and would obviate the need to prove negligence in a protracted medicolegal process.

Diagnosis of cerebral palsy in early childhood is difficult<sup>448</sup> and often changes with time. Children may go through periods of transient motor abnormalities and may outgrow cerebral palsy in the same way as the motor signs abate after head injuries and acquired brain diseases.<sup>449</sup> Other conditions may resemble cerebral palsy.<sup>449</sup> Brain magnetic resonance imaging is helpful in distinguishing genetic-metabolic from acquired causes of extrapyramidal cerebral palsy.<sup>450–453</sup> In a very large American cohort most children considered to have definite cerebral palsy at 1 year had outgrown it by 7 years and very few of those considered to have probable or possible cerebral palsy had abnormal motor signs by this age.<sup>411</sup> In a study conducted in 1975 of children considered to show symptomatic hypoxia–ischemia only a quarter showed continuing motor signs in later childhood,<sup>454</sup> though there was an excess of children with learning difficulties.

Infants withstand 10 minutes of total intrapartum hypoxia–ischemia without long term consequences, but are very unlikely to survive more than 20 minutes of this. Of those who have suffered an intervening period of total hypoxia–ischemia, the effects are variable. The typical outcome is one of dyskinetic cerebral palsy, with or without seizures but with relative intellectual sparing or normal intelligence. MRI scans show lesions in the basal ganglia and/or thalamus in most affected children.<sup>455</sup> Only with very prolonged subtotal intrapartum hypoxia–ischemia is it likely that a child will suffer major learning difficulties<sup>456,457</sup> and only in association with severe cerebral palsy (as with sensorineural hearing loss). Children with known biomedical causes of learning disability can have low Apgar scores at birth without any hypoxia–ischemia.<sup>458</sup> The combination of low tone and severe learning disability in a child of school age is likely to be the result of a constitutional disorder, not acquired intrapartum damage.

In court, much may be made of cardiocotographic abnormalities but this is an unsatisfactory technique for preventing symptomatic hypoxia–ischemia.<sup>459,460</sup> The practice, during the last 40 years, of widespread continuous fetal heart monitoring has led to increased cesarean section rates, with associated maternal morbidity and mortality and no significant effect on perinatal morbidity or mortality,<sup>461,462</sup> though conflicting opinions have been expressed.<sup>463</sup> It has been of minimal benefit for low risk patients and its use in high risk patients has yet to be subjected to adequate evaluation. In the current medicolegal climate perhaps it never will be. If midwifery staffing is adequate, as it should be, intermittent fetal heart recording by Pinard stethoscope or hand-held ultrasound monitors is competent practice. This would not detect total hypoxia–ischemia due to placental separation during the second stage in a breech delivery but cesarean section is not an option in such circumstances and attempts at heroic emergency vaginal deliveries are likely to cause more harm than good. When staffing is inadequate there is a temptation to use cardiocotography as an electronic babysitter.

The greater number of premature infants who survive with cerebral palsy reflects a greater survival of such infants, most of whom survive in a healthy condition,<sup>464</sup> rather than an increased risk of cerebral palsy for such children. This justifies the enthusiasm for high quality neonatal

care for premature infants. The changes in causes of cerebral palsy indicate a shift from the consequences of traumatic delivery of term infants many years ago to the higher proportion of very low birth weight survivors who would have died in time past. Overall the prevalence of cerebral palsy remains little changed.

The contribution of survivors of <1500g birth weight largely accounts for the proportion of children with cerebral palsy who have acquired it postnatally increasing to 18% in the Mersey region between 1966 and 1977.<sup>465</sup> The expected proportion is about 10%.<sup>466,467</sup> In three series from New York, Chicago and Western Australia quoted by Stanley et al,<sup>468</sup> CNS infection accounted for over 60% of 856 cases of postnatal cerebral palsy. It is hoped that the introduction of immunization against measles, mumps, rubella, *Hemophilus influenzae*, pneumococcus and meningococcus C has reduced the ongoing risk of postnatal cerebral palsy. Other causes include accidental and non-accidental head injury, anoxia and cerebrovascular accidents.

## TRANSITION TO ADULT SERVICES

As school leaving age approaches, there should be a multidisciplinary approach to transition planning and a college with the appropriate expertise should be sought.<sup>469</sup> Expert careers advice is invaluable and suitable recreational opportunities should be investigated. An adult specialist resource should be sought as a source of advice in future. Such services have been difficult to find in many places. Many adults with cerebral palsy and other disabling conditions are either not in touch with social services or specialist medical advice or are dissatisfied with the services received.<sup>470</sup> There is justified concern for the decline in adult rehabilitation services over the past 30 years<sup>373</sup> and the lack of coherent and sustained funding for academic rehabilitation research.<sup>374</sup>

## DEGENERATIVE BRAIN DISORDERS

### INTRODUCTION

The neurodegenerative disorders of childhood are a heterogeneous group of diseases that result in the progressive deterioration of neurological function with loss of speech, vision, hearing, locomotion, bulbar functions and cognitive abilities. They are often associated with seizures. They are rare with a prevalence of 0.6/1000 live births. Many are caused by specific genetic and/or biochemical defects but they can also be caused by infections and toxins with the cause of some remaining unknown.

They are important because:

1. Some of them are treatable and the earlier treatment is started the better the outcome.
2. Knowing and understanding the condition helps to predict and to plan the multidisciplinary management and ultimate terminal care needs.
3. Most have specific genetic implications with possible antenatal diagnosis.

### CLINICAL APPROACH

#### History

A history of loss of skills helps distinguish the neurodegenerative from static, nonprogressive conditions. Usually, initial development is either normal or slightly delayed. Development then plateaus over a period of time with no acquisition of new skills followed by loss of previously acquired skills. The onset may be insidious but is sometimes acute sometimes in association with viral infections. Both may cause diagnostic difficulty. Regression may progress steadily at varying speeds or else spasmodically, with periods of progression followed by a plateauing of abilities prior to the next period of deterioration. Again, periods of deterioration may be triggered by intercurrent viral infections. Sometimes the presentation is with behavioral or psychiatric disturbances, or educational

difficulties. Neurodegenerative conditions in early childhood often present with or include myoclonic or polymorphous seizures so that an epileptic encephalopathy, such as the Lennox–Gastaut syndrome may be suspected (see p. 858).

### White or gray matter involvement

Some neurodegenerative conditions are localized to white or gray matter or may involve both. White matter involvement is characteristically associated with upper motor neurone signs, episodic hypertonia and difficulties in mobility. Gray matter involvement is particularly associated with intellectual and visual impairment and seizures.

### Systemic involvement

The involvement of other organs is common. Physical examination should include a search for organomegaly and skeletal deformity. The retina should be examined carefully for pigmentation which might, for example, suggest a peroxisomal disorder or a mitochondrial cytopathy and for cherry-red spots due to abnormal perimacular deposition of storage material seen in a number of lysosomal storage disorders.

### Family history

This, especially a history of consanguinity, may be important as most of these conditions, especially the neurometabolic, are autosomal recessive.

### AGE-RELATED PRESENTATIONS

Neurodegenerative disorders (ND) can present at any age with obvious loss of skills, plateauing or delayed development with or without clinical clues.

#### Infancy (see also Table 22.33)

A loss of motor skills may not be appreciated in infancy. Regression at this age often presents with a loss of interest which may be visual or in nonverbal communication.<sup>471</sup> Hypothyroidism, the aminoacidopathies, and metabolic (organic) acidosis are the main conditions associated with regression without obvious clinical clues. Nonketotic hyperglycinemia and Menke syndrome with its characteristic twisted hair (see Ch. 26, p. 1124) often present with seizures. In this age group, irritability with extensor hypertonus can be a prominent presenting features of some conditions and may or may not be associated with organomegaly.

Table 22.33 Regression in infancy

<b>With no obvious clue:</b>
Hypothyroidism
Aminoacidopathies
Metabolic (organic) acidosis
<b>With seizures:</b>
Menke kinky syndrome
Nonketotic hyperglycinemia
Glucose transporter protein (Glut 1) deficiency
Serine biosynthesis disorders
Biotinidase deficiency
Carbohydrate deficient glycoprotein (CDG) syndromes
<b>With irritability:</b>
Krabbe
Infantile Gaucher
Tay–Sachs
Niemann–Pick
Glutaric aciduria type 1
Pelizaeus–Merzbacher
Infantile ceroid – lipofuscinosis (CLN 1)

### The toddler age group (see also Table 22.34)

In the toddler, changes are seen in speech and behavior combined with motor difficulties.<sup>471</sup> In some conditions, there are specific, but often subtle features suggesting a specific diagnosis. For example, in Sanfilippo disease there are often soft dysmorphic features and a spleen may be palpable. In Moya Moya disease dementia and regression occur and HIV encephalopathy is usually characterized by failure to thrive with brain atrophy being prominent on neuroimaging. In others, specific neurological signs at presentation may suggest the diagnosis: peripheral neuropathy with ataxia and bulbar signs suggests metachromatic leukodystrophy; ataxia with ocular apraxia and conjunctival capillary dilation suggests ataxia telangiectasia; progressive cerebellar ataxia with mild dementia suggests juvenile Sandhoff disease; impairment of eye movement control and respiration with ataxia is characteristic of Leigh disease; and splenomegaly with a vertical gaze palsy suggests Niemann–Pick disease type C. The clinical manifestations of some conditions with autistic features such as Rett syndrome and a number of psychoses also start in this age group. Again, epilepsy can be the presenting feature.

### The school-age child (see also Table 22.35)

In the school-age child regression is often manifested with a decline in school performance, including concentration and pencil skills. New learning is hindered because of poor memory and coordination is impaired.<sup>471</sup> A wide range of conditions can include epilepsy in this age group, although this is rarely the presenting problem (Table 22.35).

Table 22.34 Regression in toddlers

#### With neurological signs:

Metachromatic leukodystrophy  
Juvenile Sandhoff  
Ataxia telangiectasia  
Leigh disease  
Niemann–Pick type C

#### With autistic features:

Rett syndrome  
Infantile Batten disease  
Missed phenylketonuria  
Biotinidase deficiency  
Carbohydrate deficient glycoprotein (CDG) syndromes

#### With seizures:

Late infantile Batten disease (CLN 2)  
Alper disease

Table 22.35 Regression in school age

#### With seizures as a prominent feature:

Juvenile Batten disease (CLN 3) (although seizures only prominent in later stages)  
Lafora body disease  
Sialidosis type 1  
Myoclonic epilepsy with ragged red fibers  
Juvenile Gaucher disease  
Juvenile GM2 gangliosidosis

#### With seizures not a prominent feature:

Juvenile metachromatic leukodystrophy  
Adrenoleukodystrophy  
Subacute sclerosing panencephalitis  
Wilson disease  
Juvenile Huntington disease  
Hallervorden–Spatz disease

## CLASSIFICATION OF DEGENERATIVE BRAIN DISEASES

The neurodegenerative disorders can be classified in many different ways. One is shown below:

- lysosomal storage disease;
- sphingolipidoses e.g. GMI -, GM2-gangliosidosis, Krabbe disease, metachromic leucodystrophy, etc.;
- glycoproteinoses, e.g. mannosidosis, fucosidosis etc.;
- mucopolysaccharidoses;
- mucopolipidoses;
- peroxisomal disorders, e.g. adrenoleukodystrophy;
- organic acidurias, e.g. Canavan disease;
- trace metal metabolism e.g. Wilson disease and Menke syndrome;
- neuronal ceroid lipofuscinoses;
- spinocerebellar degeneration, e.g. Friedreich ataxia, abetalipoproteinemia, olivopontocerebellar atrophy, ataxia telangiectasia etc.;
- basal ganglia degeneration, e.g. Hallervorden–Spatz disease and dystonia musculorum deformans;
- infections, e.g. subacute sclerosing panencephalitis, progressive multifocal leuco-encephalopathy, prion disease;
- miscellaneous, e.g. Pelizaeus–Merzbacher and Alexander disease.

## SPECIFIC NEURODEGENERATIVE CONDITIONS

Detailed descriptions of all the neurodegenerative disorders for which there is a known biochemical defect are given in the chapter on metabolic disorders. There remain some conditions in which the presumed biochemical defect is unknown or the cause is due to some other mechanism, such as infection. These disorders will be considered here.

### Rett syndrome

Rett syndrome (RS) was first described in 22 girls who, after normal development for 6 months, deteriorated in a devastating fashion. It affects females almost exclusively. Incidence figures vary widely but it probably affects about 1 in 10 000 females and possibly 1 in 100 000 males. Most cases (99.5%) are due to spontaneous mutations.

The diagnostic criteria for classic Rett syndrome are:<sup>472</sup>

- apparently normal prenatal and perinatal period;
- apparently normal development through at least the first 5–6 months of life;
- normal head circumference at birth;
- deceleration of the head growth (aged 3 months to 3 years);
- loss of acquired skills (aged 3 months to 3 years), including learned purposeful hand skills, acquired babble and/or learned words, and communicative abilities;
- appearance of obvious mental deficiency;
- appearance successively of intense hand stereotypies, including hand wringing and/or squeezing, hand washing and/or patting and/or rubbing, and hand mouthing and/or tongue pulling;
- gait abnormality among the ambulant girls, including gait apraxia and/or dyspraxia and jerky truncal ataxia and/or body dyspraxia;
- diagnosis tentative until the individual is aged 2–5 years.

The muscle tone is variable. Initially patients with RS patients are hypotonic. With progression of the disease spasticity and wasting develops. Some become wheelchair bound after 10 years, but they retain some functional ability and 60% of patients with RS continue to walk.

Other problems include breath holding and apnoea during wakefulness with normal breathing during sleep, epilepsy, oral-motor dysfunction with gut motility problems (e.g. constipation, gastroesophageal reflux [GER]), scoliosis, autonomic dysfunction (cold blue extremities), and somatic growth failure). During the regression period, individuals with RS demonstrate screaming episodes, sleep disturbances and poor social interactions.

Atypical cases with Rett syndrome (Rett syndrome variant) can be difficult to diagnose. The following criteria help:

- loss (partial or subtotal) of acquired fine finger skills in late infancy and/or early childhood;

- loss of acquired single words and/or phrases and/or nuanced babble;
- RS hand stereotypies, hands together or apart;
- early deviant communicative ability;
- deceleration of head growth of 2 standard deviations (2 sd), even when still within normal limits.

Currently, diagnosis of RS is made if the patient meets defined clinical criteria. The diagnosis is supported by a positive mutational analysis of MECP2. However, as many as 20% of females meeting the full clinical criteria for RS may have no identified mutation.<sup>473</sup> Mutations on the MECP2 gene are present in 85% of cases. Males with mutations on this gene show a spectrum of symptomatology, ranging from severe congenital encephalopathy, dystonia apraxia and retardation to psychiatric illness with mild mental retardation.<sup>474</sup>

Because no cure exists, treatment is palliative and supportive. A multidisciplinary approach to care for persons with RS is recommended.

### The leukodystrophies

The leukodystrophies are disorders of cerebral white matter, either alone or combined with other CNS or peripheral nervous system problems. Many have known metabolic defects and are described in more detail in Chapter 28. There remain a few specific leukodystrophies not due to known metabolic defects and other unclassified leukodystrophies.

#### *Pelizaes–Merzbacher disease*

This is usually an X-linked white matter myelination disorder. A mutation in the PLP gene is present in about 75% of cases. The clinical severity of PMD varies widely, primarily depending upon the precise nature of the causative mutation and probably, to a certain extent, upon other genetic and environmental influences.<sup>475</sup>

The presentation of classic PMD is of *infantile-onset* (typically within the first 2 months of life) nystagmus, titubation and weakness. Ataxia, cognitive delay, and spasticity then follow. Most children never walk. Most do acquire some degree of language skills, which may approach normal levels, but the speed of expressive language is usually slow giving impression of more severe degree of mental retardation than is present. These patients may survive to the sixth decade of life or longer.

More severely affected patients, those with the so-called *connatal PMD*, have nystagmus present from birth or at least in the first week or two of life, often have stridor and respiratory difficulty and hypotonia, and may even have seizures. These patients typically have limited language skills, never ambulate, and develop severe spasticity with little voluntary movement. These individuals usually die before the third decade of life.

Individuals with the least severe form of PMD, which merges with SPG2, present with childhood-onset spastic paraplegia, mild cognitive impairment, ataxia and athetosis. Survival to the sixth decade of life or later is characteristic. Typically, neurological signs progress but at a gradual rate with reported periods of relative stability. Generally, those who learn to walk begin to lose ambulatory abilities during adolescence.

PMD typically affects males, but female heterozygotes can be clinically affected, especially those who carry alleles that are relatively mild. As the defective oligodendrocytes die and are replaced by healthy oligodendrocytes in heterozygous females, neurological function improves. Females heterozygous for the less severe alleles of PLP1 that are not believed to cause oligodendrocyte cell death or apoptosis may develop a more progressive and nonremitting syndrome that usually begins during adulthood.

Some females with PMD (such as the original PMD family) probably have a clinical course much like that of affected males, in which the symptoms do not remit and may be the result of skewed X inactivation, i.e. the majority of oligodendrocytes have inactivated the normal X chromosome and insufficient healthy oligodendrocytes are available to myelinate the CNS effectively.<sup>475</sup>

#### *Leukoencephalopathy with vanishing white matter disease*

This is a group of autosomal recessive conditions with extensive MRI changes restricted to white matter. They may present with progressive spasticity and ataxia but often show step-wise progression following infections and minor head traumas, with a sudden onset of symptoms, followed by a period of stability and then further deterioration. van der Knapp et al<sup>476</sup> described families with MRI scan changes restricted to the white matter with cavitations in the frontal and/or temporal lobes. Affected patients had a relatively mild clinical course presenting with late spasticity, cerebellar signs and macrocephaly. A more rapid course with progressive diplegia and ataxia was reported in three siblings without cystic changes.<sup>477</sup> Yet other cases have been reported with onset in infancy or early childhood who have shown progressive ataxia and spasticity with exacerbations with infections and mild head trauma.<sup>478</sup>

VWM is caused by mutations in one of the five genes that are collectively called eIF2B, or eukaryotic initiation factor 2B. Changes in these genes reduce the function of eIF2B. This reduction in function becomes a particular problem during episodes of fever, infection or head traumas, and deterioration accelerates following such episodes.<sup>479</sup>

#### *Alexander disease*

Alexander disease is a rare disorder of the nervous system. It is considered one of the leukodystrophies. Most cases begin before age 2 years (the infantile form). Signs and symptoms of the infantile form typically include an enlarged brain and head (megalencephaly), seizures, stiffness in the arms and/or legs (spasticity), mental retardation and delayed physical development. Less frequently, onset occurs later in childhood (the juvenile form) or adulthood. Common problems in juvenile and adult forms of Alexander disease include speech abnormalities, swallowing difficulties and poor coordination (ataxia).

Alexander disease is characterized by abnormal protein deposits known as Rosenthal fibers, which are found in astroglial cells which support and nourish nerve cells in the brain and spinal cord. Mutations in the GFAP gene cause Alexander disease. This gene provides instructions for making a protein called glial fibrillary acidic protein. As a result, glial fibrillary acidic protein accumulates as a component of Rosenthal fibers and interferes with the normal activities of astroglial cells. It is not well understood how impaired astroglial cells contribute to the abnormal formation or maintenance of myelin.<sup>480</sup>

Alexander disease is considered an autosomal dominant disorder. However almost all cases result from new mutations. In some rare adult cases, a GFAP mutation may be passed to children of an affected parent.<sup>481</sup>

#### *Cockayne syndrome*

Cockayne syndrome (CS) includes the classic form (CKN1) and a more severe form with symptoms present at birth (CKN2). These are also termed CS types A and B, respectively. Patients present with delayed psychomotor development, poor feeding, photosensitive rashes and cataracts. All patients with CKN1 have mental retardation, and growth failure, which includes progressive microcephaly in most patients in the first year. Ambulant patients present with an unusual gait resulting from leg spasticity, ataxia, and contractures of the hips, knees and ankles. Muscle tone and reflexes are increased or decreased. Most patients have photodermatitis that leads to dry scaly skin. Patients develop an aged appearance. Pigmentary degeneration of the retina is one hallmark of this disorder, with cataracts and optic atrophy or optic disc pallor as frequent findings. These ophthalmologic changes are progressive. More than one half of patients with CKN1 have mild to severe sensorineural hearing loss. Many patients have moderate to severe dental caries; permanent teeth have short roots.

CKN1 is caused by a defect in the Cockayne syndrome type A gene (CSA or ERCC8) located on chromosome 5. Affected persons inherit two mutant genes, one from each parent. Cells carrying ERCC8 mutations are hypersensitive to UV light. They do not recover the ability to synthesize ribonucleic acid (RNA) after exposure to UV light. In addition, the cells cannot remove and degrade deoxyribonucleic acid (DNA) lesions from strands that have active transcription.<sup>482</sup>

### **Aicardi–Goutières syndrome**

Aicardi–Goutières syndrome is an autosomal recessive mimic of congenital infection presenting either in the immediate neonatal period with microcephaly, thrombocytopenia, anemia, deranged liver function, hepatosplenomegaly and seizures or within a few weeks or months of life with irritability, feeding difficulties, seizures and a loss of skills. Affected infants develop a spastic quadraparesis with dystonia and usually demonstrate severe psychomotor retardation. Periventricular or basal ganglia calcification is often present on CT and a fronto-temporal leukodystrophy with cystic formation is observed on MRI. Raised numbers of white cells are usually, but not always, present in the CSF and CSF interferon alpha, bipterin and neopterin levels are elevated. Distinctive ‘chilblain-like’ lesions can occur on the hands and feet. The disease results from mutations in any of four genes and molecular testing is available as a first-line investigation. The diagnosis should be considered in any child with features of congenital infection in the absence of corroborating serological data.<sup>483</sup>

### **Canavan disease**

Canavan disease (CD) is a relatively rare, but always fatal, inherited, leukodystrophy. Presentation is in early infancy with variable symptoms; rapidly increasing head circumference, lack of head control, reduced visual responsiveness and abnormal muscle tone such as stiffness or floppiness. Children with Canavan disease cannot crawl, walk, sit or talk. Over time they may suffer seizures, become paralyzed, mentally retarded or blind and have trouble swallowing. Although hearing usually remains a functioning sense, deafness may also result. Most children do not live past age 10.

Canavan disease, like the more well-known Tay–Sachs disease, is one of a number of genetic disorders which affect Ashkenazi Jews at high frequency.

Canavan disease is autosomally recessive inherited. It can be diagnosed antenatally by blood test that screens for the missing enzyme or for mutations in the gene that controls aspartoacylase. The ASPA gene is located on the short (p) arm of chromosome 17 between the end (terminus) of the arm and position 13.<sup>484</sup>

### **Progressive neuronal degeneration of childhood (PNDC, infantile poliodystrophy or Alper disease)**

This term encompasses a group of diseases characterized by presentation in infancy or early childhood with neuronal degeneration with or without liver failure. The clinical picture is with hypotonia, fail to thrive, developmental delay, seizures and hepatic derangement. Epilepsia partialis continua is common, as are episodes of status epilepticus and often late hepatic failure develops with rapid progression to death. Sodium valproate can precipitate hepatic failure and some cases of ‘valproate hepatotoxicity’ in young children may have been PNDC.

The condition can be familial, usually autosomal recessive or sporadic. It has been associated with deficiencies of pyruvate carboxylase, pyruvate dehydrogenase and respiratory chain abnormalities. Many cases appear to be associated with mutations of the POLG1 gene which is a nuclear gene encoding the catalytic subunit of mitochondrial DNA polymerase. POLG1 is a major disease gene in mitochondrial disorders. Mutations of it can be associated with multiple deletions, depletion or point mutations of mitochondrial DNA (mtDNA). In turn, these different molecular phenotypes lead to an extremely heterogeneous spectrum of clinical outcomes, ranging from rapidly fatal hepatocerebral presentations, including Alper syndrome to adult-onset progressive ophthalmoplegia to juvenile ataxic syndromes with epilepsy.

### **Pantothenate kinase-associated neurodegeneration; Hallervorden–Spatz disease**

This is a progressive neurodegenerative condition with characteristic accumulation of iron in the basal ganglia. The onset is in the first two decades of life with progressive dystonia, rigidity, choreoathetosis and cognitive deterioration. Other variable features are retinitis pigmentosa, optic atrophy, sensorineural deafness and acanthocytosis. Epilepsy is not

prominent. The rate of progression is very variable and misdiagnosis as cerebral palsy is common. Neuro-imaging (MRI) demonstrate the characteristic basal ganglia ‘tiger eye’ sign. Many patients have detectable mutations in PANK2, the gene encoding pantothenate kinase 2.<sup>485</sup> Iron chelation has not proven useful.

### **Spinocerebellar and peripheral nerve degenerations**

These are primary neuronal degenerations, without metabolic markers. Their common features are their selective nature affecting one or only a few parts of the central or peripheral nervous system, their progressive nature though not necessarily fatal, and the likelihood of symmetrical involvement. With the rapid advances in neurogenetics, many of them now have a specific molecular DNA test. As knowledge of the different genotypes grows, it is evident that the same gene defect can lead to heterogeneous clinical features. This variable clinical picture with overlapping symptom and sign complexes has made classification difficult. The recognized conditions included in the group are summarized in Table 22.36. Particularly rapid advances have been made in the genetics of the spinocerebellar degenerations (which are considered elsewhere in this chapter) and in ataxia telangiectasia.

### **Neuroaxonal dystrophy**

This is an autosomal recessive condition or conditions. The histopathological hallmark is the spheroid which is an axonal swelling formed by branched tubular structure and bundles of filament with mitochondria. Spheroids are present in peripheral nerves, especially presynaptically, but are also widespread throughout the CNS.

The infantile form starts between 6 months and 2 years of age with motor difficulties. The child is hypotonic but with pyramidal signs differentiating it from a neuromuscular condition. The condition progresses to severe dementia with spasticity and eventually decorticate rigidity. Nystagmus and optic atrophy commonly occur by the age of 3 years while seizures are a late feature. Death occurs by 5–10 years. Neuroimaging reveals cerebellar atrophy with, on MRI, increased signal on T2 in the cerebrum and cerebellum and sometimes basal ganglia calcification. EMG shows denervation with nerve conduction studies being normal. Visual evoked potentials disappear after a few months. The diagnosis is confirmed by the finding of spheroids on peripheral biopsy of skin, conjunctiva, nerves and/or muscle.

Rare cases of late onset (juvenile type) neuroaxonal dystrophy are reported. Onset is in late childhood with progressive myoclonic epilepsy and retinal degeneration. The diagnosis is by rectal or skin biopsies.<sup>486</sup>

No treatment or antenatal diagnosis is available.

### **Hereditary spastic paraparesis (HSP)**

HSP is not a single disease entity, but rather a group of clinically and genetically diverse disorders that share the primary feature of progressive and generally severe lower extremity weakness and spasticity.

HSP is generally classified as uncomplicated or complicated. In uncomplicated HSP, symptoms are usually limited to gradual weakening in the legs; urinary bladder disturbance; and, sometimes, impaired sensation in the feet.

In complicated HSP, which is rare, additional symptoms may include peripheral neuropathy, epilepsy, ataxia, optic neuropathy, retinopathy, dementia, ichthyosis, mental retardation, deafness, or problems with speech, swallowing or breathing.<sup>487</sup>

The inheritance mode of HSP may be X-linked, autosomal dominant or autosomal recessive, with each type having several subtypes based on the location of the gene. The mode of inheritance cannot be used to predict severity of the disorder since symptoms can vary greatly within each type. Several genes have been located. There are ten types of dominantly inherited uncomplicated or complicated HSP, seven types of recessively inherited HSP and three types of X-linked HSP.<sup>488</sup>

The classic symptom of HSP is progressive difficulty in walking of variable severity. Some patients continue to be mobile while others eventually may require the use of a wheelchair. Patients usually have difficulty lifting their toes, which results in them dragging the toes when

Table 22.36 Spinocerebellar and peripheral nerve degenerations

Disorders	Genetics	Age at onset	Neurology and other clinical features
Dentatorubra rubro pallidolusian atrophy (DRPLA) (Ramsay–Hunt syndrome)	Familial (triplet repeat disorder)	Late childhood to adolescence	Myoclonic epilepsy; cerebellar ataxia
Friedreich ataxia	AR triplet repeat disorder (chromosome 9)	Mean 10.5 years (range 2–16 years)	Presenting: ataxia (limbs and trunk), scoliosis, tremor, cardiomyopathy (T inversion and LVH). Later: dysarthria, pyramidal signs with extensor plantars and diminished reflexes, proprioceptive loss, pes cavus, distal amyotrophy (distal wasting and weakness), optic atrophy and nystagmus, deafness, CCF or arrhythmias, gradually progressive diabetes mellitus; sudden cardiac death in the thirties
Familial spastic paraplegia	AR AD	11.5 years 18.5 years	Slow learning to walk; mild spastic paraplegia; stiff gait; scissoring of legs; slowly progressive (variable)
Progressive cerebellar ataxia	AR	Mean 9.4 years	Dysarthria, pyramidal signs, absent ankle jerks (others normal); sensory loss. Better prognosis than Friedreich ataxia
Familial spastic-ataxic syndrome	AR		Progressive insidious involvement with signs relative to cerebellum, corticospinal tract and ocular signs. Death over 5–20 years
Olivopontocerebellar atrophy (OPCA) (Types I–V)	AD–OPCA (Types I, III, IV, V) AR–OPCA (Type II)		With retinal degeneration, progressive cerebellar ataxia; parkinsonian rigidity; resting tremor; impairment of speech
Ataxia telangiectasia (Louis–Barr syndrome)	AR (chromosome 11)		Progressive neurological deterioration with ocular and cutaneous telangiectasia. Early: cerebellar ataxia (often less than developmental progress). Later: decreased IgA, dysarthria; choreoathetosis; titubation. Sometimes progressive dementia. Telangiectasia of conjunctiva, pinnae, face, V of the neck, and flexures begins after 3 years; oculomotor dyspraxia, growth retardation; with wheelchair by 10–12 years; survivors show distal weakness, wasting, posterior column signs after 10 years; death before adulthood. Immunological: tonsils hypoplastic, abnormal IgM, thymic hypoplasia. Neoplasia: lymphomas, sarcomas, leukemia, Hodgkin, lymphosarcomas, ovarian and gastric tumors. Blood: lymphocytopenia. Endocrine: abnormal carbohydrate metabolism
Ataxia with oculomotor apraxia	AR. Two forms (Types 1 and 2) caused by mutations on the APTX and SETX genes respectively		Resemble ataxia telangiectasia but without the telangiectasia and the systemic features
Infantile neuroaxonal dystrophy	AR	6 months to 2 years	Loss of motor and mental milestones with regression; early visual involvement (ocular wobble); symmetrical pyramidal tract signs; marked hypotonia; anterior horn cell involvement (peripheral motor and sensory defect); dementia and decerebration
Multiple sclerosis in childhood		12–13 years	Death less than 10 years. Remitting course (1–2 episodes in childhood); optic/retrobulbar neuritis bilaterally (a quarter of childhood cases subsequently develop MS); gait disorder (with spasticity or ataxia)
Giant axonal neuropathy	AR	Early school years	Chronic peripheral mixed neuropathy; regression of gait, movement and IQ; fits; nystagmus; precocious puberty; pale, slightly reddish tightly curly hair

walking and catching them on stairs or on uneven sidewalks or curbs. In the later stages of the disease, patients experience difficulty flexing the thigh muscle to raise the leg when walking. A reduced sense of balance is noted. Some people also experience urinary problems.

The amount of spasticity experienced is variable depending on the circumstances. Many people notice that their muscles seem tighter when they are emotionally stressed or upset. Other factors that can

affect spasticity are cold temperature, poor posture, high humidity and illness. The increasing stiffness in the legs is associated with frequent tripping, particularly when the patient is walking on uneven terrain.

### Infectious progressive encephalitides

Some neurodegenerative conditions result from some slow viral infections. The main examples are: subacute sclerosing panencephalitis

(SSPE), progressive rubella panencephalitis, Lyme disease, HIV dementia and prion disease. Lyme disease and HIV dementia are considered elsewhere in this chapter and in the section on aseptic meningitis in this chapter and in the chapters on immunodeficiency and infections (see Chs 27 and 28). Here SSPE and prion disease will be considered.

### **Subacute sclerosing panencephalitis (SSPE)**

SSPE is by far the most common of the chronic encephalitides. It most frequently follows measles infection in the first 2 years of life with an incidence of 1:1000 000. It represents an altered host response to the virus. The interval between measles and the onset of SSPE is usually 5–7 years. The onset is often insidious with slow intellectual and bizarre behavior followed by the onset of intractable myoclonus. Occasionally unilateral symptoms and signs make early diagnosis difficult. Extrapyrimal and pyramidal features follow and the condition progresses to dementia. The speed of progression is variable, but more than half of patients have a rapid course.<sup>489</sup>

The EEG shows a characteristic pattern with so-called periodic complexes. The CSF shows evidence of intrathecal antimeasles antibody production. CT scan and MRI may be normal, especially early in the disease. Later, they may show variable cortical atrophy and ventricular dilation. Focal or multifocal white matter abnormalities may also be seen.

The prognosis is poor and the SSPE invariably results in profound disability or death. Rapidly evolving forms may lead to death in only a few months. A combination of intraventricular interferon and isoprinosine was reported to increase the rate of remission from 10% up to 45%. However late reoccurrence may happen after several years of remission.<sup>490</sup>

### **Prion diseases**

Prions are infectious agents which affect only the CNS, are distinct from viruses and have very long incubation periods. The diseases caused by these agents were previously called the transmissible spongiform encephalitides and include scrapie in sheep, the human disease Kuru and Creutzfeldt–Jakob disease (CJD). Attempts to identify specific nucleic acid within highly purified preparations of prion were not successful.<sup>491</sup>

The major infectious component of prions is composed of a protein designated PrP<sup>Sc</sup>. Cloning the prion protein gene resulted in the discovery of a point mutation for humans with familial CJD and established that prion diseases are genetic and infectious in humans.

**Creutzfeldt–Jakob disease.** Progressive dementia, loss of intellectual functions, sometimes with cerebellar and visual defects, are the main characteristics of CJD. The onset is usually in adults though there is a reported case in a 10-year-old. CJD is transmissible through growth hormone derived from human pituitary glands, through corneal transplants and by contaminated surgical instruments. The infectious agent is highly resistant to sterilization.<sup>492</sup>

**New CJD variant.** In the UK, there have been reports of a new variant of CJD occurring in adolescents and young adults. The characteristic features are personality changes, mental disturbance, dysesthesia and progressive dementia and ataxia. Myoclonus may be a feature. Affected young people often present with severe depression. A period of dysphoria follows accompanied by the onset of a florid, worsening ataxia. Dementia and an evolving spastic quadriparesis then follow with death occurring in 2 years or so. MRI shows high signal in the posterior thalamus. The place of tonsillar biopsy and specific CSF proteins in diagnosis is being defined. The histopathology is different from that of classic CJD.

## **INVESTIGATION OF DEGENERATIVE DISEASES**

The clinical history, including the age of onset of the condition, together with specific clinical features referable to the nervous and other systems, may suggest a differential diagnosis. However, frequently specific features are lacking and in such cases ‘screening’ in relation to the age of onset can be useful. In all cases MRI is indicated.

In infancy, screening should include thyroid function tests (for hypothyroidism), urine and plasma amino acids (for aminoacidopathies), urine organic acids (for organic acidosis) and white cell enzymes (WCE) (for the neuropilidoses such as Niemann–Pick and Tay–Sachs diseases). EEG can sometimes be useful, for example revealing hypsarrhythmia, suggesting infantile spasms as a cause of apparent regression or a burst suppression pattern in nonketotic hyperglycinemia. Other investigations which may be useful include plasma copper (low in Menke syndrome), CSF with simultaneous blood and urine glycine (raised in nonketotic hyperglycinemia) and DNA studies such as for Pelizaeus–Merzbacher disease and mitochondrial cytopathies.

Screening in toddlers should include urine and plasma amino acids and urine organic acids. Metachromatic leukodystrophy (MLD) and the neuropilidoses can be detected from WCE. The diagnosis of Batten disease is undergoing a transformation. Previously neurophysiological studies along with skin and rectal biopsies (to detect neuronal inclusions) were required. However, nearly all cases of CLN 1, 2 and 3, can now be diagnosed using a combination of enzyme assays done on blood combined with molecular DNA studies. DNA studies now also assist in the diagnosis of Rett syndrome. Liver function tests and CSF and blood lactate levels can be helpful in Alper disease due to mitochondrial cytopathies.

In school-age children (Table 22.37) investigations should include WCE for juvenile metachromatic leukodystrophy, juvenile Gaucher disease and juvenile GM2 gangliosidosis; investigations (as above) for Batten disease; DNA for juvenile Huntington and in some cases of Hallervorden–Spatz diseases; muscle biopsy, EEG and DNA for mitochondrial cytopathies; very long chain fatty acids for adrenoleukodystrophy; EEG and CSF measles antibodies for SSPE; plasma ceruloplasmin and copper and urine copper for Wilson disease. Depending on the clinical picture, other investigations may need to be considered but the temptation to undertake all known tests should be resisted.

**Table 22.37** Investigation for neurodegenerative conditions in school-age children

<b>Blood</b>
Liver function tests
Copper, ceruloplasmin
Lactate
Amino acids
Very long chain fatty acids
Immunoglobulins
Thyroid function tests
Autoantibodies, including antinuclear antibodies
White cell enzymes (targeted for conditions being considered)
Toxicology
Appropriate genetic tests, esp. DNA studies for specific disorders
<b>Urine</b>
Amino acids/organic acids
Renal epithelial metachromatic granules
<b>CSF</b>
Immunoglobulins
Electrophoresis
Cells (cytospin)
Measles IgG
Lactate
Neurotransmitters
<b>Neurophysiology</b>
EEG
Electroretinogram
Visual evoked potentials
<b>Neuroimaging</b>
CT scan
MRI

## MANAGEMENT OF THE NEURODEGENERATIVE CONDITIONS

A very few neurodegenerative conditions have specific treatment. These include D-penicillamine for Wilson disease, specific diets and vitamins in some aminoacidopathies, pyridoxine and pyridoxal phosphate dependent seizures, folinic acid responsive seizures, biotinidase deficiency, glucose carrier protein deficiency (Glut 1 deficiency), serine biosynthesis disorders and creatine deficiency syndromes. The vast majority of the neurodegenerative disorders are untreatable, resulting in progressive neurodisability and death at variable ages. Having an accurate diagnosis is essential for appropriate genetic counseling. There is still much that can be offered to children and their families to tackle and ease the main difficulties facing the daily care and activities such as feeding and mobility, and to prevent or delay unwanted and inevitable complications such as bed sores and severe contractures.

Management can be arbitrarily divided into three stages: early, middle and late phases.

In the early phase the emphasis is likely to be on maintaining normal function, such as mobility, and normal activities, such as mainstream schooling, as long as is possible. Feeding difficulties often respond well to specific measures, as do associated medical problems such as seizures. In the middle phase as the child or young person becomes more dependent involvement of hospices and other shared care arrangements are often of immense value to the child and their family. Careful attention to nutrition will often help maintain health and general well-being, including mood. In the late phase mood disturbances including dysphoria and agitation can be problematic and often respond to medication. Opiates should not be considered as a last resort. Their judicious use may greatly enhance the quality of the child's life. Following death, if the diagnosis remains unclear, postmortem examination should be encouraged as its findings may be of great help in planning future pregnancies. Finally, families should be offered an opportunity to discuss unresolved issues at a suitable interval following the child's death.

## NEUROMUSCULAR DISEASE

### MODES OF PRESENTATION

In neuromuscular diseases the principal problem lies at the anterior horn cell (the spinal muscular atrophies), the peripheral nerve (the peripheral neuropathies), the neuromuscular junction (the myasthenic syndromes) or the skeletal muscle (the myopathies and muscular dystrophies). It used to be considered that the central nervous system was not involved. However, it often is. For example in Duchenne muscular dystrophy learning difficulties are common while the congenital muscular dystrophies are associated with a variety of structural brain disorders. Mitochondrial cytopathies often feature prominent muscle involvement but are of course multisystem disorders. Clinical evaluation can often be helpful in defining the likely site of involvement in neuromuscular disorders. Hence fasciculation, muscle atrophy and severely decreased or absent tendon reflexes are characteristic of anterior horn cell disease. In peripheral neuropathies absent tendon reflexes and muscle atrophy, but not fasciculation, are characteristic. Myasthenia is characterized by fatigability. Tendon reflexes are usually normal or only slightly depressed. In the myopathies and muscular dystrophies the main finding is of weakness; tendon reflexes are usually preserved. Beyond such broad generalizations, the presentation of neuromuscular disorders shows considerable variation according to the age of the child.

### Neonatal period

Pregnancy with a fetus with a neuromuscular condition may be complicated by polyhydramnios and reduced fetal movement.

Neuromuscular conditions must be suspected in infants who have arthrogryposis, are hypotonic, have feeding difficulties, respiratory problems or a need for respiratory support in the absence of any significant pulmonary pathology.

As any examination candidate knows conditions which may lead to a 'floppy infant' are legion. How does one distinguish infants who may have a neuromuscular condition? The traditional teaching, that these infants are weak in addition to being hypotonic, holds true. However, even if an infant is profoundly weak, without any antigravity limb movement, there are pitfalls to recognizing that the infant has a neuromuscular condition. An infant who unexpectedly fails to breathe after birth may be thought to have a hypoxic-ischemic encephalopathy and subsequent lack of movement may be attributed to the sequelae of this. Indeed, to confuse matters further, the infant may have had a degree of hypoxic-ischemic encephalopathy secondary to profound respiratory muscle weakness. Assessment of level of consciousness is difficult in neonates and is particularly difficult in an infant with ptosis and facial weakness.

Arthrogryposis may be caused by any condition resulting in restricted fetal movement. Neuromuscular disorders reported in patients with arthrogryposis include distal spinal muscular atrophy, neuropathy, congenital myopathy and congenital muscular dystrophy.

Feeding difficulties may be profound, with inability to suck and swallow and respiratory embarrassment on attempted feeding, or may mean feeds take longer than expected with weight gain less than ideal.

Conditions presenting in the neonatal period with limb weakness and respiratory and feeding difficulty include myotonic dystrophy and the congenital myopathies. The birth of an infant with congenital myotonic dystrophy is often the first presentation of this condition in the family. It is always useful to examine the mother of a weak neonate for ptosis, facial weakness and myotonia. The congenital myopathies, which are most likely to present with a need for respiratory support, are nemaline myopathy and myotubular myopathy. Ophthalmoplegia in a male infant is particularly suggestive of myotubular myopathy and there may be a history of neonatal death in other males in the family. Antenatal onset of spinal muscular atrophy is rare but severely affected neonates with deletions in the SMN1 gene are described.<sup>493</sup>

Congenital myasthenic syndromes must always be considered in neonates with feeding difficulty and episodes of respiratory distress or apnea.

### Infancy and early childhood

Delayed motor development with age-appropriate cognitive abilities should prompt consideration of a neuromuscular condition. Global developmental delay may be the presenting feature in dystrophinopathies<sup>494</sup> and, in a boy with developmental delay, investigation should always include creatine kinase estimation. Episodic weakness or exacerbations of weakness during intercurrent illnesses suggest metabolic myopathy or congenital myasthenic syndrome.

### Later childhood

The manifestations of limb muscle weakness include difficulty with or inability to run, abnormal gait, difficulty climbing stairs and rising from the floor (Fig. 22.31). Fatigability should suggest a myasthenic disorder. Muscle pain or cramp on exertion and episodes of rhabdomyolysis are suggestive of metabolic myopathy.

Occasionally neuromuscular disease presents with 'abnormal liver function tests'. When creatine kinase is very elevated, other enzymes such as alanine transferase (ALT) may also be elevated, leading to the suspicion of liver disease. When ALT is elevated but other measures of liver function such as bilirubin and coagulation studies are normal, checking the creatine kinase level may reveal the true source of this enzyme and lead to appropriate investigations.

Toe-walking may be a manifestation of many conditions in childhood. Neuromuscular conditions, particularly dystrophinopathy, Emery-Dreifuss muscular dystrophy and Charcot-Marie-Tooth disease (CMT), must be considered in the differential diagnosis. Foot deformity is a frequent presenting feature of CMT and is also seen in distal spinal muscular dystrophy.

Fig. 22.31 A child with hip girdle weakness demonstrates a Gower maneuver: on rising from supine he turns prone then pushes himself up with his hands on his legs to the standing position.

## INVESTIGATION

Appropriate investigation is only possible when preceded by comprehensive clinical assessment with particular attention to pattern of muscle weakness.

There are a few neuromuscular conditions in which specific and highly sensitive DNA tests are available (Table 22.38). These are myotonic dystrophy, spinal muscular atrophy and fascioscapulohumeral muscular dystrophy. DNA analysis is an appropriate first-line investigation for such conditions. Around 65% of boys with dystrophinopathy have a deletion in the dystrophin gene. DNA analysis for such a deletion is an appropriate early investigation to confirm the clinical diagnosis. If such a deletion is found opinion is divided as to whether muscle biopsy is indicated in order to determine with certainty whether the boy has Duchenne or Becker muscular dystrophy. In boys in whom initial DNA analysis is negative but a dystrophinopathy is confirmed on muscle biopsy further more detailed DNA analysis may detect other defects, such as point mutations. In a large number of other neuromuscular conditions DNA analysis can be helpful in confirming or further defining the diagnosis.

## Muscle biopsy

Muscle biopsy may be by needle or with an open technique. Needle muscle biopsy is usually sufficient but may not yield enough muscle for biochemical enzyme analysis or comprehensive immunoblotting in limb girdle dystrophy.

Analysis of muscle biopsy may include:

- hematoxylin and eosin;
- fiber typing;
- immunohistochemistry;
- oxidative enzyme staining;
- immunoblotting;
- enzyme analysis;
- mitochondrial DNA analysis;
- electronmicroscopy.

## Neurophysiology

Nerve conduction studies will usually confirm the presence of neuropathy and define whether this is of the demyelinating or axonal type.

EMG may show a clear myopathic or denervating pattern, however the picture is often mixed. Moreover, it is often normal even in confirmed myopathies.

Repetitive stimulation and single fiber EMG may be helpful in confirming a defect of neuromuscular transmission.

## Biochemistry

Biochemical tests which may be useful in the investigation of neuromuscular disorders are shown in Table 22.39.

## Muscle imaging

Muscle ultrasound can be valuable in detecting myopathies and muscular dystrophies, both of which are associated with increased

Table 22.38 DNA analysis in investigation of neuromuscular disease

DNA analysis for diagnosis	DNA helpful following diagnosis
Myotonic dystrophy	Charcot-Marie-Tooth 1
Spinal muscular atrophy	Limb girdle dystrophy
Facioscapulohumeral MD	Congenital muscular dystrophy
+/- dystrophinopathy	Congenital myopathies – nemaline, myotubular, minicore, central core
	Emery-Dreifuss MD
	Ion channel disorders
	Congenital myasthenic syndromes

Table 22.39 Biochemical investigations

Creatine kinase	Marked ↑ in most muscular dystrophies, may be mildly ↑ in neuropathic conditions Often normal in myopathies
Lactate	↑ May occur in mitochondrial myopathy
Carnitine/acylcarnitine profile	May be helpful in fatty acid oxidation defects
Glycolytic enzyme analysis	Useful in metabolic myopathy
Forearm ischemic exercise test	< Fivefold rise in lactate in glycogen storage defect < Fivefold rise in ammonia in adenylate deaminase deficiency

echogenicity of involved muscles. MRI can identify the pattern of muscle groups involved. Currently information is being gathered, largely in relation to the congenital myopathies, and it may ultimately become a useful clinical tool. The place of MR spectroscopy in helping to define the metabolic myopathies is still at the research stage.

## MANAGEMENT

Accurate diagnosis is the first step in management and allows some estimation of the future course of the child's condition. Accurate diagnosis can also predict the need to be watchful for the development of particular complications such as respiratory insufficiency in minicore myopathy (see below). If a molecular genetic diagnosis can be made this allows accurate genetic counseling and antenatal testing.

To date, with the exception of some of the congenital myasthenic syndromes and metabolic myopathies, there is no specific treatment for inherited neuromuscular conditions.

The aims of management are therefore:

1. family support and education;
2. prevention and management of complications;
3. enhancing function;
4. palliation of symptoms.

### Family support and education

Family support is vitally important, not only following diagnosis, but also in negotiating the various hurdles encountered by the family of a child with physical disability. Families now have access to a vast array of information about their child's condition but making sense of what all this means for an individual child can be challenging. Although there are principles for good practice, for example in disclosing a diagnosis, families vary and no single approach fits all so it is important support is tailored to an individual family's need with the aim of enabling them to achieve the best for their child.

### Prevention and management of complications

#### Contractures

Contractures are inevitable in neuromuscular conditions when there is marked weakness. In some conditions there is a propensity to early contractures, for example in Emery–Dreifuss muscular dystrophy flexion contractures at the elbows and Achilles tendon contractures develop in the presence of only mild weakness.

Passive stretching of joints and splinting are the mainstays of contracture prevention. Physiotherapy entailing extensive exercises may be recommended, but there is no evidence that it is helpful and it is very difficult to comply with. Brief passive joint stretching is more likely to be tolerated by child and parents. Achilles tendon stretching can be carried out for a few minutes twice a day without major interruption of daily routine. A period of prone lying will stretch the hip flexors.

When there is useful muscle strength around a joint, splints which interfere with function are unlikely to be worn. In the prevention and management of Achilles tendon contractures, daytime ankle–foot orthoses (AFOs) will be helpful if there is marked ankle dorsiflexion weakness. If ankle dorsiflexion is not weak or there is a dynamic advantage from toe-walking, daytime AFOs will not be tolerated and night splints can be used. For example, in ambulant boys with dystrophinopathy daytime AFOs are unlikely to be tolerated so night splints are used; once ambulation is lost AFOs can also be used.

Surgery for release of contractures is of benefit in ambulant patients or may be needed prior to rehabilitation in knee–ankle–foot orthoses. Particular care is required in assessing the role of surgery in children with Achilles tendon contractures and weak hip flexors as tendon lengthening may cause a loss in ambulation.

#### Scoliosis

Bracing probably does not prevent progression of scoliosis in neuromuscular conditions; however it may facilitate seating in a child with marked truncal weakness.

Surgery is well established in the management of neuromuscular scoliosis. Posterior fusion is the procedure usually performed as respiratory compromise usually precludes an anterior approach.<sup>495,496</sup> More recently, rods which may be repeatedly extended have been useful in children who require surgery at a younger age and risk the development of secondary crankshaft deformity during the adolescent growth spurt. Careful attention must be paid to respiratory function in this group, so that completion of lengthening is performed while the child is still fit for surgery.

#### Respiratory management

Respiratory insufficiency is inevitable in the late stages of progressive neuromuscular conditions. In some conditions, however, respiratory muscles are selectively involved so respiratory insufficiency may occur when limb weakness is mild.

Weakness of inspiratory muscles restricts lung capacity. Weakness of inspiratory and expiratory muscles reduces the effectiveness of the cough. Bulbar dysfunction and aspiration will also contribute to respiratory compromise. The presence of a scoliosis or spinal rigidity will also complicate the picture.

Regular monitoring of forced vital capacity (FVC) is important in predicting the development of symptoms and should be performed at each clinic visit and before surgery is contemplated. When FVC is < 50% of predicted for height (arm span equates well with height in those unable to stand) there is a high risk of respiratory complications.

Assessment of bulbar function is important (Table 22.40) and the possibility of gastroesophageal reflux with aspiration also needs to be considered. If there is significant risk of aspiration because of bulbar weakness it may be necessary to limit oral intake, giving most of the nutritional requirements by nasogastric tube or gastrostomy.

*Hemophilus influenzae* vaccination is included in routine childhood immunizations. Pneumococcal vaccine and an annual flu vaccine should be offered to those at risk of respiratory problems. Chest physiotherapy is helpful during respiratory infections and when there are retained secretions. There is conflicting evidence about the relative efficacy of the various methods available. Cough assist devices may also be helpful in removing secretions. There is no strong evidence that respiratory muscle training is of benefit.

Table 22.40 Assessment of bulbar function

Questions in clinic	Any coughing or choking on eating or drinking? How long does it take to complete meals? What consistency of food can be managed?
Specialist assessment	Speech and language therapy assessment Videofluoroscopy of swallowing

Respiratory tract infections should be treated early and aggressively.

The first stage of respiratory failure is the development of nocturnal hypoventilation with oxygen desaturation during rapid eye movement (REM) sleep. Sleep is disturbed so the affected child wakes more frequently (this may be attributed to a need for turning), is not refreshed after the night's sleep and is tired during the day. Nocturnal hypoxemia with hypercapnia causes morning headache and a loss of appetite for breakfast. Left untreated, daytime hypoxemia and hypercapnia will ensue, with eventual cor pulmonale.

Nocturnal hypoventilation can be effectively managed with nocturnal non-invasive positive pressure ventilation (NIPPV). In boys with Duchenne muscular dystrophy this has been shown to prolong life and provide a quality of life equivalent to that of individuals with nonprogressive conditions receiving ventilatory support.<sup>497,498</sup>

Respiratory complications vary in different conditions. For example, in the dystrophinopathies and limb girdle dystrophies, respiratory muscle weakness will usually lead to nocturnal hypoventilation before there are significant bulbar problems. In spinal muscular atrophy, bulbar weakness often, but not invariably, contributes to recurrent respiratory tract infections before nocturnal hypoventilation occurs.

### Cardiac complications

Ventricular dysfunction may be seen in many of the muscular dystrophies, in female dystrophinopathy carriers and in metabolic and congenital myopathies. Treatment for cardiac failure will relieve symptoms. Some children with dystrophinopathy with mild or even no skeletal muscle involvement may develop severe cardiomyopathy necessitating cardiac transplant.

Young people with some neuromuscular conditions have a propensity to develop cardiac dysrhythmias. Those with Emery–Dreifuss muscular dystrophy should have annual 24-hour ECG monitoring. Individuals with myotonic dystrophy are also predisposed to cardiac dysrhythmias.

### Malnutrition

Children who have restricted mobility can easily gain weight excessively and the encouragement of healthy eating habits from the time of diagnosis is recommended. Bulbar weakness and secondary orthodontic problems may cause failure to thrive. Assessment of swallowing and dietary intake will indicate appropriate lines of management, which may be nutritional supplements, advice on consistency of food, or need for supplementary feeds via nasogastric tube or gastrostomy (Table 22.40).

### Enhancing function

**Prolonging mobility and standing.** Prolongation of mobility and standing has been shown to delay the onset of scoliosis. Mobility may be prolonged with the use of ischial weightbearing long leg splints, knee–ankle–foot orthoses (KAFOs). These may be used in any neuromuscular condition. The use of a standing frame is of particular benefit in children with spinal muscular atrophy type II and in children with congenital myopathies and congenital muscular dystrophy.

**Independent mobility.** Electrically powered indoor–outdoor chairs (EPIOCs) allow children who have only very limited or no mobility to join others safely in the playground or elsewhere to partake in activities with their peers.

**Education.** Physical disability should not preclude education in mainstream school with access to the full curriculum. Adaptations may be needed. Use of information technology may be helpful: many children find a keyboard allows them to be more productive than they can be when writing. Many children with neuromuscular conditions also have learning needs which need to be addressed.

**Adaptations and aids.** Adaptations to the home and the use of environmental controls increase the independence of young people with neuromuscular conditions. Accessibility to public buildings and transport also allow a degree of independence.

### Allowances

Individuals with physical disability and care needs may be entitled to financial help.

### Palliative care

Most care in neuromuscular disease is palliative rather than curative. It is important that not only the physical but also the psychosocial and spiritual needs of the individual are met. Affected young people and their families should have an understanding of the benefits and burdens of treatment, be given an opportunity to express their views on those benefits and burdens and an assurance that there will be appropriate action in the light of those views.

In the progressive conditions, however, there comes a time when despite active management a terminal stage is reached, at which time alleviation of symptoms should be a priority (see Ch. 38).

## MUSCULAR DYSTROPHIES

This group of conditions is characterized by the finding of dystrophic change on muscle biopsy: variation in fiber size, fiber splitting, necrotic fibers, excess of fatty and fibrous tissue. Classified originally according to clinical phenotype, these conditions can now frequently be defined at the level of the specific protein deficiency with immunohistochemistry and immunoblotting and at DNA level by mutation analysis.

### Duchenne and Becker muscular dystrophy – dystrophinopathy

The dystrophinopathies are the most common form of muscular dystrophy seen in pediatric practice and have X-linked recessive inheritance. There is a wide spectrum of severity, boys with loss of ambulation before 13 years of age are considered to have Duchenne muscular dystrophy (DMD), those with preservation of ambulation beyond 16 years are considered to have the Becker variant. Boys losing ambulation between 13 and 16 years of age are said to have an intermediate type.

Dystrophin is a 427-kDa protein, which forms part of the cytoskeleton of the muscle cell plasma membrane. It consists of an N-terminal domain, which binds actin, a central rod domain, a cysteine-rich domain and a C-terminal globular domain. The N-terminal and rod domains bind to actin filaments with the greatest affinity at the N-terminal; the C-terminal domains bind to the transmembrane dystroglycan complex. The cysteine-rich domain, the beginning of the C-terminal globular domain and the N-terminal actin binding domain are very important for dystrophin function, with those deleted for this region having more severe phenotypes. The central rod domain is less important with deletions for much of this region resulting in mild phenotypes.

The dystrophin gene is located on the X chromosome and at 14 kb is the largest human gene cloned so far. Around 65% of males with dystrophinopathy are found to have a deletion of one or more exons of the gene, 5% have a duplication, the remainder have point mutations. Approximately one third of the mutations are new mutations. The clinical phenotype depends on the amount of functional dystrophin. Boys with the more severe Duchenne phenotype have absence of dystrophin, males with the milder Becker phenotype have partial dystrophin deficiency.<sup>499-501</sup> Clinical severity cannot be predicted by the size of the deletion or the region of the gene deleted.<sup>502</sup> The main factor that appears to determine clinical severity is whether there is disruption of the reading frame.<sup>503</sup> If the exons flanking the deletion share the same reading frame, protein translation can continue to produce a protein which, although it is missing amino acids, retains some biochemical function. If there is disruption to the reading frame no functional protein is produced.

With the identification of the gene and its protein product has come the realization that the clinical phenotype of dystrophinopathy is very wide indeed and includes asymptomatic cases with elevated creatine kinase (CK) only, cases with dilated cardiomyopathy and no skeletal muscle involvement and cases with elevated CK, cramps and myalgia.

Occasional female cases are seen, with a translocation involving the X chromosome.<sup>504,505</sup> Female carriers, heterozygous for a dystrophin gene mutation, occasionally exhibit overt muscle weakness, which can often be asymmetrical. Approximately 10% of isolated females, with a muscular dystrophy with high CK and proximal muscle weakness, can be shown to be manifesting carriers.<sup>506,507</sup> About 17% of female carriers have some demonstrable muscle weakness. Female carriers without muscle weakness may have cardiac involvement, with approximately 8% showing evidence of dilated cardiomyopathy.<sup>508</sup>
