In a study of a cohort of 33 males born between 1953 and 1983, the mean age of diagnosis of DMD was 4.6 years, the median age of wheelchair dependency was 10 years and the median age of death 15 years.<sup>509</sup> Non-invasive ventilatory support can extend the length and quality of life considerably. The rate of learning disability is higher in the population with DMD than in the normal population. A meta-analysis of 1224 cases of DMD found a mean full scale IQ (FIQ) of 80.2. Of these children, 34.8% had a FIQ less than 70, of these 79.3% had mild (FIQ 50–70) learning difficulty, 19.3% moderate (FIQ 35–50), and 1.1% profound learning difficulty. In this study 6% of the children had FIQ > 110.<sup>510</sup>

Fatal rhabdomyolysis during anesthesia has been reported in a patient with BMD.<sup>511</sup> Smooth muscle involvement also occurs with acute gastric dilation and intestinal pseudo-obstruction.<sup>512</sup> Boland et al<sup>509</sup> found cardiac failure in 21% of males with DMD at a median age of 21.5 years.

### The use of steroids in Duchenne muscular dystrophy

There is evidence from randomized controlled trials that corticosteroids produce a significant improvement in muscle strength and function in the short term (6–24 months).<sup>513–516</sup> The most effective dose of prednisolone appears to be 0.75 mg/kg/day. There appears to be an increase in muscle strength in the first 6 months of treatment followed by stabilization for up to 2 years and then decline in muscle strength which is slower than that in natural history controls. Other steroid regimens have been used. Deflazacort may produce less weight gain but cataract occurs more frequently. A regimen of intermittent prednisolone may produce some benefit but fewer unwanted effects.<sup>517</sup> There are no data from randomized controlled trials (RCTs) on long term effects; there is a suggestion from nonrandomized trials that there may be a benefit on respiratory and cardiac function in the longer term.<sup>518,519</sup> Significant unwanted effects include weight gain, behavior changes, vertebral fractures and cataract.

The exact mechanism by which corticosteroids produce an increase in strength in DMD is unknown. Potential mechanisms include: inhibition of muscle proteolysis; increase in myogenic repair; anti-inflammatory effect; stimulation of myoblast proliferation; and upregulation of utrophin.

### Limb girdle dystrophy (LGMD)

This is a group of genetically heterogeneous conditions which have in common a syndrome of proximal limb weakness. Each condition can vary in severity from a severe Duchenne type phenotype to a mild phenotype. Even within a family there may be variation in severity between affected family members.

Classification of limb girdle dystrophies is now by mode of inheritance (autosomal dominant or recessive), protein deficiency and gene mutation. To date, the protein deficiency in three autosomal dominant and ten autosomal recessive LGMDs have been identified (Table 22.41). In addition, the gene loci for two more autosomal dominant LGMDs have been identified.

### Facioscapulohumeral dystrophy

Facioscapulohumeral muscular dystrophy (FSHMD) is an autosomal dominant condition. The characteristic pattern is of facial weakness and weakness of scapular fixation, with winging of the scapulae and difficulty raising the arms. Weakness is frequently asymmetrical. Later there is weakness of biceps and triceps, truncal weakness and lower limb weakness, which usually starts distally, but proximal lower limb weakness is frequently present.

Table 22.41 Limb girdle muscular dystrophy

Inheritance	Classification	Gene product
Autosomal dominant	LGMD1A	myotilin
	LGMD1B	laminA/C
	LGMD1C	caveolin-3
Autosomal recessive	LGMD2A	calpain 3
	LGMD2B	dysferlin
	LGMD2C	$\gamma$ -sarcoglycan
	LGMD2D	$\alpha$ -sarcoglycan
	LGMD2E	$\beta$ -sarcoglycan
	LGMD2F	$\delta$ -sarcoglycan
	LGMD2G	telethonin
	LGMD2H	E3-ubiquitin ligase
	LGMD2I	fukutin-related protein
	LGMD2J	titin

In the severe infantile onset FSHMD there is marked facial weakness and a severe lumbar lordosis.

High frequency hearing loss is detected in most affected individuals. This is most likely to be clinically significant in the infantile onset FSHMD. The majority of affected individuals also have retinal telangiectasia on fluorescein angiography; only rarely does Coats syndrome, an exudative retinopathy with retinal detachment, occur. Cardiac involvement is rare and is most commonly manifest as dysrhythmia.

FSHMD is linked to 4q35. There is a deletion of an integral number of copies of a 3.3-kb DNA repeat. Affected individuals have 10 or fewer repeats, normal individuals 15 or more repeats.<sup>520</sup> No transcribed gene sequences are contained within this area. The proposed mechanism by which the deletion produces the condition is by position effect variegation, where the deletion may influence expression of distant genes.<sup>521</sup>

### Emery–Dreifuss muscular dystrophy

Emery–Dreifuss muscular dystrophy (EDMD) is characterized by early contractures, particularly involving Achilles tendons, elbows and paraspinal muscles causing spinal rigidity, slowly progressive muscle weakness in a humeroperoneal distribution and cardiomyopathy with a propensity to dysrhythmias and a risk of sudden death.

EDMD is genetically heterogeneous. Two genes have been identified so far, the emerin gene on Xq28 and the laminA/C gene on 1q11–q13. The products of both these genes form part of the inner nuclear membrane. Emerin-deficient EDMD is inherited in an X-linked recessive fashion. Female carriers occasionally have cardiac conduction abnormalities and so warrant cardiology assessment. EDMD due to laminA/C deficiency may be inherited in an autosomal dominant or recessive fashion.

### CONGENITAL MYOPATHIES

The congenital myopathies are a group of conditions that frequently, but not always, manifest in infancy with hypotonia and motor delay. Classification has traditionally been on the morphological appearance of muscle biopsies. It has long been recognized that the morphological appearances may not be specific and some changes may be seen in other conditions. With the elucidation of the genetic basis of some of these conditions it appears that the same morphological changes and clinical features may be seen in genetically heterogeneous conditions. Most notable to date, nemaline myopathy may be caused by defects in five different genes (Table 22.42). Determination of the genotype in a child with a congenital myopathy allows more informative genetic counseling and the possibility of antenatal diagnosis.

Most of these conditions are apparently nonprogressive, or only very slowly progressive, but important specific clinical features may occur, for example respiratory failure and paraspinal muscle contractures in minicore myopathy.

Table 22.42 The congenital myopathies

Congenital myopathy	Pathology	Important clinical features	Inheritance	Gene locus	Gene product
Myotubular	Central nuclei surrounded by clear area without myofibrils	Ophthalmoplegia, respiratory insufficiency in neonatal period, coagulopathy and hepatic dysfunction with subcapsular hemorrhages	XR	Xq28	MTM1 Myotubularin
Nemaline	Rod bodies derived from Z-band material	Respiratory insufficiency in neonatal period, occasional cardiomyopathy, selective diaphragmatic involvement with early respiratory insufficiency in milder cases	AD	1q21–q23	NEM1 $\alpha$ -tropomyosin
			AR	2q21.2–q22	NEM2 nebulin
			AD/AR	1q42.1	ACTA1 Alpha actin, skeletal muscle
			AD	9p13.2–p13.1	TPM2 $\beta$ -tropomyosin
			AR AD	19q13.4 15q21–q24	TNNT1 troponin T1 ?
Central core	Central areas of derangement of sarcomeres with absence of oxidative enzyme activity	Congenital hip dysplasia may occur, cardiomyopathy and respiratory insufficiency rare	AD	19q13.1	CCD Skeletal muscle ryanodine receptor
Minicore	Multiple small areas devoid of oxidative enzyme, type 1 fiber predominance	Contracture of paraspinal muscles with complicated scoliosis, early diaphragmatic involvement and respiratory insufficiency	?AR	?	

### Myotubular myopathy and centronuclear myopathy

These terms may be used interchangeably or myotubular myopathy may be used for the severe X-linked early onset form and centronuclear myopathy used for sporadic, dominant or recessive cases. Muscle fibers, with centrally located nuclei with a surrounding halo devoid of myofibrils, resemble myotubes. In all types, ptosis and ophthalmoplegia are frequent features. Calf hypertrophy is described in late onset cases.

The X-linked form is due to mutation in the myotubularin (MTM1) gene. The gene product is a protein tyrosine phosphatase, which is required for muscle cell differentiation.<sup>522</sup> The severe X-linked early onset form is frequently associated with respiratory insufficiency and ventilator dependency. In a study of 55 males with confirmed MTM1 mutations Herman et al<sup>523</sup> found a survival rate at 1 year of age of 74%; 80% of these remained ventilator dependent. Care must be taken to distinguish this condition from congenital myotonic dystrophy. In the latter condition, examination of the mother may be helpful and DNA analysis will identify the CTG triplet repeat (see below).

Spherocytosis, gallstones, renal stones and a vitamin K-responsive coagulopathy are described<sup>523</sup> and it is prudent to assess coagulation prior to any operative procedures.

Later onset disease is usually only very slowly progressive. Cardiomyopathy is rare but has been reported as the presenting feature. Mutations in the dynamin2 gene have recently been found to cause a dominant centronuclear myopathy.<sup>524</sup> In females, care must be taken to exclude manifesting carrier status for the X-linked variety.

### Nemaline myopathy

Nemaline myopathy is defined by the presence of nemaline rods in muscle fibers. These rods contain Z disc material. Intracellular rods, which

are identical to cytoplasmic rods, may be seen and may indicate an unfavorable prognosis.<sup>525</sup>

Various clinical phenotypes are seen. In the severe congenital form, there are no spontaneous movements or respiration. In the typical congenital type, onset is in infancy or early childhood with weakness predominantly affecting neck flexors, facial, bulbar and respiratory muscles. The course is slowly progressive but respiratory insufficiency may occur. Onset in later childhood or adult life may also occur. Nemaline myopathy has also been reported in the fetal akinesia sequence.<sup>526</sup>

Mutations in five genes: alpha-tropomyosin (TPM3),<sup>527</sup> nebulin (NEB), alpha-actin (ACTA1),<sup>528</sup> beta-tropomyosin (TPM2)<sup>529</sup> and troponin T1 (TNNT1)<sup>530</sup> have been found in nemaline myopathy. Autosomal dominant and autosomal recessive inheritance has been found in families with TPM3 and ACTA1 mutations. All TPM2 mutations have been autosomal dominant and all NEB and TNNT1 mutations autosomal recessive.

Genotype and mode of inheritance cannot be predicted from the clinical severity. Neonatal presentation has been seen with recessive mutations in NEB and TPM3 and dominant mutations in ACTA1. In the group with adult onset only dominant mutations have been found.

### Central core disease (CCD)

The characteristic histological feature of CCD is the presence of central cores devoid of oxidative enzyme activity in type 1 muscle fibers (Fig. 22.32). In addition there is type 1 fiber predominance.

Inheritance may be autosomal dominant or recessive. Mutations in the ryanodine receptor gene (RYR1) have been identified in a few patients with CCD.<sup>531,532</sup> Mutations in this gene have also been found in families with susceptibility to malignant hyperthermia and these two conditions may coexist within a few patients and families.

Fig. 22.32 Central core disease: the cores show absence of staining with NADH.

CCD is usually nonprogressive or only very slowly progressive even in the severe cases described.<sup>533</sup> Presentation is usually with hypotonia and delayed motor development in infancy. Congenital hip dislocation, contractures, scoliosis or foot deformity may occur.<sup>534</sup> Cardiac involvement and respiratory insufficiency do not usually occur.

### Minicore myopathy (multiminicore disease)

Minicore myopathy is defined by the presence of small cores, which do not extend through the full fiber length but are histochemically and ultrastructurally similar to central cores. They are not confined to type I fibers.

Mutations of the selenoprotein N gene (SEPN1) have been found in individuals with recessively inherited minicore myopathy.<sup>535</sup>

Presentation is most frequently with hypotonia and delayed motor development. Muscle weakness is most marked in axial muscles and proximal limbs. Ophthalmoplegia is described. The weakness is static or very slowly progressive. Scoliosis, cardiomyopathy and respiratory insufficiency may occur in ambulatory patients.<sup>536,537</sup>

### Other congenital myopathies

Other congenital myopathies occur more rarely. Desmin-related myopathies are clinically and genetically heterogeneous. Some types are associated with cardiomyopathy, others with respiratory insufficiency. Actin-related myopathy, a congenital myopathy with an excess of thin myofilaments, has been described in a small number of severely affected infants and has been associated with mutations in the ACTA1 gene.

## CONGENITAL MUSCULAR DYSTROPHY

The congenital muscular dystrophies are a group of genetically heterogeneous conditions. The clinical features which they have in common are muscle weakness and hypotonia, which is present from birth or the first few months of life, contractures, which occur early or may be congenital, raised or normal CK levels and dystrophic changes on muscle biopsy. All are autosomal recessive and a number of gene defects have been identified to date. Some of the defective proteins responsible for congenital muscular dystrophy (CMD) interact with components of the extracellular matrix. Several congenital muscular dystrophies have been found to be due to mutations in glycosyltransferase genes responsible for the post-translational glycosylation of  $\alpha$ -dystroglycan.

Important clinical features, which may help define a specific diagnosis, include whether intellect is normal or there is associated learning difficulty, and the presence of muscle hypertrophy or distal joint laxity. Brain MRI may be normal or may show the presence of abnormalities such as white matter changes, neuronal migration disorders, cerebellar or brainstem abnormalities. There may also be associated eye abnormalities such as myopia, glaucoma, cataract and retinal dysplasia.

### Congenital muscular dystrophy without mental retardation

#### Primary laminin- $\alpha$ 2 (merosin) deficiency

This is the most common form of CMD and accounts for 50% of CMD cases in the Caucasian population.<sup>538</sup> Severe muscle weakness involves the face, trunk and limbs symmetrically and is present from birth. CK is markedly elevated. Feeding and respiratory difficulties are common. Some improvement in muscle strength is usually seen so that independent sitting is achieved. Only very few children with complete laminin- $\alpha$ 2 deficiency are able to stand or walk a few steps. Muscle strength tends to remain fairly stable through childhood.

All patients have white matter changes on brain imaging<sup>539</sup> (Fig. 22.33). Structural abnormalities such as occipital agyria and cerebellar hypoplasia have also been reported.<sup>540</sup> Most children are of normal intelligence unless there is gross occipital agyria. Epilepsy occurs in up to 30% of affected children.<sup>540</sup> A demyelinating neuropathy also occurs in this condition.<sup>541</sup>

Patients with partial laminin- $\alpha$ 2 deficiency may have a clinical phenotype ranging from early onset of weakness and hypotonia to adult onset of limb girdle weakness.

Laminin- $\alpha$ 2 is expressed in skin basement membrane and in the trophoblast. Immunofluorescence of fetal trophoblast may be used along with haplotype analysis or mutation analysis for antenatal diagnosis.

#### Secondary laminin- $\alpha$ 2 (merosin) deficiency

Several families with an abnormality of laminin- $\alpha$ 2 staining, but not linked to the LAMA-2 gene on chromosome 6q2, have been described. Mutations in a fukutin-related protein gene (FKRP) on chromosome 19q13.3 have been found in a number of families.<sup>542</sup> The clinical features are onset in the first weeks of life, severe weakness and wasting

Fig. 22.33 CT scan in laminin- $\alpha$ 2 deficiency showing extensive white matter changes.

of the shoulder girdle muscles, hypertrophy and weakness of leg muscles with inability to walk and respiratory failure in the second decade. Mutations in this gene are also described in children with limb girdle dystrophies of varying severity.

### **Ullrich syndrome**

Recently mutations in the collagen VI genes COL6A1, COL6A2 and COL6A3 have been demonstrated in this condition.<sup>543</sup> The characteristic clinical features are proximal contractures and marked distal joint laxity. Intelligence is normal.

### **Rigid spine syndrome**

Spinal rigidity is a feature of many myopathies. A group of children with early onset spinal rigidity, axial and proximal muscle weakness and severe respiratory failure have been described and classified as having a type of congenital muscular dystrophy (RSM). In some of these families mutations have been found in the selenoprotein N gene (SEPN1).<sup>544</sup>

### **Congenital muscular dystrophy with mental retardation**

#### **Fukuyama congenital muscular dystrophy (FCMD)**

This condition is essentially only seen in the Japanese population or patients of Japanese descent. Muscle weakness and learning difficulty are usually severe. Seizures occur in around 60%. Over 80% have high myopia, 60% glaucoma and 90% retinal dysplasia. The MRI brain scan shows abnormal signal in periventricular white matter in addition to neuronal migration defects.

Mutations in the fukutin gene on chromosome 9q3 are responsible for the condition.

### **Muscle eye brain disease (MEB)**

Most children with MEB are severely affected. Brain MRI shows neuronal migration defects in addition to partial absence of the septum pellucidum, corpus callosum dysplasia, hydrocephalus, pontine and cerebellar hypoplasia and periventricular white matter changes. Eye abnormalities are severe with severe myopia and glaucoma. Most patients have severe visual handicap.

Mutations in the *O*-mannose  $\beta$ -1,2-*N*-acetylglucosaminyltransferase gene (POMGNT1) have been found in this condition.<sup>545</sup>

### **Walker–Warburg syndrome**

In this condition there is almost complete lissencephaly (absence of cortical sulcation), microphthalmia with persistence of hyaloid vasculature and retinal detachment in combination with a muscular dystrophy. Other features may include encephalocele, ocular colobomas, cataract, genital abnormality and cleft lip and palate.<sup>546</sup>

Mutations in the *O*-mannosyltransferase 1 gene (POMT1) have been described.<sup>547</sup>

## **MYOTONIC DYSTROPHY**

Myotonic dystrophy is an autosomal dominantly inherited condition in which there is a combination of a progressive myotonic myopathy and multiorgan involvement. There are two distinct types defined by their underlying molecular genetic cause.

### **DM1 (Steinert)**

Muscle weakness predominantly affects facial muscles, levator palpebrae, neck flexion and distal limb muscles. Muscle weakness is commonly more extensive and often involves the diaphragm and intercostal muscles. Myotonia is unusual before the age of 6 years. Smooth muscle involvement causes dysphagia, which may be life threatening, and bowel dysfunction. Cardiac conduction defects and tachyarrhythmias are common and may occur when neuromuscular involvement is mild.<sup>548</sup> Central nervous system involvement causes learning difficulty in children and somnolence and lethargy in older individuals. Endocrine

disturbances include subfertility and in females there is a high rate of fetal loss.<sup>549</sup>

DM1 is a trinucleotide repeat disorder with an expansion of CTG repeats. There is a relationship between the size of DNA expansion and clinical severity<sup>550</sup> with those presenting with the condition in adult life having a DNA expansion band size between 0.25 and 3.5 kb, whereas about one in three children presenting in the newborn period will have DNA band expanded above 5 kb. Germ line instability accounts for the tendency of the mutation to expand in subsequent generations. Diminution may occur but is much less frequent. Expansion of the mutation accounts for the anticipation recognized clinically in this condition before its genetic basis was elucidated.

Congenital myotonic dystrophy is characterized by marked muscle weakness and hypotonia from birth (Fig. 22.34). Affected neonates have feeding difficulty with reduced reflexes and may have respiratory insufficiency. Mechanical ventilation may be required and the need for this is associated with a high mortality. Affected babies have a characteristic facial muscle posture with an open mouth and a tent-shaped or inverted V-shaped upper lip. Foot deformity and hip dislocation are occasionally seen. The finding of a large head with ventricular dilation in association with talipes on an antenatal ultrasound scan should prompt consideration of this diagnosis. All have learning difficulties with a wide spread of ability, some mild, some severe though few are able to obtain employment in adult life.<sup>551</sup>

With few exceptions congenital myotonic dystrophy is maternally transmitted.<sup>552,553</sup> Two thirds of the affected mothers have minimal or no symptoms of their own disease at the time of delivery.

Children with congenital myotonic dystrophy have a 25% chance of death before 18 months and a 50% chance of survival into the mid-thirties.<sup>551</sup> Life expectancy for adults is shortened, with a mean of about 60 years for men and women. Death usually results from respiratory insufficiency or cardiac arrhythmias. About half those with adult onset disease become wheelchair users. A higher proportion of those with childhood onset disease will use a wheelchair for mobility.

As childhood progresses, and particularly through adolescence, treatment for myotonia can be considered. Phenytoin and procainamide have been used successfully.

### **Type 2 (PROMM)**

Features are similar to but less severe than type 1, the social and cognitive difficulties seen in DM1 are mild or absent. Anticipation does

**Fig. 22.34** Congenital myotonic dystrophy in a 1-year-old child with facial weakness, foot deformity and developmental delay.

not occur so no severely affected children are described. The condition is due to a repeat expansion (CCTG)<sub>n</sub> in the zinc finger protein 9 gene (ZNF9).<sup>554</sup>

## ION CHANNEL MUSCLE DISEASES

This group of disorders is caused by abnormalities of membrane excitation caused by specific mutations in genes coding for various ion channels in the muscle fiber membrane.

### Myotonic disorders

#### *Chloride channel myotonias*

Point mutations, deletions or an insertion in the skeletal muscle chloride channel gene (CLCN1) on chromosome 7q35 cause Thomsen myotonia congenita (dominant inheritance) and Becker myotonia congenita (recessive generalized myotonia).<sup>555</sup>

In Thomsen myotonia congenita myotonic stiffness is usually present from early childhood and causes toe-walking and clumsiness. The myotonia is worse after a period of rest and improves with repetition of movement. The myotonic stiffness is sometimes painful. Muscle hypertrophy is frequently seen. Tightness of the tendo-Achilles often occurs. Tapping a muscle produces an indentation for a few seconds (percussion myotonia). Lid lag and/or blepharospasm may be present. More recently it has been recognized that there may be considerable variation in the age of onset and severity of symptoms both between and within families. Some individuals may be minimally affected with only lid lag or electrical myotonia on EMG. Males tend to be more severely affected than females.

The recessive form is more common with an incidence of about 1 in 23 000 to 50 000. The clinical features are very similar to the dominant type, but they often appear after the age of 10 years and the myotonic stiffness is generally more severe. There is usually generalized muscle hypertrophy. On initiating movement there is muscle weakness but after a few contractions muscle strength becomes normal.

Should treatment be necessary, the myotonic stiffness responds well to drugs that reduce the increased excitability of the cell membrane by interfering with the sodium channel and these include local anesthetics, antifibrillar and antiarrhythmic drugs with mexiletine being the drug of choice.

#### *Sodium channel myotonias and paramyotonia*

Mutations in the skeletal muscle sodium channel (SCN4A) on chromosome 17q23, lead to a variety of dominantly inherited conditions including paramyotonia congenita with or without hyperkalemic periodic paralysis.

In paramyotonia congenita the myotonia appears with exercise and increases with continued exercise. It is exacerbated by cold and is most obvious in the muscles of the face, neck and distal upper extremities. The myotonic stiffness may be painful. Myotonia may be very difficult to detect on clinical examination unless movements are repeated, e.g. repeated forceful closure of the eyes may elicit eyelid paramyotonia. Symptoms may vary between individuals with the same mutation.<sup>556,557</sup> Many individuals with an SCN4A mutation will have episodes of weakness in addition to the myotonic stiffness, these are usually brief and are exacerbated by cold and by rest after exercise.

SCN4A mutations may also cause myotonia fluctuans in which the myotonic stiffness fluctuates in severity. It is not associated with episodes of weakness and may be exacerbated by rest after exercise but not by cold. Mutations may also lead to myotonia permanens with severe myotonia particularly affecting muscles of the neck, shoulder and chest which may at times lead to impairment of ventilation with hypoxia and loss of consciousness with the possibility of a misdiagnosis of epilepsy.

Sodium channel myotonic stiffness may be exacerbated by oral potassium. It is often responsive to acetazolamide. If this is not effective mexiletine or tocainamide may be.

## Periodic paralyses

### *Hypokalemic periodic paralysis*

Dominant point mutations in the muscle calcium channel dihydropyridine gene, CACNL1A3, on chromosome 1q31–q32 lead to hypokalemic periodic paralysis.<sup>558</sup> More rarely this can be caused by mutations in the skeletal muscle sodium channel gene (SCN4A)<sup>559</sup> or the potassium channel gene (KCNE3).<sup>560</sup>

With an estimated incidence of 1 in 100 000 this is the most common of the periodic paralyses. Maximum weakness usually develops during the night and early hours of the morning and attacks are often provoked by high dietary intake of sodium or carbohydrate especially late at night and in association with alcohol. Weakness affects the legs more than the arms and begins proximally. Previous exercise increases the likelihood of an attack and muscles which have previously been exercised may show the greatest weakness. There may be a sinus bradycardia during an attack. During episodes the potassium decreases (not always below normal) and there is urinary retention of sodium, potassium, chloride and water. Attacks are initially infrequent but increase in frequency and may be daily. In the fourth and fifth decades attacks become less frequent again but patients often have some fixed weakness after many years of attacks.

Management is by adjustment of lifestyle to avoid provoking factors. Attacks of weakness can be treated with potassium. Acetazolamide or dichlophenamide may be helpful in preventing attacks.

### *Hyperkalemic periodic paralysis*

This is a dominantly inherited condition caused by mutations in the skeletal muscle sodium channel gene (SCN4A). It may present with or without paramyotonia or myotonia (see above). Attacks usually begin before the age of 10, are of shorter duration and more frequent than the attacks in hypokalemic periodic paralysis. The episodes are triggered by rest and they are often provoked by previous exercise. Potassium loading often precipitates an episode, and these are worsened by cold, stress, glucocorticoids or pregnancy. Some episodes are heralded by paresthesia or a sensation of muscle tension.

During an episode the sodium channels open and sodium moves into muscle cells causing a fall in serum sodium of between 3 and 9 mmol/L. Water follows the sodium causing hemoconcentration and an increase in the serum potassium. This in turn leads to potassium excretion in the urine, which may itself curtail the attack. Preventative therapy consists of frequent meals, rich in carbohydrate, a low potassium diet and the avoidance of fast and strenuous work and exposure to cold. The prompt intake of a thiazide diuretic or acetazolamide or the inhalation of a beta-adrenergic agent can curtail episodes in some people. Continuous use of these diuretics is not recommended.

### *Andersen syndrome*

This condition is the triad of periodic paralysis, prolonged QT with ventricular dysrhythmias and dysmorphic features. The dysmorphic features include low set ears, retrognathia or micrognathia, short stature and clinodactyly but may not be very striking. There may be a mild degree of fixed muscle weakness. Episodes of weakness may occur with normal, low or high serum potassium. Inheritance is autosomal dominant and mutations have been demonstrated in a potassium channel gene (KIR2.1).<sup>561</sup>

## THE INFLAMMATORY MYOPATHIES

### *Juvenile dermatomyositis* (see also Ch. 29)

The estimated incidence of juvenile dermatomyositis in the UK and Ireland is 1.9 per million aged under 16 years.<sup>562</sup> The median age of onset in this study was 6.8 years with five girls affected to each boy. The cause remains unknown. There is an association with HLA-B8/DR3 but the adult association with malignancy is not seen in children. It is a systemic vasculopathy associated primarily with inflammation of skin and muscle. About 10% of children with dermatomyositis test positive for myositis-associated antibody (MSA) (compared to about 50%

of adults), and 60% are positive for antinuclear antibodies. The MSA is most commonly directed against Mi-2 (in adults it is most often toward one of the tRNA synthetases). About 50% of children have circulating evidence of endothelial damage, while others have different indicators of disease activity such as elevated neopterin, or increased circulating B cells with peripheral lymphopenia.<sup>563</sup> Heterogeneity of this sort may well be associated with differing outcomes and in time define more specific approaches to therapy.

### Presentation

The onset is usually insidious with slowly increasing proximal muscle weakness. Affected muscles are stiff, sore and tender and occasionally indurated. Nonpitting edema or thickening of the overlying skin may be seen. Bulbar muscles may be involved and occasionally weakness is so severe that respiratory failure ensues.

The skin lesions often have a characteristic violaceous (heliotrope) hue best seen on the eyelids (Fig. 22.35). The skin over the extensor surfaces of joints often becomes erythematous, atrophic and scaly, capillary loops may be prominent in the nail beds. Pigmentation may appear in these areas in time. A papular or pustular eruption may appear in the same position in oriental children.<sup>564</sup> A malar butterfly rash may appear similar to that seen in systemic lupus erythematosus. Calcification of subcutaneous tissues may occur.

There may be gastrointestinal involvement with functional large or small bowel symptoms or bleeding, arthropathy, fever, pulmonary disease, iritis and very occasionally seizures.

### Diagnosis

High levels of muscle enzymes usually mirror muscle inflammation. Biopsy shows an inflammatory infiltration with muscle fiber necrosis and macrophage activity. Real diagnostic difficulty only arises when the rash is not evident. The differential diagnosis then includes conditions that may give insidious weakness including postinfectious polyneuropathy, metabolic and endocrine myopathies, myasthenia gravis or acute infectious myopathies.

### Treatment

Many children will respond well to corticosteroid treatment. A starting dose of prednisolone 1 mg/kg/day is used, tapering off over 6–12 months. Further immunosuppression may be required and azathioprine is a valuable agent in a dose of 2.5 mg/kg/day. Low dose ciclosporin may also be used starting at 4 mg/kg/day.

A number of centers have reported that intravenous immunoglobulin therapy has allowed the dose of steroid to be reduced in resistant cases.<sup>565</sup> Intravenous methylprednisolone and methotrexate may prove to be effective in children with severe dermatomyositis – defined as those with associated dysphagia and severe vasculitis.<sup>566</sup> Great care must be taken with the supportive care of those children with bulbar involve-

Fig. 22.35 Dermatomyositis: heliotrope rash around eyes.

ment. Oral feeding should be suspended when dysphagia is present and serial measurements of forced expiratory volume made. Ventilatory support may be required.

### Outcome

The outlook with modern immunosuppressant therapy is generally good. Before steroids up to 40% died, usually from bulbar and respiratory involvement. Tabarki et al<sup>567</sup> followed 36 children for a mean of 4.9 years. Twenty-eight of the children (78%) were well without functional impairment; five had inactive disease but with functional impairment and three had retained their active disease. Fifteen children developed dystrophic calcifications, which in five affected function. There is no satisfactory treatment for calcinosis, though aluminum hydroxide<sup>568</sup> and alendronate<sup>569</sup> have both been reported to bring benefit. Excision might be considered where functional impairment is significant. The best indicators of a good outcome were early treatment and a low creatine kinase level at diagnosis.

## Acute infectious myositis

### Viral myositis

This may occur in association with Coxsackie, echo and influenza viral infections. The presentation is of acute, distressing muscle aches, which are often symmetrical, and most commonly affects the thighs. There may be associated weakness. Occasionally it is very focal, affecting only one group of muscles. Viral invasion of muscle has not been demonstrated, but biopsy does show muscle cell necrosis and an inflammatory cell infiltrate. The creatine kinase may not be raised, although it usually is. Treatment is symptomatic and the condition is self-limiting and benign.

### Pyogenic myositis

The commonest cause is *Staphylococcus aureus*. It is usually secondary to a penetrating injury, although in the tropics it may result from spreading infection from a superficial wound. There is intense local pain, swelling and loss of function. Treatment is with antibiotics and drainage as appropriate.

### Parasitic myositis

Infestation with *Trichinella spiralis* results from the ingestion of undercooked, infested pork. Fever and myalgia are the commonest presentations. There may be periorbital edema, if periorbital muscles are involved or even dysphagia where bulbar muscles are involved. The calves, forearms or paraspinal muscles may be painful. Treatment is with thiabendazole 25–50 mg/kg/day or with mebendazole 100–200 mg twice daily and steroids. Mebendazole may have fewer unwanted effects.<sup>570</sup> Recovery is usually complete. In heavy infections of cysticercosis muscle may be affected.

## Rarer forms of myositis

### Congenital or infantile myositis

This was described by Shevell et al<sup>571</sup> and more recently by Vajsar et al.<sup>572</sup> Hypotonia and weakness are marked. Ventilatory support has often been required. The diagnosis is by muscle biopsy. Some cases are steroid responsive but the pathophysiology is poorly understood.

### Inclusion body myositis

This is exceptional in childhood and presents as a chronic myositis simulating a dystrophy. The biopsy shows sarcoplasmic vacuoles containing basophilic and eosinophilic inclusions. The cause is unknown and treatment is usually ineffective.

## METABOLIC MYOPATHY (see also Ch. 26)

Metabolic myopathies are the result of genetic defects of energy production, which may affect muscle alone or may also affect other high energy dependent tissues. The defect may be in glycogen or fatty acid metabolism or in mitochondrial oxidative phosphorylation.

Presentation may be with progressive weakness, recurrent symptoms of exercise intolerance, reversible weakness and myoglobinuria or both. Neonates and infants frequently present with severe multisystem disorders. In recent years advances in the understanding of the biochemical and genetic basis for many of these disorders has led to new diagnostic tests. Nonetheless a specific enzyme abnormality could be detected in only 24% in a series of children with recurrent myoglobinuria.<sup>573</sup>

### The glycogenoses

These defects of glycogen metabolism are rare and only those with prominent muscle involvement are included in Table 22.43. Recognition of Pompe disease (see Ch. 29, p. 1112) is now important because of the availability of enzyme replacement therapy.

### Defects of mitochondrial fatty acid oxidation

Beta-oxidation results in the sequential cleavage of two carbon atoms from fatty acids and provides an important energy source during times of fasting and metabolic stress. Clinical features of muscle involvement include recurrent rhabdomyolysis and/or weakness and muscle pain provoked by prolonged exercise, which may occur some time after the exercise. Rhabdomyolysis may also occur during intercurrent infection. Proximal weakness without pain or rhabdomyolysis may also occur. Cardiomyopathy frequently occurs with dysrhythmia and/or progressive cardiac failure. Pigmentary retinopathy and peripheral neuropathy may also be seen. The most common presentation of this group of conditions in childhood is with hypoketotic hypoglycemia. These are all autosomal recessive conditions.

Diagnosis requires a high level of suspicion. It is essential to obtain urine and blood samples during the acute episode as biochemical abnormalities may not be present when the patient is well. Initial investigations should include urine organic acids, CK, lactate, carnitine and acylcarnitine profiles. Mutational analysis is available for the common mutations found in medium chain acyl-CoA dehydrogenase (MCAD) and long chain 3-hydroxyacyl-CoA dehydrogenase (LHCAD) deficiency. Specific enzyme analysis can be performed for many of these conditions on cultured fibroblasts. Table 22.44 lists the features of muscle involvement in some defects of beta-oxidation.

### Defects of oxidative phosphorylation (OXPHOS)

Oxidative phosphorylation occurs in the mitochondria. Mitochondrial DNA encodes for only 13 subunits of the OXPHOS enzymes with more than 70 nuclear encoded subunits.

Isolated muscle involvement is unusual in this group of conditions in childhood. In a population-based study of OXPHOS disorders in childhood in Sweden eight out of 32 patients had myopathy, six infantile mitochondrial myopathy with cytochrome oxidase (COX) deficiency and two myopathy.<sup>574</sup>

A defect of OXPHOS is suggested by high plasma lactate and the finding of ragged red fibers or COX-deficient fibers on muscle biopsy. Electron microscopy of muscle biopsy may show structurally abnormal mitochondria with paracrystalline inclusions. OXPHOS enzyme analysis can be performed on muscle.

## THE MYASTHENIC SYNDROMES

### Myasthenia gravis

This is an autoimmune disorder, which is heterogeneous with respect to age at onset, ophthalmic changes and distribution of muscle weakness.

The annual incidence is between 0.25 and 2 people per 100 000. Although there has been an increase in the incidence in the over forties the incidence in childhood appears to be static. Boys and girls are equally affected in the first decade although the incidence in adolescence rises in girls with a ratio of three girls to two boys.

In most young people, myasthenia gravis is caused by autoantibodies specific for the human nicotinic acetylcholine receptor (AChR), which is concentrated at the postsynaptic region of the neuromuscular junction. These antibodies cause impaired neuromuscular transmission and muscle weakness.

There appears to be an immunogenetic predisposition to the development of idiopathic myasthenia gravis. Those with early onset myasthenia gravis have different HLA associations from those with late onset myasthenia gravis. Those with onset in childhood and adolescence also have an increased frequency of other autoimmune diseases. Monozygotic twins are at increased frequency of concordance and some families have more than one member affected. In Chinese and Japanese populations up to 30% present in early childhood, many with ocular myasthenia only. They show an association with HLA-BW46. This suggests that a particular environmental agent could be important. In Caucasians, about 60% of those with early onset myasthenia gravis are HLAB8 and DR3 positive.

Myasthenia gravis is associated with 30–60% of thymomas and about 10% of affected people of all ages have a thymoma.

### Clinical features

The onset may be insidious or sudden. A common presentation is with ptosis and diplopia due to weakness of the extraocular and levator palpebrae muscles. This may or may not then spread to involve proximal limb and bulbar muscles. Respiratory muscles may also be involved. The weakness is variable and commonly progresses as the day goes on. This may lead a child to have difficulty with chewing and swallowing at the time of the evening meal. The weakness can remain localized to one group of muscles for many years, commonly the eye muscles. In some the weakness may only be obvious with tests of fatigue, for example, sustained upward gaze or repetitive shoulder abduction. Tendon reflexes are normal and there is no sensory impairment.

Table 22.43 Glycogen storage diseases with muscle involvement

Enzyme defect	Clinical features	Inheritance
Acid maltase (Pompe disease)	Infantile	Hypotonia, weakness, cardiomegaly, hepatomegaly, respiratory and feeding difficulty, death usually before 2 years
	Juvenile	Muscle weakness proximal > distal, selective respiratory muscle involvement
	Adult	Slowly progressive myopathy, one third present with respiratory failure
Myophosphorylase (McArdle disease)	Muscle pain, weakness, stiffness during slight-moderate exertion, 'second wind' phenomenon, ↑ CK	AR
Phosphofructokinase (Tarui disease)	Exercise intolerance, hemolysis	AR
Phosphoglycerate kinase	Exercise intolerance, muscle cramps, myoglobinuria, CNS involvement, learning difficulty, epilepsy	XR
Debranching enzyme deficiency	Protuberant abdomen, muscle aching, progressive weakness	AR

Table 22.44 Defects of beta-oxidation of fatty acids

	Clinical features
Primary carnitine deficiency	Progressive muscle weakness, cardiomyopathy, hypoglycemia in some
Carnitine palmitoyl transferase II deficiency	Recurrent myalgia, rhabdomyolysis induced by fasting or prolonged exercise
Very long chain acyl-CoA dehydrogenase deficiency	Exercise-induced myalgia and rhabdomyolysis (presentation most often with hypoglycemia)
Medium chain acyl-CoA dehydrogenase deficiency	Rarely muscle pain, lipid storage myopathy, rhabdomyolysis
Short chain acyl-CoA dehydrogenase deficiency	Slowly progressive proximal lipid storage myopathy, secondary carnitine deficiency
Riboflavin responsive multiple acyl-CoA dehydrogenase deficiency	Muscle pain, proximal weakness, improvement with riboflavin
Long chain 3-hydroxyacyl-CoA dehydrogenase deficiency and mitochondrial trifunctional protein deficiency	Proximal myopathy, rhabdomyolysis, peripheral neuropathy, pigmentary neuropathy

If symptoms and signs remain confined to the eyes (ocular myasthenia) for longer than 2 years, the risk of subsequent development of generalized myasthenia gravis is low. Titers of antibodies to AChR are lowest in ocular myasthenia, although if the disease does become generalized the antibody titers tend to become positive.

Hoch and colleagues<sup>575</sup> showed that a high proportion of people without antibodies to AChR have antibodies to a muscle-specific receptor tyrosine kinase, MuSK.

Antibodies in myasthenia gravis lead to a functional loss of acetylcholine receptors at the neuromuscular junction by complement-dependent lysis of the postsynaptic membrane; cross-linking AChRs on the surface of the membrane lead to an increase in the rate of internalization and degradation of AChR and also direct inhibition of AChR function.

The importance of the recently discovered presence of MuSK antibodies in AChR negative myasthenia gravis has yet to be defined. MuSK is an essential component of the developing neuromuscular junction and MuSK antibodies might cause complement-mediated damage to the neuromuscular junction.

The thymus gland is probably necessary for the deletion of autoreactive T cells and has an important role in the pathogenesis of myasthenia gravis, even without the presence of a thymoma. In most children and adolescents the thymus is typically enlarged and contains many germinal centers with T and B cell areas very similar to those seen in lymph nodes. B cells obtained from the thymus spontaneously synthesize anti-AChR and thymic T cells are clonally restricted. A few T cells cloned from the thymus have proved specific for AChR epitopes. It seems probable that thymoma epithelium sensitizes T cells to these AChR epitopes and that T cells leave the thymus and initiate antibodies against AChR and other muscle antigens.

### Investigations

AChR antibodies are positive in 85% of young people with generalized disease. When present this finding is diagnostic. Peripheral neurophysiology shows an increased decrement (greater than 10%) of the evoked compound muscle action potential in response to repetitive supramaximal stimulation.

Edrophonium (Tensilon) is a short acting anticholinesterase. When this is given intravenously there is a rapid (usually within 2 minutes), but often short lived (less than 5 minutes) improvement in strength (Fig. 22.36). Interpretation can be difficult, however. It must be remembered there is a small risk of inducing a cholinergic crisis with respiratory arrest.

Once the diagnosis is made, CT or MRI of the mediastinum should be carried out to exclude an associated thymoma. Thyroid function and thyroid antibodies should be measured because of the association with other autoimmune disease.

In childhood and adolescence, where ocular myasthenia is relatively common, the main diagnostic dilemma is distinguishing it from mito-

chondrial cytopathy. It must be remembered that 50% of those with ocular myasthenia are AChR antibody negative. For those with generalized myasthenia who are also antibody negative the difficulty is differentiating their problem from other neuromuscular disorders and other disorders of the neuromuscular junction. If the onset of bulbar myasthenia is sudden, a brainstem stroke also enters the differential diagnosis.

### Treatment

The first-line management is with oral anticholinesterase drugs such as pyridostigmine. The dose should be titrated carefully with the response, remembering that too high a dosage can lead to a cholinergic crisis. Children under 20 kg should receive a dose of 30 mg initially. Those over about 20 kg should have 60 mg initially. The dosage can then slowly be increased in increments of 15–30 mg daily until maximum improvement is obtained. Total daily requirements are usually in the range of 30–360 mg. The effect of the drug usually wears off within 3–4 hours and the timing of the doses needs to be made accordingly. Unwanted gastrointestinal effects may occur, in particular abdominal pain and diarrhea. These may be countered with the use of propantheline. In generalized myasthenia gravis immunosuppression is indicated. Alternate day prednisolone is generally used, starting with a low dose, which is gradually increased (high doses may exacerbate myasthenia). On remission, the dose is gradually reduced. Azathioprine may have a steroid-sparing effect. In severely affected young people, plasma exchange or intravenous immunoglobulins can bring temporary improvement. These are useful strategies if the person involved poses an anesthetic risk prior to thymectomy.

Thymectomy is usually performed in children or adolescents who are AChR antibody positive with generalized myasthenia. Evidence from retrospective uncontrolled studies suggests benefit.<sup>576</sup> Thymectomy is rarely carried out for ocular myasthenia and for those who are AChR antibody negative. It nonetheless demands careful consideration where the symptoms prove to be anticholinesterase resistant.

### Other neuromuscular junction disorders

#### The Lambert–Eaton syndrome

This is caused by antibodies to voltage gated calcium channels on the presynaptic nerve terminals of the motor nerve. Peripheral neurophysiology reveals a small compound muscle action potential at rest and an increase in the amplitude of the action potential after maximal voluntary contraction. Antibodies to voltage gated calcium channels can be detected in most. 3,4-Diaminopyridine prolongs the motor nerve action potential thus increasing neurotransmitter release. It can be effective when used in combination with the anticholinesterases.

#### Acquired neuromyotonia

This is caused by antibodies to the voltage gated potassium channels present on motor nerve terminals. Most patients present with muscle twitches (fasciculations and myokymia) and cramps. The condition may

(a)

(b)

Fig. 22.36 Myasthenia gravis: (a) before and (b) after intravenous edrophonium.

be present alongside neuropathies or those with myasthenia gravis (particularly in the presence of a thymoma). Muscle weakness is often the major complaint. Membrane stabilizers such as carbamazepine may improve symptoms.

### Congenital myasthenic syndromes

The congenital myasthenic syndromes are a group of genetic disorders of neuromuscular transmission. Fatiguable muscle weakness occurs and in some, progressive weakness and wasting may occur. They are

rare conditions but notable because respiratory crises may occur, especially in childhood, and some will benefit from treatment with anticholinesterases. The defect may be presynaptic, synaptic or postsynaptic. Gene mutations responsible for a number of these conditions have now been identified.

In childhood, presentation is usually with feeding difficulty, episodic respiratory difficulty, motor delay, facial weakness, impaired eye movements and fatiguable ptosis. With the exception of slow-channel syndrome, inheritance of these conditions is autosomal recessive.

Confirmation of the diagnosis may be difficult. A trial of an anticholinesterase may lead to improvement in muscle strength and help confirm clinical suspicion but some conditions will not respond to anticholinesterases or may even be worsened. Neurophysiology may be helpful especially if a decrement of more than 10% in compound muscle action potential occurs on repetitive stimulation or increased jitter is found on single fiber EMG. Cytochemical and morphological analysis of the neuromuscular junction is confined to centers with a research interest in this group of conditions. Increasingly the underlying genetic defect will be used in diagnosis and classification [Table 22.45](#).

### SPINAL MUSCULAR ATROPHY

Spinal muscular atrophy (SMA) is the result of anterior horn cell disease. The spinal muscular atrophies are clinically and genetically heterogeneous. By far the most common type of SMA is proximal SMA caused by deletions in the SMN1 gene. Other types of SMA are very much rarer.

#### Proximal SMA

Spinal muscular atrophy (SMA) is the second most frequent lethal gene disorder in Caucasians after cystic fibrosis. Prevalence is 1/10 000. SMA is inherited in an autosomal recessive fashion; carrier frequency is estimated to be 1/40–1/60. The majority of cases are due to deletions within the SMN1 gene, the telomeric copy of the survival motor neurone gene on chromosome 5q12.2–q13.3. This area on the short arm of chromosome 5 is complicated with an inverted duplication containing the SMN, neuronal apoptosis inhibitor protein (NAIP) and P44 genes.<sup>577</sup> The SMN1 gene is the causative gene in SMA. The telomeric copy (SMN1) and the centromeric copy (SMN2) of the SMN gene differ by seven base pairs, which results in a splicing difference. There is evidence in transgenic mice that increasing the number of copies of the SMN2 gene ameliorates the severity of the disease. In humans some mutations in SMAII and SMAIII patients may be gene conversions with SMN1 being replaced by SMN2.<sup>578</sup> There is some correlation between SMN protein levels and disease severity.

In proximal SMA, weakness is more severe in the legs than the arms and is more marked proximally than distally. Intercostal muscles are affected with diaphragmatic sparing. Clinically there is a wide spectrum in the severity of SMA. Classification is clinical and based on age of onset and motor function. Life span however depends on respiratory and bulbar function. Within a type there is also a range of severity such that Dubowitz suggested classification should be on a decimal scale, type 1.0 to 1.9 and so on.<sup>579</sup>

Onset may be prenatal, with profound weakness, including facial weakness, contractures and respiratory failure in the neonatal period. Onset within the first 2 months of life is associated with early death. A few infants with SMA type I will have more prolonged survival. Infants with SMA type I are alert with normal facial expression; there is tongue fasciculation, and the limbs are profoundly weak ([Fig. 22.37](#)). Often the forearms are contracted in pronation leading to the classic 'jug handle' posture. Bulbar problems with aspiration and the need for tube feeding are invariable. Death is from respiratory causes.

Children at the more severe end of SMA type II may develop respiratory compromise early and will benefit from aggressive management of respiratory complications including the use of NIPPV. The majority of children with type II SMA can be expected to survive beyond childhood. Children with SMA have a hand tremor, polyminimyoelonus, which is very characteristic.

Table 22.45 The classification of the congenital myasthenic syndromes

		Clinical features	Response to anticholinesterase	Inheritance	Gene defect
Presynaptic	Congenital myasthenic syndrome with episodic apnea	Onset in neonatal period Episodic severe respiratory and bulbar weakness causing apnea, may be provoked by fever, infection or excitement Facial weakness Fatiguable ptosis No eye movement impairment	+	AR	Choline acetyltransferase (CHAT)
Synaptic	End plate acetylcholinesterase (AChE) deficiency	Childhood onset Fatiguable generalized weakness Slowly progressive (deterioration)	–	AR	ColQ mutations (ColQ polypeptide binds AchE tetramers)
Postsynaptic	Acetylcholine receptor (AChR) deficiency	Early onset Feeding difficulty Ptosis Impaired eye movements Motor delay	+	AR	AChR $\epsilon$ , $\beta$ or $\delta$ subunit mutations
	Fast channel syndrome	Similar to AChR deficiency	–	AR	AChR $\epsilon$ , $\alpha$ or $\delta$ subunit mutations
	Slow channel syndrome	Onset variable Weakness of scapular muscles and finger extensors Slowly progressive	–	AD	AChR $\epsilon$ , $\alpha$ , $\beta$ or $\delta$ subunit mutations
	Congenital myasthenic syndrome with rapsyn deficiency	Onset variable, at birth may be associated with arthrogryposis or facial malformation, apnea may occur especially in febrile illnesses Later onset may mimic antibody negative myasthenia gravis	+ 3,4-Diaminopyridine may produce further benefit	AR	RAPSN mutations

Fig. 22.37 SMA type 1: alert infant with severe limb and intercostals muscle weakness.

Individuals with SMA type III walk with a waddling gait and increased lumbar lordosis. Life expectancy is not affected [Table 22.46](#).

### Spinal muscular atrophy with respiratory distress (SMARD)

The presentation of this condition is usually with respiratory distress due to diaphragmatic paralysis; often there is eventration of the diaphragm. Limb weakness is more marked in the upper limbs and distally.

SMARD is genetically heterogeneous. Inheritance is autosomal recessive, mutations in the immunoglobulin mu-binding protein2 have been found in patients with the condition.<sup>580</sup>

### Pontocerebellar hypoplasia type 1 (PCH 1)

This condition is characterized by neonatal onset, congenital contractures, ventilatory insufficiency and early death.<sup>581</sup> There is neurophysiological and histopathological evidence of anterior horn cell disease. Hypoplasia of the brainstem and cerebellum is seen on brain imaging. Linkage to the SMN1 gene has been excluded.<sup>582</sup> No gene locus has yet been identified.

Table 22.46 SMA; clinical spectrum

Type	Age of onset	Motor skills	Life expectancy
I Werdnig–Hoffmann	< 6 months	Never sits alone	80% die by 1 year
II Intermediate	6–18 months	Sits alone, unable to walk	Variable
III Kugelberg–Welander	> 18 months	Walks more than 4 steps alone	Normal

## Spinal muscular atrophy, congenital benign with contractures

A number of families have been described with lower limb deformity present at birth and complete sparing of the upper limbs.<sup>583</sup> Motor and sensory nerve conduction is normal with giant motor units present on EMG. The condition is nonprogressive and inheritance is autosomal dominant. The gene locus is on chromosome 12q23-q24.<sup>584</sup>

## THE INHERITED NEUROPATHIES

### Introduction

Tooth, in 1886, described five cases with predominantly distal limb weakness and wasting, later referred to as peroneal muscular atrophy, suggesting that the primary pathology was in nerve.<sup>585</sup> In the same year Charcot and Marie described five further cases of peroneal muscular atrophy.<sup>586</sup> Despite their conclusion that the primary pathology was probably in the spinal cord, their names along with that of Tooth became eponymously associated with inherited neuropathies. Over the past decade, rapid progress has been made in defining the mutant genes causing this heterogeneous group of conditions. The nomenclature used has therefore also been in a state of flux with neurologists tending to use the term hereditary motor sensory neuropathy (HMSN) while in the genetic literature the term Charcot–Marie–Tooth (CMT) is more commonly found. The population prevalence of hereditary peripheral neuropathies is approximately 1 in 2500.

CMT is classified as type 1, demyelinating with a median nerve motor conduction velocity of less than 38 ms, or type 2, axonal with normal nerve conduction velocity.

### The genes and proteins involved

CMT 1A is the most common form of CMT1, accounting for 70% of cases, and is caused by a 1.5-Mb duplication of chromosome 17p11.2.<sup>587</sup> The gene involved is peripheral myelin protein 22 (PMP22). Deletions in this gene can also occasionally cause CMT 1A, although they are usually responsible for hereditary neuropathy with liability to pressure palsies (HNPP).<sup>588</sup> HNPP usually presents in adult life. Autosomal dominant point mutations in the human myelin protein 0 (P<sub>0</sub>) gene on chromosome 1q22-q23 lead to CMT 1B and occasionally the axonal neuropathy CMT 2 phenotype.<sup>589</sup>

Mutations in the early growth response 2 gene (EGR2) on chromosome 10 can cause either a dominant or recessive inherited demyelinating neuropathy.<sup>590</sup>

Point mutations in the Connexin 32 gene (CX32) cause X-linked CMT.<sup>591</sup>

The myelin proteins PMP22, P<sub>0</sub> and CX32 all play a part in the maintenance of myelin integrity. P<sub>0</sub> is an abundant myelin protein accounting for 50% of peripheral myelin protein. It transverse the Schwann cell membrane once and contributes the homophilic linkages between adjacent myelin lamellae thus bonding together the concentric myelin wraps. PMP22 accounts for only 2–5% of peripheral myelin protein. Its role is unknown, though it is thought to play a part in cellular growth.

Connexin 32 is a gap junction protein. It mediates the formation of intracellular gap junctions between the folds of Schwann cell cytoplasm, particularly in the paranodal regions. These act as a channel for the transport of electrolytes and metabolites between the myelin wraps of an individual cell, the flow extending to the axon.

### Phenotypes

CMT 1 refers to autosomal dominant demyelinating CMT. Most affected people present in childhood or adolescence with a slowly progressive distal wasting and weakness, associated with evolving areflexia, distal sensory loss and pes cavus. Affected people show evidence of demyelination and remyelination with onion bulb formation and Schwann cell proliferation on nerve biopsy.

Affected males with X-linked CMT arising from point mutations in the CX32 gene present in a way indistinguishable from those with CMT 1. Carrier females are mildly affected.

Dejerine–Sottas disease and congenital hypomyelinating neuropathy (CHN) represent a more severe phenotype. They present in the first 10 years of life with extremely slow motor conduction velocities. Point mutations in PMP22, P<sub>0</sub> and EGR2 can exist in either the heterozygous or the homozygous state, meaning these conditions may be either dominant or recessive.

To date five genes have been identified in families with autosomal recessive demyelinating neuropathies (referred to as HMSN type 1 autosomal recessive or CMT 4).

Autosomal dominant CMT 2 carries the same phenotype as CMT 1 though symptoms tend to develop later, in less severe form with preserved reflexes. Three loci and nine genes are described. An X-lined form of CMT 2 has been described in association with deafness and mental retardation.<sup>592</sup>

### The clinical approach

Most children presenting with CMT present with motor difficulties of some sort. There may be an earlier history of motor developmental delay and hypotonia, or the story may be of slowly increasing unsteadiness, falling off in performance in games at school, or increasing tightness in the tendo-Achilles with the emergence of pes cavus making shoe fitting ever more difficult. Sensory symptoms tend to be mild and late.

More severe forms, particularly those with recessive inheritance, may present with what appears to be a cerebellar ataxia with a scanning dysarthria. This means when children are investigated for ataxia the possibility of CMT should be considered.

The common clinical picture is that of a pattern of wasting and weakness of the calves and small muscles of the feet, pes cavus, hammer toes and broadening of the forefoot appearing later (Fig. 22.38). Weakness and wasting of intrinsic hand muscles is also frequently present (Fig. 22.39). The tendo-Achilles tends to be tight. In the forms of CMT

Fig. 22.38 CMT: pes cavus and clawing of toes.

Fig. 22.39 CMT: wasting of intrinsic hand muscles.

with a faster rate of progression, bilateral foot drop may emerge. These forms tend to have an earlier loss of tendon reflexes with the emergence of sensory symptoms and signs.

The first investigation is peripheral neurophysiology. In most children, assessment of the motor nerve conduction velocities will help define whether this is a demyelinating or axonal neuropathy. Where the neuropathy is demyelinating a common duplication in the PMP22 gene can be sought. This will account for almost 70% of children in the CMT 1 group.

Clearly the family history is a useful adjunct in reaching a diagnosis and in this way the CMT may be classified as dominant, recessive or in the absence of male to male transmission probably X-linked. In a typical small family, however, this is often impossible.

Many laboratories also offer screening for PMP22, P<sub>0</sub> and CX32 point mutations though the other rarer genes mentioned have only been identified in interested research laboratories.

In a child or adolescent with clinical and neurophysiological CMT 1, where there is no evidence of male to male transmission, no chromosome 17 duplication and nothing to suggest Dejerine–Sottas disease or congenital hypomyelinating neuropathy, screening should be carried for CX32 mutations. If negative, mutations in P<sub>0</sub> and PMP22 should then be screened, followed lastly by ERG2, if available. In the very small number of remaining demyelinating cases, especially the more severe ones

with a suggestion of recessive transmission, the MTMR2 and periaxin genes should be screened where possible.

In the axonal form of CMT screening for mutations in the known genes is not yet widely available. If there is no male to male transmission, and especially if the index case is female, CX32 should be screened first. If this is negative, P<sub>0</sub> should be screened next. If these are both negative the rarer genes might then be sought.

### Hereditary sensory and autonomic neuropathies (HSAN)

Hereditary sensory neuropathies are rare, accounting for 3% of hereditary neuropathies in the European population.<sup>593</sup> In this group of disorders there is loss of one or several modalities of sensation with less prominent clinical involvement of motor and autonomic function. Prominent features in presentation therefore are a conspicuous alteration of pain sensation related to the preferential progressive atrophy of small myelinated (delta) and usually the unmyelinated (C) nerve fibers.

Affected children may well therefore cause concern with painless burns, fractures, indolent ulcers and self-mutilation in infancy. Repeated injury may lead to an incorrect diagnosis of non-accidental injury.<sup>594</sup>

The HSANs are clinically and genetically heterogeneous; Table 22.47 gives the characteristics of the main types.

Table 22.47 The current classification of HSAN

Type	Clinical features	Inheritance	Gene
I	Onset after first decade Lack of pain sensation, reduced sweating especially over distal lower limbs Mild-moderate lower limb weakness Hyporeflexia Abnormal sensory conduction, motor conduction normal	AD	SPTLC1 (serine palmitoyl transferase long chain base subunit 1)
II	Early onset Fungiform papillae absent from tongue Repeated trauma, ulcers, infected sores on hands and feet Diminished pain, temperature and touch sensation No weakness Reflexes absent or decreased Absent sensory nerve action potentials, normal motor nerve conduction velocities	AR	Unknown
III Riley–Day	Feeding difficulty from birth Absence of tears Abnormal temperature control Postural hypotension Emotional lability Absent fungiform papillae from tongue Absent corneal reflexes Relative indifference to pain Absent flare to intradermal histamine Reflexes decreased or absent Motor nerve conduction velocities slightly slow Sensory conduction normal	AR	IKBKAP (inhibitor of kappa light polypeptide gene enhancer in B cell, kinase complex-associated protein)
IV	Anhydrosis with recurrent fevers Painless injury and self-mutilation Learning difficulty frequent Reflexes preserved	AR	Receptor tyrosine kinase for nerve growth factor TRKA
V	Early onset Painless injuries of extremities No weakness Normal reflexes Normal motor and sensory conduction	Uncertain, presumed AR	Unknown

## DECREASED CONSCIOUSNESS AND COMA (INCLUDING HYPOXIC–ISCHEMIC, TOXIC AND METABOLIC ENCEPHALOPATHIES)

The approach to the child with decreased conscious level should be systematic. There are many potential causes and many specific treatments need to be considered. Reduced conscious level may be difficult to detect in infants and in all children may be obscured by the other features at presentation.

Initially it may not be apparent that the child has a primary neurological problem. For example, a high fever or abnormal cardiac or respiratory signs may distract the clinician. Conversely, reduced conscious level is most commonly caused by problems outside the CNS, e.g. hypoxia of primary respiratory or cardiac origin. Treatment of these will often improve CNS function and conscious level. In the emergency situation, the approach recommended in the APLS (Advanced Pediatric Life Support) manual<sup>95</sup> should be followed. These follow the ABC (Airway, Breathing, Circulation) principles of resuscitation. This systematic approach will address problems in other organ systems that are affecting the CNS. For example, in a child with meningococcal septicemia, reduced conscious level may be prominent at presentation but securing an adequate airway, optimizing oxygenation and treating shock will improve CNS function.

### CLINICAL ASSESSMENT

The main causes of decreased conscious level are shown in Table 22.48. The initial history should concentrate on detecting these and, for example, a history of recent trauma, previous seizures or potential drug ingestion will guide appropriate investigations and may suggest specific treatments.

Symptoms of raised intracranial pressure (ICP) include poor feeding, vomiting, irritability, lethargy and seizures. Signs include a full fontanel (in babies), scalp vein distension, macrocephaly, bradycardia, hypertension, abnormal respiratory patterns, and focal neurological deficits including false localizing signs, particularly sixth nerve palsies.

Clinical examination should be thorough. General examination should seek signs suggestive of the causes in Table 22.48, e.g. the rash of meningococcal disease. In school-age children the conscious level should be assessed using the Glasgow Coma Score (GCS) (Table 22.49). In the preschool child the verbal response component of the GCS is unreliable and modified coma scores have been proposed (Table 22.49). In the intubated child modifications to the GCS use grimace rather than vocalization. While in adults the GCS is well validated and scores have been shown to have prognostic significance, this is not yet the case in children. However, a coma score of 8 or less should generally prompt intubation, as the child is unlikely to be able to protect the airway adequately. The coma score is a useful tool for the ongoing assessment of the encephalopathic child, in order to detect improvement or deterioration in the child's condition.

It is important to complete and document a neurological examination early in the assessment of the unconscious child. Management of the child may include ventilation, sedation and muscle paralysis, which are likely to interfere with later assessments. Particular attention should be paid to pupil size and reactivity. Pinpoint pupils may be a sign of poisoning, particularly with opiates and barbiturates. Small reactive pupils are a feature of medullary lesions and mid-size, nonreactive pupils of midbrain lesions. Fixed dilated pupils are an ominous sign, often indicating terminal coning, but can also occur temporarily, after severe hypoxia and as a consequence of hypothermia, seizure activity and occasionally after the administration of certain drugs, notably barbiturates such as thiopental. Metabolic conditions can cause all these types of pupillary abnormality. A unilateral dilated pupil may indicate incipient herniation, causing dysfunction of the third cranial nerve. This is particularly likely to occur with ipsilateral space-occupying lesions, such as extradural hematomas.

Table 22.48 Important causes of acute encephalopathy

<b>Infectious and parainfectious encephalopathies</b>
Meningitis (mainly bacterial, rarely fungal, protozoal and viral)
Cortical thrombophlebitis
Cerebral abscess and empyema
Primary viral encephalitis
Postinfectious encephalitis
Acute disseminated encephalomyelitis
Cerebral malaria

GCS total 3–15; CCS total 3–15.

The fundi should be examined for signs of metabolic disease, retinal hemorrhage and papilledema. Absence of papilledema does not rule out raised ICP and does not indicate that it is necessarily safe to do a lumbar puncture. Voluntary and reflex eye movements should be assessed, facial weakness and asymmetry looked for and bulbar muscle functions tested. When oculocephalic reflexes are preserved (doll's eye movements) the eyes are able to maintain fixation when the head is moved side to side or up and down. When these are lost the eyes move with the head. Oculovestibular reflexes (caloric responses) are usually tested as part of brainstem death tests and require the eardrum to be intact. Deviation of the eyes toward a cold water stimulus and away from a warm water stimulus occurs.

The child's body posture and any abnormal movements should be noted. The presence of decorticate (arms flexed, legs extended) or decerebrate (arms and legs extended) postures are particularly significant. Tone, power, reflexes and plantar responses in the limbs should be documented and interpreted in the light of recently administered drugs such as neuromuscular blockers.

## INVESTIGATIONS

During the primary assessment and resuscitation blood should be taken for FBC, U&E, calcium, blood cultures and blood glucose. Specific treatments such as glucose for hypoglycemia, antibiotics for meningococcal septicemia and calcium for seizures caused by hypocalcemia may be indicated. Further investigations which will aid the supportive care of the child include arterial blood gases, coagulation screen and urine and plasma osmolality (Table 22.50).

Subsequently, further investigations may be indicated for specific conditions. These may include a toxicology screen, blood alcohol level, specific drug levels (such as anticonvulsants), plasma ammonia and lactate levels and liver function tests. Urine for amino and organic acids and porphyrins should be collected. An early CT scan is usually indicated unless a cause for the child's condition is apparent. Lumbar puncture should usually be deferred at least until the results of this are known.<sup>596,597</sup> An X-ray skeletal survey may be useful at this point if non-accidental injury is suspected. Children who are hypoglycemic should have blood and urine collected while hypoglycemic or immediately thereafter for later metabolic investigations. Laboratory

advice should be sought on the samples required and their subsequent handling and storage.

## CONTINUING MANAGEMENT

The continuing management of the child with reduced conscious level is directed at maintaining homeostasis and at detecting and treating the underlying cause. Maintenance of cerebral perfusion pressure (CPP), cerebral blood flow (CBF) and normal cerebral metabolism are important. Raised ICP should be detected and treated. However, CPP is also affected by systemic factors such as hypotension. Children in coma require repeated reassessment and skilled neurological nursing usually on an intensive care or high dependency unit. Specific therapy for certain causes of encephalopathy, such as hemodialysis for removal of drugs after overdose, may be required.

EEG

## The physiology of intracranial pressure, cerebral perfusion pressure and cerebral blood flow

### *Intracranial pressure*

Raised ICP can arise by a number of different mechanisms. The commonest causes are intracranial space-occupying lesions, CNS infections, hydrocephalus, intracranial hemorrhage, metabolic disease (with cerebral edema), meningeal inflammation (reducing CSF resorption) and dural sinus thrombosis (raising venous pressure) are the commonest. A rise in ICP may lead to secondary brain shifts with herniation of brain contents. A critical reduction in perfusion to the brain may result, leading to disability or death.

Cerebral edema has several pathological types. Both focal and generalized cerebral edema can cause raised ICP and decreased consciousness. Focal cerebral edema may be associated with localized brain dysfunction and focal neurological signs. Generalized cerebral edema may be associated with false localizing signs. Vasogenic edema results from changes in capillary permeability and occurs with CNS infections, head trauma and in encephalopathies due to toxins, hypertension and seizures. Osmotic edema is seen in hyponatremia, diabetic ketoacidosis and excessive fluid resuscitation. Cytotoxic edema is secondary to intracellular energy failure and occurs with hypoxic-ischemic insults, status epilepticus and severe infection. Hydrocephalus may result in transependymal resorption of CSF and periventricular interstitial edema. Finally, loss of cerebral autoregulation as occurs with systemic hypertension and in hypercapnia results in hydrostatic edema.

In children under 12–18 months the open sutures enable the skull volume to increase and large intracranial masses may accumulate without rapid or large rises in ICP. After 2 years of age the cranial cavity behaves more like the adult with a fixed volume. The development of cerebral edema as a normal response of the central nervous system to injury causes an increase in the volume of the brain. With the volume of the skull cavity fixed there will inevitably be either diminution in the total volume of CSF spaces and/or diminution of the pool of venous blood within the skull. As ICP increases there will be an increased resistance to inflow of arterial blood and thus a fall in the cerebral perfusion pressure. Cerebral perfusion pressure (CPP) equals the mean systemic blood pressure (SBP) minus the mean ICP. A fall in CPP leads to a fall in the CBF and if this is below 20 ml/100 g of tissue per min, brain ischemia will develop. Brain ischemia further increases the formation of cerebral edema leading to a further rise in ICP. If CBF falls below 10 ml/100 g per min electrical dysfunction of the neurones and loss of intracellular ion homeostasis occurs.

Generalized rises of ICP will first cause transtentorial and eventually transtentorial herniation. Unilateral increases in ICP, for example secondary to hematoma, will cause ipsilateral uncal herniation and compression of the third nerve against the free border of the tentorium with ipsilateral pupillary dilation secondary to loss of parasympathetic constrictor tone to the ciliary muscles. Uncontrolled further herniation will cause, in addition, contralateral third nerve palsy. At the same time the brainstem is shifted downward to the foramen magnum, which impairs the blood supply to the brainstem from the perforating branches of the basilar artery and results in brainstem ischemia. The signs of cingulate gyrus herniation, tentorial herniation and foramen magnum coning are given in (Table 22.51).

Monitoring ICP can be useful in head trauma, certain metabolic encephalopathies and in intracranial infection. There is little evidence of benefit in Reye syndrome, hepatic encephalopathy or hypoxic-ischemic injury (such as postcardiac arrest). A number of techniques have been described for monitoring ICP.<sup>598</sup> All depend on the principle, which is generally but not invariably correct, that the pressure within the cranium is the same in all departments. The preferred technique will depend on whether ventricular dilation is present or whether the ventricles are small and shifted as a result of the brain swelling. In the child with cerebral edema it is possible to monitor the ICP continuously by the use of a subdural or subarachnoid Teflon catheter. In infants this can be placed percutaneously through the anterior fontanel. Ventricular transducers record either the

ventricular pressure, or if not in the ventricle, the brain parenchymal pressure. Cerebral intraparenchymal devices are also available. The normal ICP in adults is 0–15 mmHg (0–2 kPa). In the newborn, older infants and toddlers the upper limits are 3.5 mmHg, 5.5 mmHg and 6.5 mmHg respectively.<sup>599</sup>

Brief rises in ICP may occur during coughing, straining and crying, as well as other physiological activities that increase the central venous pressure. Sustained elevations or intermittent rises in pressure in the form of pressure waves may also occur and may require treatment. An increase in the ICP may come about as a result of increasing the brain, blood or CSF contents of the skull. The increase in ICP that results from a given increment in volume depends on the ICP–volume status. As the ICP increases small changes in volume may result in significant changes in pressure.

### *Cerebral perfusion pressure*

With increasing ICP there is an increase in the cerebral venous pressure. This remains about 3 mmHg below the ICP so that cerebral circulation continues. The cerebral perfusion pressure is the difference between the mean systemic arterial pressure (MAP) and the ICP, i.e.  $CPP = MAP - ICP$ .

The relationship between ICP and cerebral perfusion pressure is complex. Raised ICP may be caused by an increase in CBF or it may be the limiting factor producing a reduction in CBF. In encephalopathies the brain is frequently pale and devoid of blood flow as a result of raised ICP producing ischemia. The normal cerebral perfusion pressure is 60–70 mmHg. There is a progressive fall in brain perfusion with decreasing CPP down to a CPP of 40 mmHg. Below this ischemic infarction may result.

### *Cerebral blood flow*

During acute encephalopathy there are changes in general and regional cerebral blood flow (CBF). Cerebral autoregulation is the maintenance of cerebral blood flow by alteration of the cerebral blood volume in response to large changes (increases or decreases) in the systemic perfusion pressure. Cerebral autoregulation is often impaired (globally or regionally) with encephalopathy so that CBF is related directly to systemic arterial pressure. Excessive blood flow (luxury perfusion) is sometimes seen after hypoxic-ischemic injury. It is possible using the Fick

principle to measure changes in CBF but this is rarely used in clinical practice. Ordinarily there is coupling between CBF and brain metabolism but in coma the cerebral metabolic rate for oxygen falls as well as the CBF.

The main determinant of CBF is the arterial PaCO<sub>2</sub>. Increases in the arterial PaCO<sub>2</sub> increase CBF due to cerebral vasodilation while decreases in arterial PaCO<sub>2</sub> reduce CBF due to cerebral vasoconstriction. Changes in CBF cause changes in the cerebral blood volume and this influences the ICP. Inducing hypocapnia by hyperventilation can reduce ICP (if the raised ICP had been due to cerebral vasodilation). If, however, the CBF is already low from cerebral edema then hyperventilation will result in worsening ischemia. The cerebral circulation will readjust vascular tone to lowered PaCO<sub>2</sub> levels over time. The effect of hyperventilation can be used for controlling acute rises in ICP. In the intensive care setting PaCO<sub>2</sub> is generally kept at 4.0–4.5 kPa. Levels below this risk causing infarction in areas of relative ischemia.

### Treatment of raised ICP

Major principles involved in the treatment of raised ICP are summarized in Table 22.52. The child's airway should be secured. Intubation is usually indicated if the GCS is 8 or less. As previously discussed, the arterial concentration of CO<sub>2</sub> has a significant effect on CBF and hence cerebral perfusion. Maintenance of a normal or high normal blood pressure is beneficial and inotropic support is often beneficial. Adequate pain relief and sedation are important to reduce changes in ICP from arousal, coughing, etc. Reducing fever will reduce whole body and cerebral metabolism.

Specific treatment may be aimed at reducing the volume of CSF, blood or brain (including brain edema). Removal of CSF is possible through a ventricular cannula but this may not be possible if the ventricles are compressed. The technique has been particularly advocated in tuberculous meningitis. Hyperventilation should not be used prophylactically, as prolonged hyperventilation is associated with a significant risk of brain ischemia. However, it can be useful to treat episodic increases in ICP. The PaCO<sub>2</sub> level should be reduced to no lower than 3.5–4.0 kPa. At other times it should be kept at 4.0–4.5 kPa.<sup>600</sup>

Seizure activity should be promptly controlled. Clinical detection of seizures may be difficult or impossible, particularly when neuromuscular blocking agents are being used. Continuous EEG monitoring has an important role. Phenytoin and phenobarbital are the antiepileptic drugs most commonly used in the ICU setting. Both have important

cardiorespiratory depressant effects and these should be looked for carefully.

There is no role for the routine use of steroids to control raised ICP.<sup>601,602</sup> However, they are useful in reducing the focal edema around mass lesions and postoperatively. In *Hemophilus* meningitis, steroids reduce the incidence of subsequent sensorineural deafness.<sup>603</sup>

Mannitol increases serum osmolality and reduces brain water by controlled hyperosmolar dehydration. If mannitol and furosemide (dose 0.5–1 mg/kg) are used together, the circulating volume is decreased and, depending on the central venous pressure, volume expansion may be necessary. Mannitol is given in a dose of 0.25–0.5 g/kg per dose. The effect may last only 6 hours and rebound rises in ICP may be seen. Mannitol is used to treat acute rises in ICP rather than as a regular or prophylactic agent. It should be used with caution in the presence of impaired renal function as hyperosmolality and renal failure may ensue.<sup>604</sup>

Barbiturates produce a reduction in cerebral metabolic rate and CBF. Their use is restricted to those patients with unrelieved raised ICP despite appropriate use of other therapies such as inotropes, ventilation, mannitol and, if appropriate, steroids. It is important to monitor the systemic blood pressure carefully during their use since hypotension, causing a reduction in the cerebral perfusion pressure often occurs. Inotropes are usually needed.

The role of controlled hypothermia in the treatment of raised ICP is controversial. There are theoretical benefits from reduction of cerebral metabolism. Complications of hypothermia include respiratory infection and cardiovascular compromise that impair optimal oxygenation and could have a deleterious effect. Current published studies are inconclusive. Reports of the benefits of decompression craniotomy are anecdotal.

Once the ICP has remained normal for 48 hours the measures instituted can be gradually reversed, one at a time while monitoring continues.

### OUTCOME

The underlying cause of the coma determines the outcome. In nontraumatic encephalopathy, overall mortality is around 30%. In those children who survive, 25% will have a degree of neurological impairment. Children whose encephalopathy has an infectious or hypoxic–ischemic cause do worst while children with metabolic causes for their coma generally do better. The factors affecting outcome in traumatic head injury are dealt with in the relevant sections below. As children recover from their encephalopathy regular neurological and developmental assessment is required in order to detect impairments. Physical problems such as hemiparesis or quadraparesis are often detectable within the first few weeks. Cognitive, psychological and behavioral impairments may take months to become apparent. This is particularly recognized after traumatic brain injury. Tests of hearing and vision should be routinely undertaken. Involvement of a clinical or neuropsychologist in the rehabilitation period to assess deficits and advise on behavioral and educational support is useful. The establishment of dedicated rehabilitation teams, often nurse led, will facilitate optimal recovery<sup>605</sup> and give expert advice to hospital and community services with regard to long term management.

### The persistent vegetative state

There has been considerable interest in the diagnosis of the persistent vegetative state. This is characterized by the patient being awake, but without being aware, and occurs in those who have suffered severe and irreversible damage to their cerebral cortex, but whose brainstem function remains to some degree intact. Those affected may open their eyes, have sleep–wake cycles and chew and swallow. Such skills may be misinterpreted as signs of awareness. The diagnosis is particularly difficult in children and it is extremely hard for the family not to hope for improvement. There is a continuum of awareness and responsiveness and it may not be possible to draw a line beyond which a child is said to be in the persistent vegetative state, even for legal purposes. In children who have very low levels of functioning,

Table 22.52 Management of raised intracranial pressure

1. Optimize metabolic state	Maintain normal blood glucose Avoid hyponatremia and hypocalcemia Maintain normal temperature
2. Maintain cerebral perfusion	Maintain cerebral perfusion pressure above 60 mmHg Maintain BP at normal levels or above Ventilate to achieve low normal PaCO <sub>2</sub> (4.0–4.5 kPa) Maintain high-normal oxygenation PaO <sub>2</sub> (12–14 kPa)
3. Improve cerebral venous return	Head-up tilt (15–20 degrees)
4. Reduce effect of cytotoxic edema	Fluid restriction to 75% of maintenance Once hemodynamically stable give intravenous mannitol (0.2–0.5 g/kg)
5. Avoid secondary insults	Prompt treatment of seizures (anticonvulsants) Minimize external stimuli (appropriate sedation and paralysis)

good nursing care and support for the family is important. Decisions around resuscitation, should deterioration or cardiac arrest occur, should only be made after full discussion with the family and should be regularly reviewed to ensure they are still appropriate. Cultural and religious views must be taken into account (see Ch. 10).

### Brain death

In the UK it is accepted that permanent functional death of the brainstem is equivalent to brain death. In patients where brainstem death is established actual death always follows, although this may be delayed if mechanical ventilation is continued. Its diagnosis depends on the absence of brainstem function for at least 24 hours, once hypothermia and drug intoxication have been excluded. At least in the UK, EEG evidence is not needed and the diagnosis remains clinical. The use of organs of brain dead individuals for transplantation has led to standardized methods for diagnosis of brain death.

Two senior doctors working independently perform tests of brainstem function. The core temperature should be above 35°C and there should be no hypovolemia or biochemical abnormalities. No drugs that can affect the level of consciousness or respiratory function should be still acting. It may be difficult to establish if this criterion is satisfied in children who have been given anticonvulsants, especially barbiturates, during their illness. Drug levels may be helpful. There should be no treatable metabolic or endocrine cause for the coma. The mechanism of injury or underlying cause for the irreversible coma should be known. The child must be unconscious with no change in state and no sleep–wake cycles. There should be no response, including heart rate, to a central painful stimulus, e.g. supraorbital pressure. There must be ophthalmoplegia with fixed dilated pupils and no gag, cough, oculoccephalic or oculovestibular reflexes. An apnea test is carried out (5–8 minutes of apnea without any ventilation at the end of which the PaCO<sub>2</sub> should be equal to or greater than 6.7 kPa (56 mmHg). Adequate oxygenation is provided throughout the test by oxygen introduced at 6–10 L/min via a tracheal cannula.

If the brain death criteria are satisfied, then ventilation may be terminated or, where indicated by the relatives and where there is no objection from the legal authorities (coroner in England and Wales, procurator fiscal in Scotland), organ donation may take place.

It has been debated whether adult criteria for brainstem death apply to children, particularly infants. The President's Commission in the USA, that developed brain death criteria, believed that they did, and recommended that evidence of the cessation of higher mental function, in addition to that obtained from clinical evaluation, is required. This may involve the use of EEG and brainstem evoked potentials along with techniques to demonstrate absence of CBF. These include radionuclide cerebral angiography, cerebral Doppler ultrasound and xenon CT. Such techniques may be particularly useful if the administration of drugs makes clinical assessment difficult. There are no published reports of children who have survived after fulfilling adult brain death criteria.

### HYPOXIC–ISCHEMIC ENCEPHALOPATHY

Children who are successfully resuscitated from cardiac arrest may have experienced a critical period of hypoxia and/or ischemia. If this has been severe, the child may not recover consciousness and criteria for brain death may be fulfilled. Unlike adults, in whom primary cardiac arrest is common, most children who suffer cardiac arrest have had a period of respiratory and/or cardiovascular failure prior to the arrest.

Initial hypoxia is followed by a build-up of carbon dioxide and lactic acid leading to acidosis. There then follow two major mechanisms:

1. Ion pumps on the brain cell membranes are inhibited resulting in accumulation of extracellular K<sup>+</sup> and intracellular Na<sup>+</sup> and Ca<sup>2+</sup> and in depletion of ATP and phosphocreatine. The result is cytotoxic edema, which contributes to raised ICP and infarction. The release of glutamate causes a rise in intracellular calcium and this activates proteases resulting in secondary cell death.
2. Cardiac muscle dysfunction results in a fall in systemic blood pressure below that necessary to maintain cerebrovascular

autoregulation. This results in a failure of cerebral perfusion and ischemic infarction is added to the hypoxia. The low systemic pressure also causes a degree of vasogenic brain edema.

The brain is able to withstand hypoxia without ischemia by anaerobic metabolism but is especially vulnerable to ischemia, which is associated with a failure in the delivery of metabolic substrates and an accumulation of lactic acid causing severe intracellular acidosis. This inhibits the activity of enzymes causing lysosomes to rupture.

The hypoxic–ischemic causes of encephalopathy and coma are listed in Table 22.53.

CT scan done within hours of resuscitation from an hypoxic–ischemic insult may be normal. Progressive edema may then be seen over the following 24–48 hours. Changes indicating severe brain injury include generalized hypodensity of cerebral cortex, marked brain swelling and loss of gray–white differentiation. Low density areas indicating infarction in the cortex or basal ganglia may take 1–2 weeks to become apparent.

Decisions on whether active treatment is appropriate following hypoxic–ischemic insults are heavily influenced by the likely severity of subsequent neurological sequelae. However, early on, the extent of long term damage may be very difficult to predict. The presence of a burst suppression pattern on EEG is associated with a poor outcome, but lesser abnormalities are not very helpful in predicting outcome. Children with encephalopathy due to hypoxic–ischemic injury generally have a worse outcome than other causes of acute encephalopathy. No specific interventions have been shown to be effective. The use of calcium channel blockers and glutamate antagonists is not supported by clinical trial data.

It is important, when cardiac arrest follows near drowning, that resuscitation is continued until the child is no longer hypothermic.<sup>606</sup> However, in a study<sup>607</sup> all patients submerged for more than 9 minutes and requiring more than 25 minutes of cardiopulmonary resuscitation either died or were severely impaired.

### TOXIC ENCEPHALOPATHIES

#### Carbon monoxide poisoning

This may be caused by faulty domestic heating equipment or from car exhaust fumes. Mild poisoning causes headaches, vomiting, sweating and breathlessness. Severe poisoning leads to coma and seizures. Residual neurological deficits, particularly extrapyramidal signs, are common following recovery. CT scan may show extensive white matter and basal ganglia lesions. Treatment is through supportive care and the provision of high flow or hyperbaric oxygen.<sup>608</sup>

## Burn encephalopathy

In severe burns (greater than 30% of body surface) an encephalopathy may be seen several days to 2 weeks after the injury. Seizures, lethargy, reduced conscious level with personality change are common.<sup>609</sup> Correction of hypovolemia, metabolic abnormalities and treatment of infection are also important aspects of management in this setting. The course is generally favorable.

## Drug poisoning

In toddlers and young children accidental poisoning is common. It should be considered in all children with acute encephalopathy and samples for urine and blood toxicology taken. Deliberate administration of drugs to children in Munchausen syndrome by proxy (see Ch. 4, p. 50) is rare.

The signs and symptoms seen in association with the encephalopathy vary with the drug ingested. A history of all possible drugs within the household should be elicited. Specific features on examination or initial investigations may give further clues. Although specific antidotes are rarely available, enhanced removal of the drug from the body by hemofiltration or dialysis is sometimes needed. The features of common poisons are shown in Table 22.54.

In older children alcohol intoxication is common. Detection of associated hypoglycemia is important. Abuse of cannabis, cocaine, heroin and solvents is widespread but presents infrequently to acute medical services.

Encephalopathy due to lead is now rarely seen since the reduction in exposure to environmental lead. It may present in toddlers with acute encephalopathy with seizures, ataxia and visual loss. Acute ingestion of iron tablets may also lead to an encephalopathy and seizures. Many children with accidental iron ingestion show a period of apparent recovery after the initial illness. However, continued cellular toxicity of iron is occurring and deterioration may occur unless specific therapy is given.

## METABOLIC ENCEPHALOPATHIES

Details of specific inborn errors of metabolism are given in Chapter 26. Some of these conditions can present with an acute or relapsing encephalopathy. The history may highlight previous similar episodes or features of chronic illness such as poor growth or intermittent vomiting. Examination, in addition to the neurological signs of encephalopathy, may show liver enlargement, cardiomyopathy or respiratory abnormalities.

All children who present with acute encephalopathies should have blood glucose, urea and electrolytes checked. If the glucose is low or borderline on stick testing, a laboratory glucose measurement should

be taken before dextrose therapy is given. If hypoglycemia is the cause of the encephalopathy then further specialist advice should be sought and investigations undertaken to determine the cause of hypoglycemia. Although it is common for children who are acutely unwell to become hypoglycemic, this should not be assumed.

Encephalopathy from hyperammonemia, secondary to urea cycle disorders, is an important consideration. Measurement of the ammonia should be undertaken. The incidence of Reye syndrome in the UK has decreased significantly since the reduced use of aspirin in children. The clinical picture of vomiting and deteriorating level of consciousness, hypoglycemia, abnormal liver function tests and hyperammonemia is characteristic. Some inborn errors of metabolism such as mitochondrial beta-oxidation defects and organic acidemias can present with a Reye-like illness. Specialist advice and specific investigations will determine the cause of hyperammonemia. In addition to the general care of any child with encephalopathy, specific treatment with sodium benzoate and sodium phenylbutyrate can help to reduce the blood ammonia and subsequent cellular damage.

Lactic acidosis in association with encephalopathy may be caused by a mitochondrial disorder. Many children who are critically ill, particularly with septicemia, will have a lactic acidosis and differentiating these in the acute phase may not be possible. Other signs of mitochondrial disorders such as poor growth, intermittent vomiting, retinopathy, seizures or nerve deafness should be sought. Mitochondrial disorders can mimic many neurological conditions and are often considered in the differential diagnosis. Investigations including blood and CSF lactate, skin and muscle biopsies with assay of respiratory chain enzymes are often necessary to pinpoint the metabolic defect. Although mitochondrial DNA sequencing is now widely available, many mitochondrial disorders are nuclear in origin and diagnostic testing is difficult.

## INFECTIOUS AND INFLAMMATORY DISORDERS OF THE CNS

Most organisms are capable of invading the nervous system. Direct effects can include cerebral edema, cerebritis, encephalitis, cerebral congestion, hydrocephalus, subdural effusion, empyema, ventriculitis, thrombophlebitis and abscess. Encephalopathy may also result from the effects of extracranial infection by inappropriate antidiuretic hormone secretion, inflammatory brain edema, thrombophlebitis, status epilepticus, severe endotoxemic shock and disseminated intravascular coagulation. *Escherichia coli* O157, *Shigella* and *Campylobacter* secrete neurotoxins that can cause coma and/or seizures.

Viruses may cause an acute encephalopathy by direct invasion of the brain or may attack specific parts of the central or peripheral

Table 22.54 Clinical features following common types of poisoning

Drug	Neurological manifestations	Non-neurological manifestations
Amfetamines	Depressed consciousness, delirium, agitation, mydriasis, hyperreflexia, choreiform movements	Cardiac arrhythmias, hyperpyrexia, hypertension, sweating, tachycardia
Anticonvulsants	Depressed consciousness, behavioral disturbances, ataxia, diplopia, seizures	Cardiac arrhythmias and hypotension (phenytoin), hyponatremia (carbamazepine), blood dyscrasias
Antidepressants (tricyclics)	Agitation, muscle rigidity, seizures, coma, mydriasis	Sweating, tachycardia, hyperpyrexia, vomiting
Antihistamines	Depressed consciousness, hallucinations, tremulousness, mydriasis, convulsions	Dry mouth, urinary retention, hypotension
Barbiturates	Ataxia, coma, absent tendon reflexes, miosis, respiratory depression	Hypothermia, hypotension
Lithium	Nausea, drowsiness, dysarthria, tremor, ataxia	Vomiting, cardiac arrhythmias
Methadone	Depressed consciousness, respiratory depression, miosis	Fecal and urinary retention, hypotension
Phenothiazines	Dystonia, extrapyramidal signs, lethargy	Hypotension
Piperazine	Ataxia, hypotonia	Vomiting, diarrhea
Salicylates	Depressed consciousness, convulsions, tinnitus	Hyperventilation, hyperpyrexia, hypoglycemia, metabolic acidosis
Theophylline	Seizures, depressed consciousness	

nervous systems, e.g. polio and the anterior horn cells, causing limb paresis, chickenpox and the cerebellum, causing ataxia and mumps and the aqueduct of Sylvius, leading to hydrocephalus. Viruses may also produce an acute postinfectious encephalitis that is characterized by demyelination.

## BACTERIAL MENINGITIS

Bacterial meningitis remains a significant cause of acute encephalopathy in childhood despite the introduction of vaccination for *Hemophilus influenzae* and *meningococcus* group C. Children usually present with the classic symptoms of headache, photophobia, vomiting, neck stiffness with fever and encephalopathy. The characteristic rash may be present in meningococcal disease. In infancy, the classic symptoms and signs are often absent. The child is often nonspecifically unwell with vomiting, fever, pallor and lethargy. A bulging fontanel may be present where the ICP is raised. Seizures, either focal or generalized, or tonic extensor spasms caused by raised ICP are a common accompaniment.

In acutely unwell children broad-spectrum antibiotics such as cefotaxime or ceftriaxone should be given immediately after taking blood cultures. Antibiotics vary in their ability to penetrate the CSF but third generation cephalosporins are broad spectrum and penetrate CSF quite well. Papilledema is usually absent initially. Lumbar puncture should be deferred in any child with a GCS of less than 13, focal symptoms or signs, papilledema or radiological evidence of raised ICP. A normal CT scan does not exclude raised ICP. Characteristically the CSF shows a raised white cell count (predominantly neutrophils), a raised protein level and a low glucose level compared to the blood glucose level. More details of the CSF features of bacterial meningitis are discussed elsewhere along with details on the responsible organisms and drug treatment.

Seizures occur in 30–40% of children with meningitis and are managed as in any child with acute encephalopathy. A vasculitis often complicates bacterial meningitis with both arterial and venous occlusion and infarction causing focal deficits, including spinal cord infarction. Subdural effusions are commonly seen but rarely require intervention. Subdural empyema is rare. Raised ICP in meningitis may be secondary to cerebral edema, acute hydrocephalus, venous sinus thrombosis or cerebral abscess. Fever is prolonged for more than 10 days in 13% of patients and usually no cause is found.

The outcome from bacterial meningitis in childhood varies according to the organism involved, the delay in starting treatment and the development of complications. In a review of outcome data from 45 published reports Baraff et al<sup>610</sup> found a mortality rate of 5–8%, but no major sequelae in 74–83%. Deafness was seen in 10% and was profound in 5%. The use of steroids in *H. influenzae* meningitis may reduce this figure.<sup>611</sup> Severe learning difficulties are unusual, but in prospective studies, up to 40% of children were found to have subtle learning deficits. Major motor deficits occurred in 4%.

Bacterial meningitis in the first month of life differs from that seen later. The signs and symptoms at presentation are less specific. Common presentations are with irritability, drowsiness, poor feeding, prolonged jaundice and focal seizures. Some babies look clearly septic. Interpretation of CSF results may be difficult. Many healthy newborns have up to 10 white cells/mm<sup>3</sup> and a raised protein level. The most common causative organisms are *E. coli* and the beta hemolytic streptococcus. However, many other organisms have been reported. Initial antibiotic treatment is often with ampicillin and gentamicin or a cephalosporin. The outcome is poorer than in older children. Mortality is 25% and up to 50% of survivors have cognitive and/or neurological deficits.<sup>610</sup> Hydrocephalus and epilepsy are frequent.

## VIRAL ENCEPHALITIS

Viruses can cause encephalitis either by direct infection of the CNS (primary viral encephalitis) or by indirect immune mediated mechanisms (postinfectious viral encephalitis). Viral encephalitis, especially if postinfectious, often has a rather insidious onset compared to meningitis.

There may be a history of headache, lethargy, vomiting and behavioral change in the few days prior to more definite encephalopathic features. The depth of the impairment of consciousness is variable and focal neurological signs, referable to any part of the brain, may occur. Seizures, particularly focal, are common. They may be difficult to control with status epilepticus. In a series from the USA, examining status epilepticus in pediatric intensive care, 50% of cases were associated with viral encephalitis.<sup>612</sup> In the UK it has become accepted practice to treat children presenting with encephalopathy and seizures with intravenous aciclovir, to cover herpes simplex virus infection, a third generation cephalosporin, to cover meningitis and erythromycin, to cover mycoplasma infection, while further investigations are undertaken.

Enteroviruses such as Coxsackie virus, herpesviruses (simplex, zoster and HHV6), measles virus and mumps virus are among the more frequent causes of viral encephalitis in the UK. Many of these can cause both primary and postinfectious viral encephalitis. The specific cause of encephalitis is often not found despite appropriate investigations having been undertaken. These include blood serology, viral cultures (throat, stool and CSF) and polymerase chain reaction (PCR) for specific pathogens. Although false positive and false negative results occur, PCR offers an extremely useful test for the rapid diagnosis of, in particular, herpes simplex encephalitis.

Herpes simplex virus is the commonest single identified cause of viral encephalitis in the UK. It has a predilection for the temporal lobes, but other parts of the brain may be involved, particularly in younger children. The 'typical' EEG pattern of triphasic waves over the temporal lobes is neither particularly sensitive nor specific for herpes simplex encephalitis. Brain biopsy is no longer recommended.

The CSF in viral encephalitis may be acellular or show an increased white cell count usually lymphocytes. The protein level is normal or slightly raised and the glucose level is normal. In some patients, initial CSF examination is normal and a repeat may be necessary after an interval of 5–7 days. CT scans are often normal, particularly in the early stages of the illness. MRI scanning, particularly if contrast and techniques such as diffusion weighted imaging are used, is more sensitive and may show localized areas of inflammation, particularly in herpes simplex encephalitis. In many cases, brain imaging shows evidence of diffuse brain swelling, which if severe may be associated with herniation.

Specific antiviral treatment with aciclovir is available for herpes simplex encephalitis. It must be given intravenously and for at least 10 days and possibly longer.<sup>613</sup> Other agents are active against certain other causes of viral encephalitis and can be especially useful in immunocompromised children. Advice from a virologist should be sought.

Neurological sequelae are common following viral encephalitis. Cognitive and motor deficits, epilepsy and behavioral change are present in up to 50% of survivors.<sup>614</sup> The immunocompromised child is especially vulnerable.

## TUBERCULOUS MENINGITIS, CAUSING ACUTE ENCEPHALOPATHY

Though this is not often seen in the UK now it remains an important cause of death and neurological disability worldwide. Tuberculous meningitis can occur despite BCG immunization. The clinical manifestations are extremely variable and virtually any combination of neurological symptoms and signs can occur. A prodromal phase of irritability, vomiting and apathy is often followed by fever, headache, focal neurological signs and meningism. Signs of raised ICP and coma will occur if treatment is not started. Ventricular dilation is present in nearly 80% of cases and urgent ventricular drainage may be needed.

There is often no history of exposure to TB and skin testing is unreliable. CT scanning is often done in the initial assessment and may show tuberculomas, hydrocephalus or meningeal enhancement. Lumbar puncture should be deferred until after CT scan. CSF usually contains a high lymphocyte count, a raised protein (often > 1 g/L) and a low CSF

glucose. Acid fast bacilli are rarely seen but culture may be positive in up to 50%. The use of PCR for mycobacterium DNA on blood and CSF has aided rapid diagnosis but false positives are seen. Further consideration is given to this illness under aseptic meningitis below.

### CEREBRAL ABSCESS AND SUBDURAL EMPYEMA

Cerebral abscesses can result from hematogenous spread of infection, often in association with congenital heart disease, local spread of infection from sinusitis or mastoiditis or arise as a complication of meningitis. *Streptococcus*, *Staphylococcus* and anaerobic organisms are the most common causes, but many other organisms have been reported. Abscesses are usually located in the cerebral hemispheres and present with encephalopathy, seizures and sepsis. CT with contrast is usually diagnostic, often showing enhancement of the abscess cavity with intense surrounding edema.

Intravenous antibiotics are the main treatment although surgical drainage may be needed. A prolonged course of 4–6 weeks is often needed with progress monitored by serial scans. Mortality is around 10% with 30% of survivors developing epilepsy.

Subdural empyemas are essentially abscesses lying in the subdural space. Their presentation is similar to that of cerebral abscesses in general. Surgical evacuation is usually necessary combined with prolonged antibiotic treatment.

### ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)

This acute patchy demyelination, occurring in the central nervous system, is thought to be an abnormal immunological response to infection. It may be considered a special form of postinfectious encephalitis. After an interval, following the precipitating viral infection, the child develops focal neurological signs, headache, mild encephalopathy and occasionally seizures. The focal neurological deficits depend on the sites of demyelination and may follow any pattern. There may be fluctuation or progression of signs in the days after presentation. CT scanning in the acute phase may be normal. MR scanning is usually diagnostic. The spinal cord may be involved. CSF examination characteristically shows a mild pleocytosis, usually lymphocytic, a normal or mildly raised CSF protein level and a normal glucose level. Oligoclonal bands may be present in some patients. Investigations looking for evidence of the precipitating infection often prove negative.

A good response is usually seen to steroids although it is unclear if the final outcome is influenced by such treatment. A 3- to 5-day course of intravenous methyl prednisolone is often given. More than 90% of children with ADEM make a full recovery from the initial episode, although this may take many months. Relapses are occasionally described.

### MULTIPLE SCLEROSIS

Clinically it is not possible to distinguish between ADEM and the first attack of demyelination due to multiple sclerosis. Long term follow-up studies have suggested that as many as 10% of patients with ADEM later develop multiple sclerosis and 2.7% of adults with MS had onset before 16 years of age, but it is rare under the age of 10 years. Clinical features include the relapsing remitting course. Visual and sensory symptoms are prominent as in adults. Seizures occur more commonly than in adults. Optic neuritis is characterized by a sudden reduction in monocular or binocular vision. A large central scotoma and papillitis are usually found on ocular examination. Though often considered a principal feature of multiple sclerosis in adults, few children with optic neuritis go on to develop multiple sclerosis.

Diagnosis of multiple sclerosis depends principally on the clinical picture combined with the results of MRI. CSF examination and visually evoked responses remain useful adjuvant investigations. High dose steroid treatment is effective for acute relapses but the use of beta-interferon remains controversial.

## CHRONIC INFLAMMATORY AND INFECTIOUS MENINGOENCEPHALOPATHIES

### Aseptic meningitis

Not all children with CNS sepsis present with acute encephalopathy. The onset may be insidious, diagnostically confusing, and if appropriate therapy is not initiated significant disability may result. Thus, the child with subacute or chronic meningitis who fails to respond to adequate antibiotic therapy presents the pediatrician with a worrying and perplexing problem. Most of these children will present with fever, nuchal rigidity and headache, probably after an insidious prodromal illness of general malaise and anorexia. The CSF initially may show pleocytosis changing to lymphocytosis within a few hours or a day or two. Antibiotic therapy for at least 48 hours is appropriate until cultures are shown to be negative, along with supportive therapy with fluids, analgesia and antipyretics.

As for acute encephalopathy a variety of viruses are potentially implicated. The enteroviruses account for 80% of all cases of aseptic meningitis in American studies. The UK picture is similar in infancy, but the mumps virus is a more common pathogen in the 1- to 9-year-old age group. This may change with the advent of mumps, measles, and rubella vaccination. Other common causes of aseptic meningitis include herpes simplex, adenovirus, measles, cytomegalovirus, rubella, varicella, Epstein-Barr, influenza, parainfluenza and rotavirus. The Epstein-Barr and Coxsackie virus in particular may run a subacute or chronic course. A rash may accompany the illness, which can be specific. Febrile convulsions may occur. Generally, younger children are irritable and resent handling, while older children complain of myalgia, photophobia and retrobulbar pain with evidence of nuchal rigidity in only about 50%.

It is generally accepted that after 12 hours of illness, almost all (97%) of the cellular response in CSF will be lymphocytic and that antibiotics can be withheld if the child seems otherwise well. CSF glucose may be low in up to 20% and CSF protein may be increased in up to 50%. Laboratory tests for bacteria will be negative but should be complemented by specific viral culture of CSF and other sites, including throat, feces and urine, as well as the measurement of serum viral-antibody titers. Raised alpha-interferon levels usually indicate a viral meningo-encephalitic illness, but slightly raised levels may also occur in bacterial infection. Viral identification can shorten antibiotic courses and reduce time spent in hospital.

After 48 hours of treatment the main alternative diagnoses to consider with a sterile polymorphic or pleocytic CSF are partially treated bacterial or tuberculous meningitis (TBM). Partially treated meningitis is particularly likely if there is a history of a course of oral antibiotics given for an intercurrent infection. This treatment may render microbiological techniques unreliable, and it is reasonable at this stage to stop all antibiotics in order to clarify the situation. If deterioration ensues, antibiotic therapy may be reinstated.

### Tuberculous meningitis

Tuberculosis (TB) of the CNS occurs in all ethnic groups; diagnosis and treatment are difficult. Late diagnosis carries an associated high morbidity and mortality. The incidence of TB of the CNS is increasing in part as a result of the acquired immunodeficiency syndrome becoming more common. In children, TB of the CNS is often a complication of primary infection with or without miliary spread. TB of the CNS should be considered in any child with a subacute history of fever, headache, seizures, vomiting, behavioral change or impairment of consciousness. Respiratory symptoms may or may not be present. It is important to note that tuberculous meningitis (TBM) results from Rich's focus produced in an intensive inflammatory response, particularly at the base of the brain. There is an associated vasculitis, which may result in convulsions, cranial nerve palsies, dyskinesia, hemiparesis or signs of a mild radiculopathy.

The CSF sugar is typically low, but may be normal in up to 10% of patients. When the ratio of blood to CSF sugar is greater than 2:1 in the presence of a lymphocytic meningitis, TBM must be given very serious consideration. The Mantoux test may remain negative for some

weeks due to anergy following primary exposure; the combination of lobar consolidation on a chest X-ray and aseptic meningitis is a particularly strong indication for antituberculous therapy. The decision to treat is rather easier when the X-ray shows classic miliary mottling, or examination of the fundi reveals choroidal tubercles.

Neuroimaging with MRI or CT with contrast may be helpful in diagnosis; tuberculomas may not be evident on an unenhanced scan. Lumbar puncture may be negative for culture of acid-fast bacilli, this diagnosis being made only on ventricular drainage. Acid-fast bacilli have to be searched for carefully in CSF specimens. The use of the polymerase chain reaction to detect antigen or metabolic products of tubercle bacilli can be misleading, with a one in ten false positive rate.

Treatment of tuberculous meningitis involves administration for at least a year of two antituberculous therapeutic agents that penetrate the blood-brain barrier and tuberculomas. Isoniazid and rifampicin are the mainstay of continued treatment during this period. Initially, four drugs are required, usually rifampicin, isoniazid, pyrazinamide and ethambutol. Steroids are of value when there is progressive neurological disorder or deteriorating consciousness, once appropriate antituberculous chemotherapy is begun. Further detail on treatment is given in Chapter 29.

### Other causes

When a child with lymphocytic CSF does not improve as expected, a full reappraisal of the history and findings is appropriate, and thoughts on differential diagnosis should be broadened. Possibilities are rarer bacteria (see below), an immune paresis with opportunistic infection, a fistula, autoimmune disease or toxins.

Five percent of all children with acute lymphoblastic leukemia have CNS disease at presentation. The CNS is the most common site for relapse. Usually, associated signs of bone marrow failure (anemia, thrombocytopenia, recurrent infection) will aid diagnosis. Rarely, primary CNS lymphoma may present in this way. It is essential that bone marrow investigation is performed before the use of steroids.

In an immunocompromised or severely debilitated child, fungal infection, including candida and cryptococcus, may spread to the CNS from specific skin or oral lesions. Stains for fungi, swabs, cultures, antibody titers and urine microscopy should identify the cause. When the degree of debility is severe, and particularly when there is marked and rapid wasting of muscles, it may be justified to administer a course of amphotericin. In immunocompromised children, in addition to severe illnesses caused by the common agents, opportunistic pathogens may cause an encephalopathy.

Neurological manifestations of nervous system infection with *Borrelia burgdorferi* (a spirochete) are protean. It is a multisystem disorder, known also as Lyme disease, affecting the skin, joints, nervous system and cardiovascular system. *Borrelia* inhabits the gut of the *Ixodes* tic. The tic is widespread throughout the UK but found in greater numbers in woodland.

Man is infected by the bite of a tic producing (in most cases) a slowly enlarging patch of erythema (erythema chronicum migrans). A nonspecific flu-like illness may occur at this stage. These symptoms may be followed by cranial poly- or mononeuropathies, aseptic meningitis, transverse myelitis, postinfectious polyneuritis and encephalitis. A history of skin lesion or a tic bite is not always obtained.<sup>615</sup> Diagnosis is difficult, and serological studies may not be positive at the time of neurological presentation. Specific IgM is the most valuable serological test and intrathecal synthesis of specific antibodies which immunoblot the spirochetal antigen may also (in due course) be helpful diagnostically. Treatment in childhood is usually with penicillin or erythromycin. Nervous system disease must be treated aggressively as chronic encephalopathy may ensue. There is increasing evidence<sup>616,617</sup> in neuroborreliosis that intravenous cephalosporins are superior to penicillin, because of the latter's relatively poor CNS penetration.

The protozoon *Toxoplasma gondii* may cause meningitis in immunosuppressed children. It is usually accompanied by lymphadenopathy. The histology of an affected node may give the diagnosis, as may the presence in the serum of specific IgM. Treatment with sulphonamides, pyrimethamine or spiramycin is effective.

Leptospirosis results from contact with infected animal urine (mainly rats), usually in contaminated water or from farm machinery. After an incubation period of 10 days, the illness typically produces a high fever, sweating, headaches, conjunctival suffusion, muscle tenderness and pain with meningitis. Cardiac or renal failure may occur, with spontaneous improvement after 3 weeks. Diagnosis is based on cultured blood and urine and rising antibody titers after the first week. Penicillin, erythromycin and tetracycline are the treatment options, along with supportive therapy, though the immune-mediated effects of the illness may not be affected. Tetracyclines are contraindicated in renal failure and, depending on the severity of the illness, are contraindicated in children. Usually high doses are given for 10 days. Cerebral malaria may need to be considered in those who have recently traveled abroad.

*Mycoplasma pneumoniae* is reported to cause CNS disease in 7% of those admitted to hospital with associated upper or lower respiratory tract illness. A meningoencephalitis, which may be severe, is the commonest result, but polyneuropathy or transverse myelitis may also occur.

Neurobrucellosis may also cause meningoencephalitis. It is usually contracted from animals known to harbor the organism, or from the ingestion of unpasteurized milk products. Sweating, abdominal pain, fever, hepatosplenomegaly and arthritis commonly accompany the illness. Axonal polyneuropathy has been reported. *Brucella melitensis* may be isolated from CSF and there may be rising antibody titers. Regimens advocated include (either alone or in combination) co-trimoxazole, rifampicin or streptomycin. In chronic brucellosis suppression of intracellular infection may be attempted in the hope that the host's immunity will eventually eliminate or contain infection. Regimens advocated include protracted courses of the antibiotics used in acute brucellosis. Tetracyclines are useful but obviously cannot be used in children unless there is no alternative. Most children make a full recovery.

Kawasaki disease or mucocutaneous lymph node syndrome is a relatively uncommon disorder. It predominates in the under-fives and, although the etiology is uncertain, infective agents have been implicated in its etiology. Presentation is with persistent fever, characteristic skin rashes, with desquamation of the extremities, mucosal and buccal involvement and lymphadenopathy. It may be associated with aseptic meningitis though rarely as an isolated feature. The association of aseptic meningitis with an autoimmune vasculitis is dealt with in Chapter 29.

Aseptic meningitis may follow the administration of certain drugs. These include OKT3 (in renal transplantation), immunoglobulin (in idiopathic thrombocytopenic purpura and Kawasaki disease), isoniazid, sulfamethiazole, co-trimoxazole and azathioprine. A cellular response has also been reported in lead poisoning, although meningism is rare and reduced conscious level common.

It must also be remembered that migraine at times leads to a cellular response in the CSF, particularly in complicated migraine. If the hemiplegia is fleeting, the child's presentation at hospital may be with headache and the picture of an aseptic meningitis. Migraine may also present with fever, neck stiffness and aseptic meningitis. Although uncommon, recognition of this syndrome should help to avoid unnecessary invasive investigations.

The clinician needs to be aware that aseptic meningitis may well be the presenting feature of a number of less common but important conditions specified here. While the diagnosis is being investigated, due attention should be paid to the child's parents, who will also be feeling worried and perplexed. Adequate time needs to be allocated to inform them of investigation and treatment strategy at each stage, in order to maintain their confidence at a time when the medical team themselves may be feeling unsure.

## Recurrent or chronic meningitis

Recurrent meningitis may result from anatomical abnormalities of the inner ear or craniovertebral axis. The causes are acquired (following trauma) or congenital, immunodeficiency or distant untreated foci of infection.

In any child with recurrent meningitis, a communication between the CNS and the exterior must be assiduously sought. Congenital abnormalities of the inner ear leading to fistulae may present with recurrent meningitis. Otoscopy is usually normal, and diagnosis requires expert neuroradiological and possibly radioisotope investigation. CSF fistulae may also result from trauma or infection. Recurrent meningitis (often with unusual organisms for age) may result from infection via a midline dermal fistula (often referred to as a sinus), usually associated with spina bifida occulta. The fistula can occur at any point in the midline, though the natal cleft is the commonest site. There may be associated cord tethering, intraspinal dermoid, lipoma or cyst or diastematomyelia.

The second commonest site for a fistula is the occiput, and there may be associated cerebellar or brainstem signs of hydrocephalus. Infection of a dermoid cyst and proximal end of a neurodermal sinus may result in intraspinal abscess rather than meningitis.

Any neurodermal sinus that ends above the sacrum should be dealt with neurosurgically. Surgical results are poorer when definitive treatment is delayed until after the occurrence of meningitis.

## Other infectious encephalopathies

Chronic encephalitides include subacute sclerosing panencephalitis (SSPE), progressive rubella panencephalitis and HIV encephalopathy. SSPE is an exceptionally rare disease caused by direct invasion by the measles virus of the CNS and usually first manifests some years after the initial measles illness, which has often occurred within the first 2 years of life. It has been described after measles immunization. An initial stage marked by intellectual and behavioral changes is followed by repetitive involuntary movements, resembling myoclonus. Dementia and early death follow inexorably. Diagnosis is by the detection of an oligoclonal CSF pattern and raised measles antibody titers in the CSF. SSPE is covered in detail in the section on neurodegenerative conditions (see p. 903). There is no specific treatment. HIV encephalopathy is dealt with in detail elsewhere (see Ch. 27, see pp. 1269).

## ACUTE PARAPARESIS OR QUADRAPARESIS

It may be difficult to determine if an unwell child has actual muscle weakness. Many children present with nonspecific symptoms of irritability, lethargy and pallor. Some conditions with acute weakness are commonly associated with encephalopathy and this may be the predominant feature at presentation. Children with abnormal gait, limp or refusing to walk may present to orthopedic or trauma clinics, or be suspected of 'putting it on'. Failure to consider a neurological cause for nonspecific presentations is a common reason for delay in diagnosis of treatable conditions such as Guillain-Barré syndrome and acute myelopathy.

Initial assessment of any acutely ill child should concentrate on the ABC principles of resuscitation especially where there is co-existing encephalopathy. Neurological assessment should determine the pattern of weakness so that it can be classified according to the likely site of the lesion. The pattern of weakness will generally be that of hemiplegia, quadriplegia, paraplegia or asymmetrical variants of these. Further information from the pattern of tendon reflexes, sensory signs and symptoms of bladder and/or bowel involvement are important. Although not always clear after the initial neurological examination, it should be possible to determine whether the weakness is due to a lesion in the brain, spinal cord, anterior horn cell, peripheral nerve, neuromuscular junction or muscle. Points on history taking which aid the diagnosis are dealt with in the relevant sections below.

Children with weakness due to upper motor neurone lesions present initially with a flaccid limb weakness and loss of reflexes. Typical upper

motor neurone signs of increased tone and brisk reflexes may not be present for several days or weeks.

There are a number of conditions that present with acute weakness where specific treatment is available and improves long term outcome. Diagnosis of these and early referral to specialist advice is important. Guillain-Barré syndrome, acute myelopathy due to cord compression and myasthenia gravis are important examples. In the child with an acute hemorrhagic or ischemic stroke, neurological and neurosurgical advice should be sought immediately. Children with acute stroke often have associated cerebral edema and raised ICP.

In children who present with an acute hemiparesis the differential diagnosis includes hemorrhagic and ischemic stroke, brain tumor, extradural or subdural hematoma, focal central nervous system infection (encephalitis or abscess), hemiplegic migraine, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS), acute demyelination and Todd paresis secondary to an epileptic seizure.

The differential diagnosis in children with paraplegia or quadriplegia includes Guillain-Barré syndrome, acute dermatomyositis, myasthenia gravis, acute peripheral neuropathy other than Guillain-Barré syndrome, CNS infection such as poliomyelitis or spinal cord abscess, acute transverse myelitis, spinal cord compression from tumor, abscess or hematoma and multifocal cerebral cortical dysfunction (although in the latter an encephalopathy is often prominent).

In paraparesis the weakness is confined to the lower limbs. A quadriplegia affects all four limbs. In the acute situation these are usually caused by lesions of the spinal cord, although anterior horn cell disease such as poliomyelitis and polio-like illnesses due to enteroviruses, lesions of the cauda equina or peripheral nerves, such as in Guillain-Barré syndrome, also need to be considered. Vascular lesions of the cord such as anterior spinal artery infarction and spinal arteriovenous malformations may need excluding. A very acute onset of dermatomyositis may present in a similar way. A raised CPK, heliotrope rash, muscle tenderness and irritability are useful diagnostic clues. Acute periodic paralysis should also be considered in the differential diagnosis. Vertebral osteomyelitis or discitis can present with lower limb weakness.

The main clinical distinction to be made is usually between spinal cord compression and Guillain-Barré syndrome. The onset of spinal cord dysfunction may be very acute, such as in transverse myelitis, or slowly progressive. A history of bony dysplasias or storage disorders such as a mucopolysaccharidosis suggest spinal cord compression. Guillain-Barré syndrome can have a very acute onset and differentiating it in the early phase of the illness can be difficult. Both disorders will show a flaccid, relatively symmetrical weakness of the lower limbs and trunk (depending on the site and extent and of the lesion). Autonomic dysfunction may be seen in both with skin changes, sweating and pulse and blood pressure instability. Cardiovascular instability can be life threatening. There may be dysfunction of bladder and bowel in both disorders although it is more consistently present in spinal cord lesions. Sensory signs with loss of pain, light touch, temperature discrimination and proprioceptive loss are commonly seen in spinal cord lesions. A sensory level may be apparent. Although sensory symptoms are present in Guillain-Barré syndrome, sensory signs are usually absent.

## SPINAL CORD COMPRESSION

In children in whom spinal cord compression is slow in onset a history of progressive weakness and spasticity on examination may be seen. If the posterior columns are involved a loss of proprioception is expected. More extensive compression involving spinothalamic tracts will impair pain and temperature sensation. Corticospinal tract involvement leads to weakness, spasticity, hyperreflexia and extensor plantar response. Symptoms related to spinal route compression are unusual in childhood but may be seen in children with bony abnormalities or neurofibromatosis. Voluntary control over the bladder may be affected with difficulty in initiating micturition. Constipation may be seen.

## TRANSVERSE MYELITIS

This is an inflammatory lesion of the spinal cord thought to be immune-mediated. Pathologically changes are similar to acute disseminated encephalomyelitis (ADEM) and similar preceding illnesses have been implicated. Direct viral infection of the spinal cord is unusual, but needs to be considered, and treatment with aciclovir may be necessary until herpes simplex virus infection is excluded. Borrelia infection may present in this way.

Transverse myelitis often presents over a matter of hours or days with symptoms and signs of acute spinal cord dysfunction, both sensory and motor. In 80%, the level is thoracic. Segmental edema of the spinal cord is seen on MRI imaging, although this may not be clear in the acute phase. An intraspinal tumor may be difficult to exclude on initial imaging.

There is no treatment that is of proven benefit. Steroids and intravenous immunoglobulin have been given to patients, but no systematic trials support their use. Investigation of blood and CSF for evidence of viral infection is often undertaken but rarely reveals a specific cause.

Clinical management follows the same lines as acute cord compression. Recovery from transverse myelitis may continue for 2 or 3 years. Return of sensation, motor function and finally bladder function often occurs sequentially. The prognosis, however, is difficult to predict. Approximately 20% of children have little or no recovery of function. Others recover fully.

## PROGRESSIVE MYELOPATHY

Children who develop slowly progressive compression of the spinal cord may present diagnostic difficulties. Initial symptoms are usually a subtle stiffening of the legs followed by increasing difficulty caused by weakness of hip flexion and ankle dorsiflexion. Pyramidal weakness with hyperreflexia may then become apparent. Initial sensory involvement may cause paresthesiae below the level of the lesion, or if spinal thalamic pathways are involved, unpleasant and painful limb sensations.

Conditions that predispose to progressive myelopathy, particularly cervical myelopathy, include Down syndrome, the mucopolysaccharidoses and other storage disorders, bony dysplasias such as spondylometaphyseal dysplasia and, in children with CNS malformations, particularly, hindbrain malformations. It is important in boys to consider the peroxisomal disorder adrenomyelopathy, which is a form of adrenoleukodystrophy.

Children with spinal cord developmental disorders may develop progressive myelopathy due to lesions in the lumbar spinal cord or cauda equina. A small number of these may be due to the effect of tethering of the spinal cord and neurosurgical release of this may be useful. Tethering of the cord may lead to damage from traction as the cord cannot ascend with growth of the spinal column. The child may present with weakness in one leg or with bladder or bowel problems. Progressive neurological deterioration is an indication for surgery. If prophylactic untethering is not undertaken then careful neurological follow-up is mandatory, especially at peak growth periods. With modern MRI scanning it is now possible to diagnose the condition with more accuracy and criteria for operation should become clearer.

An important cause of tethering is a bony or fibrocartilaginous spur, which arises from a vertebral body and passes between the halves of a bifid cord—diastematomyelia. In some cases this fixes the cord and results in increasing traction with growth. In other cases the cord divides well above the spur and passes around the diastematomyelia in two separate dural canals—diplomylelia.

Damage from tethering or compression may cause spastic paraplegia. More frequently, however, the child presents with distal weakness of the foot with clawing of the toes and equinovarus posture and weakness of the peronei. Dribbling incontinence of urine may be an early feature and there may be sensory loss in the sacral territory, loss of ankle jerk and anal reflexes and trophic changes in the feet.

The presence of a cutaneous lipoma or lipomeningocele may penetrate in dumb-bell fashion into the spinal canal. It may cause an increase

in pressure within the canal. Treatment of the lipoma can be difficult, as the cord itself, as well as nerve roots, may be enmeshed in fatty tissue.

## GUILLAIN–BARRÉ SYNDROME

This is a form of acute or subacute polyneuropathy seen at all ages. Several variants are described including acute inflammatory demyelinating polyneuropathy, acute motor axonal neuropathy and Miller–Fisher syndrome. All have an immunological basis.

The clinical presentation in Guillain–Barré syndrome is with progressive motor weakness of more than one limb, and areflexia, of varying degree. The weakness should not be still progressing 4 weeks into the illness and should be relatively symmetrical. Most patients report a prodromal upper respiratory or gastrointestinal illness in the 4 weeks prior to the onset of weakness. Pain and paresthesia, without sensory signs, is a common feature at presentation. Autonomic symptoms, such as constipation, urinary retention and vasomotor disturbances, may occur. Although lower limb weakness is the usual presentation, it may be generalized and proximal or distal. Facial and bulbar weakness occurs in around a quarter of children. Abnormal eye movements, meningeal irritation and papilledema (rarely) may be present, making distinction from a primary cerebral problem difficult. Deep tendon reflexes are lost in most children early in the illness, but this is variable.

The most serious complication of Guillain–Barré syndrome is respiratory failure and ventilation is required in around 10% of cases. A rapid onset, cranial nerve involvement and high CSF protein are associated with the need for ventilation.<sup>618</sup> Monitoring of respiratory function through peak flow or formal forced vital capacity measurements (which may be difficult in the preschool child) is essential.

The maximum weakness is often present for several days before improvement starts. Recovery may take several months, but is complete in the majority of children. In 25% or so of children, mild long term problems such as foot drop or hand weakness is found. Mortality is 2–5%, usually related to respiratory failure. Features influencing prognosis include severity of distal weakness and length of time from maximal weakness to onset of recovery.

The CSF protein level is raised in almost all children with Guillain–Barré syndrome. The cell count should be > 10 cells/mm<sup>3</sup>. However, the protein may be normal during the first week of the illness. Nerve conduction studies characteristically show a patchy conduction block consistent with demyelination. They also may be normal in the first week of the illness. Investigation of the preceding infection may be useful. Many cases are associated with *Campylobacter jejuni* infection. This in turn may be associated with antiganglioside antibodies.

Treatment in Guillain–Barré syndrome is mainly symptomatic and supportive. Particular attention must be paid to symptoms and signs suggesting respiratory failure and autonomic instability. Regular measurement of respiratory function and consideration of elective ventilation are vital. Bulbar dysfunction may require nasogastric feeding. Chest and limb physiotherapy are helpful.

Specific treatment is now by the use of intravenous immunoglobulin (IVIg) or plasmapheresis. Studies have shown these to be equally effective.<sup>619</sup> The former is considerably easier to administer. IVIg in a dose of 2 g/kg split over 5 days is the conventional regimen although single dose regimens and regimens given over 3 days are also described. Treatment is usually given when the patient is non-ambulant or appears to be losing the ability to walk. Steroids are not beneficial. Symptomatic treatment for pain and paresthesia may be needed.

## TRAUMATIC (ACCIDENTAL AND NON-ACCIDENTAL) BRAIN AND SPINAL CORD INJURY AND NEUROREHABILITATION

### EPIDEMIOLOGY

Traumatic brain injury (TBI) is the commonest cause of acquired brain injury in children, and it is the commonest cause of accidental death in children. Severity is scored according to the Glasgow Coma Scale (GCS)

(Table 22.49). Five percent are severe (GCS  $\leq 8$ ) and another 5–10% are moderately severe (GCS 9–12). In severe TBI the male to female ratio is 2.75:1. Around 4 per 1000 children per year aged 15 years or under are admitted to hospital in the UK with TBI. The majority are minor head injuries but 5.6 per 100000 per year are admitted to intensive care (ICU).<sup>620</sup> They are more likely to be socially deprived and pedestrian injuries are common in those requiring admission to ICU with a summer peak in the UK. The mortality rate is highest in pedestrian TBI, and the overall mortality rate for all severe TBI from the scene of trauma through ICU is 20–30%. Environmental as well as health care factors have a bearing on incidence and outcome, such as access to, and provision of, health care facilities, socioeconomic status of the child's family, the local environment (city or rural) and the amount of preventive legislation.<sup>621</sup>

It is probable that published figures for both incidence and mortality of head injury are an underestimate of the true figures. Though mortality is reducing with modern assessment and management (Fig. 22.40), there is still a major role for preventative measures such as compulsory seat belts, rear-facing baby car seats, speed control by cameras and traffic-calming measures, cycle helmets and modification of children's playgrounds with a forgiving surface such as forest bark and rails on slides. Most injuries result from falls or road traffic accidents, with the child as pedestrian, although the causes of head injury vary with the age of the child (Fig. 22.41).

The Royal College of Pediatrics and Child Health have published guidelines on the acute management of head injury in children.<sup>622</sup>

## MECHANISMS OF BRAIN INJURY

Trauma can cause primary (or immediate) brain injury and secondary (or delayed) head injury.

## Primary brain injury

A high velocity, high energy impact over a small area will cause depressed or complex skull fractures and penetrating trauma. Knives, scissor blades and screwdrivers can penetrate the vault of the skull. Gunshot wounds are rare in the UK. Accidental penetrating injuries through the orbit or nose with sticks, pencils and toys occur. Objects in the mouth may penetrate the tonsillar fossa and cause carotid artery injury. There may be a delay of a day or more before the onset of neurological signs, as a dissecting aneurysm forms. Cavernous sinus thrombosis or caroticocavernous fistulae can result from intracranial injuries to the carotid artery. Blows, car accidents and falls commonly cause low velocity impacts and often lead to linear skull fractures. At the time of injury, linear or rotational forces of acceleration or deceleration cause deformation of the skull and its contents. The commonest primary brain injuries seen are due to shearing or contusion.

Shearing injury occurs when the brain moves, often with a rotational component, at the time of impact. The exact cascade from diffuse axonal injury to cerebral oedema is not yet fully understood, but children are more susceptible than adults to diffuse cerebral oedema. Secondary brain injury may ensue from this with compromise of cerebral perfusion. Inflammation, oxidative injury and iron-induced damage may provide therapeutic targets.<sup>623</sup> Primary contusions are best demonstrated on MRI. Deeper lesions correlate with poorer functional outcome at discharge, whereas initial GCS is more predictive of outcome at 12 months.<sup>624</sup> The frontal lobes are commonly affected, even in the absence of focal lesions on MRI.<sup>625</sup> Volumetric MRI studies indicate reduced cerebral volume after TBI. Serial imaging implicates a degenerative process, with evidence of hemosiderin deposits as well as volume loss.<sup>626</sup> Contusion is often seen on the side of the brain opposite to the site of impact (contra coup injury), thought to be due to the brain abutting on bony prominences especially in the frontal and temporal lobes. Compression injuries and lacerations of the brain are occasionally seen.

Collections of blood intraparenchymally, in the subarachnoid space, subdural or extradural spaces will add to cerebral irritation and increase intracranial pressure, diminishing cerebral blood flow.

Regional cerebral blood flow varies within a contused area compared with the surrounding brain, being reduced in the contusion.<sup>627</sup> Also cerebral vascular reactivity varies over time.<sup>628</sup> Such findings have consequences for targeting therapy. Ischemic change occurs in three phases.<sup>629</sup> The first is one of depressed metabolism with increased extracellular  $K^+$  and intracellular  $Ca^{2+}$ . The second phase is one of energy failure and anoxic depolarization with loss of normal electrochemical gradients across the neuronal cell wall for different ions and concomitant release of neurotransmitters.<sup>630</sup> The third phase is neurodegenerative, which may take hours or days. The effectiveness of reperfusion and recovery processes will influence the final outcome.

## Secondary brain injury

Much of the focus in the management of head injury has been on the prevention of secondary brain injury. It is assumed that primary brain injury is established by the time the child is seen at hospital. The clinical scenario of the child who 'talks and dies' is well known and although not all of these deaths are preventable, a number are.<sup>621</sup>

Associated thoracic, abdominal and pelvic injuries have the potential to cause additional brain injury through extracranial hypoxia and ischemia. Skilled resuscitation will minimize the impact of these on the brain. Status epilepticus will cause a further rise in intracranial pressure (ICP). Seizures require prompt recognition and management. Cerebral autoregulation of cerebral perfusion may be impaired in diffuse TBI. Raised ICP and status epilepticus need to be recognized and promptly treated. Cerebral autoregulation may be impaired. Diffuse cerebral edema may take 24 hours or more to reach its peak.

Intracranial hemorrhage (extradural hematoma, acute subdural hematoma, subarachnoid and intracerebral hemorrhage) needs prompt neurosurgical assessment and appropriate management. Extradural and subdural hematomata may occur very soon after injury and may

be evident on an initial CT scan. However they can accumulate over a period of hours or even minutes after admission. Repeat imaging is essential if GCS changes or neurological signs, such as focal weakness or pupillary asymmetry, appear. Subdural collections may take weeks to present clinically. Subarachnoid and intraventricular hemorrhage can lead to an acute or subacute hydrocephalus. Intraparenchymal hemorrhage with focal contusion may very occasionally require resective surgery to contain ICP. It is unusual, except very occasionally in infants, for the amount of blood loss intracranially to, by itself, cause shock and other sources of blood loss should be sought. Intracranial hemorrhages are usually seen in moderate or severe head injuries and rarely occur as an isolated injury.

## MANAGEMENT OF ICP

The protocols most widely advocated for prevention of secondary injury depend on ICP monitoring and maintenance of cerebral perfusion pressure (CPP). Precise protocols vary between centers but all include attention to head-up neutral position in nursing and adequate sedation during ventilation. Significant rises in ICP which are sustained (over 5 minutes) may be managed with boluses of 20% mannitol or hypertonic saline. In adults there is evidence for a significantly greater and more sustained reduction of ICP with hypertonic saline.<sup>631</sup>

If these lines of management fail to contain ICP within accepted norms for the child's age other interventions which are still under clinical trial include moderate hypothermia and craniectomy. Outcome from TBI has been shown to relate to ICP and CPP. Younger children may tolerate a lower CPP. They also have a lower normal ICP than older children.<sup>632</sup> Moderate hypothermia may have more potential benefit

for children than adults and trials so far show it to be safe.<sup>633</sup> In adults craniectomy has shown a significant increase in blood flow velocity and decrease in cerebrovascular resistance but no clear correlation with outcome yet.<sup>634</sup> A randomized controlled trial of early craniectomy after pediatric head trauma showed a clear benefit,<sup>635</sup> but a consensus on indications for such an invasive intervention has not yet been reached. There are consequences for the child in terms of a period of disfigurement and possible restrictions by education authorities on returning to school because of perceived vulnerability of the resected areas of the cranium. It may be several months before repair of the craniectomy can be effected.

## Neuroimaging

The use of CT scanning has revolutionized the management of head injuries. CT scans are excellent for visualizing blood, bone and CSE. The main advantages are precise anatomical location of intracranial hematomas and accuracy in the diagnosis and differentiation of intracerebral, subdural and extradural hematomas.

Ultrasound may be useful in young children with an open anterior fontanel both for imaging and by utilizing Doppler for monitoring possible raised ICP and its subsequent response to treatment. There are great advantages in a portable, bedside and easily repeatable investigation with no radiation risk. The main disadvantages are the need for a 'window' through the skull through which to operate. MRI is mainly used to correlate neuroradiological abnormalities with functional disability in those children with residual neurological or neuropsychological deficits.<sup>636</sup>

Guidelines published on neuroimaging following head injury by the Royal College of Pediatrics and Child Health are shown in Figure 22.42.

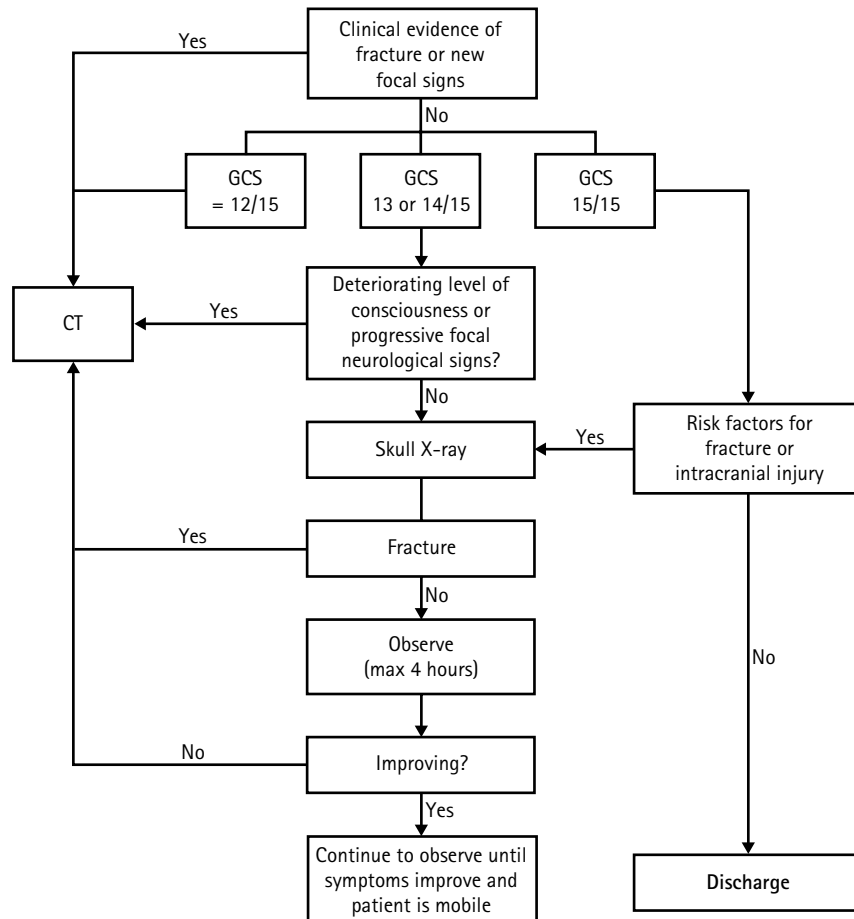

Fig. 22.42 Use of radiographic investigations in patients (> 5 years of age) with a head injury.

## EARLY COMPLICATIONS OF TRAUMATIC BRAIN INJURY

### Skull fractures

Forty percent of infants hospitalized with cranial trauma have skull fractures, but sequelae in the form of intracranial hematoma occur in only 8–22%. Leggate et al<sup>637</sup> showed that all infants, under 6 months of age, operated on for an extradural hematoma, had either a skull fracture or suture separation seen on X-ray. In a group of 40 infants with extradural hematomas, 90% had an abnormal X-ray. Most skull fractures are linear.

The skull in the neonate consists of poorly mineralized membranous bone. Linear fractures due to birth trauma occur but are rare in the compressive head injuries associated with traumatic deliveries, unless the baby is postmature. Under these circumstances, it offers little protection to the underlying brain, which is easily compressed in a ping-pong ball or Pond fracture. These may be associated with severe localized bruising and hemorrhage into the brain with minimal fracture.

Skull fractures do not heal by callus formation and so dating of the time of injury is difficult. If the edges are rounded and smooth, it is more than 2 weeks old. At autopsy, the margins are heaped, smooth and discolored with hemosiderin. A skull fracture normally heals in 2–3 months and has disappeared on X-ray by 6 months. In small infants the fracture site may not heal but form a growing skull fracture. This may present as a palpable, pulsating lump. Diagnosis is by X-ray. Management consists of closure of the underlying dural defect with natural or artificial membrane and closure of the bony defect either with an acrylic graft or a graft from the patient's own bone.

Most skull fractures are only medically significant if they:

- are depressed;
  - go through the anterior fossa and cribriform plate, allowing CSF rhinorrhea and a risk of meningitis;
  - go through the petrous temporal bone into the ear, allowing CSF otorrhea and a risk of meningitis;
  - enter the sinuses or are across the skull base with brainstem injury.
- Compound fractures, secondary to penetration injuries, may be obvious, or subtle (e.g. orbital trauma from an object such as a pencil or sharp pointed stick penetrating the medial aspect of the orbit, passing into the ethmoid sinus and through the cribriform plate into the intracranial cavity in its subfrontal compartment). Another common site for a penetrating injury is the temporal region. In all such cases, extensive preoperative investigation is required, including CT scanning and MRI angiography, prior to a thorough exploration of the penetrating tract with debridement of damaged brain and formal closure of the dura. The use of prophylactic antibiotics is controversial, but intravenous cefotaxime is often used.

### Infection

Basal skull fractures may present with bilateral 'black eyes', or CSF leaks from the ear or nose. The eardrums should be examined routinely in all TBI to look for evidence of bleeding behind the tympanum, another sign of basal skull fracture. Prophylactic use of antibiotics in basal skull fracture is also controversial, but meningitis complicating such head injuries can be early or late with CSF leakage and must always be borne in mind. A persistently raised core temperature with raised peripheral white count and inflammatory markers signal possible meningitis. Lumbar puncture may be hazardous in acute TBI as peak oedema can be as late as 3–5 days in severe trauma. Repeat imaging and the clinical picture guide the decision whether to use antibiotics without LP. This is not infrequently the case unless ventricular CSF is available from a ventricular drain. A third generation cephalosporin (with metronidazole if anaerobic infection is possible as with penetrating wounds) given intravenously is the preferred choice.

### Deafness

Fractures of the petrous temporal bone, with or without CSF otorrhea, can result in deafness and/or facial nerve palsy from direct cranial

injury. Deafness can ensue with such events with only mild or moderate TBI. All such patients need formal audiology as part of head injury rehabilitation care, as do all children with severe TBI.

### Diabetes insipidus

Diabetes insipidus may be seen following basal skull fractures and following any brain injury. Most cases are transient. Management consists of maintenance of the systemic blood pressure by adequate fluid replacement and desmopressin (DDAVP) to reduce the continuing urine output. In other cases, diabetes insipidus develops following profound and prolonged raised ICP. This is a poor prognostic indicator and is often accompanied by incipient brain death. Some children will survive with chronic diabetes insipidus following basal skull fracture and severe TBI. Patients in this situation should be assessed later for the possible development of panhypopituitarism.<sup>638</sup>

### Extradural hematomas

An extradural hematoma consists of a collection of blood lying between the skull and the dura. It results either from torn dural veins or bleeding from meningeal arteries. Half of all cases occur in children under 2 years. The development of symptoms and signs may be rapid but, often in children, occur over several hours or days. Following a significant head injury, the child will become progressively drowsy with a deterioration in the GCS. Vomiting, focal weakness and ipsilateral third nerve palsy may be seen. A skull fracture is seen in only half of children. CT scan will show the hematoma. Neurosurgical evacuation is usually necessary although a few cases may be managed conservatively.

### Subdural hematomas

These result from tearing of the bridging veins as they cross the subdural space. The hematoma lies between the dural and the arachnoid membranes. Subdural hematomas are conventionally classified as acute or chronic, although there is significant overlap. Subdural hematomas are nearly always caused as a result of trauma, with rotation between brain and dura. This causes shearing of bridging veins and is the likely mechanism in non-accidental injuries caused by shaking, with or without impact. Subdural hematomas are occasionally seen as a consequence of bleeding from penetrated vessels in depressed skull fractures<sup>639</sup> or in primary penetrating injuries, or in association with brain contusions with oozing from surface veins.

Acute subdural hematomas may be isolated or can be associated with brain contusion and/or skull fracture. The symptoms are those of raised ICP. Seizures are common. If there is no clear history of significant accidental trauma then the possibility of non-accidental injury should be considered. The management is that of raised ICP, with possible evacuation of the hematoma. Some thin hematomas with no evidence of midline brain shift or significantly raised ICP can be managed non-operatively. All should be discussed with a neurosurgical team. CT scan will show a high density, often unilateral, collection. If the scan is done some days after the injury, the collection may be isointense to brain and can be missed. After 2–4 weeks it becomes hypodense in comparison with brain tissue.<sup>640</sup> The collection usually lies over the convexity of the cerebral hemispheres, but may involve the posterior fossa, particularly in babies and infants. Underlying brain injuries may best be visualized with ultrasound and MRI.

Chronic subdural hematomas occur mainly in children under 1 year of age and may follow known trauma or may be apparently idiopathic. They may arise following instrumental delivery. Non-accidental injury must always be considered. The presentation may be with signs and symptoms of raised ICP, isolated macrocephaly, vomiting, failure to thrive or seizures. Chronic subdurals are usually bilateral lying over the frontoparietal regions. Though bleeding is probably responsible for initiating the process, why the hematoma organizes and becomes chronic is incompletely understood. A membrane surrounds the clot and fluid is probably absorbed across it by osmosis. The collection acts as a space-occupying lesion. There may be associated hydrocephalus, although the role of subarachnoid blood should then be considered.

The most appropriate management of chronic subdural hematomas is not straightforward. If the collection is evacuated, it will often reform within 24 hours or so, since a gap between brain and skull is formed by the chronic nature of the lesion allowing fluid to collect again. Tapping is usually reserved for treatment of symptoms of raised ICP rather than done routinely. In some children, placement of a subdural–peritoneal shunt may be required if accumulation of fluid continues.

Chronic subdural hematomas on CT scan appear as extra-axial collections of fluid iso- or hypointense to brain tissue. Depending on whether there has been associated damage to the brain, brain atrophy may be seen. MRI scanning may be helpful in determining the age of the collections.

The prognosis for subdural hematomas depends on the underlying cause and any associated brain injury from raised ICP or direct trauma. There is a mortality (mainly from acute subdural hematomas) of up to 3%. At follow-up 57–80% of survivors have normal development.

### Intraparenchymal hemorrhage

Most intraparenchymal hemorrhages are associated with edema or contusion and are small in size, although often multiple. They are usually seen in the white matter, brainstem, cortex and corpus callosum. Operative treatment is rarely needed. Management is of the raised ICP, which almost always accompanies intraparenchymal hemorrhages. Intracerebellar hemorrhage is rare but may present with acute cerebellar signs, raised ICP, bilateral sixth nerve palsies or acute hydrocephalus.

### Hydrocephalus

This may occur early in the period after head injury, in association with subarachnoid or intraventricular hemorrhage or localized brain edema. It may also be seen in the weeks or months following injury resulting in prolonged coma. It can be difficult, in some cases, to distinguish between hydrocephalus and postinjury cerebral atrophy with ventricular dilation. Pressure monitoring may be required. Treatment is by ventriculoperitoneal shunt or third ventriculostomy.

### Seizures

In the conscious or nonparalyzed child, seizures will usually be clinically obvious. In an unconscious or paralyzed, ventilated child there may be clinical signs of seizures such as changes in systemic blood pressure or ICP, accompanied by tachycardia with or without pupillary dilation. Similar signs can also be seen during the recovery period after head injury as a non-epileptic phenomenon and are termed brainstem release symptoms. Immediate control of the seizure may be effectively obtained with lorazepam (0.1 mg/kg) given intravenously or diazepam (0.5 mg/kg) given rectally. Continuing treatment consists of intravenous phenytoin (18 mg/kg) or phenobarbital (15–20 mg/kg) and thereafter by maintaining blood levels in the therapeutic range. Resistant seizures may require control with a thiopental or midazolam infusion.

In the acute phase of injury antiepileptic drugs can be used to treat observed seizures. However EEG monitoring has shown that electrical seizures may still be recorded in spite of apparently protective levels of medication.<sup>641</sup> There is no evidence that continuation of treatment after the acute phase is protective against late seizures. With increasing awareness of potentially adverse effects of anticonvulsants on neurodevelopmental pathways such as the promotion of apoptosis, prophylactic treatment is not recommended.

### OUTCOME

The prognosis for a head-injured child is related to the severity of the initial impairment of consciousness. Modern imaging techniques and easy access to neurosurgical units have diminished the mortality of treatable lesions such as acute extradural hematomas. The mortality of extradural hematoma in the pre-CT scan era was between 10% and 30% but is now reduced to almost zero. Overall most series of severely head-injured

patients show a combined mortality and morbidity of approximately 30%. About 10% will die, 5% at the accident scene and 5% in the first few days. Details concerning the long term morbidity of head injuries is given in the section, in this chapter, on rehabilitation

### TRAUMATIC SPINAL INJURY

Trauma is the commonest cause of acute spinal injury in children. However children comprise 1–10% of all spinal injury patients. They are relatively protected, compared with adults, by their greater ligamentous laxity and differing anatomy. However they can sustain serious spinal cord injury without radiological abnormality (SCIWORA). This comprised 6% of pediatric spinal injuries in a recent study from Baltimore.<sup>642</sup> Motor vehicle accident is the commonest cause in infants. Birth injury and non-accidental injury are other possible causes but their incidence is unclear. Falls are commonest in the 2–9 year olds, and sports injuries in the 10–14 year olds. The overall mortality rate is around 4%, attributable mainly to associated injuries especially TBI.

Spinal protection should govern the physical handling and management of all unconscious children with injury. The ABC of critical care must always apply to spinal injury with or without coma. Examination may reveal tenderness, swelling, bruising, or a palpable defect along the spinous processes.<sup>643</sup> Acute and severe spinal cord compression may cause spinal shock. There is complete flaccid paralysis, loss of reflexes and retention of urine and feces. Autonomic involvement may be severe and life threatening. In spinal shock there is both a direct effect on nerve conduction by the compressing lesion and also an indirect effect due to compromise of the vascular supply to the cord leading to ischemia and edema below the site of compression. MRI can reveal soft tissue, ligamentous or disc injury.<sup>644</sup> Cervical cord lesions may lead to respiratory and diaphragmatic muscle weakness requiring ventilation. Surgical decompression may reverse paralysis and MR scanning is urgent in this context. Intravenous dexamethasone is of proven benefit.

In the medium term, respiratory insufficiency, temperature control, bowel and bladder function and skin integrity may need weeks and months of expert medical and nursing management. These complex needs are best met in a spinal unit. Long term problems include possible paralysis with spastic elements, a neurogenic bowel and bladder, ventilator dependency and pressure sores. Overall the prognosis is better for children than adults.<sup>645</sup> Severe high grade injuries tend to be at the atlanto-occipital level with early death and complete cord involvement. Cervical dislocation carries a poor prognosis. However recovery for other categories can proceed over a prolonged postinjury period of 1 year at least.

### REHABILITATION OF TRAUMATIC BRAIN INJURY

#### Long term sequelae

##### *Physical*

Physical neurological deficits often appear the most serious initially. Occasionally a severe physical deficit may remain with long term dependency. More often, sometimes several weeks or days from the injury, an accelerated phase of recovery is seen, leading to independent walking and restoration of fine motor skills for self-care. Fine motor deficits tend to be more prevalent than gross motor 12 months into recovery.<sup>646</sup> Where there has been basal ganglia injury there can be a delayed onset of choreoathetosis, which is difficult to treat. Early onset visual impairment and extrapyramidal signs often settle over the early weeks though visual perceptual difficulties may persist for longer. Otherwise measurable improvement in physical recovery may be detectable over 2 years or more.

Problems with feeding and swallowing, and protection of the airways may be pseudobulbar or dyspraxic in origin. Delayed return of language and articulation difficulties can be expected in this situation. A tracheostomy may be required to enable the child to be weaned from the ventilator, but was required in the long term in only 1 out of 82 children in the North West of England brain injury rehabilitation study.<sup>646</sup>

## Risk of epilepsy

Seizures following TBI are classified as early in the first week, and thereafter they are classified as late. A Finnish study<sup>647</sup> showed that children of 7 years or under were more likely to have early seizures than adolescents or adults. Overall early fits with depressed skull fracture related to the origin of late post-traumatic seizures. Risk factors for late seizures include persisting neurological deficit, linear skull fracture and a persisting lesion on imaging. Late seizures did relate to a worse functional outcome in this study, and in the North West of England brain injury rehabilitation study<sup>646</sup> the need for anticonvulsants at 12 months from discharge correlated with a worse cognitive and behavioral outcome. In the Finnish study there was no correlation between late seizures and severity of brain injury scores without focal lesions. Barlow et al in Edinburgh concluded that the severity of early post-traumatic seizures related to the severity of the primary brain injury and the neurodevelopmental outcome.<sup>648</sup>

A large study of 4541 children and adults with TBI of varying severity showed an overall standardized incidence ratio for late epilepsy of 3.1. This ranged from 1.5 for mild head injury, 2.9 for moderate head injury to 17.0 for severe brain injury. Significant risk factors for late seizures in this study included cerebral contusion with subdural hematoma, skull fracture, loss of consciousness or amnesia for > 24 hours and an age > 65 years.<sup>649</sup>

## Language, behavior and cognition

These have overlapping consequences for return to the family environment, to education and to society at large. Long term disorders are common, having far-reaching effects beyond childhood into adult prospects for family life and success in the workplace. Behavioral change has been reported by mothers of brain-injured children and young men 13 years after injury. Significantly those mothers were more likely to suffer from depression.<sup>650</sup>

### Language

Language involvement is obvious in a mute or grossly dysphasic child but lesser degrees will be missed unless a planned assessment approach is adhered to. This is important because impairments of more complex higher language processing will disable information processing. This has consequences for education and social integration, compounding behavioral disorder. Language deficits detected by speech therapy assessment into the second year of recovery are associated with long term problems in written expressive language.

Early speech difficulties range from mutism, through dyspraxia to dysarthria and related swallowing difficulties.<sup>651</sup> Word-finding problems are common, as is lack of organization of thoughts, leading to expressive limitations that can be frustrating for the child with consequent behavioral reactions. The use of language can become concrete, alongside inappropriate social interactions such as impulsiveness, a tendency to tactless outspokenness and untimely interruption.

### Behavior

The emotional and behavioral characteristics of frontal lobe dysfunction are most frequently associated with TBI. Executive functioning is usually affected, influencing cognitive as well as social performance. Commonly agreed aspects of executive function include the initiation, choosing and planning of tasks, 'seeing ahead', shifting thoughts and attention to find solutions, retaining information actively in working memory, monitoring one's own behavior and attaining social discernment. These aspects have been reviewed in detail by Levin and Hanten.<sup>652</sup> Normal executive function allows individuals to recognize when a problem-solving strategy is failing, moving them on to another logical approach. In executive dysfunction the individual is distractible/haphazard in the approach to problem solving and may return to failed strategies.

Prefrontal and frontotemporal damage may lead to typical psychiatric symptoms of mood swings, impulsiveness, attention deficit, disinhibition, aggressive reactions and agitation. Other features may include over-talkativeness, repetition and obsession with ideas that, in extreme

cases, may lose touch with reality. This can be associated with extreme restlessness, making the child difficult to contain. Over-familiarity and lack of normal social inhibition frequently disenchant friends and teachers who regard the child as rude and disruptive. The child's social set of friends may change on return to school as they may attract more dysfunctional children, leading them into trouble or delinquency. Frontal lobe dysfunction is found in about two thirds of severely brain injured children.<sup>646</sup>

Family functioning is affected.<sup>653</sup> In the home environment, parents experience the effects of the cognitive and emotional changes in terms of the child's impulsivity, flaring tempers, lack of motivation and poor judgment. The stress is multifactorial for a parent trying to steer between safe containment on the one hand, and encouragement toward independence on the other. Siblings are affected and family happiness may be seriously diminished.

Though the concept of plasticity of the immature brain may apply to aspects of severe brain injury recovery, there is a lack of evidence for the popular concept that the young recover better. In one study of 118 head-injured children under 12 years, children injured under the age of 5 years with left hemisphere injury had the poorest cognitive scores.<sup>654</sup> Frontal lobe damage at such an age may not become fully apparent in its social consequences until adolescence when frontal lobe development accelerates.

### Cognition

Recent learning may be lost in severe head injury and the processes of new learning affected. Problems reside with attention, encoding information into memory, and retrieval of information when needed. Some brain-injured children exhibit many features of attention deficit hyperactivity disorder but slowing of information processing speed appears to be specific to TBI. Classroom learning will be hindered also by the distractions in that environment. Studying or revising for examinations becomes difficult and stressful, increasing the cycle of behavioral dysfunction with anxiety, poor self-esteem and possibly depression. Prolonged post injury headache patterns and fatigue are likely to worsen in an unsupported school situation.

It usually takes between 6 and 9 months for behavioral and cognitive consequences to be recognized. By this time, the child may seem to his/her teachers to be the same person physically as before the injury. The outcome, without planned re-entry to education, is usually criticism of behavior and 'lack of effort', leading to failure or even exclusion from school. In secondary years, leading to important exam years, the timetable may be overwhelming for the severely or moderately head-injured teenager. A reduction in timetable can allow achievement to progress in time to consolidate that aspect of recovery, especially into the second year. Otherwise the child may 'drop out' of educational opportunities altogether, with all the associated adverse consequences for adult life.

The effects of language deficits on learning have been discussed above. Dominant hemisphere injury may hinder sequencing abilities important to spelling and mathematical concepts. Additionally, frontal lobe deficits in executive functioning interfere with the logistical approach to problem solving. Visual-perceptual deficits as well as fine motor problems will impair the accurate and speedy recording of work. It is easy to conceive how such deficits will be compounded by frontal lobe dysfunction.

Detailed psychometric testing, as well as clinical psychological support for the child and family is essential but the timing is crucial, as tests done too soon will be too pessimistic in an evolving recovery.

## PREDICTION OF OUTCOME

The GCS 72 hours after injury was found to correlate with survival and degree of disability of the child at discharge in a study by Michaud et al.<sup>655</sup> The quality of eye movements has also been shown to relate to outcome. Children may recover from ventilation and sedation initially with purposive movements, which are then lost in a phase of brainstem

release mechanisms of extensor posturing, sweating and sympathetic instability. This may take a number of weeks to subside before more encouraging physical signs emerge. It is important to be alongside the child to assess the early examination in the recovery phase. Jaffe et al<sup>656</sup> found a correlation between the GCS in the emergency admission room and later cognitive impairment. Post-traumatic amnesia (PTA) lasting for more than 7 days is also associated with greater cognitive and psychiatric deficits. PTA parallels neurosurgical severity of injury scores in this way.

Intracranial pressure measurements above 20 mmHg appear to correlate adversely with survival rather than quality of outcome in Michaud's study of TBI. In Minns' study of medical brain injury, cerebral perfusion maintained above 40 mmHg predicted a better quality of survival.<sup>657</sup> However there are age-related norms for ICP and cerebral perfusion pressure.<sup>632</sup>

Mention has already been made of the relationship between the depth of MR scan lesions and the severity of head injury.<sup>624</sup> Single photon emission tomography (SPECT) has a stronger relationship with neuropsychological outcome than MR findings.<sup>658</sup> Functional MR is likely to be more informative still, but limited in its availability at this time.

## BRAIN INJURY REHABILITATION

### In the intensive care unit (ICU)

In a severe brain injury this is a time of invasive procedures and intensive monitoring, such as the evacuation of extradural collections, exploration of depressed fractures and insertion of intracranial pressure monitoring systems. Many disciplines may be involved in the circumstances of multiple injury. The records quickly bear witness to important multidisciplinary interventions. However it is very important to find time to document a full pediatric history and examination. It is very occasionally the case that the 'head injury' may not be the cause of the child's loss of consciousness. The history also allows the pediatric neurologist to get to know the child and family, which may be important to the clinical care of the child in ICU, and will most certainly be of prime importance in supporting and providing for the child and family in the recovery phase. For those children who do not survive, this getting to know stage is of no less importance for later counseling.

The neurological examination is important in interpreting possible seizures and abnormal patterns of posture and movement. Purposeful movements recorded when sedation is first lifted may be overwhelmed by a phase of brainstem reflexes with increased extensor tone and excessive sympathetic drive. This is reflected in periods of hypertension, excessive sweating with notable sodium losses and blotchy flushing of the skin. Most often the original picture of purposeful patterns of movement will reappear with a resumed recovery, though uncertainties may reign over a period of weeks.

The family needs preparation and explanation of the stages ahead. These stages will entail adjustments to new environments such as a high dependency ward, a children's ward, and eventually the care of the pediatric teams in the child's district of residence. It is advantageous to the child and family to coordinate the continuing care of various surgical specialties in a neurorehabilitation setting.

### The rehabilitation ward

After the ICU, multidisciplinary care is essential allowing all participants to meet on a regular basis to share information and observations. This needs to be facilitated by a nominated member of that team to whom the family and various specialties can refer usually on a weekly basis. When the child is well enough it is important to include them according to age and awareness, and sometimes siblings can join in to the mutual benefit of the child and his/her sibling. In the UK the consultant community pediatrician (CCP) for the child's district should be informed at an early stage. A visit by the CCP and relevant district therapy representative enhances the early provision of services, and some will be assisted by a

period of stay in their district hospital to allow all members of the child development center (CDC) team to plan continuation of rehabilitation.

Those involved will include a combination or all of the following.

### *The child and family*

The family supply information about the child before the injury. This is important on a clinical and developmental level, and is important to the understanding of the child's personality, likes and dislikes. Parents need to express their concerns and receive support and understanding at a time which is inevitably fraught. They will be most aware of subtle changes in their child and provide one of the few constant factors in this situation. Parents need to have their confidence restored by being involved in their child's care, after the experience of ICU, when they handed over that role to others. They need to learn about the likely recovery pattern clinically, and the recovery pathway practically and temporally. There will be many items important to them and the child, like returning to favorite activities, advice on degrees of freedom and supervision, and how they will get back to their school and friendships. There must be a point of contact made clear before discharge.

The child and family will need to be encouraged to engage with changing teams of carers in the moves from ICU to the ward, on to district level and finally home. Teams in these different situations need to be mutually supportive and share information. However, no matter how much information is handed over, each service has to be allowed space and opportunity to get to know the child and create their own relationship with the child and family. Each team must use their own skills and initiative to assess changing needs in an evolving recovery. The need for team meetings carries on through all stages of recovery, including pre-discharge planning meetings with community services and in the early months/years of return to education. Specialist head injury liaison nurses play a valuable role.

### *Pediatrician/pediatric neurologist*

Regular examination, integration of advice from other specialties and facilitation of team meetings constitute the main elements of care. The importance of pediatric input at every stage has been discussed above, especially to communicate with the child and family.

### *Nursing staff*

Nurses spend most time with the child and family. They will be next to the parents in their perception of the child's recovery, physically and psychologically. Parents tend to share their anxiety or frustration first with them, and in this way the nurses can alert appropriate team members to address those problems. They are in a position of advocacy for the child and family, and are able to look ahead at the practical challenges of living at home.

### *Physical therapists*

Physiotherapy and occupational therapy need a distraction-free working area and access to equipment. Therapy may be passive in the bed-bound patient, to limit contractures and provide chest care. As awareness improves they will work through elements of postural control. Early therapy may be limited by a confused pattern of recovery in the child who resists interaction. Such a pattern is often followed by fluctuating lucidity interspersed with intense tiredness and the need to sleep. All the team then need to plan their interventions so as to take advantage of the more wakeful times without overwhelming the child.

Equipment that can be important at this time includes tilt tables enabling a gradual readjustment to the upright posture as well as stretching tight Achilles tendons; wheelchair; walking aids; orthoses to help contain positional deformities; access to pool therapy and gymnasium areas.

Therapists work to restore independence to the child for personal and everyday needs. Occupational therapists contribute to the assessment of the child in the preparation for return to school, including implications of fine motor and perceptual deficits. Keyboard skills may need to be introduced to enhance the recording of work. Fine motor control and

sitting position may also be crucial to an appraisal of feeding, which overlaps with the speech therapist's and nurses' roles.

In the community, the therapists need to plan ahead with colleagues for the return home, including housing implications and school placement. They will visit and assess those environments to give advice for adaptations and supervision. Initial school timetables can depend to some extent on the outcome of these assessments.

### Speech therapy

Where there is bulbar and brainstem dysfunction affecting mouth opening and safe swallowing, the speech therapist may first have a role in desensitization programs to overcome reflex patterns before tastes or feeds are offered. They may contribute to assessments of tongue, lip and palate movements when airway protection is uncertain. Augmentive communication (the use of communication aids) is very important to children who have lost speech centrally with aphasia or dyspraxia, or peripherally with bulbar weakness. Awareness and degrees of understanding return in advance of expressive language, leading to frustration for the child who cannot speak. Where there has been base of skull fracture, the possibility of deafness must be examined.

Examination of higher functioning complex language performance is extremely important as a more likely long-lasting disability, especially when detected into the second year of recovery. Deficits have consequences for cognitive performance in the long term. Social language tends to return to a degree that may mask higher deficits. Semantic-pragmatic difficulties may be perceived alongside frontal lobe dysfunction as subtle personality change by family and friends.

### Teaching

A hospital-based teaching facility is an essential component of rehabilitation, concerned with assessing and facilitating remediation of learning difficulties consequent upon brain injury. The teacher needs to be involved at an early stage of ward recovery, even when the patient is still drowsy or confused. This assists in planning assessments according to the pattern of recovery. Fundamental elements of learning are worked through so as not to take anything for granted in terms of basic perceptual skills. Dedicated teaching areas with mainstream curriculum facilities are essential, and it is important to be aware that the availability of teaching in hospital for children with acquired disability such as traumatic brain injury is a statutory right of the child in many countries such as the UK.<sup>659</sup>

Parental permission should be obtained early to allow the hospital teacher to contact the child's mainstream school to obtain background information on pre-injury ability and attainment, and to inform the child's school about the likely degree of recovery and persisting difficulties when the child returns to education. The school's special educational needs coordinator should be encouraged to visit and should be involved in discharge planning meetings.

In the UK the school health service, including community pediatric nurses, will support teachers as they get to know the child during home teaching and as reintegration into school takes place. The community pediatrician will liaise with the Educational Psychology Service, which will be notified well before discharge.

Educational psychology involvement needs to be more flexible than the standard approach in the UK of a statement of special educational needs, the legal instrument for ensuring the provision of appropriate support for the child. In the 6 months that assessment and provision usually takes, the child with brain injury is likely to have changed, usually improved, in their abilities. A modification of the child's school timetable or a reduction in the proposed number of state examination subjects, including a reassessment of aims for post 16 years, is essential for children entering years 10 and 11 of mainstream school.

### Clinical psychology and psychiatry

The clinical psychologist provides an essential understanding of the emotional, behavioral and psychometric consequences of the injury. This involves an inclusive approach to the family, including siblings. The

consequences of frontal lobe dysfunction can be modified by a behavioral approach, and the clinical psychologist can engage directly with education in the formulation of a return to school. The psychologist's input into team meetings very often provides support to the team as well.

Psychiatry and psychology roles overlap, since social disinhibition is a specific psychiatric feature characteristic of traumatic brain injury. Occasionally the marked restlessness and aggressive mood swings that accompany the early confused phase of recovery merit treatment with medication such as methylphenidate or risperidone.

### Social services

The learning support limb of the social services team can provide important practical support to families on discharge where safe containment of the child is an issue. They also have a role, with community occupational therapy advice, in assessing housing needs, including access (steps and stairs, corridors and doorways, toilet and bathing facilities, seating) and financial budgeting for adaptations in the home in the event of persisting physical deficits.

### Discharge planning

The success of this depends on early involvement of the district community team of CCP and therapists. In fact it is likely that the severely injured child will need a period of time in their district hospital under the care of the CCP to enable all of this team to get to know the child and embark on their own problem solving approach. The North West rehabilitation study<sup>646</sup> showed that this enhances discharge provision of need compared to those children who have no CCP visit or district stay.

While the child is an inpatient, it is essential that the family, including the child whenever possible, should participate in weekly rehabilitation meetings where progress reports can be shared and plans adjusted accordingly. Caregivers need to understand the program that will take over well before discharge. Restrictions on activities need to be considered in a practical way that does not stifle the child's independence nor expose them to physical risk. This situation must be revisited and the family helped to adjust as recovery continues.

Children injured in their early years may not reveal the full consequences of frontal lobe dysfunction until adolescence, when frontal lobe development occurs. It is advisable therefore to follow all these children throughout their school years, with good liaison between Community Child Health, Social Services and Education. A proportion will need support into adulthood. There can be long term effects on employment prospects, social integration and prospects for a family life.

### Outcome measures and standards of service provision

Outcome and standards of care are linked, one influencing the other. Standards of care should be part of the clinical process, and the outcomes should allow comparison. Disability outcome scores may attempt to incorporate the adequacy of provision of need, but generally this is confounded by the influence of medical factors that may not lend themselves to therapeutic correction. It is difficult to show the outcome benefit of, for instance, physiotherapy, occupational therapy, speech therapy or even surgical intervention such as intracranial pressure monitoring on the basis of disability scores. This is the problem when considering impairments consequent upon irreversible aspects of neurological injury. The King's Outcome Scale for Childhood Head Injury (KOSCHI) is a modification of the Glasgow Coma Scale for children.<sup>660</sup> Outcome is expanded descriptively under categories 1–5 as follows:

1. Death.
2. Vegetative.
- 3a and b. Severe disability.
- 4a and b. Moderate disability.
- 5a and b. Good recovery.

Interobserver reliability is less good for categories 3, 4 and 5, than 1 and 2. More studies are needed on the ways that effective help can be delivered to children with deficits and to their carers.<sup>661</sup> This demands

an agreed assessment of need, provision of care, assessment of progress, and quality of life scores that take account of the adaptive competence of the child and their environment. Adult studies have shown that patients self-report a greater recovery than do their relatives or clinicians. Patients focus on residual physical deficits, whereas carers are more aware of cognitive and behavioral change.<sup>662</sup> This may partly reflect the lack of insight accompanying frontal lobe dysfunction. Relatives' questionnaires show a large degree of consistency over time.<sup>663</sup> In children, the Pediatric Quality of Life Inventory promises to be a useful tool, with versions developed for infants and toddlers, as well as self-reported (child) forms for children aged 5 and older.<sup>664</sup>

Setting standards according to unmet needs requires an approach to care that serves a spectrum of disorders needing rehabilitation and identifies environmental and personal factors, which may act as barriers or facilitators toward a successful outcome. It allows monitoring according to met and unmet needs. Key outcomes such as family adjustment, psychosocial adjustment, re-entry to education, the attainment of life skills progressing to employment and later family life all identify the essential members of a rehabilitation team. Standards of care start with the resourcing of these services, according to the phase of recovery, not only in pediatric hospitals but also locally with community pediatric services, educational services and transitionally into adult services as well.

#### NON-ACCIDENTAL HEAD INJURY (see also Ch. 6)

Child abuse has an incidence of 6/1000 of the childhood population.<sup>665</sup> However, less than 10% of all physically abused children will have a significant head injury, with brain involvement. In these children, approximately 75% also have bruises, 20% have burns, 40% have fractures and intracranial damage is seen in 40%. All socioeconomic groups are involved and 60–90% of abusers were themselves abused as children. Children born prematurely, children with learning difficulties and those with cerebral palsy are especially vulnerable. The outlook for children who survive non-accidental head injury is worse than following accidental injury. Neurological sequelae were reported in 30% of survivors with 57% having an IQ below 80.<sup>666</sup>

#### Neurological presentation of child abuse

The neurological presentation is not specific and may not immediately suggest abuse. The history may be vague. The child may present as an acute encephalopathy. Meningitis, encephalitis or metabolic disease may be suspected, rather than poisoning or shaking. Some children may present with repeated episodes of encephalopathy. Fabrication of symptoms, especially seizures (fictitious epilepsy), is a form of child abuse in Munchausen by proxy (Meadows syndrome). Seizure or status epilepticus is a possible presentation of non-accidental head injury; they are usually accompanied by encephalopathy. Attempts at suffocation may present as odd turns, seizures, apneic attacks, cyanotic attacks, rigidity or coma. It may be perpetrated in hospital as well as at home.<sup>667</sup>

The abused child may present with a traumatic head injury with scalp bruising, swelling, lacerations, skull fracture and neurological signs and symptoms. Injuries remote from the head may cause seizures and coma (e.g. burns, encephalopathy). In shaking injury, there may be no evidence of trauma to the head unless there has been an associated impact. The commonest presentation is as an unwell child who is irritable or excessively quiet, refusing feeds and vomiting. The infant is often hypothermic, pale and shocked with low blood pressure and tachycardia suggesting sepsis, hypoglycemia or intussusception. There may be seizures, tonic extensor spasms, breathing difficulties and cyanotic attacks.<sup>668</sup> A history of an attempted resuscitation is often given. It may be contended that the child was shaken because he/she was found gravely ill rather than this being the cause of the illness. Studies have shown that the force required to produce shaking injury in an infant is such that 'no reasonable parent would apply such force' (American Academy of Pediatrics). Rib fractures and retinal hemorrhages are

commonly associated and are extremely rare after cardiopulmonary resuscitation.<sup>669,670</sup>

#### Skull fractures

Most accidental fractures are simple linear fractures, usually parietal and over the vertex or coming from the coronal suture. If the fracture line branches, crosses suture lines, is bilateral, stellate, multiple with separate fractures, more than 50 mm wide at presentation or expands as a growing fracture, then non-accidental fracture is more likely. A depressed fracture, especially of the occipital bone in a child under 3 years, is suggestive of abuse. Any of these features merits a full skeletal survey.<sup>671</sup>

A history that the infant fell from a couch or suffered some similar trauma is often obtained. Of 330 children under 2 years of age who were witnessed falling from couches, cots, etc., skull fractures occurred in only three and a subdural hematoma in only one. Fewer than 10% had evidence of concussion.<sup>672</sup>

#### Shaking whiplash injuries

The injury most characteristic of non-accidental head injury is the whiplash shaking injury. The full picture, originally described by Caffey,<sup>673</sup> consists of a subdural hematoma, massive cerebral edema, hemorrhagic retinopathy, fractured ribs and metaphyseal injury. These may occur in any combination. Often there is no skull fracture, bruising of the scalp, scalp edema or other evidence of direct head trauma. However, when present, these features suggest direct impact. This may be due to the head banging against a hard surface during the shaking, or the child may be thrown or dropped on the floor after the shaking or may be hit against a wall. The manner in which shaking injuries are caused have been admitted to by a number of perpetrators.<sup>668,674,675</sup>

The commonest age for shaking injury is 5 months. In children under 2 years of age 64% of head injuries and 95% of severe head injuries are due to abuse.<sup>676</sup> Of 100 children studied in a carefully controlled prospective study,<sup>677</sup> 24% of head injuries were presumed inflicted and these carried a higher mortality and risk of permanent brain damage than true accidental injuries. Many children die from their injuries.

The child may be shaken by the shoulders and upper arms, causing spiral humeral fractures or periosteal avulsion. Humeral fractures in very young children, excluding supracondylar fractures, were all found to be due to child abuse.<sup>678</sup> Alternatively the smaller child may be held by the rib cage, which is often severely squeezed, leaving finger-mark bruising and fractured ribs and causing a high central venous pressure which may contribute to the retinopathy. Rib fractures are very rarely caused in young infants by falls, coughing or birth injury; even very vigorous cardiac massage and resuscitation do not normally fracture ribs.<sup>669</sup> Concurrent injuries to the cervical spine with spinal epidural hemorrhage and bruising of the cervicomedullary junction are probably underestimated; they were found in five of six fatal cases of whiplash shaking injury by Hadley et al.<sup>679</sup>

#### Pathophysiology of brain injury from shaking

Shaking causes the brain to swirl first in one direction and then the reverse. The brain and skull start and stop rotating at different times causing tearing of bridging veins. Gray matter is firmer than white matter and they move at different velocities causing small tears that can best be demonstrated on ultrasound imaging.<sup>680</sup> The tentorium anchors the brainstem and the midbrain acts as a pivot upon which the cerebral hemispheres can rotate. This may cause a primary brainstem injury with concussion.

In child abuse, tears in the white matter of the orbital, first and second frontal convolutions and temporal lobe are common. Shaking may cause slit-like cavities in white matter and the ependyma may be torn so that necrotic brain extrudes into the ventricles.<sup>681</sup> Shearing injuries occur in the white matter of the hemispheres, particularly the corpus callosum, superior cerebellar peduncle and in the midbrain. Lesions in the latter may be unilateral or bilateral but are usually asymmetrical

and often multiple. Although CT is the initial imaging method of choice, in cases of suspected non-accidental injury, MRI should also be obtained and serial imaging performed. This greatly helps in dating injuries, particularly subdural hematomas.<sup>682</sup> In shaking injuries combined with impact, cerebral edema is often very severe but may take some hours to appear after the injury. The cause of the edema is probably multifactorial.<sup>683</sup>

Retinal hemorrhages are most characteristic of non-accidental shaking injuries with chest compression. In Duhaime's series nine out of 10 children with retinal hemorrhage had been subjected to physical abuse; the one other case was a fatal high speed impact injury in a car.<sup>677</sup> Retinopathy can occur without subdural hemorrhage or cerebral edema but is seen in 50–70% of subdural hematomas. The bleeding involves all retinal layers and is also preretinal, extending into the vitreous or backwards, i.e. subretinal, to cause retinal detachment. Severe visual defects are common in survivors.

Subdural hematomas in the first 2 years of life are more commonly acute and due to child abuse than birth injury or accidental injury. Interhemispheric hematomas are particularly likely to be the result of being shaken. Most fatal non-accidental head injuries and many of those with persisting handicap have subdural hematomas (Fig. 22.43). Seventy-five percent of subdural hematomas are bilateral, 90% are supratentorial and 10% infratentorial. Eighty percent of interhemi-

Fig. 22.43 Acute subdural hemorrhage over right hemisphere with hemispheric swelling and poor gray–white differentiation and some shift of midline.

spheric subdural hematomas, caused by non-accidental injury, have an associated retinopathy.

Arteriovenous malformations can bleed into the subdural space and hemorrhagic diatheses can cause spontaneous subdural bleeding, but this is rare without trauma. Scurvy, Menke disease, osteogenesis imperfecta, coagulopathies, thrombocytopenia and glutaric aciduria may also be included in the differential diagnosis.

The majority of small acute subdural hematomas, without mass effect, will resolve spontaneously. Larger or persisting hematomas can be treated by aspiration through the fontanel or drained via burr hole. This may, in addition to relieving symptoms, also be of medicolegal significance. The hematoma may re-accumulate. If it becomes chronic, a subduroperitoneal shunt may be required.

## CHILDHOOD STROKE SYNDROMES

Stroke is defined by the World Health Organization as 'a clinical syndrome typified by rapidly developing signs of focal or global disturbance of cerebral functions, lasting more than 24 hours or leading to death, with no apparent causes other than of vascular origin'. Although in adults acute presentation with focal neurological signs such as hemiparesis is likely to have a vascular basis, the range of underlying pathologies is much wider in childhood and etiology will *not* be vascular in up to a third.<sup>684</sup> Childhood stroke has an annual incidence of 3–8/100 000 children, with equal proportions being ischemic and hemorrhagic. Stroke is one of the top 10 causes of childhood death in the USA,<sup>685</sup> contrary to common belief the majority of survivors have residual neurological impairments. Here we will focus on the acute evaluation and management of arterial ischemic stroke (AIS), sinovenous thrombosis (SVT) and nontraumatic intraparenchymal hemorrhage (IPH) in children beyond the neonatal period.

In the child presenting with acute hemiparesis distinction between the above pathologies, and nonvascular disorders such as tumor or demyelination, will require brain imaging. CT readily identifies intracranial hemorrhage and over 80% of cases of SVT. CT is commonly normal in the first 24 hours following infarction and either repeat CT or MRI will be required (Fig. 22.44). Cranial ultrasound is relatively sensitive in identifying intracranial hemorrhage in the newborn but is less reliable at excluding focal ischemia. Diagnoses such as Todd paresis or hemiplegic migraine should only be made after exclusion of vascular pathology by neuroimaging. Many children with transient focal symptoms are subsequently shown to have cerebral infarction on imaging.

## ARTERIAL ISCHEMIC STROKE

Arterial ischemic stroke (AIS) is an acute focal neurological deficit secondary to cerebral infarction in an arterial distribution. As the

Fig. 22.44 CT scan (left) and axial T2-weighted MRI scan (right) of right basal ganglia infarction in childhood. Although the lesion is evident as a focal area of low density in the right lentiform nucleus, it is more easily identified on the MRI scan. In addition, MRI will identify abnormalities earlier than CT and permit concurrent examination of the cerebral circulation.

territory of the middle cerebral artery is most commonly affected, clinical presentation is usually with acute hemiparesis. Neonates may present with seizures and minimal focal symptoms or signs. Seizures occur at presentation in around 20% of older children. Large infarcts associated with mass effect, particularly in the posterior fossa, may present with coma. Early recognition of impaired consciousness and neurosurgical referral for cerebral decompression can be life saving. Posterior circulation stroke accounts for around 15% of all cases; there is a striking male preponderance. Recent data which suggests that posterior circulation arteriopathy may be a feature of stroke related to Fabry disease (see Ch. 26, p. 1104) may partially account for this male preponderance.<sup>686</sup> Half of cases of posterior circulation stroke in childhood are caused by vertebral artery dissection.

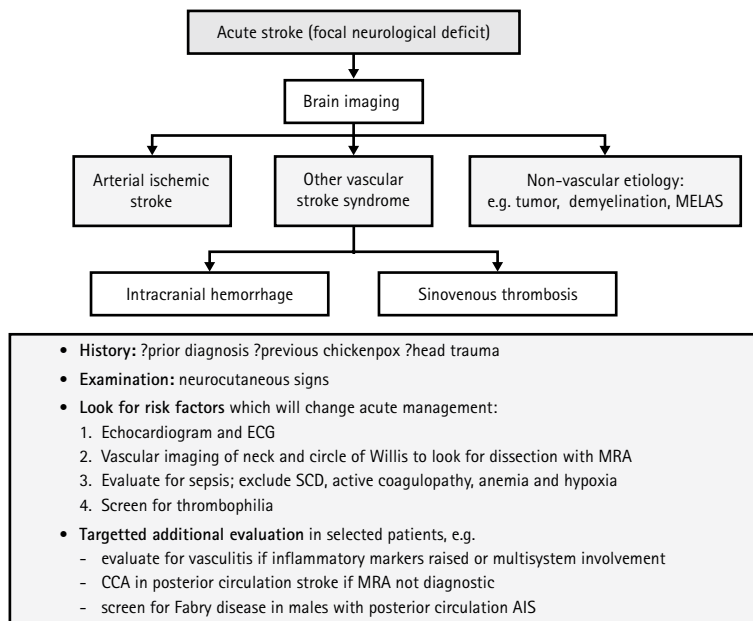

The evaluation of the child with AIS should include identification of risk factors, especially those which may influence clinical management. Half of children with AIS have a prior diagnosis, such as sickle cell disease (SCD) or congenital cardiac disease. The history should include enquiry about antecedent trauma, previous chickenpox (relevant if within the previous 12 months), associated medical conditions and family history of thrombosis or premature vascular disease. Clinical examination should include evaluation of vital signs, conscious level, neurological and cardiovascular examination, including blood pressure and peripheral pulses. A proposed algorithm for investigation is summarized in [Figure 22.45](#).

Abnormalities of the cerebral circulation are identified in 80% of children with AIS; although these are commonly intracranial, arterial dissection affects the cervical arteries, thus the arterial circulation should be

imaged from the aortic arch to the circle of Willis. This is most efficiently achieved using magnetic resonance angiography (MRA). Ultrasound of the carotid arteries can be a useful method of identifying dissection. Catheter cerebral angiography (CCA) is the gold standard for vascular imaging but is usually reserved for cases where MRA is nondiagnostic or there is potential pathology in smaller arteries that those visualized using MRA, for example in suspected cerebral vasculitis. CCA should also be considered in posterior circulation stroke as MRA is less sensitive for pathology in this area. Stenosis of the terminal internal carotid or proximal anterior and/or middle cerebral arteries is often transient ('transient cerebral arteriopathy' – TCA). TCA is thought to be due to transient arterial inflammation and is often related to antecedent chickenpox infection.

Moyamoya, endemic in Japan but also seen elsewhere, is a rare but potentially treatable arteriopathy ([Fig. 22.46](#)). This commonly bilateral disorder comprises occlusive disease of the terminal internal carotid arteries with basal ganglia collaterals, commonly described as a 'puff of smoke'. Most cases are idiopathic although there is a long list of associated conditions including Down syndrome, cranial irradiation, SCD and neurofibromatosis. Around 20% of affected children have abnormalities of other large arteries, for example renal artery stenosis. Affected children are at high risk of recurrent stroke as well as of intracranial hemorrhage. Vascular bypass procedures appear to reduce the risk of recurrent AIS.<sup>687</sup>

There are two major clinical guidelines for the management of childhood AIS. These are summarized in [Table 22.55](#). Supporting the airway and circulation are essential components of the acute management of

**Fig. 22.45** Algorithm for investigation of childhood arterial ischemic stroke. Thrombophilia screening should be undertaken following advice from a hematologist; specific tests undertaken will vary according to the local prevalence of genetic thrombophilia. Evaluation for vasculitis should include measurement of inflammatory markers (ESR, CRP), CSF examination for cells and protein, autoimmune and coagulation profile, and assessment for other organ involvement, e.g. urine dipstick and blood pressure measurement. Catheter angiography, including selective visceral angiography, may need to be considered. Assessment for Fabry disease involves measurement of alpha galactosidase A. ECG, electrocardiogram; MELAS, mitochondrial encephalomyelitis, lactic acidosis and stroke like episodes; SCD, sickle cell disease; MRA, magnetic resonance angiography; CCA, catheter cerebral angiogram; AIS, arterial ischemic stroke.

**Fig. 22.46** Catheter cerebral angiogram (lateral view). **Left:** Normal anatomy of the left internal carotid artery and its branches. **Right:** (Common carotid artery injection) features of moyamoya, including occlusion of the terminal left internal carotid artery and profuse lenticulostriate collaterals.

**Table 22.55** Summary of acute and longer term treatment recommendations from the two current [UK] clinical guidelines for management of acute childhood arterial ischemic stroke (AIS)

	RCP Guideline <sup>a</sup>	'Chest' guideline, <sup>ab</sup>
<b>Acute treatment of AIS<sup>a</sup></b>		
SCD	Exchange transfusion, target HbS < 30%	As RCP; iv hydration
All others	Aspirin 1–5 mg/kg/day	Anticoagulate for 5–7 days
<b>Secondary prevention in AIS<sup>a</sup></b>		
SCD	Blood transfusion, HbS < 30%; consider BMT	Long-term transfusion
Dissection	Anticoagulate for up to 6 months	Anticoagulate 3–6 months
Cardioembolic	Consider anticoagulation depending on other clinical factors	Anticoagulate 3–6 months
Moyamoya	Evaluate for surgical revascularization	–
Other arteriopathy	Aspirin 1–3 mg/kg/day	Aspirin 2–5 mg/kg/day (after cessation of anticoagulation)
Recurrence on aspirin	Anticoagulate	–

RCP, Royal College of Physicians.

<sup>a</sup> <http://www.rcplondon.ac.uk/pubs/books/childstroke>.

<sup>b</sup> Monagle et al.<sup>690</sup>

AIS. Derangements in homeostasis, such as fever or hypoxia, should be corrected and infection should be treated. Specific treatment will be directed by the underlying risk factors but can be summarized as (i) exchange transfusion for patients with SCD (ii) anticoagulation for cardioembolic stroke and extracranial dissection and (iii) low dose aspirin in the rest. Childhood AIS recurs in up to 30% of children; this is related to moyamoya, multiple risk factors and some prothrombotic states such as protein C deficiency. Recurrence affects over 60% of children with SCD in whom regular blood transfusion is used to maintain HbS% < 30% and hemoglobin > 10 g/dl. Secondary prevention is also summarized in [Table 22.55](#).

### SINOVENOUS THROMBOSIS (SVT)

Thrombosis of the cerebral venous system may affect either the venous sinuses or the cortical veins. The latter is more difficult to identify as clinical features may be subtle and the normal anatomy is highly variable. Clinical presentation of SVT is with symptoms and signs of raised intracranial pressure (headache, vomiting, papilloedema) or with signs related to focal venous infarction (hemiparesis, seizures). It is impossible to distinguish between arterial and venous thrombosis on clinical grounds and a high index of suspicion is needed to make the correct diagnosis. Over 80% of SVT is identified on CT,<sup>688</sup> as with AIS, venous infarction may not be apparent if the CT is done within 24 hours. Venous infarction is often hemorrhagic and needs to be distinguished from primary intracranial hemorrhage. The venous sinuses can be imaged using MR venography or CT venography if CT is uninformative.

Up to 90% of children with SVT have one or more identifiable predisposing factors. These include infection of the head and neck, for example, sinusitis and otitis media. Many also have a prothrombotic disorder.

Other risk factors for SVT include dehydration, chemotherapy (especially L-asparaginase) and nephrotic syndrome (due to loss of anticoagulant proteins). Once the diagnosis is made, current guidelines recommend anticoagulation for 3–6 months.<sup>689</sup> The presence of hemorrhage is not a complete contraindication to anticoagulation but decisions regarding the risks (mainly bleeding) and benefits (preventing extension of the thrombosis) should be assessed on a case by case basis. Thrombolysis (systemic or local) is also sometimes used but the evidence supporting this is anecdotal. As with AIS supportive treatment with adequate hydration and treatment of sepsis is crucial. Up to two thirds of children with SVT have long term sequelae; this is more likely if there has been venous infarction or seizures in the acute period.

### NONTRAUMATIC INTRAPARENCHYMAL HEMORRHAGE (IPH)

The clinical presentation of IPH may be indistinguishable from other stroke syndromes. However, coma and seizures are more common compared with AIS. Mortality is around 10%. IPH is a neurosurgical emergency and patients should be referred to a neurosurgical center as soon as the diagnosis is made. Subsequent evaluation will be directed toward identification of the underlying etiology which may be vascular (arteriovenous malformation (AVM), arterial aneurysm (AA) or cavernoma, or nonvascular (e.g. hemophilia or hemorrhage into a tumor).

AVMs represent abnormal communications between arterial and veins without an intervening capillary network. Clinical presentation is as a consequence of hemorrhage or local effects of the abnormal vessels (e.g. focal seizures, hemiparesis). The lifetime risk of hemorrhage related to AVM can be expressed using the formula (100 – (age in years)) expressed as a percentage; thus the lifetime risk of hemorrhage in a child is greater than in an adult, justifying a more aggressive treatment approach in childhood. Potential treatment options include surgical excision, endovascular occlusion or stereotactic radiosurgery. AA (dilation of the arterial wall) is a less common cause of IPH; it may be secondary to genetic conditions such as Ehlers–Danlos syndrome (especially type IV, the vascular type) or may be acquired (e.g. secondary to infection or trauma). Treatment is surgical or endovascular occlusion. Cavernomas are clusters of abnormally dilated blood vessels lined with endothelial tissue, without intervening neural tissue. There is no arteriovenous shunting and blood flow is slow. Cavernomas may be multiple and are inherited in an autosomal dominant manner in some families. They are not evident on CCA due to the slow flow but are usually identified on MRI. Treatment is usually by surgical excision.

In the child presenting with IPH, clinical status will strongly influence the immediate investigations and management. If the patient's clinical state mandates urgent evacuation of the hematoma, the child may have an abbreviated CCA in the operating theatre so that any associated AVM can be excised at the same time. If patients do not require urgent surgery evaluation options include CTA, MRI, MRA and CCA, according to the clinical context and likely underlying pathology. Patients should be also be evaluated for neurocutaneous disorders (e.g. PHACE (posterior fossa malformation, hemangioma, arterial, cardiac and eye anomalies) or Osler–Weber–Rendu syndromes) and have a routine coagulation screen. If no vascular or structural etiology is identified coagulation studies should be extended with advice from a hematologist.

### VEIN OF GALEN MALFORMATION

Although rare, vein of Galen malformation (VGM) is a potentially treatable vascular malformation that may present to the pediatrician. It represents abnormal persistence of the median prosencephalic vein, a normal embryological structure. The net result is abnormal arteriovenous shunting. In the neonate this results in high output cardiac failure, often with multi-organ involvement. In older children venous hypertension can present as acute white matter ischemia ('melting brain syndrome'), with seizures and acute focal deficits, or more insidiously as

macrocephaly. Hemorrhage is rare but is occasionally seen in adults. The advent of endovascular treatment (where glue injected via a microcatheter is used to occlude the abnormal communications between arteries and veins) has revolutionized the outlook and may be curative. However, it is a high risk intervention and many children will have sustained irreversible cerebral injury prior to treatment. Once the diagnosis is made prompt referral should be made to a center with appropriate neurovascular expertise.

## SPEECH AND LANGUAGE DELAY AND DISORDERS

### INTRODUCTION

Children have inbuilt capacities to communicate by words, sounds, gestures and music.<sup>691</sup> Even neonates when awake and not hungry will show interest in a face and will mimic a facial expression. From early infancy, children will enjoy making reciprocal noises when alert and comfortable. Babble, which is the same throughout the world, emerges any time after 6 months and subsides by about 15 months. Children with severe hearing impairment babble normally, but fall silent thereafter. The function of babble is to engage adults in conversation. The nature of the words the child learns to speak depends on the adult language they hear. Later, the accent they use depends on that of their peers. There are inbuilt capacities to infer language rules to save time in learning. Sometimes these will lead a child to say words they have never heard from anyone else – ‘I goed to my gran’s’, ‘I got some chocolate mices’ – for instance. The alternative – learning all language by listening and copying – would take far too long.

Delay refers to a normal pattern of speech and language acquisition but at a later age than most children. It may be specific in a child whose development is otherwise age appropriate. It may be associated with other specific delays, e.g. in motor development.<sup>692</sup> In children with global moderate learning disability the usual pattern of speech and language development is one of delay. Disorder refers to a pattern of development that is not seen in general. Speech examples include dysarthria or dyspraxia. Language disorders include word finding difficulty, receptive or expressive dysphasia or the excessively literal ‘concrete thinking’ of autistic children.

The age of uttering first words is variable, from well before the first birthday, to long after the second, in children who turn out to be university graduates, never mind mainstream schoolchildren. It is not related to social class, but there may be a family history of late talking and a higher proportion of boys are late to talk. By the age of 2 years, all but 6% of children have uttered their first words.<sup>693</sup> By the age of 3 years all but 4% can utter appropriate three-word phrases (Fig. 22.47).<sup>694</sup> Extension

Fig. 22.47 Onset of four-word sentences. Term boys, —; term girls, ---; preterm boys — and girls — without cerebral palsy; boys and girls with cerebral palsy, —.<sup>620</sup>

of language into phrases and sentences is related to social class and is predictive of subsequent academic progress. Of children not yet talking in phrases at 3 years, 30% have walked before 1 year and 40% walked between 12 and 16 months but 30% walked after 16 months. Early talking in phrases and sentences predicts a good academic performance. Late talking in sentences, but early walking (before 12 months) predicts a good outcome, but with an increased risk of literacy difficulties (dyslexia). Late talking in sentences and walking after 16 months predicts limited academic performance and an increased likelihood of a need for learning support or special education.

Two thirds of children<sup>695</sup> have:

- first words between 9 months and 1 year;
- first phrases between 17 months and 2 years;
- and are intelligible to strangers at 2 years.

Children seem much more intelligible to those who hear them speak regularly – siblings and mothers particularly – than to professionals or strangers. By 3 years 9 months Morley reported that only 6% had incomplete sentences, but that 11% were unintelligible to strangers and 10% to health visitors, who reported 5% as unintelligible at 4 years 9 months and 0.7% as unintelligible at 6 years 6 months. The improvements were the consequence of maturation rather than treatment. In the National Child Development Study,<sup>696</sup> reduced intelligibility at 7 years was reported for 14% of children by doctors (but only for 1.4% was the problem marked). Teachers reported reduced intelligibility in 11% of the same children (marked in 2.6%). Phonological difficulties such as omissions, substitutions and reversals are common and are seen in early written work also.

### PRESENTATION OF SPEECH AND LANGUAGE DISORDERS

When children have difficulty understanding speech they may be thought to be disobedient or deaf. When they have difficulty expressing themselves in speech they may become aggressive or frustrated and may have tantrums or behave destructively. Attempts to attract the attention of others by tapping them or pulling on their sleeves may be interpreted as aggressive behavior. In children who are late to talk, evidence of good comprehension is reassuring. Pure expressive dysphasia is rare and it is more likely that the child is simply showing a variant of normal development and will be fine shortly. Autistic children usually show signs of being remote from the first weeks of life, but a fifth show promising early development then regress. In girls, this should prompt consideration of Rett syndrome.<sup>697</sup> However Rett syndrome only affects 1 girl in 20 000 and the usual diagnosis is idiopathic autism or acquired aphasia. In boys, it is likely to be diagnosed as idiopathic autism. Some consideration may be given to fragile X, in that some children who appear odd, very withdrawn and uncommunicative in groups may have this condition, even though in individual consultation the child’s communication is not autistic. Children who have communication problems, including those who are deaf, may be thought to be hyperactive until the problem is diagnosed.

### PATHOLOGICAL SPEECH AND LANGUAGE DELAY AND DISORDER

There may be a known pathological cause for speech and/or language difficulties (Table 22.56). The child may have a *global learning disability*, due to a chromosomal abnormality, or other demonstrable medical cause. The child may have a suprabulbar palsy, due to *cerebral palsy*. There may be a bulbar palsy, due to a *neuromuscular disorder*. The mean verbal quotient of boys with Duchenne muscular dystrophy is 80 with a distribution from profound communication difficulty and autism to superior intelligence, compatible with university education. In the mouth there may be structural malformations such as *cleft palate* or *micrognathia* (moderate in Down syndrome and severe in Pierre Robin syndrome). One child in 500 has bilateral severe *sensorineural hearing loss*, which explains lack of early speech and language. *Central auditory*

*inattention*<sup>698</sup> describes a condition in which the child behaves as if deaf although the ears can be demonstrated to hear normally by physiological tests. It is analogous to developmental visual inattention and, as with that condition, may resolve spontaneously.

Semantic and pragmatic language disorders are seen in children with *autism/autistic spectrum disorders*, which it is considered result from a developmental brain disorder. The condition known as *selective mutism* is a very persistent condition, often continuing into adult life, with a probable biological cause. Congenital suprabulbar palsy<sup>699-701</sup> may be associated with bilateral parasagittal areas of cortical dysplasia or with an abnormality of chromosome 22. Around the age of 3–9 years some children who have seizures, not necessarily severe ones, may lose their receptive language skills, either acutely or progressively over time, with acquired epileptic aphasia.<sup>702-705</sup> This condition has no known cause and can occur in children. About a third of all cases have not had seizures, but show left hemisphere seizure discharge on EEG.<sup>706</sup> The type with acute onset has a better prognosis for recovery. Cerebrovascular accidents, head injury, accidental or abusive, meningoencephalitis and encephalitis are causes of acquired pathological speech and language disorders (Table 22.57).

## AUTISM AND AUTISTIC SPECTRUM DISORDERS

(see also Ch 34)

Autism, Asperger syndrome, high functioning autism, autistic spectrum disorders, atypical autism and pervasive developmental disorders are discussed elsewhere from a child psychiatric perspective (see Ch. 34). Here they are considered within the context of speech, language and communication disorder, which is a core feature of the autistic syndrome. Autistic behavior has long been regarded by pediatricians and pediatric neurologists as a familiar feature of children who have had

infantile spasms which were idiopathic or associated with tuberous sclerosis.<sup>707</sup> It is also seen as a symptom in some children with idiopathic learning disability and/or in some children with epilepsy. This triad causes confusion for parents in the sense that they ask 'what is wrong with my child – is it learning disability, autism or epilepsy?'

For the pediatrician, all of these are symptoms of an underlying biological disorder of brain development, to be diagnosed medically if possible as the cause of the child's condition. To give autism, learning disability or epilepsy as 'the diagnosis' risks closing minds to the need to continue to search for the cause. However, in spite of much excellent work on the subject,<sup>708-713</sup> it remains the case that an underlying medical cause is still unknown for most autistic children. There is an excess in males, which is still present when boys with fragile X are excluded. The concordance for autism in monozygotic twins is 36–89% in published studies. Concordance in dizygotic twins is up to 30% and there is a substantial excess of autism (about 3%) and heterogeneous developmental language disorders in non-autistic twins and siblings of autistic children.

There has been a growing acknowledgment among pediatricians that children with autistic behavior present particular challenges to their families, their teachers and all who come in contact with them. It has implications for teaching methods, for speech and language therapy and for behavioral management. The voluntary organizations for families of autistic children have published very helpful and informative literature for parents and professionals. They put parents in touch with each other and provide innovative, appropriate local and national services for autistic people. For such reasons, pediatricians have become increasingly willing to diagnose children as having an autistic disorder, to discuss this with families and colleagues and to seek help from child mental health services. Many children who would have been considered to be 'loners', dyspraxic, eccentric or to have a schizoid personality disorder, in the past, are now being recognized as having autistic features. This increasing identification has contributed to the apparent increase in the prevalence of autistic children in recent years. The Medical Research Council in Britain has published an extensive Autism Review<sup>714</sup> on the Internet.

Childhood autism is characterized by the following developmental features:

- communication difficulties;
- problems with social interaction;
- behavioral problems including stereotypies and obsessional interests;
- onset in the first 3 years.

The communication difficulties in higher functioning autistic children, or children with Asperger syndrome, are described as a semantic/pragmatic disorder.<sup>715</sup> By this is meant that children use words without understanding their meaning and in an inappropriate context. It is a sophisticated form of echolalia. Some such children can pick up and repeat long passages of film score in appropriate accents. They may come out with apparently grown-up language, in a variety of settings, throughout the day but, if pressed, cannot explain their utterances. Their speech is monotonous in tone (a disorder of prosody). They do not understand similes or metaphors, and have a very concrete, literal understanding of words and objects. They do not understand or engage in symbolic play where one object can represent something else, e.g. a box representing a boat or a pencil representing a rocket. Their visual learning may be well ahead of their auditory learning and they may be hyperlexic (much better at the mechanics of reading than at reading comprehension). The use of visual prompts may be helpful in structuring their learning and other activities.

A key component of their problems with social interaction is a lack of empathy, analogous to color blindness, in that it cannot be taught. This inability to know how others are feeling or to predict how others would be likely to feel in response to the autistic child's remarks or behavior leads to much conflict and confusion. Autistic children will regard the responses of others as bullying, persecution and utterly unjust. The children will involve themselves in activities along with other children, but not in a collaborative manner. Their highly developed sense of rules may

lead them to remonstrate with other children, who may be up to mischief, or to report such children to their teachers, which is not the best way to make friends. The ability to ignore social constraints in able autistic people can lead to unconventional inventions and solutions to problems so there may be a biological advantage to society in having some autistic people among us.

The behavioral problems of autistic children are often misconstrued. Their communication and social disabilities can lead to considerable anxiety and a difficulty in coping. This may boil over into tantrums and screaming, e.g. in response to the request from a teacher to 'give me your hand' prior to crossing a road. They are prone to obsessional interests and may break into a rage if their routines are not followed. Reorganization of furniture, redecoration, tidying up toys without discussion, a clock telling the wrong time, taking a different route for a walk, a different vehicle being supplied for transport home from school, interruption of a wheel-spinning ritual, siblings or friends playing football in the garden are factors which may provoke tantrums in autistic children. These become much less frequent when all those dealing with and caring for the child work out how his/her mind works.

An autistic 12-year-old boy began to try to kiss other boys and girls at his school. There was concern that he might have been the recipient of inappropriate sexual behavior. It transpired that he had been watching a repeat television transmission of the Morecambe and Wise show, a classic British comedy series. At the end of the program, Ernie Wise berated Eric Morecambe at length for behaving so badly throughout the show. In response, Morecambe leant forward and said to Wise 'Give us a kiss'. This 'brought the house down' (an expression the boy would not have understood but he did realize that the offer of a kiss could have sensational results – as he found out for a while). He was told he must not kiss other pupils or staff at school and stopped trying to do this immediately.

Obsessional interests may be harmless, for example an intense interest in stick insects. Young people need to be told before they leave school how to conduct themselves at interview and to refrain from telling the panel, for example, about the life story of the latest hero of popular culture. Occasionally an autistic pupil will reveal an alarming preoccupation in a clinic, having said nothing about this to parents or teachers, for example ways of killing people without weapons. Sometimes there are reinforcements for such interests within the home and a residential school may be considered.

Early behavioral intervention by families for children with autism has become popular, for example by the Lovaas method,<sup>716</sup> although there is a dearth of published research evidence for benefit of this therapy. UK parents, prompted by American experience, set up their own support group, in 1996: Parents for the Early Intervention of Autism in Children (PEACH UK). By the summer of 1999, 250 Lovaas-style programs had been established for autistic children in Britain. Of these, 109 had taken their local authorities to court to fund the program and 100 of these cases had succeeded. Families from PEACH UK took part in an audit of their experience of this method. They report that it is helpful to have the support of a therapy team, especially if staffing is stable, but find the limiting factors include their own time availability and their energy.

All sorts of anecdotal reports of remedies for autism are picked up by newspapers and from the Internet. Some are inherently improbable (e.g. brushing the skin with paint brushes, serotonin therapy, gluten and milk-free diets, swimming with dolphins or trace element and multivitamin therapy based on analysis of hair samples). None has been shown to be beneficial in any published scientific study. A randomized, double-blind, placebo-controlled trial of the effectiveness of intravenous porcine secretin on autistic behavior in 95 children aged 2–7 years showed no benefit in language development or autistic behavior 3 weeks after treatment. Yet many parents have spent a lot of money pursuing secretin and other treatment. When a condition has no medical cure it is understandable that parents choose to try alternative remedies. A British Paediatric Association working party<sup>717</sup> proposed

criteria for health service purchasers considering requests for funding for alternative treatment:

- the scientific plausibility of the program proposed;
- the evidence for its effectiveness (if available);
- the extent to which parents may benefit from the opportunity to try the method they prefer;
- the right of parents to choose;
- the potential difference in benefit between orthodox programs and the one favored by the parents;
- whether the magnitude of the difference could justify the difference in cost between the management available in the local statutory services and that desired by the parents.

There are professional responsibilities to protect parents from exploitation, to ensure regular pediatric review of the children and to understand that rejection of statutory services may be an expression of anger within the grief process. When there is anxiety from parents or professionals that treatment is harmful or causing distress, it is necessary to weigh this against observed benefits to the child and family and to come to an individual decision for counseling.

### MMR vaccine and regression in communication including autism

Some newspapers and anti-vaccine parent lobbies exploited the publication of small studies by Thompson et al<sup>718</sup> and Wakefield et al<sup>719</sup> to whip up panic about MMR vaccine which had replaced single vaccines in 1988. Wakefield et al did not claim to show evidence that MMR vaccine had caused either autism or inflammatory bowel disease. They have not replicated their initial research and nor has any other research team. The accumulation of scientific evidence to support the use of the vaccine in 94 countries worldwide became a misplaced argument about families' rights to choose vaccination methods with an implication that there was an official cover-up of 'vaccine damage' caused by MMR in the British government's attempt to induce doctors to hit immunization targets. A factor in this was the lack of preparation of professionals for the introduction of the MMR booster.<sup>720</sup> However a review of the data on 473 children with classic or atypical autism in five health districts in north-east London from 1979 to 1998<sup>721</sup> has shown no significant change in the proportion of autistic children with a regressive history (25%) or bowel symptoms (17%) throughout the study, before or after the introduction of MMR vaccine in the middle of the assessment period of the register.

### Treatment and management of autistic children

The principal elements in helping autistic children are consistent, appropriate management at home and suitable educational provision. Health input comes, mainly, from speech and language therapists and clinical psychologists after the initial diagnostic work by pediatricians and child psychiatrists. Teachers work closely with health colleagues, parents, social services and voluntary agencies in working out the best means of helping the children to learn academically and socially. Whether the children are educated in mainstream schools with support, in language units within mainstream schools, in special schools for children with learning disability or in schools for autistic pupils depends in part on local availability and in part on associated cognitive and social capabilities of the child. The presumption is that the most inclusive provision is the first priority. Some children's needs are so complex and their capacity to cope with the hurly-burly of mainstream education is so problematic, in spite of good support, that special provision is required.

Medical help may be needed in the management of behavior problems. Pediatricians are wise to liaise with psychiatric colleagues before using medication in these children, some of whom benefit from methylphenidate, carbamazepine or lamotrigine, used for their psychotropic properties. A third of the children experience epilepsy at some stage in childhood or adolescence and require antiepileptic drug therapy, puberty being a time of higher risk. Melatonin has a place in helping autistic children to get to sleep. When the problem is night

waking, chloral hydrate may be used though it leaves some hangover effects next day. Administration may be a problem as autistic children can be adamant as to what they are or are not prepared to eat and drink.<sup>722</sup>

### SPEECH AND LANGUAGE DELAY AND DISORDER IN CHILDREN WITH GENERAL LEARNING DISABILITY

Speech and language delay/disorder may be a feature of general learning disability (moderate or severe mental retardation). The communication ability may be similar, developmentally, to the rest of the child's age-equivalent progress. It is quite common for children with learning disability to have greater difficulty with communication than with practical and social development. It may be thought by parents that the only problem faced by such children is their speech ('he understands everything'). It requires careful observation by professionals alongside the parents and detailed developmental assessment by a clinical psychologist, as well as full assessment by a speech and language therapist, to understand the child's condition accurately. Such children's communication needs deserve full attention, including consideration of augmented communication when appropriate, within a context which understands their learning disability.

### SPECIFIC DEVELOPMENTAL SPEECH AND LANGUAGE DELAY AND DISORDER

When no underlying cause has been discovered for the child's communication difficulties, the child is described as having a specific developmental speech and language delay or disorder. This is frustrating and unsatisfactory for parents and professionals who would like a medical explanation. Nonetheless this is how it is for about 85% of children who present.<sup>694</sup> There are some known risk factors and associated features:

- low socioeconomic class ;
  - males/females 2:1;
  - unremarkable home background (not abusive or disturbed);
  - later children;
  - large families;
  - family history of language, literacy or autistic problems;
  - average or near to average general intelligence;
  - higher chance of left-handedness;
  - hearing normal or fluctuating hearing loss;
  - often a mixed receptive/expressive language and articulatory problem;
  - may have general developmental coordination difficulties;
  - may have features of autistic spectrum disorder in early years;
  - problems with reading and spelling in school.
- Examples of developmental speech and language delay/disorder:
- Mild to moderate phonological:
    - lispings – a form of dyslalia;
    - stammering – dysfluency (Gordon<sup>723</sup>);
    - sound substitutions, omissions and reversals.
  - Moderate articulatory:
    - developmental verbal dyspraxia.
  - Moderate to severe language difficulty:
    - word finding difficulty;
    - expressive dysphasia.
  - Severe language difficulty:
    - receptive dysphasia;
    - mixed receptive/expressive dysphasia.
  - Profound communication difficulty:
    - central auditory processing difficulty (auditory imperception).

The part played by fluctuating hearing loss with secretory otitis media with effusion (OME) has been investigated extensively but inconclusively.<sup>724-727</sup> The nasopharynx increases in size with age but, between the ages of 3 and 5 years, the adenoids grow more rapidly and decrease

the size of the palatal airway, particularly in those children who develop OME. Children with Down syndrome have a smaller nasopharynx than most children and are at particular risk from adenoidal encroachment. Subsequently the adenoids remain relatively constant while the nasopharynx increases, so the airway enlarges. Surgical procedures produce good short term gains but less predictable long term benefits. Maw<sup>727</sup> reviews the findings of numerous prospective studies over 15 years and proposes recommendations based on factual evidence rather than anecdotal practice. Only 1 in 40 children with developmental speech and language problems will be found to have moderate or severe bilateral sensorineural hearing loss. However high quality hearing testing is essential for all.

### COMMUNICATION BEFORE SPEECH

From birth onwards an alert infant interacts with carers by attending to their faces, by phonating and by movements such as wriggling when held. Fixation on faces and smiling emerge in the early weeks after birth, often long before the frequently quoted 6-week milestone. Facial expressions can be imitated from the first days of life. Attention to movement of other people, to patterns, preferably complex ones, and to handling begins in the early weeks. Reciprocal phonation with others begins then too. Parents of no experience may say that there is no point talking to babies because they cannot talk back. The reverse is the case. Infants have a repertoire of types of cry – tired, hungry, uncomfortable, experimental – to which parents become attuned and to which they become responsive. The biological purpose of incessant crying at 3 months ('colic') is hard to fathom – it is certainly a test of parental commitment and resourcefulness. When parents are intolerant of this, their children are in grave danger.

Reaching for objects and for the faces of carers becomes increasingly rewarding for the infant as control improves and the child finds that actions can have gratifying and predictable results. This progresses to pointing and imitation of gestures later in the first year. Phonation gives way to babble, which is international and uttered by children with severe hearing impairment. Adults babble back with variations of inflection, which amuses the child. They also talk to the child, who begins to show signs of comprehension. At the end of the first year or early in the second year the child will begin to indicate body parts on request and will be pleased by adult approval. Requests will be indicated by pointing, gestures and phonation. When adults 'misunderstand' as part of a game it amuses the child up to a point. Then it is 'game over'. In the child with severe hearing impairment, babble gives way to silence, but in the hearing child it develops into jargon – word-like noises which are incomprehensible. Even when understandable words emerge, such as doggie, names of family members, juice, no, more, ta, there are other 'words' which are consistent but jargon, e.g. loadalah (motor car) or brewstie (what are you doing? I'm doing a brewstie – the child was pinching the thumb and forefinger and never explained the term). In children with learning disability, the era of communication before speech is much extended. Interpretation is rewarding and development of gestures into signing or of pointing into or pointing at symbols can develop into a method of communication, which takes the pressure off the dearth of expressive language. Far from delaying speech it seems to accelerate it.

### TREATMENT AND MANAGEMENT OF CHILDREN WITH SPEECH AND LANGUAGE DELAY OR DISORDER

- Identify the problem.
- Investigate possible causes which can be treated, or which have genetic implications.
- Assess the child's general development including a clinical psychology assessment and motor coordination assessment.
- Assess speech and language function: expert help from a speech and language therapist.

- Discuss the findings with the parents who may bring a grandparent, friend or professional.
- Inform the local education authority.
- Contribute to the interdisciplinary process of considering the appropriate form of education.
- Review progress at regular intervals – discuss findings with teachers, therapists and parents.

Speech and language therapists have a key role as consultants and advisers of parents, teachers, doctors and others in regular contact with children affected by speech and language delay and disorder. They are the experts, in collaboration with clinical psychologists, teachers and parents, in working out the way children's minds are working, in the way they are understanding and using language, including context and syntax and in the state of their phonological development. However the 'treatment' is not in the therapy sessions but in the day to day communication between adults and children, the anticipation and avoidance of frustration and the way the children are encouraged to succeed. Progress reassessment and revision of goals by therapists guide those who are in daily contact in helping the children. Sometimes parents complain that it seems they are being expected to adopt a treatment role but they should not be expected to spend too much time grappling with the limits of the child's ability. Rather they will be helping their children to consolidate on their abilities, finding out what their children do best and helping them to make the most of these.

### Augmented communication

There are many ways of augmenting spoken language in everyday life. Gestures and other forms of body language are part of our repertoire. Actors develop these to a subtle and remarkable extent. For children whose speech is lacking or incomprehensible, systems involving

Fig. 22.48 Augmentative communication with Reybus Introtalker (pictograms) being used by an anarthric child with severe mixed cerebral palsy.

gestures or symbols can be beneficial. Instead of being reactive, the child can become proactive for the first time. There are specialist centers for augmentative communication, with expertise in signing, symbol and switching methods. The local speech and language therapy service will have a specialist expert who can advise on the best source of help (Fig. 22.48).

Many different factors, including environment, diet and illness can affect the blood picture, so that 'abnormalities' of the blood count are relatively common in childhood. Children have more reactive bone marrow than adults resulting in more impressive changes with relatively smaller stimuli. Infection commonly results in a mild or moderate degree of anemia and particularly produces elevation of the platelet count. The more serious hematological disorders will form the focus of this chapter. Hematological laboratory parameters in children must be assessed against normal ranges for age as these may be significantly different from adults. A table of normal ranges is given in Appendix 1. Developmental hemopoiesis is covered in Chapter 12. Normal ranges for hematological values in the neonatal period, including coagulation factors, are given in Appendix 1.

## HEMATOLOGICAL ASSESSMENT IN CHILDHOOD

Hematological disorders present with nonspecific symptoms. Anemia may be profound before a child has any symptoms – pallor is eventually noted in an otherwise well child. Children with severe anemia may have respiratory distress and be misdiagnosed.<sup>1</sup> Children with leukocyte abnormalities may present with infection; thrombocytopenia is often asymptomatic until the count is profoundly low (less than  $10 \times 10^9/L$ ). Demonstration of anemia, or a reduction of any one of the cell lines, is not a diagnosis

in itself. Once an abnormality has been identified the next step is to establish the cause, which will determine the course of action. The quality of the blood sample from a child is important. Traumatic or lengthy venepuncture or difficult capillary collection often results in activation and partial coagulation, and visual inspection may miss small clots in a sample. The commonest cause of a low platelet count is a poorly collected sample which can also result in a falsely low white cell count or low hemoglobin.

## ANEMIA

### APPROACH TO ANEMIA

Anemia is a sign, not a diagnosis. The diagnosis may be clear from the history and examination together with the result of the blood count.

1. Is the child anemic? Results must be assessed against normal ranges for age. Many hospitals only quote adult normal ranges; this may lead to a mistaken diagnosis of anemia in a child, as the normal range is lower.
2. What are the characteristics of the red cells? The red cell indices and smear appearances may suggest potential diagnoses and initial investigations (Fig. 23.1 and Table 23.1).
3. What is the pathophysiological mechanism of the anemia? This requires synthesis of the clinical and laboratory findings, and consideration of the mechanisms shown in Figure 23.2.

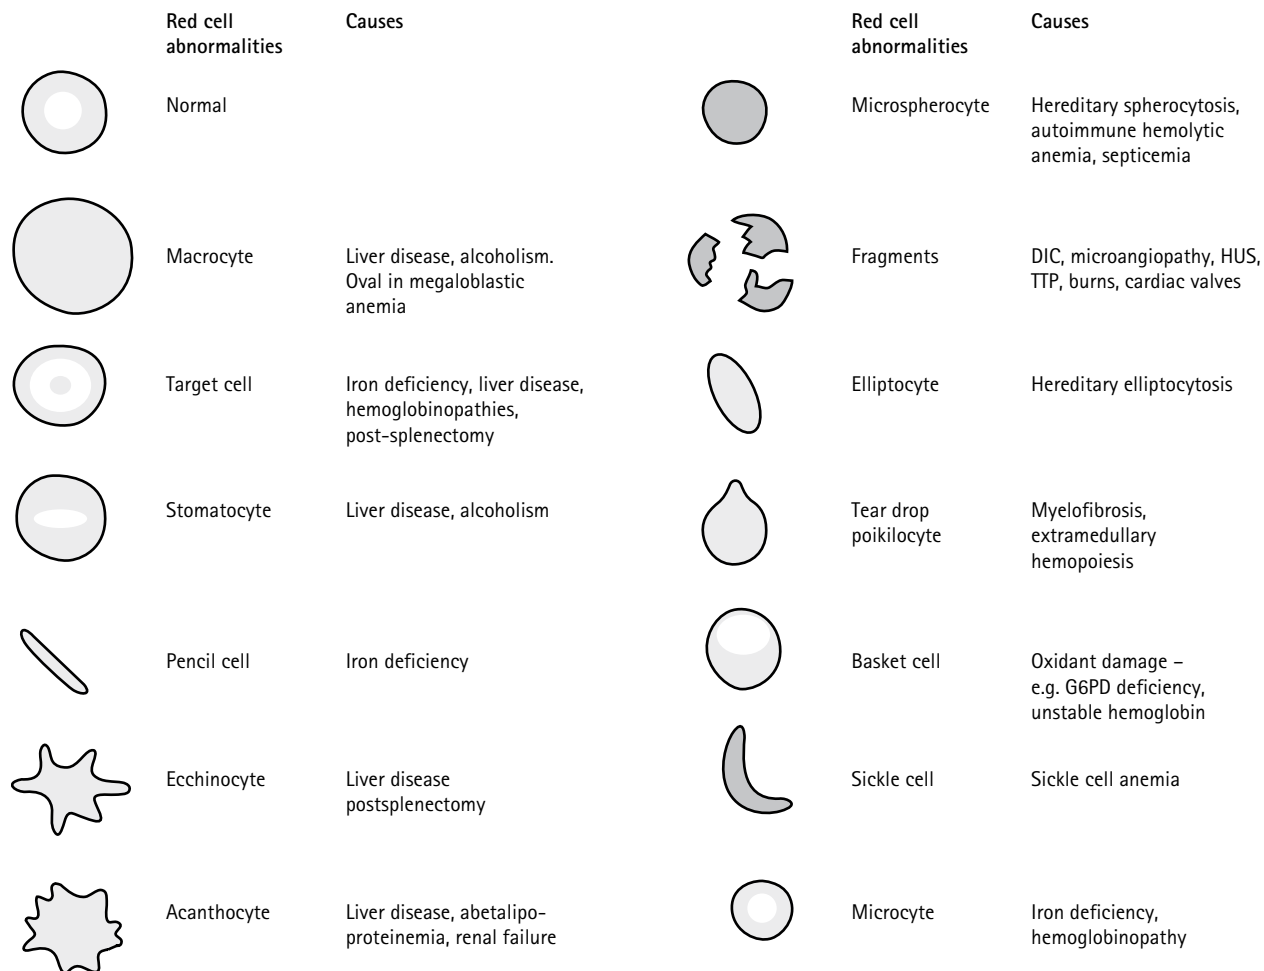

Fig. 23.1 Morphological appearance of red blood cells in different anemias. DIC, disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase; HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura. (From Hoffbrand et al 2001<sup>36</sup> with permission.)

Table 23.1 Morphological diagnosis of anemia

Red cell appearances <i>Discriminatory test</i>	Hypochromic microcytic		Normochromic normocytic		Macrocytic

Result	Reduced	Normal or increased	Reduced	Normal or increased	Megaloblastic	Non-megaloblastic
Possible diagnoses	Iron deficiency	Thalassemia Hemoglobinopathy Sideroblastic anemia	Bone marrow hypoplasia Red cell aplasia	Hemolysis Blood loss Secondary anemia	Deficiency of B <sub>12</sub> /folate Abnormality of B <sub>12</sub> /folate metabolism	Liver disease Thyroid disease Congenital dyserythropoietic anemia

## DEFICIENCY ANEMIAS

Iron deficiency anemia is very important and common in childhood. Iron deficiency without anemia is significant because iron is also required for normal development of the central nervous system. Deficiencies of other hematinics are rare.

### IRON DEFICIENCY

#### Etiology

In contrast to adults where the diagnosis of iron deficiency prompts a search for a source of blood loss, the commonest cause of iron deficiency in children is an inappropriate diet; blood loss is uncommon. Iron deficiency

occurs from 6 months of age onwards when the child's total body mass is expanding in the face of an inadequate iron intake (Fig. 23.3).

Studies show that 10–18% of Caucasian children, and 17–31% of children of ethnic minorities, have iron deficiency with hemoglobin levels of less than 1 g/dl. Many other infants will be iron deficient (serum ferritin < 12 µg/L) without anemia. Iron is required for the developing brain (see below) as well as for red cell production, so that it is important that iron deficiency, even without anemia, is corrected. Many infants and young children admitted to hospital for other reasons have blood tests which indicate iron deficiency as an incidental finding. This opportunity to correct iron deficiency (by a combination of therapy and dietary re-education) should not be missed. Routine prophylactic supplementation

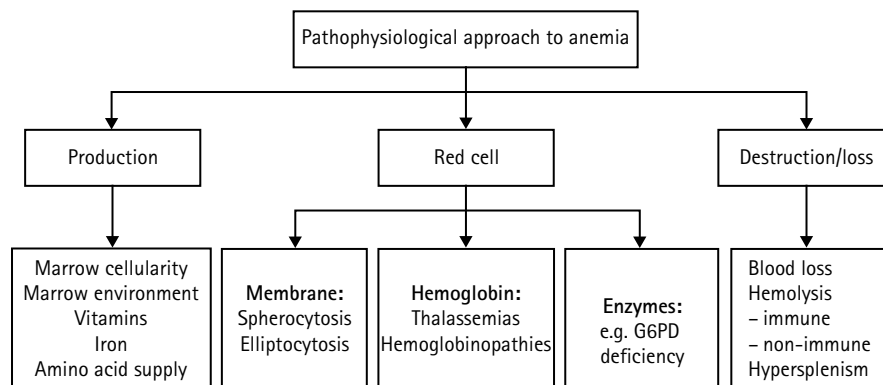

Fig. 23.2 Pathophysiological approach to anemia. G6PD, glucose-6-phosphate dehydrogenase.

of diets with iron may not necessarily be beneficial. Two randomized clinical trials have reported different results; in Nepal no difference in mortality was found,<sup>3</sup> but in a similar study of children in East Africa in a population with high rates of malaria there was an increase in hospital admissions and death in the treated group, possibly related to an increase in infection.<sup>3</sup> The inflammatory response, which leads to restriction of iron availability to erythroid precursors in infection,<sup>4</sup> may have a protective effect by reducing iron availability to micro-organisms. A Cambodian study of weekly iron and folate supplementation resulted in a decrease in the prevalence of anemia in children aged 5–11 years in two schools from 62% to 11%, and from 57% to 26%.<sup>5</sup> In resource-limited countries iron supplementation is only one part of necessary changes in child nutrition and health.

### Diagnosis

Iron deficiency may present with pallor – the hemoglobin level can be extremely low (3–5 g/dl) without symptoms. Pica (the persistent compulsive ingestion of food or nonfood substances, for example soil, stones, chalk, sand, foam rubber and carpet) is an insufficiently recognized symptom. Usually these cravings cease with correction of the iron deficiency. Other signs (such as koilonychia or angular cheilitis) are very rare. Iron deficiency causes serial changes in the blood before anemia develops (Figure 23.3). Serum ferritin is reduced and eventually a microcytic, hypochromic anemia results. Usually the MCV (mean cell volume) and MCH (mean cell hemoglobin) fall before the hemoglobin, but the changes can occur together. The MCHC (mean cell hemoglobin concentration) is less useful because it is often normal in the face of hypochromia. (The value is calculated from the PCV and Hb and may be falsely elevated due to trapped plasma in the hematocrit where there are abnormal red cells.)

Iron deficiency is suspected when:

1. The hemoglobin is normal but the MCV and MCH are slightly reduced (the most important differential diagnosis is from thalassemia traits).
2. The hemoglobin is reduced with low MCV and MCH (Fig. 23.4). Reductions in MCV and MCH are usually proportional to the reduced hemoglobin level, e.g. with Hb of 3–4 g/dl, the MCV and MCH will be markedly low, e.g. 50 and 18 respectively.

When the diagnosis is unclear it should be confirmed by measurement of ferritin (reduced) or zinc protoporphyrin (raised). A low ferritin is diagnostic of iron deficiency. (Ferritin is an acute phase reactant and will be elevated in acute inflammatory states and liver disease. A normal ferritin does not absolutely rule out iron deficiency.) Measurement of the serum iron and iron binding capacity (transferrin saturation) adds little to the diagnosis in straightforward cases. The serum iron level on its own is unreliable having significant diurnal variation. It may be helpful to request these additional tests in children with chronic disease and in those with suspected iron overload.

### Differential diagnosis

Other causes of a hypochromic microcytic blood picture are:

1. Anemia of chronic disease or 'anemia of inflammation' (modification of iron regulation by the inflammatory response).
2. Thalassemia traits – these require quantitation of hemoglobins A2 and F, and not simply hemoglobin electrophoresis. Thalassemias are not excluded by normal results and further tests (genetic analysis) may be required. The advice of a hematologist should be sought.
3. Sideroblastic anemias (see below).

	Depleted iron stores	Iron deficiency without anemia	Iron deficiency anemia
↓ Serum ferritin	↓	↓	↓
↓ Transferrin saturation	↓	↓	↓
↑ Erythrocyte protoporphyrin	↑	↑	↑
↓ MCV	↓	↓	↓
↓ Hb	↓	↓	↓

Fig. 23.4 Peripheral blood appearances in severe hypochromic iron deficiency with (a) microcytic red cells compared with (b) a normal film (same magnification).

### Iron deficiency and neuropsychological effects

Animal experiments have clearly shown that early iron deficiency irreversibly affects brain iron content and distribution, leading to neurotransmitter and behavioral alterations. Anemia due to iron deficiency is significantly associated with poorer scores in developmental testing when compared with controls, particularly in coordination and spatial orientation skills. Some trials have shown definite benefit in treating the iron deficiency, but have suggested that not all the neurological deficit is reversed. Treating the hemoglobin level without replenishing the iron stores is probably insufficient. Further trials are needed, looking at long term school performance, academic achievements and career patterns in relation to iron deficiency in infancy, but would be very difficult to do. Prevention of iron deficiency is much better than attempts to reverse damage done. This topic has been reviewed<sup>6,7</sup> and the impact of iron therapy on psychomotor development and cognitive function in children under the age of 3 years has been considered in a Cochrane review.<sup>8</sup> Another more recent systematic review concluded that iron supplementation improved mental development.<sup>9</sup>

### Nutritional aspects and diet

Iron requirements are relatively high in infancy and early childhood because of rapid growth (Fig. 23.5). Stores laid down in pregnancy are depleted after 6 months of age so it is important to establish a good intake of iron early in weaning. Preterm infants have lower iron stores at birth and may become iron deficient as early as 3 months of age.

Dietary iron occurs in two forms – heme and nonheme. Heme iron (in meat, fish and poultry) is well absorbed and its bioavailability is not affected by other dietary factors. Non-heme iron is less well absorbed and its bioavailability is affected by dietary factors because of the way it is bound in foods. It is present in beans, pulses, peanut butter, green leafy vegetables, dried fruit and fortified breakfast cereals. Absorption is enhanced by vitamin C and proteins, but is inhibited by a number of constituents of food and drink, for example tannins (in tea and legumes), phytates (in unrefined cereals), phosphates (in eggs), oxalates (in rhubarb, spinach) and polyphenols (in spinach, coffee). The main causes of iron deficiency are delayed weaning, use of cows' milk before 1 year as a main drink, excessive intake of milk and other drinks in older children, a diet low in iron-rich foods, poor intake of vitamin C and increased intake of foods which inhibit iron absorption. Primary care support and education should be aimed towards establishing good weaning practices and continued good eating patterns in later childhood.

### Therapy

#### Choice of preparation

The daily iron requirement for full-term infants is 1 mg/kg/day (maximum total daily dose 15 mg) starting no later than 4 months of age until 3 years of age. Between 4 and 10 years, the requirement is 10 mg/day and

above 11 years and through adolescence, 18 mg/day. The treatment dose for iron deficiency is 3 mg iron/kg body weight/day up to a maximum of 180 mg daily.

When a child fails to respond to iron therapy, the commonest reason is failure of adherence. Although many preparations may be prescribed three times a day, better adherence may be achieved with a single daily dose or twice daily dosing. Iron is available as iron salts and iron chelates.

- Iron salts** (e.g. sulphate, fumarate, gluconate and glycine sulphate), *ferrous sulphate*. Although ferrous sulphate is optimal for adults, the liquid is no longer recommended as it is not commercially available, and tastes terrible. Other preparations are available either as tablets, e.g. *ferrous sulphate*, *ferrous gluconate* or liquids such as *ferrous fumarate* and *ferrous glycine sulphate* 141 mg (equivalent to 25 mg Fe) in 5 ml.
- Iron chelates** (sodium iron edetate, and polysaccharide iron complex). Chelates have major advantages in paediatric practice – they do not stain the teeth and sodium iron edetate can be mixed with milk or juice without altering absorption. In general there are fewer gastrointestinal side-effects, and they are sugar-free. Perhaps most importantly, the child usually likes them.

Fig. 23.5 Changes in body iron during infancy. (From Nathan & Oski 1992<sup>124</sup> with permission.)

### Response to treatment

There is no difference in response between the types of iron medication providing sufficient iron is given. However severe the anemia, there is no advantage in giving iron parenterally. The hemoglobin increases by about 1 g/dl per week if adherence is good. Failure to respond is nearly always due to failure of adherence. If the hemoglobin is repeatedly less than 8 g/dl, a short admission to hospital may be considered in order to monitor adherence and reinforce dietary education. In severe iron deficiency anemia (Hb < 6.0 g/dl), the hemoglobin should be checked within 2 weeks to ensure that the child is responding (adhering). In very severe iron deficiency (e.g. Hb of 3 g/dl), early monitoring (e.g. within 3–4 days) will show an increase in the RDW (red cell distribution width) on the automated count, and the appearance of some polychromasia on the film. Then the monitoring interval can be extended. Children with severe iron deficiency will need a minimum of 3 months' iron therapy, often considerably more. The ferritin can be used to monitor treatment once the anemia and abnormal indices (hypochromia and microcytosis) have been corrected. In older children, the question of occult intestinal blood loss should be considered.

### Conditions that may be associated with iron deficiency – lead poisoning

Although lead toxicity is thought to lead to anemia, severe lead toxicity, manifested by serious neurological effects, can occur without anemia. Coincidental iron deficiency is more likely to cause anemia; lead poisoning and iron deficiency are likely to occur in the same population. Lead poisoning and its management has been reviewed in detail.<sup>10</sup> Typically there is punctate basophilia on the blood film.

### Anemias that can be confused with iron deficiency – the sideroblastic anemias and thalassemia traits (see later)

Sideroblastic anemias are rare, and in childhood usually congenital and may exhibit X-linked inheritance. The red cells are usually hypochromic and microcytic. The ferritin is normal or raised, and the anemia is characterized by erythroid hyperplasia and the presence of abnormal iron staining (ringed sideroblasts) in the bone marrow. Some drugs can also induce sideroblastic change, but this is rare in children.

Sideroblastic anemia (sometimes transient) may be the presenting feature of Pearson syndrome, a serious multisystem disease due to mitochondrial DNA deletions usually with pancreatic insufficiency, neurological involvement and a tendency to episodes of lactic acidosis. Liver failure may occur and the syndrome is usually lethal early in life.<sup>11</sup>

## FOLATE DEFICIENCY

### Etiology

Megaloblastic anemia is very rare indeed in children but when it does occur it is most commonly due to folate deficiency. Unlike iron, folate stores are relatively labile and in constant need of replenishment. Folate is required for nucleic acid synthesis and 1-carbon unit transfer in all cells of the body, particularly growing tissues (Fig. 23.6). Breast milk from a folate-replete mother contains about 25 µg/L of folate and provides enough folate for the normally developing child. However, if preterm babies are not supplemented with oral folate about a third will develop low serum folate levels by 6 weeks of age and 10% will develop megaloblastic anemia by 8 weeks of age when the hepatic stores have been depleted. Heating of milk results in a 40% loss of folate and reheating of pasteurized milk causes an 80% loss. In short, all babies are in a precarious state of folate balance during the first weeks of life. Rapid growth, fever, infection, diarrhea or hemolysis all increase folate requirements and may further deplete the stores to the level of clinical deficiency.

Folate is absorbed in the upper jejunum by an active transport mechanism that is impaired in malabsorption states, particularly celiac syndrome. In these disorders, the deficiency does not usually

Fig. 23.6 Role of vitamin B<sub>12</sub> and folate in DNA synthesis. Dietary folates are converted to methyltetrahydrofolate (methyl THF) by the small intestine. Inside marrow and other cells, methyl THF transfers a methyl group to homocysteine to form methionine. Vitamin B<sub>12</sub> (B<sub>12</sub>) is needed for this reaction. The THF formed is conjugated to the polyglutamate form possibly after formulation. 5,10-methylene THF polyglutamate is coenzyme for thymidylate synthetase, responsible for the methylation of the pyrimidine deoxyuridine monophosphate (dUMP). The folate coenzyme is oxidized to dihydrofolate (DHF) polyglutamate which is recycled to the fully reduced (THF) form by the enzyme dihydrofolate reductase (DHFR). dTMP is phosphorylated to thymidine triphosphate (dTTP). This is polymerized with the other three deoxyribonucleoside triphosphates, dA (deoxyadenosine) TP, dG (deoxyguanosine) TP, and dC (deoxycytidine) TP to form DNA. (From Hoffbrand 1983<sup>25</sup> with permission.)

produce a frank megaloblastic anemia. Other malabsorptive disorders such as tropical sprue, Crohn disease, multiple diverticula of the small intestine and blind loop syndrome will frequently produce folate deficiency.

Increased requirements for folate and subsequent deficiency occur in chronic hemolytic anemias, but deficiency is unusual as most children consume in excess of the necessary daily recommended intake, however deficiency may be common in poor socioeconomic groups.<sup>12</sup> Although regular folate therapy is recommended in chronic hemolytic states there is little evidence that this is always needed, and a double-blind controlled trial of folate therapy in sickle cell disease led the authors to conclude that this policy needs critical review.<sup>13</sup> Various drugs are associated with deficiency of folate, e.g. phenytoin, barbiturates, methotrexate, pentamidine and trimethoprim. Maternal folate deficiency predisposes to neural tube defects and possibly to other congenital abnormalities including Down syndrome. Congenital deficiencies of several enzymes in the folate pathway are described.<sup>14</sup>

### Clinical features and diagnosis

The presentation, like many hematological disorders, is nonspecific. Folate deficiency will produce macrocytosis (which can be masked by associated iron deficiency in conditions with malabsorption); more severe forms will be associated with leucopenia and thrombocytopenia.

Hypersegmented neutrophils on the blood film is an important clue. Serum and red cell folate levels should be requested to confirm the diagnosis.

### Treatment

Treatment is straightforward with oral folic acid in a dose of 1–5 mg daily and should be continued for several months. Where demand for the folate remains high (e.g. in chronic hemolytic anemias) lifelong supplementation may sometimes be required. There is often a dramatic clinical response within a few days with a reticulocytosis by the end of a week.

### VITAMIN B<sub>12</sub> DEFICIENCY

Vitamin B<sub>12</sub> deficiency is very rare indeed in childhood. The infant usually has an insidious onset of pallor, lethargy and anorexia, often with neurological symptoms. With the popularity of vegetarianism, maternal dietary deficiency may produce profound deficiency in infancy with neurological sequelae and is currently the commonest cause of infantile B<sub>12</sub> deficiency.<sup>14</sup> It may occur in older children as part of a more generalized gastrointestinal disease with malabsorption. B<sub>12</sub> deficiency has been reported in infants whose mothers have undergone gastric bypass procedures for obesity,<sup>15</sup> and those whose mothers are in the early stages of traditional pernicious anemia.<sup>16</sup> B<sub>12</sub> deficiency occurs in early infancy due to congenital defects in the absorption or metabolic pathway. Recent advances in the molecular and genetic mechanisms are reviewed by Whitehead.<sup>14</sup> The diagnosis should be considered in any infant who develops pancytopenia with megaloblastic anemia in the first 3 years of life. Methylmalonic aciduria with homocystinuria is associated with vitamin B<sub>12</sub> deficiency. Diagnosis is very important but treatment with B<sub>12</sub> does not necessarily reverse the neurological defects.<sup>14</sup>

### Diagnosis

The blood picture is indistinguishable from folate deficiency – there is often a pancytopenia with macrocytosis. The serum vitamin B<sub>12</sub> level will be low (less than 100 µg/ml) except in the deficiency of transcobalamin (TC) II. This latter finding occurs because the assay measures mainly vitamin B<sub>12</sub> bound to TCI. The serum folate level will be high or normal and the red cell folate misleadingly low. These infants are difficult to investigate and should be referred to specialists for further workup.

### Treatment

The usual dose of vitamin B<sub>12</sub> (as hydroxocobalamin) for children is 100 µg, given intramuscularly, three times a week until the hemoglobin is normal, followed by 100 µg monthly thereafter. Some disorders may be successfully treated with oral B<sub>12</sub> therapy.<sup>17</sup> The neurological defects may take longer to recover. In TCII deficiency very large doses are required.

### OTHER CAUSES OF MEGALOBLASTIC ANEMIA

Some very rare metabolic disorders are associated with megaloblastic anemia such as orotic aciduria, Lesch–Nyhan syndrome, and thiamine responsive congenital dyserythropoietic anemia Type I.

### APLASTIC ANEMIAS

Bone marrow failure usually presents with pancytopenia that may be moderate or severe, or initially there may only be a single lineage affected with evolution to full aplasia over months or years. Aplastic anemia may be idiopathic (70–80%) or secondary to a constitutional abnormality. Table 23.2 lists agents that may be associated with aplastic anemia. In many cases it is not possible to be certain about their etiologic role. Withdrawal may lead to improvement in the pancytopenia. Marrow aplasia is diagnosed by bone marrow examination, including trephine biopsy (Fig. 23.7). Whatever the underlying cause, severe aplasia (70%), defined as pancytopenia with neutrophils  $<0.5 \times 10^9/L$ , platelets  $<10 \times 10^9/L$  and reticulocytes  $<1\%$ , with documented bone

marrow hypocellularity, is associated with a high mortality from infection or bleeding. Good supportive care is essential, and early hemopoietic stem cell transplantation (HSCT) from an HLA-matched sibling donor is the optimal definitive treatment. These children should be referred to a specialist service early. If a sibling donor is not available the most appropriate treatment is intensive immunosuppression using antilymphocyte globulin combined with ciclosporin. Immunosuppression produces a response in over two-thirds of patients but over a long period of follow-up many patients develop myelodysplasia or leukemia suggesting ongoing clonal stem cell disorder.<sup>18</sup> An international group have published guidelines on the management of aplastic anemia.<sup>19</sup>

### CONSTITUTIONAL APLASTIC ANEMIAS

Inherited bone marrow failure syndromes are important and are responsible for about 25% of children with aplastic anemia. Patients with these disorders have a genetic propensity for bone marrow failure presenting at birth or developing later.<sup>20</sup>

#### Fanconi's anemia (FA)

This rare and heterogeneous disorder can present from birth to 48 years of age although 75% present between 3 and 14 years of age. The median age at diagnosis is 7 years. The most common presentation is with pancytopenia, single lineage defects (particularly thrombocytopenia) or malignancy (particularly leukemia). Half have typical physical findings especially short stature, hyperpigmentation, café-au-lait spots, microsome, microcephaly, thumb, ear, genital and renal anomalies, and developmental disability. FA is inherited as an autosomal recessive with a prevalence of 1–5 per million and a heterozygote frequency of about 1 in 300.<sup>21,22</sup>

Children may present with single lineage failure, particularly thrombocytopenia. Other clues are macrocytosis and fetal characteristics of red cells (raised HbF and an increased expression of i antigen). Chromosome fragility is the hallmark of this disorder, readily seen in metaphase spread from blood lymphocytes stimulated with suitable agents. FA subtyping is important because the complications and outlook vary.<sup>21</sup>

Treatment of FA is difficult – the median survival from diagnosis reported in the international registry (764 subjects) is 24 years.<sup>23</sup> Allogeneic HSCT may be curative for bone marrow failure with a 75% 2-year survival with sibling donors, but only a 33% 3-year survival with matched unrelated donors.<sup>24</sup> Patients with FA do not tolerate irradiation therapy well and modified conditioning is required. As with all cases of

Fig. 23.7 The appearances of (a) aplastic bone marrow with (b) a normal marrow for comparison (trephine biopsy).

pancytopenia, good supportive care with red cell and platelet transfusion and antibiotics is essential until more specific therapy can be instituted. Androgens have been used for many years with some success in FA.

More than 20% of FA patients develop a malignancy, the risk increasing with age, 60% hematological. Androgens may well exacerbate a genetic risk for liver tumors. The risk of malignancy persists after HSCT and may be increased by irradiation.<sup>22</sup> Significant advances in the genetics, pathology and management have been reviewed.<sup>21,25</sup> At least 11 separate genes are identified; some of these are also found in a wide variety of other cancers with mechanisms related to defects in DNA repair and cell cycle check points. Some individuals with FA have given birth to children, genetic in utero testing is possible for some cases, and gene therapy may become a reality in the future.

### Dyskeratosis congenita

Ectodermal dysplasia and X-linked recessive inheritance characterize this disorder. Skin manifestations begin during the first decade and progress. Features include reticulated hyperpigmentation of the face, neck and shoulders; dystrophic nails; mucous membrane leukoplakia; epiphora; hyperhidrotic palms and soles; poikiloderma; thin sparse hair; early loss of teeth; esophageal strictures and dysphagia; subnormal intelligence and hypogonadism. Fifty six percent of cases develop hematological manifestations, usually after the dermatological problems at a mean age of 17 years. There may be single cell deficiencies or pancytopenia and the bone marrow may show hypercellularity, at the onset, with progressive loss of cellularity. Macrocytosis and elevated HbF levels are found. In reported series, the overall death rate is about 33% at 20 years, with 45% death rate in those with pancytopenia. Thirteen percent of cases develop malignancy. Treatment is the same as for other constitutional aplastic anemias and HSCT has been carried out successfully, although the dermatological and malignant sequelae will probably not be affected. Two genes encoding components of the telomerase are mutated in some but not all families. This disorder has been reviewed by Dokal.<sup>26,27</sup>

### Shwachman–Diamond syndrome (SDS)

Children with SDS develop pancreatic insufficiency with variable blood abnormalities (most commonly neutropenia in > 80%) usually detected in infancy, often with skeletal abnormalities and additional immune dysfunction (consider in the differential diagnosis of cystic fibrosis). Anemia or thrombocytopenia can occur, and pancytopenia supervenes in many.<sup>28</sup> Multidisciplinary supportive care with aggressive management of infections, and pancreatic enzyme replacement with a high calorie diet are key therapies. The SBDS gene was identified in 2002 and is located at 7q11 encoding a protein implicated in

RNA metabolism.<sup>29,30</sup> There is a high risk of transformation (often with a myelodysplastic phase) to myeloid leukemia with a poor prognosis, so patients should have regular bone marrow examination. The median survival is 35 years with death from infection, bleeding and leukemia. Some patients have been successfully treated with HSCT. This disorder must be distinguished from **Pearson's syndrome** where affected children have pancreatic insufficiency and vacuolation of marrow precursors in association with congenital sideroblastic anemia (which may show spontaneous recovery).

### Congenital amegakaryocytic thrombocytopenia (CAT)

Severe thrombocytopenia in infancy leads to purpura and bleeding within a few months. Megakaryocytes are absent in the bone marrow and there is a genetic defect in the thrombopoietin receptor.<sup>31</sup> About half the children have additional congenital abnormalities, particularly cardiac or neurological. Bleeding is treated with platelet transfusions, but these children need urgent referral for HSCT. Amegakaryocytic thrombocytopenia with radioulnar synostosis is a defined syndrome with mutations in the *HOXA11* gene.<sup>32</sup>

### PURE RED CELL APLASIA (PRCA)

PRCA in childhood is caused by transient erythroblastopenia or constitutional red cell aplasia.

Transient erythroblastopenia of childhood (TEC) is an important cause of transient red cell aplasia, causing unexplained, sometimes severe, anemia in young children and toddlers.<sup>33</sup> The cause is unknown and may be related to infection, but parvovirus B19, implicated in aplastic crises in hemolytic states, is not the cause. Diamond–Blackfan syndrome or anemia (DBA) – constitutional and congenital red cell aplasia – presents usually at an earlier age, in the first year of life; 95% of cases by 2 years of age with occasional cases occurring up to 6 years. Diagnosis of either of these is made by the presence of anemia with reticulocytopenia and very few marrow erythroid precursors. TEC recovers within days or weeks, DBA does not. Children with TEC may need transfusion to tide them over, but usually do not.

DBA is a heterogeneous disorder with an incidence of 4–7 per million live births. There is a familial incidence of about 45%. About 50% of children have other physical abnormalities, particularly craniofacial or thumb. About 25% of patients have a mutation in the *DBA1* gene, *RPS 19*, which codes for a ribosomal protein. Some children with DBA respond to steroids (> 70%), but many remain steroid dependent (45%) and others require life-long regular transfusion therapy (39%) with iron chelation with subcutaneous desferrioxamine. An international registry has revealed an unexpectedly high incidence of treatment-associated

mortality from infection, and confirmed an increased risk of malignancy.<sup>34</sup> Some patients have been successfully treated with HSCT.

## HEMOLYTIC ANEMIAS

### GENERAL FEATURES

Hemolysis is defined by an increased rate of red cell destruction with a shortening of the normal life span of the cell from the normal 120 days to as little as a few days in severe hemolysis. The marrow can increase erythrocyte production six- or eight-fold so mild degrees of hemolysis are not associated with anemia. Mild hemolysis may be almost undetectable with no clinical clues; severe hemolysis can lead to a rapid and profound fall in hemoglobin, and be life threatening. The hemoglobin level is a balance between increased red cell destruction and ability of the bone marrow to compensate. Hemolysis is suspected when polychromatic cells are seen on the blood film (reticulocytes); further diagnostic and confirmatory tests are then indicated. A simplified diagnostic classification of causes is shown in Figure 23.8.<sup>35</sup> Hemolysis is usually associated with raised blood unconjugated bilirubin. Generally, hemolytic states are divided into those with spherocytes and those without, where the morphology may be normal, or characteristic of the underlying disorder. Hemolysis can be caused by inherited or acquired disorders. Diagnosis of the cause of the hemolysis is made according to the family history; clinical features and red cell morphology that together will indicate what further laboratory tests are required. Marrow examination is generally unnecessary.

The child with hemolysis may be pale with fluctuating jaundice (usually mild) and splenomegaly. Pigment gallstones may complicate the disorder – hemolytic anemia should always be excluded in a child with stones. Aplastic crises may occur, usually precipitated by parvovirus infection or rarely by folate deficiency, both of which are characterized by ‘switching off’ of erythropoiesis. This leads to reticulocytopenia and anemia. Parvovirus infection typically produces severe anemia

sometimes requiring transfusion, and a modest thrombocytopenia and leucopenia. Folate deficiency is uncommon.

## HEREDITARY HEMOLYTIC ANEMIAS

### Membrane defects

#### *Hereditary spherocytosis (HS)*

HS is the commonest hereditary hemolytic anemia in north Europeans, caused by a variety of different genetic defects in the red cell skeletal proteins, ankyrin, spectrin, band 3 or protein 4.2 (Fig. 23.9).<sup>36</sup> It is dominantly inherited in 75% of families. There may be variable expression – investigation of other family members may identify asymptomatic individuals with a milder phenotype. The blood film shows the typical features – multiple small dense cells termed microspherocytes. The marrow produces normally shaped biconcave cells and progressive loss of membrane results in the spherical shape (Fig. 23.10). In an individual with spherocytes and no other affected family members autoimmune hemolysis must be excluded by a negative direct antiglobulin test. The child may or may not have jaundice and anemia, but splenomegaly is usual. (This is not associated with an increased risk of rupture, and these children should lead a normal active life.) Laboratory diagnosis is usually straightforward and the osmotic fragility test is not necessary for confirmation.<sup>37</sup> For difficult cases there are better investigations (membrane protein analysis).

Individuals with HS are usefully classified as mild moderate or severe by their baseline hemoglobin, reticulocyte count and bilirubin level. This classification, which should be made when the individual is well, helps to indicate those in whom splenectomy is beneficial – generally those with severe and moderate disease.<sup>38</sup> Individuals with severe disease should probably receive folate supplements although the evidence for this is limited.<sup>37</sup>

Splenectomy cures all the clinical manifestations of HS by removing the site of destruction of the abnormal red cells, but is associated

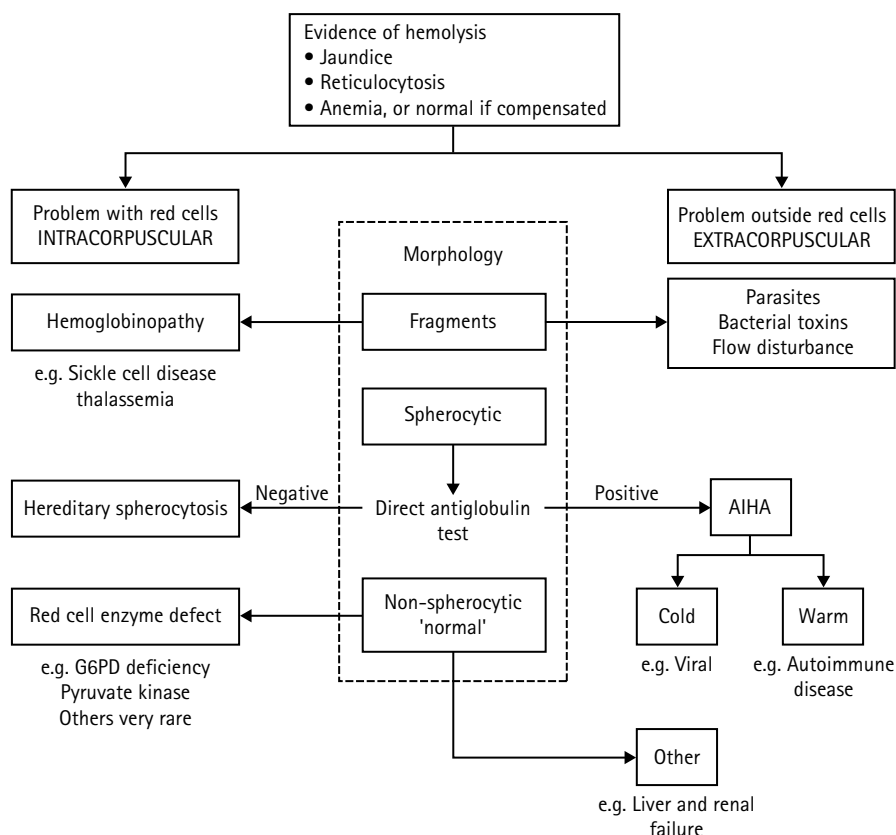

Fig. 23.8 A diagnostic approach to hemolytic anemia. AIHA, autoimmune hemolytic anemia; G6PD, glucose-6-dehydrogenase. (From Lissauer & Clayden 2001<sup>35</sup> with permission.)

Fig. 23.9 Schematic structure of the red cell membrane. Some of the penetrating and integral proteins carry carbohydrate antigens; other antigens are attached directly to the lipid layer. (From Hoffbrand et al 2001<sup>36</sup> with permission.)

with a lifelong risk of overwhelming sepsis particularly with encapsulated organisms (*Pneumococcus*). It should be avoided in all but the most severe cases, during the first 10 years of life, when the risk of postsplenectomy sepsis is highest. There are guidelines for the management of splenectomized individuals, and in families with HS there may be others who have had splenectomy in the past, who need information about their increased risks of infection.<sup>39</sup> Patients should be immunized with pneumococcal, hemophilus and meningococcal vaccines before splenectomy and warned of their increased risk of infection with malaria. Antibiotic prophylaxis should be given on a long term basis but adherence may be poor. Patients should be issued with a medical card indicating they have had a splenectomy and warned about the importance of early reporting of symptoms of infection. Children with HS may develop gallstones in the first decade of life. This is an indication for both cholecystectomy and splenectomy at the same time. Following splenectomy the individual usually has a normal hemoglobin and near-normal red cell lifespan. Annual follow up may serve to remind the individual about the postsplenectomy risks. Immunity to pneumococcus and hemophilus may wane with time, and survey of antibody levels to these agents may provide a more evidence-based foundation for repeat immunizations. There is currently no consensus in this area.<sup>37</sup>

Fig. 23.10 Peripheral blood appearance in spherocytosis with spherocytes and polychromasia. A, polychromatic cell; B, microspherocyte.

### Hereditary elliptocytosis (HE)

This common disorder is usually inherited as an autosomal dominant trait, usually diagnosed as an incidental finding when the blood count is performed for some other reason, but rare homozygous variants have been described in whom chronic severe hemolysis occurs. In the rare severe homozygous cases splenectomy usually provides symptomatic improvement.

Other less common membrane disorders are reviewed elsewhere.<sup>40</sup>

### Red cell enzyme defects

Figure 23.11 shows the pathways of glucose metabolism and energy production in the red cell. Although defects of almost all the separate enzymes have been described, most are very rare and have been reviewed.<sup>41,42</sup> They are generally associated with a nonspherocytic blood picture, with no helpful morphological features of the red cells (apart from one or two exceptions). Deficiencies of almost all of the enzymes involved in the Embden–Meyerhof pathway and hexose monophosphate shunt can be associated with significant hemolysis. Some of these are chronic with exacerbations by intercurrent illnesses such as viral infections, others are clinically silent, most of the time, with sudden hemolytic episodes which bring the patient to medical attention. Most hospitals will be able to diagnose the two commonest deficiencies; analysis of the others requires specialist investigation only available in a few centers.

### Glucose-6-phosphate dehydrogenase (G6PD) deficiency

This is the commonest cause of hemolysis worldwide, and is caused by a number of different mutations in the gene, which is on the X chromosome. These produce different phenotypes; most are associated with episodic hemolysis, the blood picture being normal at other times. A few variants are associated with chronic hemolysis. G6PD maintains glutathione in its reduced state and so is one of the vital mechanisms for protecting red cell membranes from oxidant stress. Oxidative stress induced by drugs, chemicals (Table 23.3) or an intercurrent infection can produce hemolysis. The different mutants of G6PD occur in different racial groups with differences in clinical severity. The racial incidence varies greatly from extreme rarity in northern Europeans through 1–35% in different Mediterranean races, up to 10% in African Negroes. Deficiency leads to various clinical presentations; neonatal jaundice is more common in oriental male babies, especially in the presence of infections or acidosis or if oxidant drugs are given to the mother in late pregnancy or to the neonate. Infections and diabetic ketoacidosis can precipitate hemolysis at all ages. Favism (eating broad beans) produces severe hemolysis, and is commonest in Mediterraneans and in the Middle East, although it does occur in Orientals and Europeans. Rare cases of chronic hemolysis in northern European races have also been described.

Fig. 23.11 The Embden-Meyerhof pathway and hexose monophosphate shunt. Enzymes: HK, hexokinase; GPI, glucose phosphate isomerase; PFK, phosphofruktokinase; TPI, triose phosphate isomerase; G3PD, glucose 3-phosphate dehydrogenase; PGK, phosphoglycerate kinase; DPGM, 2,3-diphosphoglycerate mutase; PK, pyruvate kinase; LDH, lactate dehydrogenase. Intermediates: G6P, glucose 6-P; F6P, fructose 6-P; F1,6DP = fructose 1,6 di-P; 3PG, 3-P glycerate; 1,3DPG, 1,3-diphosphoglycerate; G3P, glyceraldehyde 3-P; PEP, phosphoenolpyruvate; DHAP, dihydroxyacetone P.

Hemolytic crises vary in severity and degree. Favism is associated with the most explosive course and intravascular hemolysis. A typical sign is the dramatic darkening of the urine with hemoglobin and urobilinogen to produce so-called 'Coca-Cola' urine. This may lead to renal dysfunction (sometimes severe). Diagnosis depends on an enzyme assay but reticulocytes nearly always have higher levels of all red cell enzymes so the test is best done when the child (usually male) has recovered from the acute episode.

Neonatal jaundice may require exchange transfusion. At other times all that is necessary is to be aware of the problem in appropriate ethnic groups and to avoid the precipitating factors. Patients should be informed of the hazards and supplied with written information about which foods and drugs to avoid.

Table 23.3 Drugs and chemicals associated with hemolysis in G6pd deficient subjects

Group	Drugs
Antimalarials	Primaquine, pamaquine, quinacrine, quinine
Sulfonamides	Sulfapyridine, sulfisoxazole, salicylazosulfapyridine
Nitrofurans	Nitrofurantoin, furaltadone
Analgesics and related compounds	Acetylsalicylic acid, para-aminosalicylic acid
Miscellaneous	Synthetic water-soluble vitamin K analogs, chloramphenicol, phenylhydrazine, naphthalene, aniline dyes, nalidixic acid

### Pyruvate kinase (PK) deficiency

PK deficiency is the commonest cause of nonspherocytic hemolysis in Northern Europe. It is autosomal recessively inherited and produces chronic hemolysis with varying grades of severity in different individuals. Neonatal jaundice occurs and infection can also precipitate more severe hemolysis. Parvovirus infection can, as in other hemolytic states, produce a dramatic aplastic crisis. Splenomegaly is usually present. Drugs do not precipitate crises.

The blood film in PK deficiency does not have any specific diagnostic features, although irregularly contracted cells are seen, especially after splenectomy. Diagnosis depends on measurement of the enzyme level, which must be carefully corrected for high reticulocyte count. Unfortunately some poorly functioning variants of PK can produce normal assay results; this can be sorted out by specialist measurement of the intermediate products of the Embden-Meyerhof pathway in order to demonstrate a block at the appropriate point.

Because of its position in the energy pathway, PK deficiency causes a rise in 2,3-DPG levels and thus a shift to the right in the oxygen dissociation curve and a consequent improvement in oxygen availability. For this reason, patients with PK deficiency can tolerate very low hemoglobin levels (and conversely hexokinase-deficient patients may require blood transfusion at relatively high hemoglobin levels). Thus, it is very important not to transfuse PK-deficient patients unless they are clinically unwell, failing to thrive or are otherwise genuinely symptomatic. Many patients are transfused unnecessarily on the basis of a perfectly acceptable hemoglobin level of about 5–6 g/dl. Severely affected patients may require intermittent transfusions when decompensated by infections, and occasionally patients require regular transfusions with iron chelation. In these children, splenectomy usually produces a beneficial reduction or abolition of the need for blood transfusion and should be considered in severe cases.

### ACQUIRED HEMOLYTIC ANEMIAS

Acquired hemolysis in childhood is relatively uncommon but can be severe; it is important to make the correct diagnosis.

### Autoimmune hemolytic anemias (AIHA)

The development of hemolysis caused by autoantibodies to red cell antigens is uncommon and can occur as a complication of some viral infections, as part of a larger dysregulation of immune function, either in autoimmune diseases such as systemic lupus erythematosus, or in some forms of immune deficiency. Autoimmune hemolysis is suspected when the child has anemia with a reticulocytosis sometimes with jaundice, and splenomegaly. The blood film usually shows spherocytes, and the condition is differentiated from HS by a positive direct antiglobulin test due to antibodies (IgG) or complement (in IgM-associated AIHA) attached to the red cells. After viral infections the antibody is usually IgM, and reactive in tests at room temperature ('cold') rather than at 37°C which is typical of IgG ('warm') antibodies. Infectious mononucleosis, CMV and

mycoplasma are infections most commonly implicated in 'cold' autoimmune hemolysis (caused by antibodies to the i/I red cell antigens). These antibodies cause intravascular red cell destruction and may present with brown urine (hemoglobinuria) which is not usually seen in IgG-induced hemolysis where the red cells are destroyed predominantly in the spleen. Another type causing sudden onset of hemoglobinuria is paroxysmal cold hemoglobinuria caused by an unusual type of red cell antibody, a complement-fixing IgG which attaches to the red cells in the cold and lyses the cells in the warm – the Donath Landsteiner antibody. Treatment is rarely required, the hemolysis being short lived and resolving with the infection. It is prudent to keep the child warm; occasionally transfusion and steroids may be required. Hemolysis occurring as part of a wider autoimmune process can be chronic and difficult to manage; steroid therapy is often beneficial, transfusion is often difficult and best avoided because the antibodies react with all donor blood. Warm AIHA (rarely in childhood) can also be caused by drugs.

Immune hemolysis caused by maternal antibodies is discussed in detail elsewhere (see Ch. 12). AIHA may occur with immune thrombocytopenic purpura, when it is known as Evans syndrome. This is a potentially serious disorder with a chronic course and may require HSCT.<sup>43</sup>

### Microangiopathic hemolytic anemia (MAHA)

Red cell fragmentation on the blood film (schistocytes – Fig. 23.12) is the pathognomonic feature, associated with reticulocytosis. This may be associated with thrombocytopenia, depending upon the underlying cause (Table 23.4). The red cells are damaged by fibrin strands deposited in small blood vessels and consumption of platelets within the resultant microthrombi, or by trauma passing through a damaged heart valve or other cardiac abnormality. A variety of causes are recognized, particularly hemolytic uremic syndrome (HUS) described more fully elsewhere (see Ch. 18). MAHA may be the first signal of a problem with a replaced heart valve. Disseminated intravascular coagulation from any cause may be associated with MAHA.

### Other causes of hemolysis

#### Hypersplenism

Splenic enlargement, from any cause, such as portal hypertension, leishmaniasis and storage disorders, may produce a shortening of red cell survival due to excessive sequestration in the expanded reticuloendothelial system. The anemia is mild and usually associated with mild leucopenia and thrombocytopenia.

#### Infections

Malaria is an infection in which micro-organisms are present within red cells at the time of hemolysis. Mild hemolysis may occur with many

Fig. 23.12 Red cell appearances in red cell fragmentation syndromes.

Table 23.4 Causes of red cell fragmentation syndromes

Microangiopathic
Hemolytic uremic syndrome
Thrombotic thrombocytopenic purpura
Meningococcal sepsis
Disseminated intravascular coagulation
Cardiac valves or arterial grafts
March hemoglobinuria
Infections – malaria, clostridia
Chemical and physical – burns
Liver and renal disease

other infectious processes. Septicemia, particularly due to clostridial organisms, may produce an acute hemolytic process usually as part of a consumptive coagulopathy. *Bartonella* infection is another documented cause of hemolysis (see Ch. 28).

## DISORDERS OF HEMOGLOBIN SYNTHESIS

### HEMOGLOBINOPATHIES AND THALASSEMIA

#### Etiology

Hemoglobin is the essential pigment that makes blood red, and carries oxygen to the tissues. There are several different normal hemoglobins specific for different ages; hemoglobin is made up of two pairs of globin chains, each containing a heme group which can bind oxygen (Fig. 23.13<sup>44</sup>). Some hemoglobins are only evident during early stages of gestation; later in fetal life the predominant hemoglobin is HbF (alpha-2gamma2). After birth, when the oxygen affinity does not need to be so high HbA (alpha2beta2) gradually replaces this, the switch starting at about 32 weeks gestation. Normal blood also contains a small amount of HbA2 (alpha2delta2) (Table 23.5). Various hemoglobin disorders result in clinically significant effects. There may be a qualitative or quantitative defect. The most common are discussed here, but there are many others.

Fig. 23.13 The oxygenated and deoxygenated hemoglobin molecule. Alpha, beta globin chains of normal adult hemoglobin (hemoglobin A); 2,3-DPG, 2,3 diphosphoglycerate. (From Hoffbrand & Pettit 1993<sup>44</sup> with permission.)

Table 23.5 The types and quantities of different hemoglobins in infancy and adulthood

Type of Hb	HbA	HbF	HbA <sub>2</sub>
Notation	$\alpha_2\beta_2$	$\alpha_2\gamma_2$	$\alpha_2\delta_2$
Normal % at birth	20	80	1
Normal % in older children	98	1	2

## The sickling disorders

The most important structural hemoglobin disorder is due to a single amino acid change affecting the solubility of hemoglobin. Sick cell hemoglobin results from a point mutation at position 6 of the beta chain (adenine to thymine) resulting in an amino acid change of glutamic acid to valine. Sick cell hemoglobin forms crystals at low oxygen tension; these polymerise into long strands. The sickle gene has occurred from at least four separate mutation events, and is most common across the tropical zones (Fig. 23.14<sup>44</sup>). The high frequency of the gene in these areas may be related to some protection against malaria conferred by heterozygosity for the sickle cell gene. The clinical outcome depends upon whether the sickle gene is inherited from one or both parents, (sickle cell trait AS, or sickle cell disease, SS) and whether it is inherited with another hemoglobin disorder which modifies the effects (hemoglobin C, alpha thalassemia, beta thalassemia). It is important to make the correct diagnosis. Most screening tests detect the presence of sickle hemoglobin without quantification, and no information about other possible abnormalities. Full diagnosis requires analysis of the full blood count with red cell indices, hemoglobin electrophoresis with quantification of S and other hemoglobins. The affected individual then requires adequate information and counselling about the genetic implications, even if clinically mild or insignificant. A national screening program for sickling disorders and thalassemia has been rolled out across the UK between 2003 and 2005 ([www-phm.umdc.ac.uk/haemscreening/](http://www-phm.umdc.ac.uk/haemscreening/)). In the USA, 49 states have mandatory newborn screening and the resultant education and clinical management has resulted in decreased morbidity and mortality.<sup>45</sup>

### Sickle cell trait

Sickle cell trait (AS) is not a disease; affected individuals have less than 50% HbS, normal hemoglobin indices and no adverse clinical sequelae, unless exposed to severe hypoxic conditions. They should be treated as normal and reassured, but given appropriate genetic advice. No special precautions are required for anesthesia or other medical interventions in these individuals.

### Sickle cell disease

Sickle cell disease denotes all genotypes containing at least one sickle gene in which HbS makes up at least 50% hemoglobin. Homozygous SS is one of these and is a very variable disorder, but affected individuals are prone to a number of serious complications which need careful management. The red cells have reduced survival, and this chronic hemolytic anemia (Hb 6–9 g/dl) leads to marrow expansion and typical bossing of the skull. Growth is often less than anticipated. Some individuals have a relatively trouble-free life; others have many vaso-occlusive crises. The relatively insoluble HbS precipitates into crystals distorting the red cell shape (sickle cells)(Fig. 23.15<sup>35</sup>) leading to microvascular sludging and infarction of surrounding tissues producing ischemic pain. In the infant the first sign may be dactylitis. In older children the long bones are more commonly affected. These attacks may be precipitated by a variety of external events of which the most important is probably intercurrent infection. Sickling episodes can be life threatening, particularly if the lungs are involved, and are usually very painful. Early and adequate pain relief is an important component of the management which also includes a diligent search for infection, and good hydration; sickle cell disease usually produces a urinary concentrating defect. Sickling causes necrosis in bones – while the changes may be reversible, avascular necrosis of the femoral or humeral heads leads to early and severe disability. In early life the child typically has an enlarged spleen but with defective function; this gradually infarcts (autosplenectomy) increasing the risk of overwhelming pneumococcal sepsis.<sup>46</sup> Prophylactic penicillin is protective and should be started early in life by 3 months of age. Pneumococcal vaccine should be given (in the UK with the heptavalent conjugate vaccine three doses in infants 2–6 months of age and a fourth dose in the second year of life<sup>39</sup>). Such children need open access to an experienced team preferably in an established hemoglobinopathy center. Hospitals in areas with few such patients should ensure that appropriate management protocols are available. Other serious complications of sickle cell disease are aplastic crises, most commonly associated with parvovirus B19 (as with all types of hemolysis), and rare sequestration crises in which there is sudden and dramatic pooling of blood in the

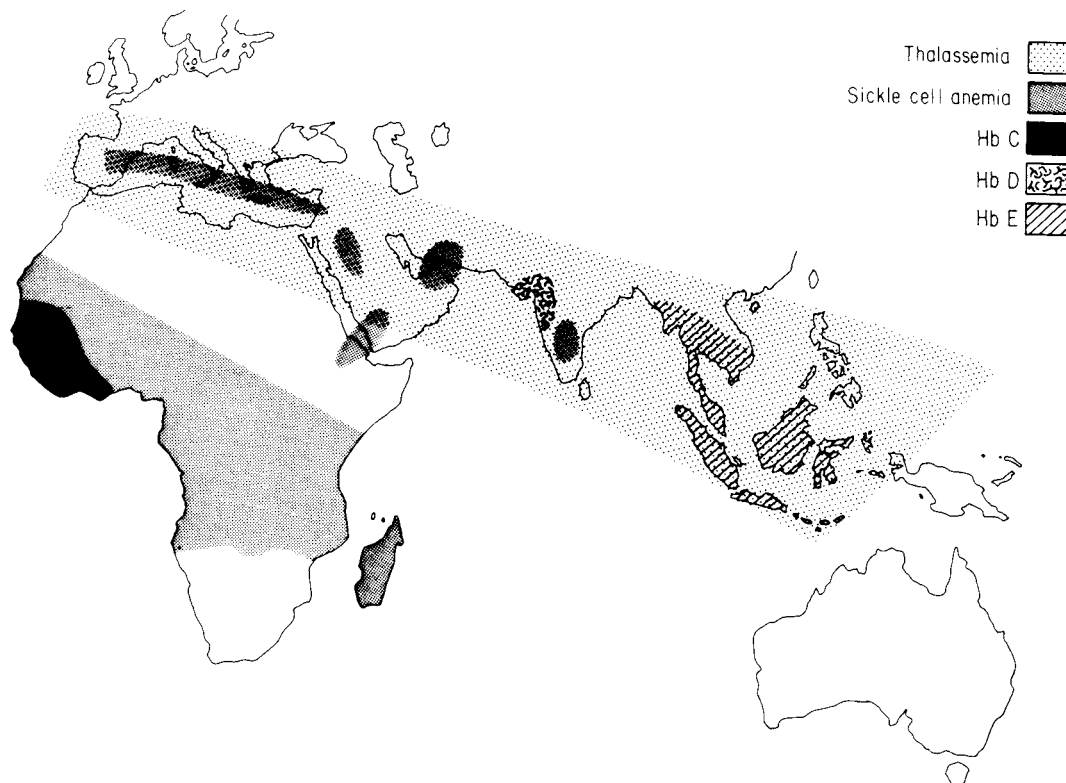

Fig. 23.14 The geographical distribution of the thalassaemias and more common inherited structural hemoglobin abnormalities. (From Hoffbrand & Pettit 1993<sup>44</sup> with permission.)

**Fig. 23.15** (a) Peripheral blood appearance in homozygous sickle cell disease with target cells, polychromasia and distorted red cells (A, sickle cell; B target cell). (b) Swelling of the fingers from dactylitis, a common mode of presentation of sickle cell disease in late infancy. (From Lissauer & Clayden 2001<sup>35</sup> with permission.)

spleen or liver; the child presents with very rapidly falling hemoglobin. Splenic sequestration is an indication for splenectomy. Other important complications occur – chronic hemolysis predisposes to the development of gallstones; vascular occlusion can result in stroke, priapism and leg ulcers and retinal vaso-occlusion leads to proliferative retinopathy. Stroke has the highest incidence between 2 and 5 years and a cumulative incidence of 11% by 20 years of age. High risk patients can be identified by transcranial Doppler ultrasound scans (which detect high flow through stenotic segments of the cerebral arteries). This screening should be carried out annually from age 2–3 years because a first stroke can be prevented by blood transfusions (90% reduction), and following a stroke, chronic transfusion therapy reduces the risk of recurrence.<sup>47,48</sup> Stroke is more common in HbSS and HbS/beta<sup>0</sup> thalassemia compared to the other sickle disorders.

Management in sickle cell disease is supportive; blood transfusion is required only under some circumstances but not simply to raise the Hb level. Recent trials have demonstrated that increasing the proportion of HbF with hydroxyurea therapy reduces sickling episodes,<sup>49</sup> particularly acute chest syndrome.<sup>50</sup> Chronic lung complications including pulmonary hypertension are increasingly recognized as an important cause of morbidity and mortality both in the sickling disorders and other hereditary hemolytic anemias.<sup>45,51</sup> HSCT may be curative.<sup>45</sup> Transplantation from an HLA-matched sibling achieves 80–85% disease free survival, and US families with affected children are encouraged to consider umbilical cord blood collection from subsequent unaffected siblings.

### Sickle cell variants

HbS can be inherited with HbC, each parent being heterozygous. The child with SC disease has a higher Hb than SS individuals, usually has fewer painful crises, but is nevertheless more prone to avascular necrosis, and to neovascularization of the eyes; these children should have regular ophthalmic review. When HbS is inherited with beta thalassemia the disorder may be less severe, but this depends upon the type of beta thalassemia (Table 23.6). For further information the reader is referred to Serjeant.<sup>52</sup>

### Thalassemia syndromes

Thalassemias are a large and heterogeneous group of red cell disorders resulting from impaired or absent synthesis of globin chains. The different globin chains are coded for on either chromosome 16 (alpha-like) or 11 (beta, delta and gamma chains) shown in Figure 23.16a.<sup>44</sup> If alpha chains are affected alpha thalassemia results, if beta chains, beta thalassemia. The clinical effects depend upon both the type and extent of gene mutations and upon whether inherited from one or both parents (thalassemia trait or a more serious disorder). Large gene deletions

**Table 23.6** The sickle syndromes – variable clinical severity

Most severe	Homozygous SS, HbS/β <sup>0</sup> thalassemia (β globin mutation with no β globin chain produced)
Intermediate	Hb SC disease
Least severe	HbS/β thalassemia (some β chains produced)
Severity also reduced by:	High HbF level Coincidental inheritance of α thalassemia genes

on chromosome 11 may affect more than one globin gene producing more complex gamma delta thalassemia. Some disorders which affect only HbF (gamma chain mutations) may produce only transient disorders (e.g. hemolytic anemia due to unstable gamma chains) in the neonatal period that disappear as the HbF is replaced by HbA. The racial and geographic origin of the patient will help point towards the most likely hemoglobin abnormalities and will help guide investigations. The pathology of the thalassemias is related to globin chain imbalance; a reduction of one chain leads to an excess of the other; this disturbs red cell production leading to anemia and other consequences of ineffective erythropoiesis.

### Alpha thalassemias

Because alpha globin chains are part of fetal hemoglobin, disorders affecting alpha chains may be evident at or before birth, depending upon the severity. There are four alpha globin genes; the clinical phenotype depends upon the number of genes affected (Fig. 23.16b).<sup>44</sup> The most severe form, where all four alpha genes are deleted, is incompatible with life and leads to hydrops fetalis (Fig. 23.16c).<sup>44</sup> The milder forms may lead to a mild hemolytic anemia due to globin chain imbalance. The red cells contain tetramers of beta globin, HbH, which tends to precipitate out and may be visualized on the blood film with special stains. The mildest forms of alpha thalassemia manifest red cells with reduced MCV and MCH. The alpha thalassemia genes are particularly common in Asia, but mild genotypes are also common in Africa, where they may modify the clinical severity of sickle cell disease.

### Beta thalassemias

The beta thalassemias occur mainly in countries bordering the Mediterranean but are also important in Asia. In some of the Mediterranean countries the heterozygote rate is as high as 20%; antenatal

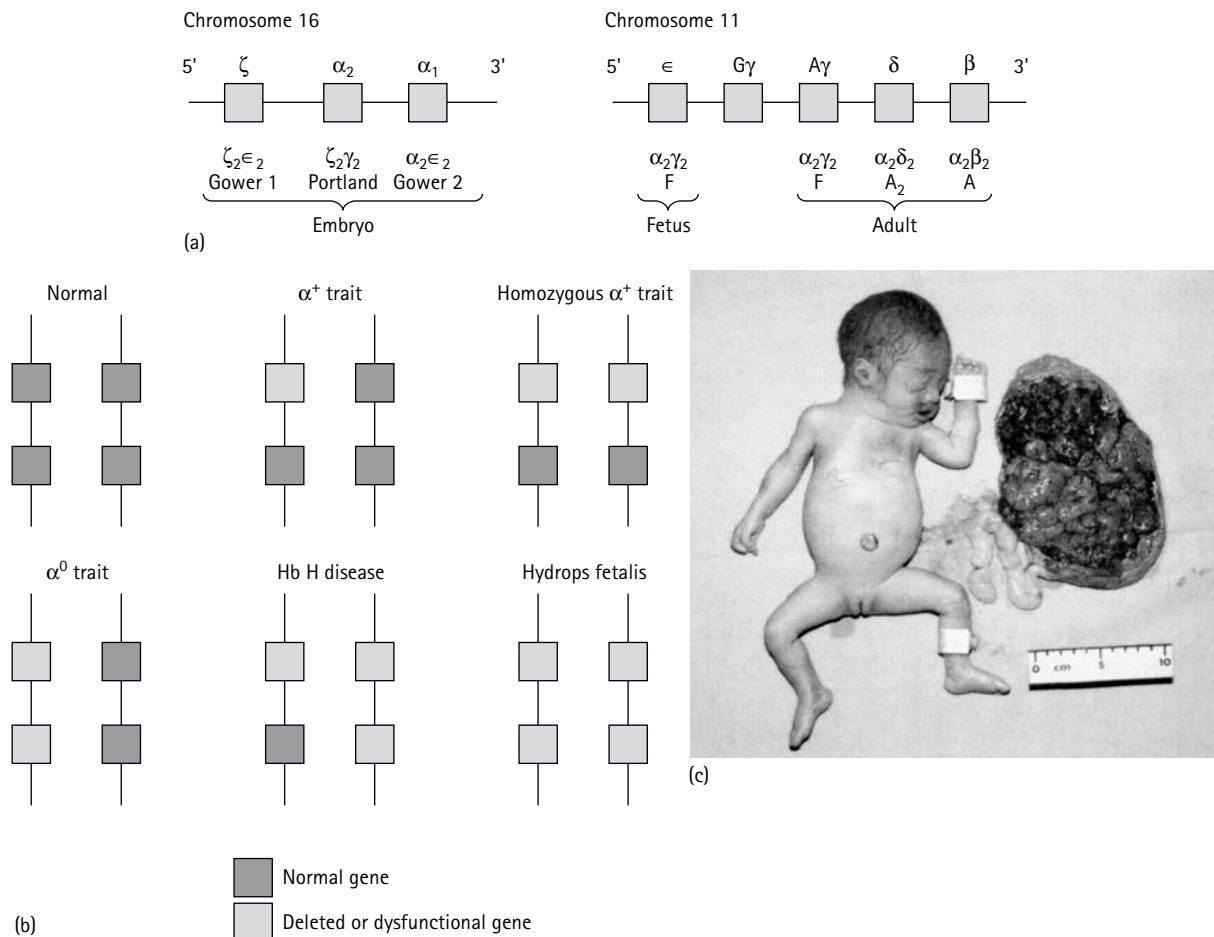

Fig. 23.16 (a) Globin gene clusters on chromosomes 11 and 16. (b) The genetics of alpha thalassemia. (c) Alpha thalassemia hydrops fetalis, the result of deletions of all four alpha globin genes. (From Hoffbrand & Pettit 1993<sup>44</sup> with permission.)

screening programmes have been particularly important in reducing the birth rate of severely affected homozygous infants. Individual mutations are common in different populations which enables screening by mutation detection. While the heterozygote state, beta thalassemia trait, is usually without symptoms or serious sequelae, the homozygous state results in beta thalassemia major – the child is unable to make HbA and usually presents with progressive anemia towards the end of the first year of life.

The pathogenesis of the clinical manifestations of beta thalassemia major is shown in Figure 23.17. Untreated, a child develops severe anemia with growth retardation, hepatosplenomegaly (extramedullary hemopoiesis), failure to thrive and skeletal abnormalities due to marrow hyperplasia. The bones are thin and prone to fracture. In addition to typical maxillary bone expansion which gives rise to the thalassaemic facies, the skull X-ray has typical 'hair-on-end' appearance due to medullary expansion (Fig. 23.18a) and there is a typical peripheral blood picture (Fig. 23.18b). Children with beta thalassemia major require regular transfusions of red cells to maintain adequate hemoglobin levels, to promote normal growth and development, and suppress the erythroid hyperplasia and skeletal manifestations. Before embarking on regular transfusion the child should receive hepatitis B vaccine, the red cells should be more fully phenotyped to enable transfusion with blood additionally matched for some of the other red cell antigens. This is particularly important where the child is of a different ethnic group in order to reduce the risk of sensitization against the other red cell antigens. Repeated transfusions lead to iron overload, which is inevitable and must be treated with an iron chelator to remove the excess. The standard chelator is desferrioxamine (DFO) usually given by subcutaneous

infusion over several hours daily for maximal effect. Iron loading results in tissue damage to endocrine glands (parathyroids, pancreas, failure to progress through puberty), skin discoloration, but most seriously can lead to heart failure and dysrhythmias. Death results from cardiac complications in inadequately chelated patients, often before the end of the second decade. Adherence is a major issue for many children, especially in teenage years. DFO itself has side-effects and the dose regimen must be carefully calculated. Children should be monitored regularly for ear and eye toxicity. There is good evidence that iron overload, as measured by high ferritin levels and liver biopsy, is clearly related to mortality. Oral iron chelation with deferiprone has been effective, particularly for cardiac iron loading, but carries concerns about toxicity.<sup>53–56</sup> A new oral agent, deferasirox, is as effective as DFO and represents a significant advance.<sup>57</sup> Further research is needed; all these agents have a place and the choice must be individualized.<sup>58</sup> The transfusion requirements (transfusion of packed red cells exceeding 180–200 ml/kg/year) will often indicate when removal of the enlarged spleen (which acts as a reservoir) may be of benefit. Patients often benefit from contact with other affected individuals and patient support groups.

Some individuals who are homozygous for a thalassemia gene show a clinically less severe course (thalassaemia intermedia). These individuals may not be transfusion dependent but can show other complications of 'homozygous' beta thalassemia, such as skeletal deformity, to a varying degree. Management may be difficult and such children should be referred to specialists.

HSCT is potentially curative in thalassemia major.<sup>59</sup> Risk factors for a poor outcome were hepatomegaly, liver fibrosis and quality of iron

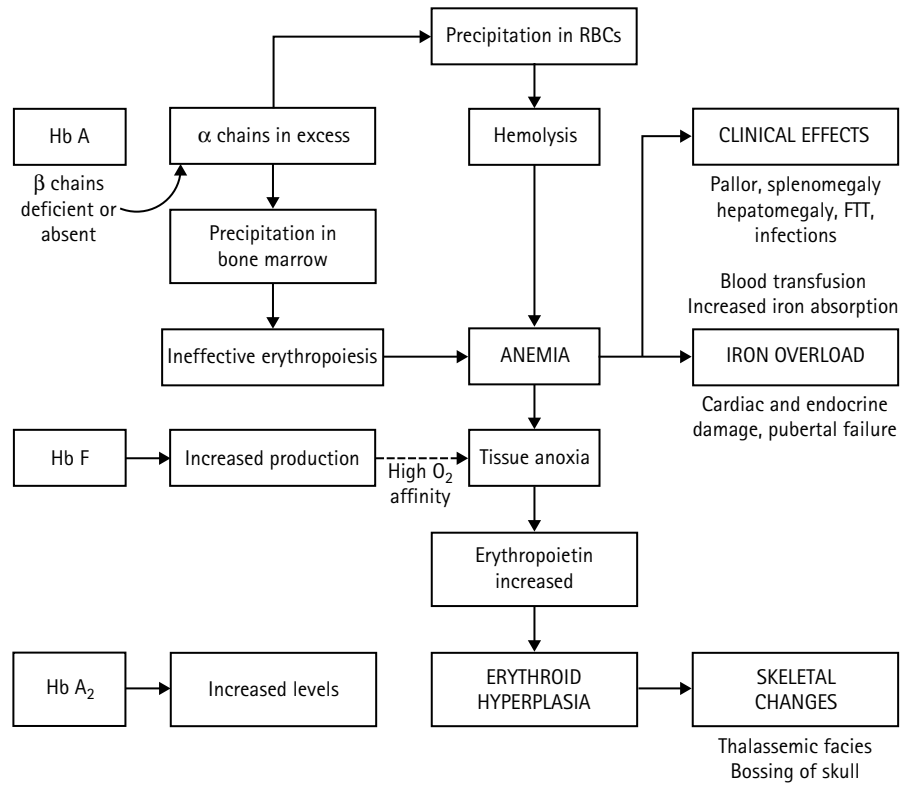

Fig. 23.17 The pathogenesis of beta thalassemia major. FTT, failure to thrive; RBCs, red blood cells.

Fig. 23.18 Beta thalassemia major. (a) Skull X-ray showing 'hair on end' appearance caused by marrow hyperplasia and expansion. (b) Peripheral blood (postsplenectomy) showing target cells, nucleated red cells, red cell fragments and hypochromia. A, nucleated red cell; B, target cell.

chelation treatment. In 'Class I' patients who lacked any risk factors the overall survival was 96% at 10–11 years with an event-free survival of 92%, whereas 'Class III' patients with all three risk factors had an overall survival of 76% with an event-free survival of 53% at 10–11 years because of increased transplant-related morbidity and mortality. HSCT should be undertaken in young children before there has been significant transfusion iron overload.<sup>60–62</sup> Cord blood from a sibling can also be used.<sup>63,64</sup> Unrelated donor transplant may also be successful.<sup>65</sup> Another approach is preimplantation genetic diagnosis enabling selection of an unaffected fetus, or a fetus which is HLA compatible with an affected sibling with a view to HSCT,<sup>66</sup> but this raises important ethical considerations.

## Rare hemoglobin disorders

### Unstable hemoglobins

A variety of mutations are described which lead to destabilization of the structure of the globin complex. Some produce congenital Heinz body hemolytic anemia. (Heinz bodies are red cell inclusions visualized by staining with methyl violet). Affected individuals may have significant clinical manifestations or none; variants affecting the beta chains tend to be worse than the alpha chain variants. Children may present with chronic hemolytic anemia or with a more sudden event such as aplastic crisis due to parvovirus or an exacerbation of hemolysis triggered by an infection. Others can produce a picture very similar to thalassemia. Some hemoglobin variants exhibit increased oxygen affinity (leading to polycythemia),

decreased oxygen affinity, or oxidization of heme iron to the ferric state (resulting in methemoglobinemia). These are reviewed by Kulozik.<sup>67</sup>

## SECONDARY ANEMIAS

The normal bone marrow produces  $10^{11}$  red cells daily – disease processes readily affect this activity. Children often develop anemia as a consequence of some other illness. Even a transient infection may cause a significant fall in hemoglobin, but this will recover rapidly when the infection clears. More chronic illness is often complicated by ‘anemia of inflammation’ due to erythropoietin resistance and iron-restricted erythropoiesis.<sup>4</sup> The inflammatory cytokine interleukin 6 up-regulates production of the iron-regulatory hormone, hepcidin. Hecpudin inhibits iron release from macrophages and probably from hepatocytes, resulting in hypoferrremia but normal or elevated ferritin. Hecpudin binds to the sole iron export channel from cells, ferroportin, leading to its loss from cell membranes. The anemia may be mild and normochromic or severe and microcytic. Chronic inflammatory disorders are commonly associated with this. Patients may become genuinely iron deficient because of poor diet or blood loss from the gut (possibly due to non-steroidal anti-inflammatory drugs). Rheumatoid arthritis is particularly complex because the patients may also develop marrow hypoplasia due to drugs, e.g. gold. Patients with connective tissue disorders such as SLE can develop autoimmune hemolysis. Other diseases associated with anemia are acute and chronic renal failure, and some endocrine disorders, particularly hypothyroidism.

## DRUGS

Drugs must always be considered as a cause of blood dyscrasias; there are several different potential mechanisms such as blood loss (aspirin and other nonsteroidal anti-inflammatory agents), development of immune phenomena or marrow suppression.

## NEUTROPENIA

The time taken to develop from a stem cell to a mature neutrophil is only 24 hours. However, the mature neutrophil may then spend up to 10 days in marrow storage before release when it then circulates in the peripheral blood for only 6–10 hours. A proportion is ‘marginated’ along the endothelium and is not counted in the full blood count, so reliance on the peripheral blood neutrophil count alone to determine risk of bacterial sepsis can be misleading. The neutrophil reserve (marrow storage pool) is about 13 times the number in the blood. The most important functions of the neutrophils are to phagocytose and kill bacteria. Disorders of neutrophil function are considered in Chapter 27.

The neutrophil count tends to be lower in children, particularly infants, than in adults, and there are racial variations – black races have absolute neutrophil counts that are  $0.2$  to  $0.6 \times 10^9/L$  lower than Caucasians. If blood is left to stand for several hours before being analysed, the neutrophil count will be falsely low. Neutropenia is defined as a reduction of the absolute neutrophil count below the normal for age, and is divided according to severity, giving some indication of the likely clinical consequences, although this is heavily dependent upon the cause.

- Mild:  $1.0$  to  $1.5 \times 10^9/L$  (adjust for the first 6 months of life) – usually no clinical problems.
- Moderate:  $0.5$  to  $1.0 \times 10^9/L$  – clinical problems more common.
- Severe: less than  $0.5 \times 10^9/L$  – risk of life threatening sepsis, especially if neutropenia is prolonged beyond a few days.

Fortunately severe neutropenia in childhood is rare. Intercurrent viral infection is the commonest reason for mild neutropenia (neutropenia occurring during the first 24–48 h and persisting for up to 6 days). If this is the likely cause, then there is no need to repeat the blood count when the child recovers just to see if the count is back to normal. It is more important to be guided by the clinical picture.

## NEUTROPENIAS SECONDARY TO MARROW FAILURE OR INFILTRATION

In children with marrow failure or infiltration the risk of serious sepsis is logarithmically increased at neutrophil counts of less than  $0.1 \times 10^9/L$ . In this group a responsible organism is identified in infections in all cases with persistent neutropenia for more than 12 weeks.<sup>68</sup> Endogenous organisms (i.e. part of the resident flora) result in the high risk of serious septicemia. Pathogenic organisms (such as *Pseudomonas*, *Klebsiella* and *Proteus* species) often replace normal less pathogenic flora in many patients with serious underlying disorders such as malignancy. *Staphylococcus aureus* and Gram negative bacilli translocate from the gastrointestinal tract when mucosal defences are breached, for example by the disease or chemotherapy. Neutrophils are normally responsible for some of the clinical features of acute inflammation such as redness, pus and swelling. Such features are therefore often minimal or absent in severe neutropenia. Because of this, and the speed with which sepsis can be fatal, any child with severe neutropenia who develops a significant fever (e.g. one reading over  $39^\circ C$  or two over  $38^\circ C$  half an hour apart) should be admitted to hospital, have blood and other relevant cultures sent, and be started on broad spectrum parenteral antibiotics while the culture results are awaited. Patients with chronic severe neutropenia should either have open access to a familiar ward, or carry a letter detailing the importance of blood culture as an initial investigation followed by admission for parenteral antibiotics if they attend the general practitioner or hospital emergency room with a fever. As most infections are caused by the child’s own resident flora, the addition of protective isolation is not of any proven benefit. It is more important to screen regularly (surveillance throat and rectal swabs) for colonization by the more pathogenic Gram negative organisms (*Klebsiella* and *Pseudomonas* species which confer a higher risk of serious septicemia) and to use selective non-absorbable antibiotics for gut decontamination. Good hygiene (including mouth and dental care) and prophylaxis against *Candida* are also beneficial. Salads may be significantly contaminated with *Pseudomonas* and other Gram negative organisms and are best avoided.

In other children with neutropenia where there is normal marrow reserve (see below) there is a reduced risk of serious sepsis despite the low count.

## AUTOIMMUNE NEUTROPENIA

Autoimmune neutropenia is probably the commonest cause of persistent neutropenia in childhood occurring in perhaps 1 in 100 000 children per annum. Fortunately it is rarely associated with severe sepsis and usually resolves spontaneously after a variable period of time. Typically the child of either sex is aged between 5 and 24 months at presentation. A useful review<sup>69</sup> described 240 children aged 5–15 months at diagnosis. Ninety percent had benign infections and 95% recovered spontaneously within 7–24 months. Bone marrow examination may show maturation arrest with lack of the more mature precursors, or some myeloid hyperplasia, or can be normal. Antineutrophil antibodies can be demonstrated in the serum, which is helpful in confirming the diagnosis. Until the clinical pattern is clear, fever should be managed carefully with appropriate cultures and parenteral antibiotics while excluding a significant infection. When the diagnosis is clear, these children can be managed conservatively and the parents should be encouraged to continue with normal living. Fevers and other infections can be managed in the same way as any other non-neutropenic child. In the rare case with severe infection (usually the younger child) neutrophils can be temporarily increased by steroids or intravenous immunoglobulin but G-CSF (granulocyte-colony stimulating factor) is the treatment of choice for severe infection or to cover surgery.

## SEVERE CONGENITAL NEUTROPENIAS

These disorders are rare, but very important to recognise because of the potential seriousness and need for aggressive management. The

important difference from autoimmune neutropenia is that these children are likely to present with septicemia or other severe bacterial infections that can lead to early death if not appropriately managed. As neutropenia can occur as a secondary feature in the course of severe sepsis (particularly in neonates and in the presence of endotoxemia), the nature of such a disorder is often not clear at initial presentation. Any child with severe sepsis in whom neutropenia persists should be investigated with bone marrow examination.

Kostmann described 24 cases of severe neutropenia (neutrophils  $<0.2 \times 10^9/L$ ) in a consanguineous Swedish family in 1956. About 200 similar cases have been described in the literature, but 'Kostmann syndrome' is now recognized to be a heterogeneous group of congenital neutropenias<sup>70</sup> – some children have been shown to have mutations in the G-CSF receptor gene. Presentation is usually before 6 months of age with severe pyogenic infections – half present in the first month of life – and the outlook was poor before the advent of HSCT and the use of G-CSF. The bone marrow shows maturation arrest. Such children should be referred to a pediatric hematologist and most do well on daily injections of G-CSF. They should also receive mouth care and antibiotic prophylaxis. Data from an international registry has confirmed an increased risk of developing acute leukemia, but it is not clear whether this is related to the underlying disorder or to the therapy with G-CSF.<sup>71</sup>

Reticular dysgenesis is another form of severe neutropenia described in Chapter 25.

*Cyclical neutropenia* is a very rare disorder where there is a nadir of the neutrophil count usually every 21 days to below  $0.2 \times 10^9/L$ . During the neutropenia the child may have mouth ulcers, gingivitis, malaise and fever, and other evidence of bacterial sepsis. There is often some asymptomatic cycling of other blood parameters. Diagnosis requires attention to detail, and twice weekly blood counts for 6 weeks. The bone marrow can show either hypoplasia or maturation arrest of the myeloid series. The condition may improve with age. G-CSF therapy, timed to prevent the neutropenic phase, can give good relief. These patients have no clear evidence of an increased risk of hematological malignancy. It is important to establish whether the neutropenia is associated with any other congenital abnormalities. Neutropenia is well-recognized in about two thirds of cases of Shwachman–Diamond syndrome (see above). Neutropenia may also be seen in other congenital immune deficiency states, such as antibody deficiency.

## ACQUIRED NEUTROPENIA

This is most commonly due to intercurrent viral infection or secondary to drug ingestion. The neutrophil count may fall to less than  $0.2 \times 10^9/L$  in an idiosyncratic and unpredictable way; any drug associated with the onset of neutropenia must be considered suspect. In the face of unexplained neutropenia it is advisable to stop the drug. Many different mechanisms have been implicated and there is no convenient diagnostic test.

## EOSINOPHILIA

Eosinophilia is arbitrarily defined at a level of greater than  $0.5 \times 10^9/L$ . The commonest cause is the presence of allergic disease, especially atopy – asthma or eczema. Parasitic diseases such as hookworm, ascariasis, tapeworm and schistosomiasis should be sought when eosinophilia persists. A good history of overseas travel is essential. There are other causes that are listed elsewhere.<sup>72</sup>

## DISORDERS OF HEMOSTASIS

The normal hemostatic mechanism depends upon the integrity of the vessel wall, and in particular the endothelial cells, the presence of normal numbers and function of platelets, and a normal coagulation mechanism. When an injury occurs these components act in concert to prevent excessive bleeding. The blood vessel wall contracts, the endothelium becomes procoagulant and platelets and coagulation factors are activated resulting in a platelet plug stabilized by fibrin. Several other

homeostatic mechanisms come into play – activation of the natural anticoagulant and fibrinolytic systems limit the extent of fibrin formation and maintains the patency of the vessels. Clinical problems with bruising or bleeding can be caused by abnormalities of any part of the hemostatic mechanism or with the connective tissues.

Differentiation of bleeding disorders from non-accidental injury may be difficult. Investigation of a bruised child is mandatory in all cases where the bruising is unexplained or implausible. The history (particularly a detailed family history of any other bleeding tendency – menorrhagia, bleeding after surgery and dental extractions) and examination play an important part in their differentiation. Screening investigations should aim to identify the commonest disorders and those associated with significant bleeding. A blood count including a platelet count, and a coagulation screen – prothrombin time (PT), activated partial thromboplastin time (APTT) and fibrinogen level should be performed. Measurement of plasma factor VIII and IX level is recommended, as significant deficiencies can occur with a near normal coagulation screen. Von Willebrand factor (vWf) antigen and activity should be measured, because von Willebrand disease (vWd) is the commonest inherited bleeding disorder and the coagulation screen is usually normal. Interpretation of these investigations, if abnormal, may need the advice of a hematologist. The demonstration of a bleeding diathesis does not exclude non-accidental injury and these children may be at greater risk of harm from such injury due to their bleeding disorder.

## PLATELET DISORDERS

### Thrombocytopenic purpuras

Thrombocytopenia is common. A poorly taken blood sample is often responsible – if the low platelet count is unexpected it may need repeating to ensure that it was not a spurious result. Thrombocytopenia is often secondary to infection; sick neonates usually have low platelet counts, and the count may drop in a variety of viral infections, either due to mild and temporary marrow suppression, or occasionally by an autoimmune mechanism.

Symptoms are related to the degree of thrombocytopenia, and if the function is normal, there are very few symptoms until the count is less than  $10 \times 10^9/L$  (Table 23.7a). A raised platelet count is common in children and is nearly always 'reactive' (Table 23.7b). The causes of thrombocytopenia are divided into those with normal or increased numbers of megakaryocytes in the marrow (thrombocytopenia caused by increased peripheral destruction) and those with reduced or absent megakaryocytes (failure of production) (Table 23.8a). Thrombocytopenia in children is commonly caused by increased destruction. The hemostatic defect is mainly due to failure of formation of an adequate platelet 'plug' at the site of endothelial damage. Coagulation screening tests will be normal.

**Table 23.7a** Clinical presentation of thrombocytopenia (normal range =  $150\text{--}450 \times 10^9/L$ )

Platelet count $\times 10^9/L$	Symptoms
50–100	Bleeding only produced by trauma or surgery. Often no symptoms at all
30–50	Bruising with minor trauma
10–30	Spontaneous bruising and dependant purpura. Menorrhagia, epistaxis
< 10	Spontaneous bruising and purpura. Mucosal bleeding. At risk for more serious bleeding, e.g. from the gastrointestinal tract or in the central nervous system, depending upon cause of thrombocytopenia (much more likely in circumstances with reduced production than increased destruction)

Table 23.7b Causes of a raised platelet count (thrombocytosis)

In children nearly always reactive or secondary:
Infection
Iron deficiency
Postoperative
Inflammation
Malignancy
Hemorrhage
Primary disease of the marrow is very rare

### Differential diagnosis

A careful clinical history and examination will point to the cause, bearing in mind the incidence of the different disorders.

Congenital thrombocytopenias are very rare and so are often missed. The time of onset of symptoms should be carefully defined, because patients with congenital disorders will have a life-long history. There may be a family history but many of these disorders are inherited recessively. Consanguinity of parents will increase the risk, so that disorders such as Bernard–Soulier syndrome are commoner in populations where cousin marriage is common.

*Bernard–Soulier syndrome* is caused by a deficiency of platelet glycoprotein 1b, resulting in thrombocytopenia (typically  $30\text{--}40 \times 10^9/\text{L}$ ) and defective function so that the bleeding manifestations (bruising, mucous membrane bleeding) occur at a higher platelet count than expected. The blood film shows giant platelets.

*Wiskott–Aldrich syndrome* is an X-linked disorder that classically leads to severe thrombocytopenia with small platelets associated with eczema; it is associated with immune defects and a significant risk of transformation to malignancy. Mild forms are recognized and not all patients have eczema at the time of presentation with bleeding; some have very severe bleeding symptoms and have been cured by HSCT.

Clearly the implications of a diagnosis of one of these disorders are quite different from immune thrombocytopenias (see below). Other inherited thrombocytopenias are associated with various physical abnormalities, and are reviewed by various authors.<sup>73–76</sup> The children have a lifelong bleeding tendency that can be very difficult to manage, and need expert management in a specialist center.

Thrombocytopenia may be the presenting feature of a more sinister disorder, such as idiopathic aplastic anemia, or one of the constitutional marrow failure syndromes (see above). Limping or bone pain, with lymphadenopathy or splenomegaly, suggests leukemia, but it is rare for this to present without other abnormalities in the blood count. If these diagnoses are suspected a bone marrow examination will help (to rule out aplasia or malignancy) and other tests of platelet function, with analysis of platelet surface molecules, may be required to exclude the congenital disorders. Careful examination of a peripheral smear by an experienced hematologist in possession of the full clinical history is essential.

Coagulation screening tests are not usually indicated unless there is a possibility of consumptive coagulopathy (e.g. in association with suspected sepsis) or hypersplenism that may be associated with hepatic dysfunction. Generally, in a well child with purpura alone, the coagulation screen is normal and unnecessary. Purpura is not a symptom of a coagulation factor defect. In a child with thrombocytopenia and a hemangioma, even if very small, a coagulation profile is essential as this may indicate *Kasabach–Merritt syndrome* with a potentially serious consumptive coagulopathy. This combination is fortunately rare, but may be very difficult to manage, with life threatening bleeding.<sup>77</sup>

### Idiopathic thrombocytopenic purpura (ITP)

Immune thrombocytopenia can be caused by a variety of different mechanisms (Table 23.8b) but ITP is the most common. Despite this, it is not a common condition; the incidence is about the same as acute leukemia, 1 in 25 000. ITP is caused by antibody production against platelet antigens, switched on as an inappropriate immune response to a trivial viral

Table 23.8a Causes of thrombocytopenia

Decreased production:
Congenital – rare
Acquired
Increased destruction:
Immune (common)
Nonimmune
Disseminated intravascular coagulation
Hemolytic uremic syndrome and its variants
Hypersplenism

Table 23.8b Causes of immune thrombocytopenia

Idiopathic autoimmune (ITP or AIITP):
Acute (80–90% in children)
Chronic (i.e. >6 months' duration)
Alloantibodies:
Neonatal (NAIT)
Post-transfusion purpura
Drug-induced
Disease-associated (e.g. systemic lupus erythematosus, immunodeficiency and some infections)

infection or immunization. There are well-recognized associations with varicella, MMR vaccine and with infectious mononucleosis.

The clinical onset is usually abrupt with presentation within 24–48 hours. Although the platelet count is dramatically decreased (80% less than  $20 \times 10^9/\text{L}$ ), the typical child, of either sex aged 1–10 years, will have predominantly, or exclusively, cutaneous symptoms and signs often, with florid purpura and easy bruising. Mucosal bleeding is less common, with epistaxis occurring in 20%, usually not severe. Severe bleeding symptoms such as torrential nose bleeds, hematemesis, melena, menorrhagia or frank hematuria are uncommon, occurring in about 4%.<sup>78</sup> Intracranial hemorrhage is rare and not as high as the 1–3% often quoted. The incidence is much closer to 1 in 500 or 1 in 1000, is not confined to early in the course of the disorder, is not necessarily fatal and may be caused by an additional underlying abnormality or provoked by an injury.<sup>79</sup> The outlook in childhood ITP is very good; most children will fully recover within a short time – sometimes even within a few days, and mostly within 6 weeks.

There is no diagnostic test; other disorders have to be considered and excluded as appropriate. Bone marrow aspiration is not required, unless there is doubt about the diagnosis, as it can only exclude other disorders and show a picture that is consistent with increased peripheral destruction (an increase of megakaryocytes in an otherwise normal marrow).

The management of this disorder is controversial because many doctors fear that a very low platelet count carries a high risk of serious or life threatening bleeding. The evidence does not support this. Surveys from Germany<sup>80</sup> and the UK illustrate the safety of a 'no treatment' policy based on mild clinical presentation rather than the platelet count.<sup>81</sup> New standardized parameters are required for the assessment of these children which take into account symptoms as well as the platelet count.<sup>82,83</sup> A clinical classification or 'bleeding index' is shown in Table 23.9. When treatment is required for bleeding symptoms the choice is between oral steroids in high doses (e.g. 1–2 mg/kg/day for 2 weeks; 4 mg/kg/day for 4 days), or intravenous immunoglobulin (IVIG). If a child is treated for a low platelet count alone, it becomes difficult to withdraw steroids as the count drops when the steroid dose is lowered. Prolonged treatment with high dose steroids is toxic and dangerous. IVIG is a blood product (from pooled plasma donations), so may carry a risk of infection (hepatitis C has been transmitted in the past); it has a high frequency of side-effects (fever, headache, malaise) and has to be given by intravenous infusion. It is usually given as 1 g/kg daily for 1 or 2 doses; 800 mg/kg as a single dose may be sufficient. It is indicated in the child with significant bleeding

**Table 23.9** Clinical bleeding assessment in children with immune thrombocytopenic purpura – irrespective of platelet count

Bleeding category	Clinical description
Asymptomatic	No symptoms. Low platelet count found incidentally
Mild	Cutaneous features only; purpura and bruising; occasional mucosal lesion; trivial nosebleeds. No interference with normal living
Moderate	More troublesome bleeding including menorrhagia, more severe nosebleeds, moderate interference with daily living
Severe	Bleeding requiring hospital admission and/or blood transfusion. Gastrointestinal bleeding; torrential nosebleeds. Serious life-threatening bleeding such as intracranial hemorrhage

(less than 4% of children) as it raises the platelet count faster than oral steroids. Many other agents have been used for the very rare child with serious hemorrhage who is refractory to steroids and IVIG. These complex cases should be referred to a specialist.

About 15% children do not remit within 6 months, which is defined as 'chronic' ITP. These children are still likely to remit (60% over 10 years) so that management can continue to be expectant.<sup>84</sup> Chronic ITP is more common in children over 10 years of age, and females. These children may develop other features of autoimmune diseases and may be screened for these on an annual basis (antinuclear factor, anti-double stranded DNA, lupus anticoagulants, anticardiolipin antibodies). In the absence of symptoms the finding of other autoantibodies may not alter the management, but will be a useful forewarning of possible trouble to come.

Splenectomy may be considered for children with severe bleeding problems, preferably more than 6 months from diagnosis. The child's lifestyle may be taken into consideration, but about 25% will not remit despite splenectomy and the longer the splenectomized individuals are followed, the higher the relapse rate with no evidence of a plateau. Splenectomy is associated with a life-long increased risk of infection (see above).

### Thrombocytopenia secondary to infection

Mild thrombocytopenia of the order of  $50\text{--}100 \times 10^9/\text{L}$  is common following recent infection in young children, sometimes accompanied by splenomegaly; both resolve within a week or two. The infection may be a simple upper respiratory tract infection but is sometimes due to glandular fever, cytomegalovirus or toxoplasmosis. Many of the more serious infections (particularly meningococcal disease) produce consumptive coagulopathy. Thrombocytopenia is common in HIV infection, and may be the presenting feature in adults.

### Drug-induced thrombocytopenia

Drugs such as alkylating agents and antimetabolites used in leukemia treatment regularly produce dose-dependent general marrow suppression. The other main type of drug-induced thrombocytopenia is that produced by immunological mechanisms, usually of the drug-hapten variety. This has been shown in adults to occur with sedormid, quinidine, quinine, sulfamethazine, antazoline and other drugs. Anti-epileptic medication can rarely produce marrow toxicity with both thrombocytopenia and leucopenia.

### Disorders of platelet function

Inherited disorders of platelet function are rare; there are many more common acquired conditions in which moderate platelet dysfunction can play a role. Platelet disorders typically lead to mucosal bleeding, prolonged bleeding from superficial cuts, bruising and purpura. The extent of bleeding is related to the severity of the disorder.

### Acquired

The main causes of acquired platelet dysfunction are indicated in Table 23.10. Many drugs cause some platelet dysfunction. Aspirin causes inhibition of prostaglandin synthetase and impaired thromboxane A<sub>2</sub> synthesis. There is a failure of the release reaction and aggregation with adrenalin and adenosine diphosphate (ADP). A single small dose can have an effect for the lifespan of the platelet, 7–10 days. Other nonsteroidal anti-inflammatory drugs cause variable interference with platelet function. Heparin and intravenous antibiotics may become important in the seriously ill patient with multiorgan failure in intensive care. Uremia and liver dysfunction may be contributory. Myeloproliferative disorders are extremely rare in childhood. Although in adults a high platelet count may indicate a marrow disorder, in children a raised platelet count is common, and nearly always reactive. It is a marker of inflammation and challenge in a nonspecific manner similar to the erythrocyte sedimentation rate, and does not need further investigation or repeated measurement.

### Hereditary

Glanzmann thrombasthenia is a serious bleeding disorder that usually presents early in life with bruising and mucous membrane bleeding. As with other autosomal recessive disorders cases are commonest in families with consanguineous partnerships. The platelet membrane lacks the IIb/IIIa receptor complex that is critical for normal platelet function. The platelet count is normal, laboratory testing shows that the platelets fail to aggregate with any of the usual agonists. Serious bleeding episodes require treatment with platelet transfusions, but these carry a risk of alloantibody stimulation, and so should be used very judiciously. Patients may need HSCT. Recent experience suggests that recombinant activated factor VII may be a useful agent for hemostasis, but the high cost precludes use except in severe bleeding episodes.

Platelets are complex organelles with several types of granule that are important for function. There are a number of inherited platelet storage pool diseases resulting in defective platelet function that produce usually only a mild bleeding tendency. The investigation of these in children is unsatisfactory, and specialist advice should be sought. The association with tyrosinase-positive albinism is called *Hermansky–Pudlak syndrome* and the bleeding problems are usually mild.

## COAGULATION DISORDERS

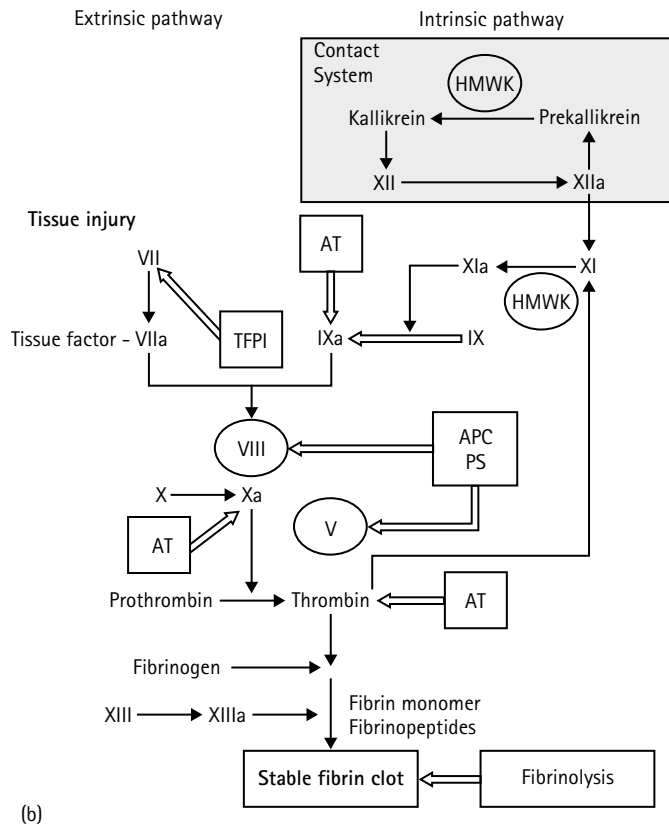

Normal blood coagulation has been described as a 'cascade', where a series of enzymes are activated sequentially, each step adding magnification to the process, leading to the formation of a fibrin clot. In recent years this theory has been revised and it is now more helpful to visualise the relevant factors being brought into proximity with one another on cell surfaces which are crucial to normal coagulation<sup>85,86</sup> (Fig. 23.19a).

**Table 23.10** Causes of acquired platelet dysfunction

1. Drugs:	Inhibition of cyclo-oxygenase, e.g. aspirin and other nonsteroidal anti-inflammatory agents
	Elevation of cyclic AMP levels:
	Inhibitors of phosphodiesterase – dipyridamole
	Activators of adenylyl cyclase
	Antibiotics – penicillins and cephalosporins
	Heparin
	Alcohol
2. Uremia	
3. Disseminated intravascular coagulation	
4. Primary marrow disorders	Acute leukemias
	Myeloproliferative disorders (very rare in children)
5. Cardiac bypass surgery	

(a)

(b)

**Fig. 23.19** Coagulation pathways. (a) Schematic models illustrating some of the phospholipid-bound reactions that are involved in the activation and regulation of coagulation. Factor VIIa binds to tissue factor and activates factors IX and X. Factors IXa and Xa together with factors VIIIa and Va, respectively, form the tenase and prothrombinase complexes that activate factor X and prothrombin, respectively. Thrombin-mediated activation of factor XI, factor V and factor VIII, which gives positive feedback amplification of the system, is not shown. Thrombomodulin is present on endothelial cells. Thrombin generated in the vicinity of intact endothelial cells binds to thrombomodulin and efficiently activates protein C. Activated protein C (APC) and protein S form a complex to the plasma membrane of endothelial cells and possibly also on other cells. This complex inactivates factors Va and VIIIa, which results in downregulation of the coagulation system. The degradation of factor VIIIa by APC is stimulated by protein S and by factor V, which in this context functions as an anticoagulant protein. (From Dahlback 2000<sup>85</sup> with permission.) (b) Schematic representation of the coagulation pathways. The physiological activation of coagulation occurs via the extrinsic system, after activation of tissue factor VII. The end result of activation is the production of a stable fibrin clot. Open shafted arrow, inhibitory action. Inhibitors: APC, activated protein C; AT, antithrombin; PS, protein S; TFPI, tissue factor pathway inhibitor. Tint box outlines the contact system; factors in this box affect the laboratory tests but do not play a significant role in hemostasis. Ovals indicate cofactors; HMWK, high molecular weight kinogen. (From Lissauer & Clayden 2001<sup>35</sup> with permission.)

Coagulation screening tests give important indications of where a coagulation problem lies, but do not take into account many other important physiological systems which add to the balance of hemostasis and thrombosis. In addition to the coagulation factors that contribute to the formation of the fibrin clot, the naturally occurring anticoagulants, antithrombin, protein C and its cofactor protein S, and tissue factor pathway inhibitor are important in preventing excessive coagulation

activation. Other so-called coagulation factors, such as factor XII, whose deficiency may produce an abnormal screening test, have no physiological role in coagulation; a defect is not associated with a bleeding disorder. Some of these interactions are shown in [Figure 23.19b](#). Although the hemophilias are the best characterized of the inherited coagulation disorders, the rare ones have taught us much about normal hemostasis. The physiological pathway for a fibrin clot is the stimulation of tissue

factor – factor VII. Infants with complete deficiency of either factor VII or factor X are particularly at risk of intracranial hemorrhage in the first week of life (also a major risk for the same reason in vitamin K deficiency), in contrast to severe factor VIII or IX deficiency where this complication is much less common.

Coagulation tests do not give any information about the fibrinolytic system, complement activation, the activity of the endothelial cell (a very important regulator of hemostasis) or of the other cell systems which may be implicated, such as monocytes and neutrophils where tissue factor expression can vary; up-regulation can produce a thrombotic milieu. At present there are no satisfactory routine ways of examining these other homeostatic mechanisms.

## HEREDITARY COAGULATION DEFECTS

The three most common serious defects are due to deficiency of factors VIII and IX and von Willebrand factor. The other disorders are autosomally inherited and either very rare (e.g. factor VII and X deficiencies, afibrinogenemia) or they produce less severe bleeding problems (factor XI deficiency). Inheritance patterns and incidence are detailed in Table 23.11.

### Hemophilia A and B

Hemophilia A occurs with an incidence of 1 in 10 000 births, and is thought to be of similar incidence in all the populations of the world. Factor IX deficiency, hemophilia B, is about 5 times less common, but all the clinical manifestations are as for hemophilia A, and both are inherited as X-linked disorders. The degree of factor VIII or IX deficiency varies in different families, but remains constant within kindreds. They are divided clinically into mild, moderate and severe on the basis of the factor level, which predicts bleeding (Table 23.12). Boys with severe hemophilia often present at 12–18 months of age with joint bleeds when they begin to walk, or with mucosal bleeding from the mouth as a result of a fall. Bleeding is typically not severe but rather a constant ooze, or may stop temporarily with a friable clot, which is easily dislodged, leading to further bleeding. These infants may also have easy bruising leading to the suspicion of non-accidental injury. Children with moderate hemophilia will mostly have been diagnosed by the age of 5 years, but those with mild hemophilia may only be diagnosed much later (even in adulthood) when they present with bleeding after dental extraction or other challenges. The hallmark of severe hemophilia is recurrent bleeding into joints and muscles starting in infancy (Fig. 23.20). If inadequately treated, these result in progressive joint deformity and a severe destructive arthropathy (Fig. 23.21). Muscle bleeds can result in permanent damage due to fibrosis and contractures. Relatively minor trauma can also lead to life threatening bleeding. Bleeding initially appears relatively mild, but is persistent and can last for weeks if no treatment is available;

**Table 23.12** Hemophilia A and B – level of clotting factor related to clinical features

Level of clotting factor (% of normal)	Clinical features
<1%	Severe disease Spontaneous bleeding into joints and muscles
1–5%	Moderate disease Bleeding after trauma Occasional spontaneous bleeding
5–40%	Mild disease Bleeding after trauma

**Fig. 23.20** Acute ankle hemarthrosis in a child with severe hemophilia A.

for example a child with a bitten tongue may bleed intermittently for 3 weeks leading to severe anemia necessitating blood transfusion as well as correct replacement therapy. Children with all grades of severity are at risk of bleeding after surgery, particularly in areas of increased fibrinolysis such as the mouth (dental extractions) and genitourinary tract (circumcision). Surgery should never be performed in a hemophilic without appropriate replacement therapy.

**Table 23.11** Hemorrhagic disorders

Deficient factor	Site of production	Synonym	Inheritance	Approximate incidence
VIII	Liver	Hemophilia A	X-linked	1:10 000 males
IX	Liver	Hemophilia B, Christmas	X-linked	1:150 000
vWF	Endothelial cell and platelets	von Willebrand	Autosomal	1:30 000
XI	Liver	PTA	Autosomal	Approximately 8% Ashkenazi Jews are heterozygous
XII	Liver	Stuart Prower	Autosomal recessive	1:100 000
VII	Liver	Proconvertin	Autosomal recessive	1:500 000
I	Liver	Fibrinogen	Autosomal recessive	1:1000 000
II	Liver	Prothrombin	Autosomal recessive	1:2000 000
XIII	Liver or platelets	Fibrin stabilizer	Autosomal recessive	1:2000 000

C, coagulant activity; PTA, plasma thromboplastin antecedent; vWF, von Willebrand factor.

(a)

(b)

Fig. 23.21 (a) Severe hemophilia in an adolescent showing fixed flexion of right knee, marked arthropathy of left knee and muscle wasting. (b) Radiological appearance of left knee.

### Diagnosis

Severe hemophilia can be diagnosed at birth in an infant with a known family history as the factor VIII:C level at birth is at normal adult levels. The initial screening test will show a markedly prolonged APTT. This will not distinguish between factor VIII:C and IX:C – the appropriate factor assay must be performed. Severe hemophilia B can also be diagnosed at birth, but milder forms may not be reliably diagnosed within the first 6 months as the factor IX level only reaches adult levels later. The quality of the blood sample for coagulation testing and factor assays is crucial. Traumatic samples may contain tissue factor causing activation of the coagulation pathways and give an inaccurate and falsely normal results.

### Genetics and counseling

About a third of hemophiliacs have no known family history and these individuals either represent new mutations or transmission via asymptomatic women over many generations. About a third of female carriers have low factor VIII:C (or IX:C) levels because in each cell one X chromosome is inactivated (the Lyon hypothesis). On average, the factor level in carriers is half normal, but in some it is low enough to cause bleeding symptoms after trauma or surgery (effectively mild hemophilia). The relevant female relatives of any hemophiliac should have factor assays

performed. A normal level will not exclude carrier status, which can generally be detected by mutation analysis of the index patient in the kindred and testing possible carriers for the known mutation. Genetic diagnosis should not be performed without consent from the possible carrier and should be delayed until the girl is old enough to understand and give informed consent. About 500 different mutations have been reported for the factor VIII:C gene, and more than 700 for the factor IX gene. It is very important to identify which women are at risk of giving birth to a severely affected boy. Parents need the opportunity to consider this, and appropriate management plans need to be in place for delivery. Most hemophiliac babies are born by normal vaginal delivery, but instrumentation should be avoided, and male infants tested at birth. It is possible to undertake antenatal testing in consultation with the appropriate services.

### Management

Hemophilia is a potentially serious and life-long disorder. Families can be taught to manage this very well indeed, but this requires considerable investment of time and support best provided by specialist centers (hemophilia centers). In addition to information and training families are often helped by being put in touch with one another, and with support organizations (hemophilia societies). Families need to learn how to live with the disorder. Fortunately with current treatment options in resource-rich countries, there need to be few restrictions on activity. Contact sports should be avoided, but sport is generally beneficial; children should be encouraged to be fit, but regular soccer football is likely to lead to damaged ankle joints in the long-term. The important principal is to give replacement therapy for bleeding episodes. Treatment can be given on demand for bleeds in severe and moderate hemophilia. A concentrate of factor VIII:C is used (or factor IX:C in factor IX deficiency), either plasma-derived or genetically engineered (recombinant). Fresh frozen plasma contains factor VIII:C and IX:C but an unacceptably large volume would be required for an adequate factor increase. Cryoprecipitate is effective in hemophilia A (but not hemophilia B) but is not virally inactivated and is less convenient because of the volume required. Plasma-derived factor concentrates have been available in resource rich countries since the 1970s and have changed the lives of severe hemophiliacs, providing early and adequate treatment of joint bleeds preventing severe joint deformity in many young men. Unfortunately the early products transmitted both hepatitis C and HIV infection with tragic consequences. More than 1000 of the total 5000 people with hemophilia A in the UK were infected with HIV between 1979 and 1985, and more than 3000 people have been infected with hepatitis C. Viral inactivation steps introduced in the 1980s have prevented virus transmission (HIV and HCV) since 1986–87. In many countries recombinant products are the treatment of choice, but at a high cost. The half-life of factor VIII in the circulation is only 8–12 hours, and is less in small children. Doses need to be given twice or three times daily for surgery, where the aim is to keep the factor VIII:C level above 50 iu/dl. Minor bleeding episodes respond rapidly to a single dose of 20–25 iu/kg; more severe bleeds may need higher initial doses and repeat doses over a few days. Factor IX:C needs to be given in higher dosage as the recovery is less (40–50 iu/kg), but less frequently as the half-life is longer.

Current treatment of severe hemophilia aims to prevent joint damage by giving prophylactic therapy. Factor VIII:C is given three times a week, or on alternate days, at a dose sufficient to prevent the trough level falling below 2 iu/dl, effectively converting severe to moderate hemophilia which is far less likely to be complicated by recurrent joint and muscle bleeds. Experience has shown benefit in serial cohorts monitored over decades.<sup>87</sup> Additional data from an orthopaedic outcomes study (data collected from 21 centers world-wide) demonstrated that those patients with more than 45 weeks of regular prophylaxis per year had better joint function at 6-year follow-up than those treated 'on demand'. Total factor VIII usage per annum also correlated with outcomes; in general, more treatment was better.<sup>88</sup> Prophylaxis is optimal therapy for young hemophiliacs, generally with a regimen of alternate day (or 25 iu/kg three times a week) therapy in hemophilia A, and twice weekly (40 iu/kg) injections for hemophilia B, starting in the first or second year of life. Prophylaxis is divided into: primary – started

before the age of 2 years or after the first joint bleed and secondary – either as continuous therapy starting after the age of 2, or after two or more joint bleeds. Secondary prophylaxis can also be periodic treatment given to settle a series of repeated bleeds. The benefit of prophylaxis has been confirmed by a controlled trial in the USA,<sup>89</sup> and other studies are underway in Canada and Italy. Several questions remain, in particular, should prophylaxis be started in the first year of life before there are any joint bleeds? (Not all individuals with very low factor levels have repeated joint bleeds.) Venous access is usually very difficult in the young child – perhaps dosing weekly with escalation with age as veins become more accessible may be as effective. Central venous lines have advantages but are complicated by infection and thrombosis. Swedish and other smaller uncontrolled studies clearly demonstrate improvement in quality of life – reduced days off school and greater satisfaction among the families – but other families have found it very hard to persist with the regular injections for a variety of reasons. The availability and cost of factor concentrates is a major issue even in resource rich countries. Even within the European Network of 20 hemophilia centers (16 countries) the proportion of severe hemophilic children on continuous prophylaxis varies from 15–100%.<sup>90</sup>

Mild hemophilia A (but not hemophilia B) can often be treated with parenteral high dose desmopressin (0.3 µg/kg i.v. or s.c.). This stimulates release of factor VIIIc from storage sites and can increase the level threefold within 1–2 hours of the end of the infusion. This is usually appropriate for minor procedures such as tooth extraction. Desmopressin is an antidiuretic hormone analogue, with potential fluid retention, which must be watched, and the risk of fits due to cerebral oedema is increased in small infants. Desmopressin is not usually given to infants less than 2 years of age. Major procedures can also be managed in this way, although the response declines after several days (tachyphylaxis).

### Von Willebrand disease (vWd)

Von Willebrand disease (vWd) is the commonest inherited bleeding disorder with a prevalence of 1 in 100 to 1 in 1000. Mild forms (the commonest) are not usually detected by a 'routine coagulation screen' as the factor VIIIc and APTT are often normal and specific assays of the von Willebrand factor are required (vWf – assays measure immunologically available protein or activity), often on more than a single occasion. The bleeding time is not usually helpful. It is the least sensitive diagnostic test in mild vWd. The defect is in the von Willebrand factor with secondary effects on factor VIIIc, normally protected from degradation in the circulation by binding to vWf. Von Willebrand factor has an important role binding platelets to the vessel wall with activity mediated through the glycoprotein 1b receptor on the platelets. Symptoms are those of 'platelet-type' bleeding – bruising, mucous membrane bleeding including epistaxis and menorrhagia in women. This is an important and often overlooked symptom. People with mild forms of vWd are likely to bleed excessively after surgery. vWf is a large molecule and can have both quantitative or qualitative defects. Von Willebrand disease has many subtypes; full workup should be performed in a hemophilia center with adequate diagnostic facilities. It is generally a mild disorder inherited autosomally with variable expression in different family members. The level of vWf is also affected by factors outside the vW gene, particularly blood group. A good family history is essential and the implications of the diagnosis explained carefully to other members of the family. Severe vWd is uncommon, usually occurring when each parent has a vWf defect which may be asymptomatic or expressed as mild vWd. Individuals with severe vWd may experience joint bleeds similar to severe hemophilia. Mucous membrane bleeding in mild vWd is often helped by antifibrinolytic drugs. Surgery can often be managed with parenteral desmopressin, but severe forms of vWd require factor replacement using a plasma-derived intermediate purity factor VIIIc concentrate containing vWf, or a vWf concentrate. Management of the different subtypes can vary; in particular there are some variants in which desmopressin is contraindicated so these patients should always be managed with appropriate hematological advice. Cryoprecipitate should no longer be used as concentrates are safer and usually effective.

### Other hereditary bleeding disorders

Congenital deficiencies of all the other coagulation factors have been described, but are rare. A coagulation screen will indicate where the defect lies (but is normal in FXIII deficiency), and which further tests and assays are required. Bleeding symptoms should always be investigated. Families with all types of bleeding disorders are often misdiagnosed initially as non-accidental injury as, sadly, this is more common. Specific factor concentrates are available for some of the severe homozygous disorders (factor VII; factor X is contained in plasma-derived factor IX concentrates). Factor XI deficiency is clinically mild even in severe deficiency and more common amongst Jewish people (with a carrier rate of 8%). Factor XIII is the fibrin-stabilizing factor (normal coagulation screen) and in deficiency typically produces delayed hemorrhage 24–36 hours after injury, with delayed wound healing and sometimes scarring. Bleeding from the umbilical stump and delayed separation of the cord also occur. Specific assays define the diagnosis of all of these disorders.<sup>91</sup>

### ACQUIRED COAGULATION DEFECTS

Although the congenital coagulation deficiencies are important, in clinical practice the acquired causes are much more common, and are usual in the sick child.

### Deficiency of vitamin K-dependent coagulation factors

Factors II, VII, IX and X, synthesized in the liver, require vitamin K-dependent addition of gamma-carboxyl group to make a functional protein. Deficiency can cause a very serious bleeding disorder with a risk of intracranial hemorrhage. Vitamin K is fat soluble and obtained from green vegetables and bacterial synthesis in the gut. Vitamin K-dependent factors are low at birth and fall further in breast-fed infants in the first few days of life. Premature and ill babies are prone to deficiency and should always be supplemented. Classic hemorrhagic disease of the newborn is rarely seen in resource rich countries, partly because of universal prophylaxis but also due to general good standards of living. Later presentation of vitamin K deficiency can occur in infants with malabsorption and should be screened for in children with celiac disease, cystic fibrosis and other long-term gastrointestinal disorders including obstructive jaundice, pancreatic and small bowel disease. Prophylaxis can be achieved with 5 mg vitamin K orally daily. The prothrombin time is very sensitive to factor VII deficiency and is a useful screening test; the APTT will also be long. Parenteral vitamin K produces a rapid shortening of the prothrombin time, within 2–4 hours, but serious bleeding must be treated immediately with concentrates containing factors II, VII, IX and C or with fresh frozen plasma (preferably pathogen inactivated). Oral supplements can be used where absorption is likely to be normal.

### Liver disease

Liver disease can produce a variety of complex alterations in hemostasis. Acute hepatocellular failure produces a rapidly progressive failure of coagulation factor synthesis detected initially as marked prolongation of the PT (effect on factor VII) and reduction in fibrinogen. Chronic disease produces variable effects often associated with thrombocytopenia. Liver dysfunction can lead to disruption of fibrinogen synthesis with abnormal forms but these do not predict bleeding. It also affects the fibrinolytic system and can be prothrombotic because of failure of clearance of activated coagulation proteins.

### Consumptive coagulopathy – disseminated intravascular coagulation (DIC)

Blood coagulation is kept in sensitive balance with other homeostatic pathways, anticoagulant, pro-inflammatory, fibrinolytic. Under many conditions these are disturbed resulting in profound clinical derangements. Normal coagulation is triggered by tissue factor activation. Tissue factor expression is increased by diverse agents and endothelial

damage leading to a pro-coagulant state. The endothelial cell has a key role as gatekeeper, regulating not only blood flow but the pro- versus anticoagulant properties. Any condition causing endothelial disturbance (shock from any cause) and sepsis can lead to activation of coagulation with consumption of platelets and coagulation factors producing disseminated intravascular coagulation. Microvascular thrombosis leads to end-organ dysfunction; consumption of factors and triggering of fibrinolysis lead to a bleeding diathesis. The condition varies from sub-clinical, detectable by testing only, to an acute florid hemorrhagic state. There are no diagnostic laboratory tests, rather a constellation of abnormalities associated with the appropriate clinical circumstances lead to the diagnosis. The commonest triggers in pediatric practice are infections, particularly Gram negative sepsis and meningococcal infection, and vascular injury (trauma, burns). Neonates with shock are particularly vulnerable, resulting in profound hypofibrinogenemia, very long coagulation screening tests and thrombocytopenia. The picture may be rapidly evolving, and repeated monitoring is essential in the acute situation. The key principal in management is to treat the underlying cause – remove the trigger; the bleeding child will need replacement therapy with blood products dictated by the laboratory tests (cryoprecipitate for a low fibrinogen, platelet transfusions for severe thrombocytopenia, and possibly plasma as well). Recently it is appreciated that the natural anticoagulants, protein C and S, and antithrombin, are usually consumed in addition; there may be a role for replacement of these, particularly in severe sepsis with protein C deficiency<sup>92</sup> particularly in relation to meningococcal disease.<sup>93</sup>

## THROMBOSIS IN CHILDREN

Thrombosis is rare in children; the incidence of venous thrombosis is 0.6 per 100,000 of the Dutch population under 14 years of age, compared to 20.2 in those aged 15–24 years, 37 in those aged 25–39 years and 74 in those aged 40–54 years. Nevertheless, sick children are at risk, particularly those with central venous lines<sup>94</sup> and thrombotic events occur in neonates often related to the use of central lines. The incidence of thrombotic events after trauma in children is negligible under the age of 13 years and this group do not need thromboprophylaxis.<sup>95</sup> In addition to such acquired causes, there is increasing interest in a number of inherited risk factors that predispose to thrombosis in adults. A mutation in the factor V gene (factor V Leiden) which makes activated factor V resistant to inactivation is particularly common in Northern Europeans (2–7% of the population); protein C, protein S and antithrombin deficiency also increase the risk in heterozygotes, but screening for these in asymptomatic offspring of an adult with thrombosis is not justified. Such genetic screening should only be performed with appropriate consent. A study of Swedish children and adolescents presenting with a first thromboembolic event found acquired risk factors in 81% (commonly central lines) but 64% of those studied were found also to have heritable risk factors, and 20% had two or more.<sup>96</sup> Long-term studies show a significant incidence of postphlebitic syndrome and recurrent events. Infants with severe protein C deficiency have a severe thrombotic phenotype that usually presents at or shortly after birth with intracerebral thrombosis, blindness and typical microvascular thrombosis of the skin (Fig. 23.22). Diagnosis is urgent as the infant may be treated with protein C concentrate. Severe protein S deficiency may produce a similar picture. Homozygous antithrombin deficiency has not been reported; it is probably incompatible with life. Anticoagulant therapy is appropriate for many of these children, and appropriate protocols are now available, but should be supervised by a suitably trained person.

## LEUKEMIA

### INCIDENCE

Leukemia is the commonest malignancy of childhood accounting for approximately 35% of the total. Acute lymphoblastic leukemia (ALL)

Fig. 23.22 Infant with severe congenital protein C deficiency. Microvascular thrombosis of the skin.

is much commoner than acute myeloid leukemia (AML) representing 80–85% of all leukemias in this age group. The incidence of leukemia is not constant throughout the world and this can partly be explained by genetic and environmental differences. In Western countries, the incidence is approximately 4/100 000 children up to the age of 15 years,<sup>97</sup> with boys having an incidence 1.2 higher than girls.

## CLASSIFICATION OF LEUKEMIA

Distinction between the different types and subtypes of leukemia is essential for optimizing treatment and predicting outcome of disease. Leukemias are classified firstly into acute or chronic forms, indicating the speed of progression of the disease without treatment. Chronic leukemia in children is very rare and is confined to chronic myeloid leukemia (CML). CML accounts for between 2% and 5% of all childhood leukemias and presents as one of two forms: chronic granulocytic leukemia (CGL), which is identical to the adult type CGL, or juvenile CML (JCML), recently renamed juvenile myelomonocytic leukemia (JMML), which is a form of myelodysplasia. CGL, JMML and other forms of myelodysplasia carry a risk of progression to acute leukemia.

Cases of acute leukemia can be classified on the basis of morphology, cytochemistry, immunophenotype or cytogenetic abnormality, or by combinations of these characteristics. Ideal classifications of acute leukemias do not yet exist and so information from all these sources must be used together (Table 23.13).

Morphologically, the acute leukemias are divided into ALL and AML. The classification most widely used now was first described by the French–American–British (FAB) group in 1976<sup>98</sup> subsequently expanded, modified and clarified over the years. Pediatric myelodysplasia is recognized as a distinct entity with a prognostic scoring system. Classification of all these disorders requires examination of both peripheral blood and bone marrow films with differential counts performed on both. Cytochemical staining can help distinguish lymphoid from myeloid leukemia and also assign the two different leukemias to specific subtypes. However, it has mostly been superseded by immunophenotyping.

Immunological typing of leukemic cells utilizes immunoenzymatic and immunofluorescent techniques employing a panel of antibodies which recognize particular blast cell-surface or cytoplasmic antigens. Immunophenotyping is particularly useful in ALL and in classifying certain types of AML (M0 and M7) where the blasts are not easily classifiable morphologically. It will also help identify the occasional biphenotypic acute leukemias where there is expression of the specific markers from both lymphoid and myeloid lines. In ALL, it confirms the diagnosis and separates cases into leukemias of T cell and B cell lineage. Further separation into categories reflecting

Table 23.13 The leukemias and myelodysplastic syndromes. (After Bennett et al 1976, 1982<sup>98,100</sup> Emanuel 1999,<sup>99</sup> Passmore et al 1995,<sup>101</sup> Bain 1999<sup>122</sup>)

the stage of maturation at which the abnormal clone expanded is possible, particularly for the B cell leukemias where precursor B cell leukemias (null, pre-B and common) are distinguishable from mature B cell leukemia. These categories show some correlation with cytogenetic subsets. It is important to identify mature B cell leukemia which is also identifiable morphologically (FAB L3), and cytogenetically [t(8; 14)] (Table 23.13), because this is treated with chemotherapy designed for B cell non-Hodgkin lymphoma, not standard ALL therapy.

The mainstay of AML classification is morphological characteristics seen on both an ordinary, stained bone marrow aspirate film and those after specific cytochemical staining. Sometimes monoclonal antibody staining is required for precise classification as in megakaryoblastic leukemia (M7). The FAB classification is based on identifying the predominant cell type and the degree of differentiation of the cells. Certain types have characteristic laboratory or clinical features such as disseminated intravascular coagulation [promyelocytic leukemia (M3)], gum hyperplasia, skin rash and raised lysozyme levels [monoblastic leukemia (M5)] and osteosclerosis and Down syndrome with M7. Certain cytogenetic abnormalities are also associated with specific morphological types and can be important prognostic indicators. These include t(15;17) in M3 and inv(16) in myelomonocytic leukemia with eosinophils (M4Eo), both associated with a good prognosis in children.

The myelodysplastic syndromes (MDS) are rare in childhood and represent between 1% and 9% of all pediatric hematological malignancies.<sup>102</sup> They are often associated with other conditions such as Down syndrome, cardiac abnormalities, neurofibromatosis type 1 and congenital bone marrow disorders. These include FA and SDS which may progress to acute leukemia. Classification by the FAB group<sup>100</sup> is not ideal in childhood as this does not accommodate JMML or infantile monosomy 7, a myelodys-

plastic condition occurring in young infants which shares many characteristics with JMML. In addition, MDS occurring in association with the congenital bone marrow disorders may not be classifiable, as the bone marrow is often hypoplastic, whereas in adult MDS this occurs in only 10% of cases.

Refractory anemia (RA), anemia with myelodysplastic features, with or without a few ringed sideroblasts, is rare and must be distinguished from the congenital dyserythropoietic anemias (see Ch. 12) and megaloblastic anemia (see above). Refractory anemia with ringed sideroblasts (RARS) is exceptionally rare in childhood and must be distinguished from a mitochondrial cytopathy such as Pearson's syndrome (see above). RA and RARS can only be diagnosed with confidence in the presence of clonal cytogenetic abnormalities, but both carry a much better prognosis than other MDS in adults. The distinction between the other types of myelodysplasia, such as refractory anemia with excess blasts (RAEB) or refractory anemia with excess blasts in transformation (RAEBT) and AML depends on the percentage of blasts in the bone marrow. Review of treatment of this group of children shows that it is appropriate for them to be treated as for AML.<sup>103</sup> The FAB classification has been expanded and a scoring system developed taking into consideration the level of hemoglobin F, platelet count and complexity of karyotype.<sup>101</sup> A favorable score gives a 5-year survival of approximately 60% with all of those with an unfavorable score being dead within 4 years of diagnosis.

## CLINICAL TRIALS

It is well recognized that the increased intensity of treatment has improved prognosis in general for leukemia. However, within a particular regimen, it is possible to increase intensity for those at highest risk while decreasing intensity for those with the best prognosis, thus

reducing both early and late toxicity. Classification of leukemias morphologically, immunologically and cytogenetically along with certain clinical features has enabled stratification of children into different risk groups within a given type of leukemia, making it possible to give risk-adapted therapy. Many groups have developed different treatment regimens over the past 30 years, building on experience and introducing new drugs or methods of delivery in a controlled way to enable the true effect of any change to be determined. In the UK, >90% of children with acute leukemia are treated within clinical trials. This enables reliable comparisons between treatments and advances to be made. By standardizing risk categories internationally, it is also possible to compare results from trials conducted in the USA or other parts of Europe, for example.

## PRESENTATION

Acute myeloblastic leukemia has a steady incidence throughout childhood although the monoblastic/monocytic types tend to occur relatively more often in infancy. Acute lymphoblastic leukemia is most common between the ages of 2 and 5 years with an increased incidence in boys. Rare cases of congenital leukemia do occur and these are usually but not exclusively malignancies of early B cells. JMML and monosomy 7 tend to occur in infants.

The diagnosis of acute leukemia usually starts from a clinical suspicion. Only very occasionally is it discovered serendipitously when a blood count is done for another reason. The clinical presentation is, for the most part, determined by the degree of bone marrow failure, but other features, secondary to the infiltration of different organs, may give specific signs and symptoms.

### General symptoms and signs

The majority of children will give a short history of fewer than 4 weeks, although a prodrome of a few months is also seen. General symptoms include lethargy, loss of appetite and exhaustion. Bone marrow failure results in anemia, neutropenia and thrombocytopenia.

### Anemia

This occurs in most cases but the fall in hemoglobin is gradual and can be very well tolerated initially. The low hemoglobin causes some of the commoner symptoms and signs such as pallor, lethargy, anorexia and breathlessness. Cardiac failure is uncommon even at very low levels of hemoglobin, but tachycardia and flow murmurs are common.

### Infection

Susceptibility to infection may be apparent for some time before presentation and some patients may have a serious infection at diagnosis. Pyrexia at presentation may be due to the disease process itself, but since many children are neutropenic, and all are immunosuppressed, the child should be treated for infection with broad-spectrum intravenous antibiotics.

### Hemorrhage

This is a frequent presenting feature and can be catastrophic. This is still the commonest cause of the rare deaths, which occur during the first few hours in hospital, and there is a strong association with leukostasis secondary to very high blast counts in the peripheral blood. Most bleeding episodes are milder and secondary to thrombocytopenia. Thrombocytopenia leads to petechiae and other hemorrhagic manifestations, especially mucosal bleeding and easy bruising. Bleeding may also be due to hepatic dysfunction and disseminated intravascular coagulation, the latter particularly with acute promyelocytic leukemia (M3).

### Bone and joint involvement

Orthopedic surgeons, rheumatologists and accident and emergency staff frequently see children with bone pain and/or arthralgia and accompanying limp or failure to walk. Up to two thirds of children with

Fig. 23.23 Lymphoblastic leukemia. Knees showing generalized osteoporosis with transverse radiolucent bands across long bone metaphyses adjacent to metaphyseal bone ends, found in malignant infiltration of bone marrow.

ALL present with bone pain and therefore a full blood count should be checked in children with such symptoms. Examination for hepatosplenomegaly and lymphadenopathy may also help to identify the true diagnosis. Roentgenograms of these children will show changes in at least half, the most frequent of which are transverse radiolucent lines at the metaphyses (Fig. 23.23) and osteopenia sometimes with vertebral collapse. In acute megakaryoblastic leukemia (M7) and other types of leukemia, osteosclerosis can occasionally occur. Bone pain responds rapidly to antileukemic therapy although there may be some exacerbation when treatment starts. Another childhood malignancy, neuroblastoma, may also present with bone pain and anemia with or without thrombocytopenia. However, abnormal cells are rarely seen on the blood film, although the bone marrow may be virtually replaced by malignant cells. Immunophenotyping may be helpful and specific tests for neuroblastoma such as urinary catecholamines should be performed.

### Hepatosplenomegaly, lymphadenopathy and other organ enlargement

Splenomegaly is present in up to 80% of children with acute leukemia and is particularly marked in CGL and JMML. The enlargement is smooth, firm and nontender unless it is chronically enlarged as in CGL when infarction can cause pain and tenderness. Hepatosplenomegaly is present in up to 60% of patients and the kidneys are palpable only occasionally, although abdominal ultrasound will reveal nonpalpable renal enlargement quite often in ALL and acute monoblastic leukemia (M5). Ovarian and testicular enlargement are rarely found at diagnosis but regular examination of the testes throughout follow-up, both on and off treatment, is essential as relapse at this site is quite common. Mediastinal enlargement, seen on chest roentgenogram, is almost exclusive to those with T cell ALL and can cause superior vena cava obstruction (Fig. 23.24). Abdominal masses of leukemia/lymphoma tissue not related to the liver and spleen typically occur in B-ALL cases. Infiltration of the sinuses may also occur (Fig. 23.25).

Gum hypertrophy occurs with all types of leukemia but is particularly common with M4 and M5 types (Fig. 23.26). Skin infiltration with leukemia is rare but does occur in the neonatal variety, when it is seen as bluish papules, and can also be seen in M4 and M5 (Fig. 23.27). JMML is associated with a nonspecific skin rash, especially on the face.

### Meningeal leukemia

Children with ALL virtually all have presymptomatic meningeal leukemia at the time of diagnosis as shown by the inevitability of relapse in

Fig. 23.24 Chest X-ray appearances in acute T cell leukemia with mediastinal widening and hilar lymphadenopathy causing superior vena cava obstruction.

those who do not receive CNS-directed therapy. However, a proportion present with blast cells in the CNS, which are often asymptomatic, but can give rise to diffuse or focal neurological signs. The commonest time to present is once treatment has stopped and such a relapse is frequently associated with the symptoms of raised intracranial pressure such as vomiting and severe headaches. Papilledema may be seen and cranial nerve palsies especially of the VIth nerve are common.

### Tumor lysis syndrome

Children with hyperleukocytosis and/or a high leukemia burden secondary to massive organ infiltration, may develop metabolic abnormalities such as hyperkalemia, hyperphosphatemia and hypocalcemia. This is a particular hazard in B-ALL. Hyperuricemia to a varying degree is a common finding at presentation but can be very marked. When treatment is started there is further lysis of the leukemic cells so the metabolic abnormalities may worsen and can lead to renal failure and death. A forced diuresis, a uric acid lowering agent and careful steroid-based cytoreductive treatment may avoid this complication. Renal dialysis, leukopheresis and/or exchange transfusion may be required in severe cases.

### DIAGNOSIS

It is essential before starting treatment for leukemia that the diagnosis has been made with certainty. Clinical examination and morphological review of well-stained blood and bone marrow films remain the most important parameters for diagnosis. If the bone marrow aspirate is inadequate, a repeat sample with a bone marrow trephine (biopsy) is mandatory. Other diagnostic techniques such as immunophenotyping are complementary but cannot alone be used to make the diagnosis.<sup>104</sup>

In young children, a relatively high proportion of lymphocytes both in the blood and bone marrow will express more immature markers, especially if there is a reactive lymphocytosis secondary to an infection for example. Aplastic anemia may also be mistaken for leukemia, as the bone marrow aspirate is often difficult and again may contain a high proportion of early B cells. If there is any doubt, supportive treatment and repeat sampling is essential.

## MORPHOLOGY

The most constant finding at presentation of leukemia is an abnormality in the peripheral blood with 99% of children presenting either with circulating blasts and/or thrombocytopenia, 90% with anemia and 67% with neutropenia. Acute leukemia is diagnosed from the bone marrow sample if at least 30% of the total nucleated cells are blasts. Cytochemical stains are sometimes prepared to help distinguish between ALL and AML. Criteria for the classification of the acute leukemias have been described above.

The presence of CNS disease is assessed from cytospin preparations of cerebrospinal fluid (CSF). The CSF is considered to be positive if  $> 5$  cells/mm<sup>3</sup> with recognizable blast cells are present. Immunophenotyping may be helpful in equivocal cases, as well as cytogenetic analysis, if enough material can be obtained. It is important to determine whether there is involvement with leukemia or not since these patients usually receive more intensive intrathecal chemotherapy and, if over the age of 2 years, cranial irradiation.

In CGL the most consistent finding in the peripheral blood is a leukocytosis, predominantly of mature neutrophils and their precursors (myelocytes and promyelocytes). Eosinophilia and basophilia are commonly present and the white cell count is usually  $> 100 \times 10^9/L$  at diagnosis. Anemia is usual and platelets are often normal or slightly raised. The bone marrow is markedly hypercellular due to hyperplasia of the granulocyte series. In its chronic phase, blasts constitute  $< 5\%$  of nucleated cells but increase in the accelerated phase and blast crisis. Cytogenetic analysis shows the Philadelphia chromosome t(9;22) in 90% of patients and the bcr/abl fusion gene can be detected in a proportion of Ph-negative patients.

JMML usually presents with thrombocytopenia and a dysplastic blood film with abnormal monocytes and blast cells. The marrow can be relatively uninformative but associated features include a reversion to a fetal type of hemopoiesis with a high hemoglobin F and the 'i' red cell antigen, and sometimes monosomy 7.

## Immunophenotyping

It must be remembered that immunophenotyping is complementary to morphological diagnosis and does not replace it; mistakes in diagnosis can be made if this technique is relied upon in isolation. Immunophenotyping is particularly useful in cases of acute leukemia that are not obviously myeloid, so that a positive diagnosis of ALL can be made and cases of M0 and M7 AML identified. A panel of monoclonal antibodies is used which combines both highly specific and highly sensitive antibodies. Additional antibodies are required for conformation of erythroid leukemia (M6) and M7. Specific antibodies include cytoplasmic (cy) CD22 for B lineage, cy CD3 for T lineage and antimyeloperoxidase (MPO) for myeloid lineage. Sensitive antibodies include CD19, expressed on B cells, CD7 on T cells and CD13/33 on myeloid cells but all may be expressed on cells of other lineage. This aberrant antigen expression is a feature of both ALL and AML and does not mean that the leukemia is biphenotypic. This description is reserved for those leukemias where the more specific antigens (e.g. CD22, CD3, MPO) of more than one lineage are expressed. The prognosis of such leukemias is related to the accompanying cytogenetic abnormalities and many are associated with the Philadelphia chromosome.

## Chromosomal analysis

Cytogenetic analysis is carried out by microscopic analysis of cells in metaphase when suitably stained. This technique can be supplemented

by fluorescent in situ hybridization (FISH). Molecular cytogenetic analysis, where the DNA from the abnormal cells is analyzed using Southern blotting, or polymerase chain reaction (PCR) for example, can be used to establish clonality and also used for detection of minimal residual disease (MRD) to help direct therapy (see later). While some cytogenetic abnormalities identify subtypes of leukemia in a highly specific way, other chromosomal abnormalities occur in both acute and chronic leukemias, ALL and AML and also MDS. Specific cytogenetic abnormalities include t(15;17) in M3, inv(16) in M4Eo and t(8;14) in mature B cell ALL. Other cytogenetic abnormalities such as the Philadelphia chromosome, t(9;22) and monosomy 7 can arise in a variety of leukemias and MDS. It is becoming clear that in both AML and ALL cytogenetic analysis plays a crucial role in assignment of patients to different risk groups, allowing risk directed therapy.<sup>105-107</sup>

## PROGNOSTIC INDICATORS

Type and intensity of treatment in ALL are the most important determinants of prognosis and changes in therapy may alter the significance of other risk factors.<sup>108,109</sup> Prognostic factors are used to stratify children into different risk groups allowing intensification of therapy in those at highest risk of relapse while decreasing intensity in those in the best prognostic group. In AML, the two parameters of greatest prognostic significance are the karyotype of the malignant cells and response to therapy.

## Demographics

In ALL, age, sex and presenting white cell count have a significant influence on outcome. The US National Cancer Institute (NCI) set internationally agreed criteria for risk classification based on these parameters.<sup>110</sup> Standard risk patients are aged between 1 and 9 years with a presenting white cell count of  $< 50 \times 10^9/L$ , while high risk patients are aged  $\geq 10$  years or have a presenting white cell count of  $\geq 50 \times 10^9/L$ . Approximately 75% of patients with B lineage leukemia are standard risk, while 75% of patients with T lineage leukemia are in the high risk category. Boys have a worse prognosis than girls even after adjusting for age and white cell count. CNS disease at diagnosis is not of prognostic significance.

## Morphology

The original morphological classification in ALL is less important than originally thought<sup>111</sup> but has enabled identification of mature B cell leukemias with a specific morphology (L3).

In AML, morphology is closely associated with karyotype which does correlate with outcome.

## Chromosomes

Karyotype has now been included in the NCI risk stratification, (see above). Bcr/abl, hypodiploidy ( $< 45$  chromosomes), or, if 12–24 months old, an MLL gene rearrangement carries the worst prognosis. The MLL gene rearrangement has a particularly poor prognosis if associated with the translocation t(4;11) but additional chromosomal abnormalities do not affect prognosis.<sup>106</sup> Recent work has shown that those with 42–45 chromosomes overall have standard rather than high risk<sup>105</sup> and that not all those with a high hyperdiploid karyotype, that is  $> 50$  chromosomes per cell, do well as was initially described.<sup>107,112</sup> This demonstrates the importance of continued refinement of chromosomal classification.

In AML, favorable karyotypes are those with t(8;21), t(15;17) seen with the M3 subtype and inv(16) seen with M4Eo.

## Response to treatment

Analysis of the United Kingdom Medical Research Council trials for ALL (UKALL), 1980–2002, has consistently shown a relationship between time to respond to treatment and outcome.<sup>112,113</sup> The ALL97 trial included three risk groups taking both response to treatment and karyotype into consideration. The standard risk group (60–65% of children) is as previously defined by NCI criteria; the intermediate risk group (20% of children) has the same parameters as the previous high-risk

group. A new high-risk group (10–12% of children) includes all children irrespective of initial risk group, who have a slow early response to treatment (assessed on bone marrow samples at day 15 for standard risk patients and day 8 for intermediate risk patients) or who have an unfavorable karyotype (see above).

In AML, complete remission (CR), that is <5% leukemic cells in the bone marrow after the first course of chemotherapy, confers the best prognosis, while partial remission (PR), that is 5–20% leukemic cells, is only slightly worse. Patients with resistant disease (RD), defined as >20% leukemic cells in the bone marrow after the first course of chemotherapy, have a very poor outlook. There is a correlation between karyotype and bone marrow status, however karyotype carries the greater prognostic weight. Good risk patients are therefore defined as those with a favorable karyotype regardless of their bone marrow status after course 1. Standard risk patients include all those who have no favorable karyotype and do not have RD after course 1. The poor risk group includes all those with RD after course 1 except those with a favorable karyotype.

### Minimal residual disease (MRD)

It is hoped that MRD, as a more sensitive measure of response to treatment, will allow a much more accurate stratification of relapse risk than the prognostic indicators described above. MRD detected prior to bone marrow transplant predicts relapse post-transplant and would allow pretransplant intensification.<sup>114</sup> Improved techniques for detection of MRD and long term prospective study of large, comparable cohorts of patients has shown that clearance of MRD is an independent prognostic factor in childhood ALL.<sup>115</sup> This has opened the way for clinical application of MRD measurement in the management of ALL and this is incorporated into the current UK ALL trial (see below).

In AML, studies on the use of MRD measurement and drug resistance are underway.

### TREATMENT

The treatment of acute leukemia requires both the eradication of the leukemic clone, so that normal bone marrow function may be restored, and supportive care during the period of bone marrow failure, both secondary to the disease itself and to the treatment. AML and ALL are both treated with a combination of chemotherapeutic drugs, with or without radiotherapy, but the pattern of treatment is quite different. In AML, the treatment is concentrated in four or five intensive blocks over a period of 6 months or so whereas in ALL, the treatment begins with an induction block, then intensification blocks followed by a period of maintenance for up to 2 years in girls and 3 years in boys.

### Supportive care

Intensive chemotherapy requires expert supportive care best given in a limited number of centers familiar with the treatment of leukemia in children. A multidisciplinary team including nurses, physiotherapists, pharmacists and social workers delivers all aspects of hospital treatment and care of the child at home. In the UK most children are treated within United Kingdom Children's Cancer and Leukemia Group (UKCCLG) centers. Results from such centers are superior to ad hoc therapy elsewhere. In many cases care is shared to some extent with pediatricians in hospitals closer to the patients' homes.

### Acute lymphoblastic leukemia

The dramatic increase in survival rates from ALL has been achieved by carefully planned progressive randomized trials.<sup>116</sup> Most regimens for ALL are based on the schema in Figure 23.28 and the drugs used are variations of these. With this type of treatment over 97% of patients achieve a remission within the first 4 weeks. Following this, additional blocks of intensification are required, including drugs not used in the first phase, to eradicate residual resistant leukemic clones. CNS-directed treatment is given during this phase. For those with CNS disease, intrathecal (i.t.) methotrexate and cranial irradiation are given, but this is not required if the CSF is negative for leukemic cells. In those with a negative CSF and a peripheral white cell count <50 × 10<sup>9</sup>/L, a long course of i.t. methotrexate is effective and for those with counts ≥50 × 10<sup>9</sup>/L high dose i.v. methotrexate is used in addition to i.t. methotrexate.<sup>112,117,118</sup>

The UKALL XI study (1990–97) failed to show benefit when compared to the previous study, UKALL X, with an event-free survival (EFS) at 8 years of 61%.<sup>109</sup> Overall survival (OS) at 8 years was significantly better however, 81% versus 74%, owing to improved management of relapse. Although patients may be salvaged with further treatment, it is at the price of greater toxicity. To address the lower EFS, the next Medical Research Council (MRC) trial, MRC ALL 97/99, used the NCI criteria assigning patients to three different risk categories increasing the intensity of induction therapy and intensification blocks with increasing risk. Once completed, maintenance therapy (daily thiopurine, weekly oral methotrexate and monthly pulses of vincristine with 5 days of steroid) continued for a total treatment period of just over 2 years for girls and 3 years for boys. Dexamethasone was compared with prednisolone and 6-mercaptopurine with 6-thioguanine in a randomized way. Patients with high risk factors such as bcr/abl, hypodiploidy or t(4;11) were considered for allogeneic HSCT during first remission of disease.

Early results (trial closed in June 2002) are encouraging showing an 81% EFS at 5 years.<sup>119</sup> Five-year EFS was significantly better for those on dexamethasone compared with prednisolone, 84% versus 76%, with a decrease in both CNS and non-CNS relapse; 6-thioguanine has been replaced by 6-mercaptopurine in both the intensification and maintenance phases of treatment due to association with veno-occlusive disease.<sup>120,121</sup> The current UKALL 2003 trial is designed to see whether treatment can be reduced without compromising efficacy in MRD-defined low risk groups and whether postremission intensification can improve outcome in MRD-defined high risk groups.

### Relapsed ALL

The commonest type of relapse occurs in the bone marrow following cessation of therapy. Most occur in the first year after stopping therapy with a diminishing risk thereafter. Further investigation may reveal disease in other sites, particularly the CNS or testicles or both. Relapse at other sites such as the ovary, eye, tonsils and skin is very rare. All relapses require intensive chemotherapy with CNS-directed therapy and appropriate local therapy. The intensity of treatment prior to relapse appears to influence the chance of success of further treatment. The usual treatment plan includes the standard four-drug induction therapy and subsequent intensification with different drugs in high dosage in an attempt to eradicate the residual resistant disease. For those in a high risk group (predominantly patients with early relapse, fewer than 6 months off treatment) once in remission, allogeneic HSCT from a

Fig. 23.28 Scheme for treatment of acute lymphoblastic leukemia. Drugs listed are only examples of those which can be used.

related or unrelated donor is indicated. A retrospective analysis of children on the UKALL R2 (R for relapse) protocol shows an OS of 56% and EFS of 47%. Duration of first remission and immunophenotype but not sites of relapse were predictive of survival. When stratified according to the Berlin-Frankfurt-Münster criteria, the OS and EFS were as follows: for standard risk 92% and 92%, intermediate risk 64% and 51%, and high risk group 14% and 15%. Those with very early isolated CNS relapse (<18 months from diagnosis) had a significantly worse outcome and are now being classified as high rather than intermediate risk. The current UKALL R3 trial is looking to improve outcome in the intermediate risk group by examining whether MRD at the end of induction is a suitable criterion on which to decide whether to proceed with chemotherapy or HSCT.

CNS relapse is the commonest site after bone marrow relapse and should be regarded as a local manifestation of systemic disease. Thus treatment should include intensive systemic therapy as well as local therapy, which is cranial or craniospinal irradiation. With this type of therapy, about one half of patients achieve a long-term remission (> 5 years) unless relapse is very early (see above).

Testicular relapse is the third likely site of relapse but can be treated with a good chance of success, especially if isolated. With intensive systemic therapy, CNS-directed therapy and testicular irradiation, there is a > 70% chance of cure.

## AML

Therapy in AML includes remission induction, CNS-directed therapy and postremission therapy. However, in contrast to ALL, treatment is given in intensive blocks over a shorter duration. This, along with improved supportive care, has resulted in a significant increase in survival over the past 15 years. The MRC AML trial, AML 12, was based on risk-directed therapy, taking account of karyotype and response to treatment (see above). In the good and standard risk groups, chemotherapy alone was recommended, with randomization of four courses versus five, whereas in the poor risk group, transplantation was considered if there was a matched sibling donor. Preliminary analysis suggests there is no survival advantage for five courses over four.

The AML 12 trial (including adults and children) resulted in a 5-year OS of 66% and EFS of 56%. Specific therapy for different subtypes of leukemia is not given except in the case of M3 which responds to all-trans retinoic acid (ATRA) in conjunction with the standard chemotherapy. CNS-directed therapy is given as three courses of triple i.t. therapy. If CNS disease is present, an extended course of i.t. therapy is given with cranial irradiation at the end of treatment for those > 2 years of age. The current AML 15 trial tests the feasibility of reducing anthracycline dosage by comparing with high dose ara-C and whether targeted chemotherapy offers an advantage.

## HSCT

The principle of HSCT is the provision of a source of hemopoietic stem cells to repopulate the bone marrow after conditioning therapy has destroyed the patient's own bone marrow cells. The sources of hemopoietic stem cells include bone marrow, peripheral blood and cord blood.

Allogeneic stem cells may be obtained either from an HLA-identical sibling, a partially matched relation or unrelated donor. The most data currently available are from transplants with matched sibling donors, although increasing experience is being gained with unrelated donor transplantation.

Preparative or conditioning therapy in leukemia is designed to eradicate residual leukemia and immunosuppress sufficiently to prevent graft rejection. Preparative regimens include high dose chemotherapy, with or without total body irradiation (TBI). The morbidity of HSCT, both early and late, is considerable and there is a significant mortality associated with the procedure. It is essential that the use and effectiveness of HSCT in the treatment of leukemia be carefully monitored in controlled trials to ensure that the benefits outweigh the morbidity and mortality.

## Late sequelae of leukemia therapy

About 30 years ago very few children recovered from leukemia; now more than half survive. Currently around one in a thousand adolescents is a survivor of malignant disease in childhood, many of whom will have been treated in an era of less intensive therapy. Recognition of the long term effects of therapy and their impact upon quality of life is of increasing importance in the management of leukemia. Risk stratification is used to try to identify those who will be cured with less intensive therapy thus reducing toxicity and to target the more intensive therapy at those at greatest risk of relapse. Both chemotherapy and irradiation have long-term effects, but irradiation can be particularly toxic leading to growth retardation, cataracts, hypothyroidism, infertility and other endocrine function disturbances. Chemotherapy can result in cardiotoxicity, predominantly from anthracycline use. The neuropsychologic effects of TBI and different modes of CNS-directed therapy are unknown.

The risk of developing a second malignancy after successful treatment of leukemia is low with an estimated cumulative risk of around 2.5% at 15 years. The majority of tumors develop in the radiation field and exposure to radiotherapy appears to have a continuous risk of a second neoplasm.

It is essential that long term survivors of childhood malignancy are carefully followed up and late effects recorded so that appropriate modifications to therapy can be made for current and future generations of patients.

## INCIDENCE AND PREVALENCE

The cumulative incidence rate for cancer in children less than 15 years in the UK from 1981 to 1990 was 1774 per million with an age-standardized rate of 122.1 per million for England and Wales and 1806 and 124.9 per million for Scotland.<sup>1,2</sup> This means that of the 10 million children in the UK approximately 1200 (1 in every 8000) are diagnosed with cancer every year, which equates to 1 child in every 600 developing a malignancy before their fifteenth birthday.<sup>3</sup> Relative and absolute incidence figures for individual tumor types are shown in [Tables 24.1 and 24.2](#) (derived from Parkin et al<sup>3</sup>). The total incidence of childhood tumors is constant around the world, with cumulative incidences (0–15 years) in the range of 1–2.5 per 1000 and age-standardized rates between 70 and 160 per million.<sup>3</sup> There are marked variations in the incidence of particular types of childhood cancer between countries and geographical areas. These variations may be caused by other diseases masking cancer and variable diagnostic and reporting methods, as well as genuine variations in incidence due to differences in a variety of genetic and environmental factors.

It is essential to have comprehensive population-based registration of all cancers in a particular region or country before firm conclusions about such variations can be drawn. This requires a universal agreement on tumor classification.<sup>4</sup> The standard system used is the international classification of childhood cancer developed in collaboration with the International Society of Pediatric Oncology based on the Birch and Marsden scheme.<sup>5,6</sup> Whereas most malignancies in the adult population are carcinomas, childhood malignancies are much more diverse and classified histologically or molecularly rather than by primary site.

Acute leukemia is the commonest individual childhood malignancy in the UK and accounts for 30% of malignant disease. Acute lymphoblastic leukemia (ALL) accounts for 80–85% of cases. A childhood peak between 2–6 years of age in ALL is seen in resource rich countries. Acute myeloid leukemia (AML) shows less variation except for apparently high rates among indigenous Pacific Island populations. Genetic variations alone, or in combination with environmental factors, may explain the high rates of certain malignancies. Infectious environmental factors undoubtedly explain the high incidence of B cell lymphomas in equatorial Africa and variations in overall and subset types of Hodgkin disease around

M/F ratio, male to female ratio; ALL, acute lymphoblastic leukemia; ANLL, acute nonlymphoblastic leukemia.

the world. Other variations such as the low incidence of Ewing sarcoma seen in West Africa and among Afro-Caribbean Americans have not yet been explained. Similarly, the reason for sex differences in incidence and survival seen for many tumors are not understood (Table 24.2).

The incidence of cancer in childhood is increasing. Significant linear increases in precursor B ALL (average annual increase 0.7%) and Hodgkin disease (1.2% average annual rise) have been reported in the North West of England over the 45-year time period 1954–1998.<sup>7–9</sup> CNS tumors and extracranial solid tumors appear to have an annual increase in incidence of approximately 1%. These increases are not solely attributable to changes in diagnostic or reporting practice and at present lack a biological explanation.<sup>7–10</sup>

The prevalence of childhood cancer patients in the general population is rising dramatically. This is to a large extent the result of improved survival. Table 24.3 shows the survival trends for individual tumor types over the last two decades (data derived from the UKCCSG scientific report compiled by C Stiller<sup>11</sup>). Approximately 1 in 900 individuals aged 20 years are now cancer survivors. Long term effects of their cancer and its treatment now present a significant public health concern. However, despite successful treatment in many cases, childhood cancer still constitutes the second commonest cause of death after accidents for those aged 5–14 years. After the first month of life cancer accounts for 1 in 10 of all childhood deaths.<sup>12,13</sup>

## CAUSATION, TREATMENT AND SURVIVAL – GENERAL POINTS

Table 24.3 gives 5-year actuarial survival showing significant improvement for the majority of cancers until 2002. Prognostic factors for each tumor type are discussed in the individual sections but some general factors are important. Improvement from 10% to 70% overall survival and 60% long term cure for all childhood cancers over the last 35 years has been achieved by the use of multi-agent chemotherapy along with radiotherapy and surgery for local tumor control. This complex treatment is delivered in specialized centers with a multidisciplinary team approach, as acute toxicity often requires intensive nursing support and a comprehensive blood transfusion service. Worldwide this treatment is only available to less than 20% of all children. One of the great challenges for the future is to extend the availability of such care throughout the world.<sup>14</sup>

Pediatric oncology has vigorously embraced the approach of randomized controlled trials and more recently the use of overview analyses.<sup>15</sup> The success of this approach is shown by the increase in survival rates for childhood leukemia at specialized centers from 77% in the years 1980–1984 to 89% in the period 1990–1994.<sup>16</sup> Five-year survival rose from 67% to 81% over this time. Entry of patients into therapeutic trials showed an even greater difference with 5-year survival figures of 64% for those treated off protocol in 1980–1984 compared with 70% when treated on a trial, while for the later time period (1990–1994) the figures were 68% and 84%. These figures translate into an increased annual survival of over 50 patients in the 1990s who would have died of their disease in the 1980s. Centralization of care has also been demonstrated to improve survival for acute nonlymphoblastic leukemia, non-Hodgkin lymphoma, neuroblastoma, osteosarcoma, Ewing sarcoma and rhabdomyosarcoma.<sup>17</sup> The effect of trial entry includes an increased emphasis on protocol compliance,

**Table 24.3** Five-year actuarial survival percentage of patients treated in United Kingdom Children's Cancer Study Group Centers 1977–1999 by period of diagnosis. more consistent supportive care, audit and sharing of toxicity data and international exchange of information. Adoption of the 'best' therapy from other reported trial groups has become a feature of modern oncology therapy.<sup>18</sup> Further improvement is likely to result from more extensive collaborative efforts on an international level to reach meaningful patient numbers in addition to a better understanding of the biology of the individual malignancy.

## ETIOLOGY

Little is yet known about the cause of most childhood cancers. Single environmental factors, e.g. smoking, which play a significant part in adult malignant disease, have not been identified for childhood malignancies (see below). Genomic damage that leads to malignant transformation takes time to develop, which explains the rising incidence of cancer with age in the general population, where cancer is a common disease. In childhood malignancies it is likely that genetic factors play a more important role in the etiology. A strong genetic basis for some childhood malignancies can be inferred from the observation of a high incidence of malignancies in certain genetic syndromes (Tables 24.4 and 24.5). These account for a minority of childhood cancers. However, susceptibility to childhood malignancies associated with genetic variation, which could affect handling of environmental factors or genomic damage, might account for a greater proportion

of childhood cancers. The UK-wide National Case Control Study was established in 1991 in order to determine the role of exposure of parental germ cells, or children, to ionizing radiation, extremely low frequency electromagnetic fields or chemicals in the causation of childhood cancer.<sup>19</sup> Overall, a picture is emerging that the role of these environmental factors in the causation of childhood cancers is very limited. However, there is emerging evidence that abnormal responses to one or more common infections may play a role in the etiology of hematological and solid malignancies. This hypothesis suggests that there might be a paucity of exposure to infections in infancy and subsequent exposure shortly before the onset of cancer symptoms. However, even if common environmental factors like infections play a role for the initiation or progression of malignant diseases in children, genetic factors, which determine the host response at a given time in life will be important.

## INHERITED PREDISPOSITION TO CHILDHOOD CANCER

The proportion of childhood tumors which are truly hereditary is estimated to be less than 5%, but might be higher.<sup>20</sup> Germline mutations may be inherited from parents (e.g. the retinoblastoma gene in familial retinoblastoma or the p53 gene in Li-Fraumeni syndrome). New genetic rearrangements and mutations may also arise within the oocyte or sperm prior to fertilization (e.g. in Down syndrome where there is a significantly increased risk of developing leukemia). Some tumors, for example nephroblastoma, are associated with more than one genetic syndrome.<sup>21</sup> Other cancers cluster in families, and predisposing genes are not all yet fully defined.

## Constitutional chromosomal disorders

These disorders are usually characterized by a specific phenotype and associated with increased risk of malignancy. Altered chromosome number (aneuploidy) or structural rearrangements can be detected by routine karyotyping. The most common abnormality is constitutional trisomy 21, Down syndrome. These children have a nearly 20-fold increased risk of developing leukemia (1 in 100 compared with the general population of 1 in 2000 by the age of 10 years).<sup>22,23</sup> Interestingly many constitutionally normal childhood ALL patients have trisomy 21 in the leukemic cells, but the relevant genetic changes involved have not yet been fully elucidated. Both ALL (60%) and AML (40%) occur in Down syndrome but with many more AML cases in young children (under 2 years) than in the overall childhood leukemic population. A high percentage of such patients have acute megakaryocytic leukemia (M7) which is very responsive to therapy. Provided toxicity can be controlled Down patients fare as well as if not better than non-Down patients.<sup>24</sup> Further studies are now underway to explore why excess material of chromosome 21 not only plays a role in the development of leukemia but also seems to lead to excess toxicity with chemotherapy.

Numerical or structural sex chromosome abnormalities are also associated with an increased risk of malignancy. The extra X chromosome material seen in Klinefelter syndrome is associated not only with an increased risk of breast carcinoma but also with acute leukemia, lymphoma and extra gonadal germ cell tumors. Sex chromosome aneuploidy is associated with retinoblastoma in the conditions where there is excess of Y chromosome material. In 45 X0 Turner syndrome, there is increased risk of malignant transformation of rudimentary gonad tissue, but also increased risk of neuroblastoma, Wilms tumor and other malignancies.<sup>20</sup>

Detailed analysis of some chromosomal abnormalities has led to the identification of important genes involved in tumorigenesis in children. For example, chromosomal analysis of children with WAGR syndrome (consisting of Wilms tumor, aniridia, genital abnormalities and mental retardation) led to the initial identification of the WT1 gene on 11p13, as a number of children with these abnormalities were found to have a deletion at 11p13. A small percentage (1–3%) of Wilms tumor patients were identified as having aniridia, often with a degree of developmental delay and genital abnormalities including hypospadias.<sup>25,26</sup> Subsequently disruption of this locus was also found in the

Denys-Drash syndrome (characterized by severe urogenital abnormalities and Wilms tumor). However, there are other families reported with apparent dominant inheritance of Wilms tumor that do not have mutations at 11p13, and Wilms tumor has been reported in many genetic syndromes.<sup>21</sup> This implies that disruption of genes encoding for proteins involved in a variety of cellular functions can contribute to the genesis of this tumor. This includes two syndromes involving tissue overgrowth, Beckwith-Wiedemann (intrauterine and postnatal overgrowth,

organomegaly, macroglossia and linear ear creases linked with nephroblastoma and hepatoblastoma) and hemihypertrophy (asymmetrical overgrowth of one side of the body, or face alone, linked with Wilms tumor). The risk in both conditions is high enough to warrant regular abdominal ultrasonography in patients recognized to have such overgrowth. The genetics of these syndromes are complex and can involve other mechanisms of genetic changes, such as imprinting. The insulin-like growth factor 2 gene (IGF2), which is normally a maternally

imprinted gene but expressed from the paternal copy, is the gene involved in Beckwith–Wiedemann syndrome.<sup>26</sup> In many pediatric tumors the normal delicate balance of proliferation, differentiation and programmed cell death, apoptosis, is disturbed by the inappropriate activation of genes that promote proliferation, and inappropriate suppression of pathways which normally prevent proliferation. A complex picture is emerging that not only points at genetic changes affecting DNA structure, but also changes involving expression, transcription and indeed post-translational modification of encoded proteins (see below).

### Single gene disorders

Table 24.4 shows some of the disorders predisposing to childhood tumors, inherited in an autosomal dominant fashion through several generations. There may be individuals with the same genetic mutation who have no or minimal overt manifestations of the malignant phenotype. The characteristics of these autosomal dominant cancer family syndromes are that:

1. inheritance can be from either father or mother;
2. multiple generations are most likely to be involved;
3. onset of the cancer will be at an earlier age compared with sporadic cases of the same cancer;
4. there are more likely to be multiple rather than single tumors;
5. there may be a clustering of increased risk of one or several different types of tumor within the family.

Retinoblastoma is the most carefully documented genetically determined tumor of childhood. In 1971 Knudson proposed that bilateral retinoblastoma was the familial form of this condition and patients had already acquired a germline mutation. His two-hit hypothesis proposed that such patients only required one further somatic cell hit for the tumor to develop whereas sporadic retinoblastoma, which occurs at an older age, requires at least two somatic mutations in the same cell for the tumor to develop. The affected gene, Rb1, is located on chromosome 13q14.1–14.2 and the normal function of the Rb1 gene product is to negatively regulate cell division (tumor suppression). Loss of this function gives rise to tumor development. Since in the inherited form all cells of the body contain the first mutation, tumors can arise not only in the retina but theoretically anywhere else. These other tumors do occur especially in the pineal gland, bone and soft tissue (particularly in response to irradiation), and skin as melanoma. In the nonhereditary form only retinal tumors develop. In the inherited form the second event may include loss of the whole chromosome 13, deletions and gene conversion. The complexity of genetic changes and phenotypic findings however is exemplified by the fact that about 15% of unilateral retinoblastoma are of the inherited type, which is not completely explained. There may also be no family history, either because the mutation has arisen *de novo* in the affected child or because there may be a mild form of the tumor in parents (known as a retinoma) which has spontaneously regressed. This sometimes can be identified by careful examination of the retina. Life-long follow-up of patients with inherited retinoblastoma shows them to progressively develop other malignancies over their lifetime including osteosarcoma and malignant melanoma as well as, in later life, carcinomas.<sup>27</sup> Another tumor suppressor gene involved in pediatric and familial cancers is the TP53 gene located at 17q12–13. Li and Fraumeni detected an increased incidence of breast cancer in mothers of young children with soft tissue sarcoma.<sup>28</sup> Considerable clustering of cancers including sarcomas, breast carcinoma, leukemias, brain tumors and adrenocortical carcinomas is seen in these families.<sup>29,30</sup> Malkin et al reported germline point mutations in the TP53 gene in a large number of such families.<sup>31</sup> However in some families with such a pattern of increased incidence of malignancy no p53 mutations have been found, suggesting that other genes within the same or interacting cellular pathways e.g. cell cycle control, can also be involved. The relationship between specific mutations within the gene and the malignant phenotype might also apply to other cancer genes. It is estimated that about 3% of osteosarcomas, 5% of rhabdomyosarcomas and probably all adrenocortical carcinomas are associated with germline TP53 mutations.<sup>32</sup>

Adenomatous polyposis coli and Gardner syndrome are characterized by the development of multiple colonic polyps in childhood and adolescence with progression to colon carcinoma in the second and third decade of life.<sup>33,34</sup> Individuals affected by these conditions also have an increased risk of other gastrointestinal and liver malignancies (including childhood hepatoblastoma). The syndrome involves the APC gene on 5q21. Molecular diagnostic testing of at-risk individuals, regular colonoscopy and surgical intervention can be life-saving in young patients. Another familial condition, hereditary non-polyposis colon cancer syndrome (HNPCC), involves right-sided colon tumors arising as early as the second decade of life. Such tumors can arise as a result of mutations in the mismatch repair gene hMSH2.<sup>35</sup> Many genes are for the maintenance of DNA integrity and mutations of these genes appear to prime cells for mutagenesis.<sup>36</sup> Turcot syndrome, in which familial clustering of brain tumors in childhood and polyposis/colon cancer is found, has been shown to involve mutations of the APC gene in some families and of mismatch repair genes in others (hMLH1 and hPMS2).

There are at least three forms of the multiple endocrine neoplasia (MEN) syndrome, all inherited in an autosomal dominant fashion. MEN2A can affect children (medullary thyroid carcinoma, pheochromocytoma), MEN2B (also includes ganglioneuromas of the gut and skeletal abnormalities) can even affect infants. The gene involved in MEN2A is the proto-oncogene RET (receptor tyrosine kinase gene) located on chromosome 10q11.2.<sup>37</sup> Neurofibromatosis type 1 which affects 1 in 2500 of the population is described elsewhere in the text. The NF1 gene (17q11.2) has been identified for over a decade. Its product, neurofibromin, acts as a transcriptional modulator during development of nerve and muscle. Mutations are associated with a range of benign and malignant neoplasms as well as the characteristic stigmata of the syndrome. NF2, which is much rarer, is related to a separate gene on chromosome 22 and is characterized by café-au-lait spots, bilateral vestibular schwannomas, neurofibromas and meningiomas and rarely presents in adolescence.

Other phakomatoses including tuberous sclerosis (TS) and von Hippel–Lindau disease (VHL) are associated with a range of benign and malignant neoplasms. In tuberous sclerosis these are mostly giant cell astrocytomas, but also other other tumors have been described; in VHL renal cysts and carcinomas, pheochromocytomas, cerebellar hemangioblastomas and retinal angiomas have been described. The nevoid basal cell carcinoma syndrome (Gorlin) is characterized by an association of early onset basal cell skin lesions and medulloblastomas.

Disorders which are recessively inherited appear to be less frequently or obviously associated with cancer early in life (Table 24.5). Some of that rarity may relate to failure to recognize the recessive disorder, without obvious family history and overt signs of disease at the time of cancer diagnosis. There are however some notable exceptions in childhood which predominantly involve genes involved in maintenance of DNA integrity and the DNA damage response, disruption of which leads to increased DNA fragility (spontaneous or in response to exogenous compounds such as irradiation or toxic chemicals) and in some cases immunodeficiency.

Xeroderma pigmentosum is characterized by eye and skin sensitivity progressing to basal and squamous cell carcinomas, melanomas and tip of tongue carcinomas. These lesions are all in sun-exposed areas but internal malignancies may occur. Some children show neurological deterioration. Mutations can occur in several genes and result in a defect in nucleotide excision repair.<sup>38</sup> There are related disorders, trichothiodystrophy and Cockayne syndrome. Ataxia telangiectasia (AT) presents in childhood with progressive truncal and subsequent limb ataxia, choreoathetosis and ocular motor apraxia. Telangiectasiae usually start in the conjunctivae in the first 5 years of life. However, many patients are missed until they present with leukemia and/or lymphomas.<sup>39</sup> Thirteen percent of UK-registered cases of AT have leukemia or lymphoma. There is associated deficiency of IgA and IgG, leading to sinopulmonary infections. It would appear that AT heterozygotes (1–2% of the population) are at much greater risk of developing breast cancer than the general

population, possibly due to increased sensitivity to environmental DNA damage such as ionizing radiation. The DNA of homozygotes is highly sensitive to damage from radiation and chemicals.<sup>40,41</sup> The AT gene on chromosome 11q22–33 encodes for a protein with kinase activity and signal transduction function.<sup>42</sup> Loss of AT results in a failure of normal cell cycle control. Nijmegen breakage syndrome (NBS) is a disorder with overlapping clinical features with AT such as immunodeficiency, but also marked microcephaly without telangiectasia, which is also associated with non-Hodgkin lymphoma, but also brain tumors and soft tissue sarcoma.<sup>43,44</sup> The inherited disease Fanconi anemia (FA) shares some clinical feature of related disorders AT and NBS1 such as microcephaly and café au lait skin pigmentations. Characteristically there is hypersensitivity to DNA damaging agents, such as mitomycin C and other cross-linkers. FA patients can exhibit complex congenital abnormalities, but can also appear entirely normal. They are at extreme risk of progressive marrow failure and acute myeloid leukemia, but also brain tumors and Wilms tumor in addition to squamous cell carcinoma. There are at least 12 genes that can be mutated in FA, which are both autosomal and X-chromosomal. Most FA patients carry mutations in the FANCA gene (60%), followed by FANCC and FANCG (both approximately 15%).<sup>45</sup> The other genes appear less commonly mutated in FA patients, but might be extremely important in familial cancer syndromes, as patients of the rare Fanconi-D1 group carry mutations in the BRCA2 gene.<sup>46,47</sup> Heterozygous BRCA2 mutation carriers are at very high risk of developing breast, ovarian and pancreatic cancer, and it is quite possible that heterozygous carrier status of mutations and also other genes encoding for proteins involved in maintenance of DNA integrity play a significant role in cancer in the general population.

### Genetically determined immunodeficiency

Where immune competence is impaired by inherited defects such as AT and NBS1 there is a high risk of leukemia and lymphoma development<sup>48</sup> (Table 24.6). Similarly, other forms of inherited and acquired immunodeficiency secondary to chemotherapy, intensive immunosuppression and infection predispose to malignancy, especially of lymphoid tissue (see below under lymphomas). With the increased burden of clinical AIDS resulting from HIV infection, especially in the resource rich world, and the more sophisticated use of immunosuppressant therapy this problem is growing.

### GENETIC SUSCEPTIBILITY

The concept that some individuals may be more susceptible to develop genetic changes leading to malignancy is currently the subject of detailed investigations. Inappropriate maintenance of DNA integrity in response to ultraviolet light is seen in xeroderma pigmentosa (XP), in response to irradiation in ataxia telangiectasia and to cross-linking chemicals in Fanconi anemia (FA). For other cancer predisposing syndromes, immunodeficiency is a common clinical feature, while epidemiological data also point to a role for infectious agents. Additional factors might arise from differences in metabolizing enzymes, which might play a role especially in early development. For most sporadic childhood tumors we now suspect a combination of environmental factors with an inherent aberrant response, probably genetically determined, at a vulnerable point during development, to be at the root cause of the malignancy.

Most progress has been made in our understanding of infant and childhood ALL. Evidence from identical twins and retrospective analysis of neonatal blood spots has identified that for some, if not all such leukemias, initiation of the first genetic changes occurs before birth.<sup>49,50</sup> Genetic rearrangements involving the MLL gene, which are present in the majority of infant leukemias, appear adequate for development of overt leukemia. However, for precursor B cell ALL (peak age 2–6 years) additional postnatal genetic events are required. Carriage of the commonest leukemia-associated gene rearrangement TEL-AML1 (a cryptic translocation involving chromosomes 12 and 21) has been found in a frequency as high as 1–2% in normal cord blood.<sup>51</sup> Genetic epidemiological studies have found that the risk of developing infant MLL-associated leukemia is increased in pregnancies where the mother carries a low functioning polymorphic variant of the metabolizing NQO1 gene.<sup>52</sup> This protein plays a role for detoxification of quinone-containing substances which include both naturally occurring and synthetic topoisomerase 2 inhibitors.<sup>53,54</sup> Topoisomerase inhibitors can cause DNA breaks to be inappropriately relegated and may lead to genetic rearrangements. Dietary bioflavonoids can induce MLL cleavage and may contribute to infant acute leukemia.<sup>55</sup> Low function of the methylene tetrahydrofolate reductase (MTHFR) appears to confer protection against infant leukemia and precursor B cell ALL with hyperdiploidy. Low function MTHFR leads to greater available folate and increased DNA stability.<sup>56</sup> There has been some evidence that dietary supplementation with folate early in pregnancy may afford some protection against the development

**Table 24.6** Recessive, sporadic and X-linked syndromes associated with childhood cancer

Syndrome	OMIM	Inheritance	Locus	Gene	Associated malignancy
Xeroderma pigmentosum	278720	AR	19q13 and others	ERCC2 and others	Skin cancer, melanoma

OMIM, Online (database of) Mendelian Inheritance in Man.

of childhood ALL.<sup>57</sup> In a similar fashion variations in genes encoding for other metabolizing enzymes have been investigated. In all of these instances dietary factors interact with the ability to metabolize/detoxify and appear to increase or decrease the risk of DNA damage. It is possible that other genetically determined factors, e.g. polymorphic variation within the more than 150 genes involved in DNA repair or genetic variants in genes that handle xenobiotics or other environmental factors as discussed below, may play a part in carcinogenesis in children.

In precursor B cell ALL abnormal response to infection may play a part in the later events or proliferation of the malignant clone. There is evidence that HLA class II alleles might influence risk.<sup>58</sup> Supportive evidence for a role of environmental, possibly infectious, agents in causation of childhood cancer comes from epidemiological studies detecting a rising incidence, onset seasonality and space–time clustering in leukemia, some lymphomas and solid tumors.<sup>7,8,59,60</sup>

## ENVIRONMENTAL FACTORS

### Ionizing radiation

#### *Prenatal exposure*

Stewart et al first reported an approximately 1.5-fold increase in childhood cancer for those fetuses exposed to X-rays performed on the maternal abdomen and pelvis during the first trimester of pregnancy.<sup>61</sup> There appeared to be a dose–risk relationship. Some but not all subsequent studies have confirmed an apparent increased risk associated with intrauterine X-ray exposure. In a series of studies on 1599 children born to mothers exposed to the Hiroshima and Nagasaki atomic bombs, those who received doses above the threshold of 10–20 cSv showed evidence of small head size, mental retardation and seizures.<sup>62</sup> Yoshimoto et al reported a 38% increase in cancer, with no dose threshold for those exposed in utero to atomic bomb irradiation, a similar rate to those exposed in the first decade of life in Japan.<sup>63</sup> In recent times there has been an interest in the concept of preconception effects particularly from radiation to the paternal germline.<sup>64</sup>

#### *Postnatal exposure*

Children who were within 1 kilometre of the epicenter of the Hiroshima bomb experienced an excess of acute and chronic myelogenous leukemia and acute lymphoblastic leukemia 3–10 years after the exposure. Young people surviving the atomic bomb have still developed thyroid and other adult cancers even decades after the event.

Therapeutic (low dose) external irradiation delivered to the scalp for tinea capitis or to the thymus have both been associated with significant increases in leukemia, brain tumors and thyroid carcinoma.<sup>65,66</sup> Dosages to the infant thyroid as low as 0.2 cGy have been reported in association with the development of carcinoma 12–17 years later. Speculation about the effects of radionuclide ingestion from fallout has mostly centered on military personnel observing nuclear tests, although there has been a reported excess of childhood leukemia in Utah following exposure to fallout from atmospheric nuclear detonations.<sup>67</sup>

An increased risk of childhood malignancy, specifically leukemia, has been reported around nuclear reprocessing plants in the UK and elsewhere.<sup>68–71</sup> Studies of known environmental nuclide levels, routes of access and associated exposure to chemicals have failed so far to explain this risk. However, population mixing, and abnormal infection response might also account as a possible etiological factors in these communities.<sup>72</sup> The UK National Case Control Study has failed to show any relationship between household radon or gamma irradiation and the incidence of childhood malignancy.<sup>73–75</sup> However, irradiation (and chemotherapy) as treatment for a primary malignancy carries a definitive risk for development of a second tumor (see section ‘Specific late effects’, p. 1000).

There may be a life-long risk for children who receive extensive diagnostic X-rays with radiation dosages in excess of 10 cSv, in terms of developing breast and prostate cancer and leukemia in later life. Since such procedures cannot often be avoided clinicians need to be careful in their choice of procedure and avoid repetitive scanning wherever

possible (a CT scan of the head and body gives an effective body radiation dose of 0.1 cSv, while for a plain chest X-ray the dose is 0.008 cSv).

It is clearly important to remember that some children (e.g. with germline mutations of the Rb1, ATM, NBS1, FA genes or nevoid basal cell carcinoma genes) are particularly sensitive to ionizing irradiation, and that they may not be recognized as carrying the risk at the time of X-ray exposure. On the other hand, current exposure to radiation with diagnostic X-rays is extremely small compared with historical data.

### Ultraviolet radiation

The fastest rising cancer incidence in the UK is for skin malignancy resulting from increased sunlight exposure on sunshine holidays and sunbed usage. The risk begins in childhood with unprotected and excessive sun exposure although the actual incidence of skin cancer in childhood is low.<sup>76</sup> Preventative measures are effective and population education needs to be enhanced (use of hats, clothing, sunscreens and avoidance of prolonged and/or repeated exposure to sun in childhood). The pediatrician has a key role in such education. Patients with xeroderma, Gorlin syndrome and albinism are at dramatically increased risk. The risk of developing melanoma appears to be increased if the sun exposure is obtained in conjunction with repeated exposure to chlorinated water in open air swimming pools. Some byproducts of chlorination are clearly mutagenic.<sup>77</sup>

### Electricity and electromagnetic fields

Wertheimer and Leeper<sup>78</sup> reported an excess of childhood cancer in those exposed to excess electromagnetic fields derived from household electrical wiring. Subsequent studies where actual magnetic field measurements have been recorded have not consistently supported this observation. In the UK the large National Case Control Study has found no evidence to support such a relationship,<sup>79</sup> although the percentage of UK houses found to have high levels of exposure (greater than 0.4 micro-Tessler) was very small. By contrast, a Swedish study relating proximity to power lines and generated magnetic fields showed an apparent dose relationship with leukemia but not with all cancers, brain tumors or lymphomas.<sup>80</sup> Overall analysis does suggest the differences in study design might explain the conflicting results but for the vast majority of UK homes there appears to be no risk from generated electromagnetic fields nor from adjacency to power lines.

### Drugs

#### *Prenatal*

Diethylstilbestrol is the only established transplacental carcinogen and exposure is associated with clear cell carcinoma of the vagina and cervix in female offspring as well as genital anomalies in both sexes.<sup>81</sup> Maternal phenytoin has been associated with increased incidence of neural crest tumors, and maternal alcohol with adrenal, neural crest and liver tumors and teratomas.<sup>82</sup> There may be a long latent period, e.g. the vaginal tumors did not occur until the children exposed to stilbestrol before 20 weeks of gestation were aged 14–23 years.

#### *Postnatal exposure*

Intensive immunosuppression (e.g. in solid organ transplantation) is associated with a 20- to 40-fold increased risk of developing lymphoma with a short latent period. Modern intensive cancer therapy carries an increased risk of inducing secondary leukemia (mostly acute myeloid leukemia) and other neoplasms (e.g. brain). Chronic malnutrition, by inducing immune paralysis, coupled with chronic infective antigenic stimulation may be important in the induction of B cell neoplasias in tropical Africa.

There is an increased risk of developing AML for those treated with alkylating agents for other tumors (at the rate of 5–10% over the 10 years following exposure).<sup>83</sup> The most common alkylating agent used, cyclophosphamide, which can induce hemorrhagic cystitis, has also been incriminated as causative of bladder cancer. The exact risk for children treated with cyclophosphamide for either cancer or renal problems has not been adequately quantified but the avoidance of combined

irradiation and alkylating agents especially when the bladder is involved appears wise. The increasing use of the highly effective cytotoxics, the topoisomerase 2 inhibitors (epipodophyllotoxins and anthracyclines) has been associated with a rise in early onset (median 30 months) therapeutically induced acute myeloid leukemia. The risk appears to be dose and schedule dependent.<sup>84</sup> For both alkylators and topoisomerase 2 inhibitors concurrent use of other cytotoxics and irradiation may increase the risk, although a genetic component is also likely to play an important role in these treatment related malignancies.

Long term use of androgens and other anabolic steroids has been associated with the development of hepatomas. Barbiturates used frequently and in high dosage in early infancy have also been incriminated in brain tumor formation, and phenytoin with lymphoma, but definitive evidence does not exist.

Golding et al reported that neonates receiving intramuscular vitamin K prophylaxis had an increased risk of developing leukemia.<sup>85</sup> Subsequent studies and more recent pooled analysis of the six major case control studies including that of Golding et al has found no convincing evidence to support the link.<sup>86</sup> The studies however have shown up major variations in clinical practice which need addressing. The risks of hemorrhage in the newborn appear to far outweigh any other risks of vitamin K prophylaxis.

## Chemicals

Table 24.7 shows some of the parental occupations or exposures which have been incriminated in childhood tumor formation.<sup>87</sup> The exposure may be maternal or paternal, e.g. solvent exposure in the aircraft industry may act on the male germ cells which is then transmitted to the fetus. Although close exposure to asbestos mines in childhood was associated with the development in later life of mesotheliomas in the South African population, the rare mesotheliomas of childhood do not appear to be related to asbestos exposure. What has proved very difficult regarding chemicals, unlike with radiation, has been the ability to assess evidence of real exposure and its extent, plus to quantify risks.

There is conflicting evidence regarding parental smoking and alcohol consumption with regard to childhood cancer. Recently some association between smoking and particular subtypes of AML ( $M_1/M_2$ ) has been suggested for young adults.

## Viruses

Although infectious agents have been repeatedly associated with childhood leukemia and cancer no definite evidence has emerged to link any specific viral agent known to cause intrauterine infection with oncogenesis. However, mainly epidemiological data support a promoting role of infection in childhood leukemogenesis while repeated searches for viral genomic inclusion in ALL patients have proved negative.<sup>88-90</sup>

**Table 24.7** Possible parental occupations associated with childhood malignancy

Occupation	Exposure	Tumor type
Petroleum industry	Petroleum	CNS
Lead industry	Hydrocarbons, lead	Wilms (lead)
Aircraft manufacturer	Organic solvents	CNS
Painting		Leukemia, ?hepatoblastoma (paints/pigments)
Paper/pulp mill workers, printing industries	Organic solvents	CNS, leukemia (sawdust)
Farming	Pesticides	CNS, leukemia, Wilms
Metal industries	Heavy metal solvents	Brain, leukemia (metal dust), lymphoma (foundries)

Postnatal exposure to Epstein–Barr virus (EBV) is associated with B cell lymphoid malignancies (Burkitt lymphoma and leukemia) in malarial areas of Africa where they comprise up to 50% of all childhood tumors. African Burkitt lymphoma occurs almost exclusively in areas of endemic malaria with early exposure to EBV (almost the whole population has been exposed by the age of 3 years). Most of the tumors in endemic areas show evidence of inclusion of viral DNA and the most consistently detectable antigen is the EBV surface capsid antigen. Infection early in life is thought to increase the size of certain pre B and B cell populations and maintains them in a proliferative state making them more likely to undergo genetic change. Alternatively EBV may induce an immortal cell clone with genetic transformation already present. Repeated infection, in particular with malaria (itself a T cell suppressor and B cell mitogen), and malnutrition lead to a major degree of T cell immunosuppression and B cell hyperplasia. It is not entirely clear whether the initial infection or subsequent events lead to the very characteristic translocation of DNA from chromosome 8 into the immunoglobulin coding sites on chromosomes 14, 2 or 22. The role of other cofactors, such as plant extracts, in promoting proliferation has not yet been fully evaluated. Outside equatorial Africa where exposure to EBV is usually much later, B cell tumors, especially extensive abdominal lymphomas, have been shown to contain viral antigen but in a lower percentage of cases. There are other differences between the endemic and sporadic cases but the same genetic translocation may be found in both forms. EBV has also been associated with nasopharyngeal carcinoma in nonmalarial areas and rare familial cases of both Burkitt lymphoma and nasopharyngeal carcinoma have been observed in tropical Africa.

EBV has also been linked to Hodgkin disease (HD).<sup>91</sup> In children and young adults it has been postulated that HD represents an abnormal outcome of delayed exposure to a common infectious agent. EBV is found in Hodgkin–Reed–Sternberg cells in a significant percentage of young cases, especially in boys and those with mixed cellularity subtype. What is not yet clear is whether the EBV is causative, contributory or a bystander in young people with altered immune responses.<sup>92,93</sup> Immune response genes may play a critical role in susceptibility to Hodgkin disease.<sup>94</sup>

Post transplantation and following severe immunosuppression for other conditions an EBV-driven lymphoproliferative disorder is increasingly observed (see lymphoma section).

Retroviruses alter the growth and differentiation of cells from various hemopoietic lineages. There is a clear relationship between infection with the retrovirus HTLV1 and a form of adult T cell leukemia and lymphoma,<sup>95</sup> and, although there has been recent speculation about in utero transmission, no childhood case has yet been reported. HIV infection, presumably as a result of its profound effect on helper T cells, predisposes to the development of a particularly virulent lymphoma in young adults. An increasing incidence of Kaposi sarcoma has been reported in African children.

Hepatitis B infection has long been associated with hepatocellular carcinoma. The mechanism of oncogenesis and the role of added effects resulting from other toxins such as aflatoxins still requires clarification.<sup>96</sup> Although some viruses may cause tumors by direct genetic transformation, some clearly induce host responses but the majority so far identified appear to function by oncogene activation. This can lead to interference with cell cycle control (e.g. HPV, E6, E7), or immortalization (EBV) or persistent activation of, for example, NFκB pathway with upregulation of the cytotoxic cascade (e.g. HTLV1 and Tax, or EBV and LMP-1) or promotional effects (mitogen exposure leads directly to proliferation, e.g. HTLV1–Tax gene leading to viral replication, HbV and HcV).

## Other factors

There are other factors that are difficult to categorize in genetic or environmental causes that have been investigated in the context of childhood cancer. The observed association of inguinal hernias in children with Ewing sarcoma as well as other studies that found an increased incidence of isolated congenital abnormalities without defined syndromic association could point to environmental as well as genetic

causes, but again might reflect gene–environment interaction.<sup>97</sup> Several case reports of malignancies occurring in children conceived by assisted reproduction technology (ART) give rise to concern about the neoplastic risk in ART. Several large national studies have failed to show an increased risk, but these studies will need to continue with the use of more sophisticated techniques in ART.<sup>98,99</sup>

## EPIDEMIOLOGICAL CONCLUSIONS

Unlike in adults we have so far failed to identify significant connections between environmental factors and the majority of childhood cancers. Strong predisposition as part of a genetic syndrome accounts for the minority of cases but increasingly it is recognized that genetic susceptibility may play a significant part in a large number of tumors by altering response to or repair of damage caused by exogenous factors including viruses, chemicals, irradiation, etc. Initiation of the genetic damage, accumulation of a full malignant phenotype and ultimately proliferation of a premalignant clone require an accumulation of contributory factors. Each childhood tumor is likely to have a different combination of such factors in its etiology.

## GENERAL PRINCIPLES OF DIAGNOSIS

A complete history and thorough clinical examination will suggest a diagnosis in most childhood malignancies. Histology is usually needed to confirm the diagnosis. Radiology is necessary to determine disease extent, and specific tumor markers (eg alpha fetoprotein in germ cell tumors) and baseline renal, liver and bone profiles are essential. Full blood count and coagulation profile are also needed, and it is useful to check the patient's antibody status to varicella and measles at diagnosis.

## PATHOLOGY

Liaison with the pathologist about the clinical picture is crucial to successful diagnosis and a regular multidisciplinary review meeting bringing together radiology, clinical findings and histopathology should be standard practice. Morphology on H&E section is complemented by immunohistochemistry, cytogenetics, and DNA studies for specific gene abnormalities. Parental consent should be sought for tumor and constitutional DNA storage (from lymphocytes) for future study. Central review of pathology is mandatory for patients on clinical trials and has enabled audit and consistency of diagnosis.

## RADIOLOGY

Specific radiological investigations will be discussed under each tumor heading but some general principles are important. Plain radiographs may be very suggestive of a specific diagnosis, e.g. suprarenal calcification in neuroblastoma, but are never diagnostic. As far as possible investigations should be rapid, noninvasive and avoid the need for general anaesthetic. Ultrasound examination is very useful as a first line, as sedation is rarely needed. Spiral CT scanners and MRI technology enable very precise tumor delineation. MRI is especially helpful for brain, spinal and liver tumors, while CT is particularly good for the detection of small chest metastases. Positron emission tomography (PET) scanning is increasingly available and offers an excellent means for monitoring residual disease.<sup>100</sup>

## BIOCHEMICAL MARKERS

A few tumors secrete specific markers which can assist in diagnosis and in monitoring the response to treatment. Re-emergence of markers frequently precedes clinical relapse. Examples are urinary catecholamine excretion in neuroblastoma (total catecholamines, VMA and HVA); serum alpha-fetoprotein (AFP) in hepatoblastoma and teratomas; and human chorionic gonadotrophin (HCG) in some germ cell tumors.

## CYTOGENETICS

Banding techniques and in situ hybridization studies have revolutionized routine karyotyping and tumor cytogenetics respectively. As more cytogenetic abnormalities are identified in tumors more specific probes have become available to detect translocations, deletions and amplifications of DNA. It is essential to combine tumor studies with analysis of nontumor DNA to exclude constitutional defects.

## BONE MARROW EXAMINATION

Most childhood tumors are highly malignant and likely to be disseminated at presentation, with many (e.g. neuroblastoma, lymphoma, rhabdomyosarcoma, Ewing sarcoma, retinoblastoma) potentially metastasizing to the bone marrow. To exclude infiltration two aspirates and two trephines from different sites are considered a minimum requirement. The posterior iliac crest is the preferred site for bone marrow sampling in children.

## PRINCIPLES OF THERAPY

The ultimate aim of therapy for childhood cancer is control of disease with minimum short and long term toxicity to normal tissue. Childhood tumors are generally extremely sensitive to cytotoxic agents in comparison with the common epithelial malignancies of adulthood. Most types of tumor will require multimodality therapy; surgery and/or radiotherapy for local tumor control, and chemotherapy for distant metastases, either macro or micro). The specific combination of therapies, and the schedule in which they are combined is tumor specific and is discussed in the relevant section.

As a general principle chemo- and radiotherapy are most effective against dividing cells; traditionally this has been felt to be the reason for their effectiveness against rapidly dividing tumor cells and for their toxicity to bone marrow and gut. In recent years the role of programmed cell death (apoptosis) both in tumor development, and as a mode of tumor cell response to treatment, has been increasingly appreciated. In normal tissue proliferation decreases the threshold for apoptosis so that cells can only proliferate in the presence of appropriate survival signals (growth factors, cytokines). This acts as a failsafe mechanism to ensure that cells can only proliferate in the right place and at the right time.<sup>101</sup> Tumor cells have acquired a relative resistance to this mechanism of engaging apoptosis so that they can proliferate without such signals, and evasion of apoptosis is felt to be a hallmark of cancer.<sup>102</sup> However tumor cells are 'primed' to undergo apoptosis if it can be triggered by an alternative route and there is an increasing focus on the modulation of apoptosis as an area for future development of more directed anticancer therapy.<sup>103</sup>

Hypoxia (a reduction of tissue oxygen to 1% or less) is a universal feature of tumors as a consequence of poorly organized tumor-derived new blood vessels. Hypoxia has profound effects on tumor cell response to radio- and chemotherapy, and has been correlated with poor prognosis in adult tumors.<sup>104</sup> Evidence is now emerging that hypoxia may also be an important contributor to tumor resistance in pediatric tumors.<sup>105–107</sup>

## TUMOR CELL RESISTANCE

There are a number of mechanisms that prevent tumors being killed by drugs.<sup>108</sup>

### Primary resistance

Extrinsic resistance occurs when inadequate drug reaches the tumor cell. This can arise from poor bioavailability, enhanced metabolism or excretion, or from inbuilt barriers to drug penetration such as the blood–brain barrier. There may be limited drug penetration into very large tumors or it may be that the concentration needed to kill the tumor produces excessive host toxicity and therefore cannot be used. In ALL therapy studies have shown that poor patient compliance as well as variable drug metabolism contribute to worse prognosis.<sup>109</sup>

Intrinsic resistance is a consequence of molecular abnormalities in the tumor cell that prevent cell death after cytotoxic damage. Primary resistance of this type is not prominent in pediatric tumors but is a common feature of adult epithelial malignancies, especially where the tumor suppressor gene p53 is mutated.

### Secondary resistance

This is more common in pediatric tumors. Relapse follows a good initial response to treatment or after finishing chemotherapy. Resistance may be against a single drug or against a range of cytotoxic agents with different mechanisms of action. To reduce acquired drug resistance it is common practice to deliver dose-intensive multiagent regimens alternating between drugs with different toxicities. A number of mechanisms for the development of tumor cell resistance have been described.

1. *Drug transport*: Decreased tumor cellular drug uptake and increased drug efflux have both been described as contributing to drug resistance. Polymorphisms in the reduced folate carrier resulting in decreased cellular methotrexate levels are associated with poorer outcome in acute lymphoblastic lymphoma<sup>110</sup>. Many cytotoxics are targets of drug efflux proteins, including p-glycoprotein (P-gp) and multidrug resistance protein (MDR/MRP). However while P-gp expression may be increased at relapse in childhood leukemia<sup>111</sup> there is minimal evidence for prognostic significance in other settings.<sup>112</sup>
2. *Drug target*: Amplification of the gene encoding the enzyme dihydrofolate reductase, the target for the widely used cytotoxic agent methotrexate, is associated with methotrexate resistance and has been reported in patients with ALL at relapse.<sup>113</sup>
3. *Drug inactivation*: Platinum drugs can be inactivated by glutathione-S-transferase (GST) mediated conjugation to glutathione. High levels of both glutathione and GST can be found in platinum-resistant tumor cells and tumor levels of GST correlate with survival in adult head and neck cancer.<sup>114</sup>
4. *DNA repair*: A number of cellular mechanisms exist to repair DNA damage induced by cytotoxic agents. Platinum compounds form DNA adducts and these are removed by nucleotide excision repair. This is a complex process involving many proteins, high levels of one of which, ERCC1, correlate with poor response to platinum.<sup>115</sup> Mismatch repair seems also to be important for response to platinum compounds and loss of mismatch repair has been reported in cisplatin-resistant ovarian tumors.<sup>116</sup>

At present our increased understanding of mechanisms of tumor drug resistance has not translated into therapeutic strategies to overcome them. However it is likely that with the next generation of rational therapeutics that many of the problems seen with resistance to conventional cytotoxic agents will become less important.

### SURGERY AND IRRADIATION

Many pediatric tumors require definitive local control for long term cure. Local control requires either surgical excision with wide margins of normal tissue, or where this is impractical or technically impossible, then local radiotherapy. There are also many situations in which local radiotherapy is needed after surgical resection, either because of poor margins of normal tissue in the resected tumor, or because of evidence of microscopic local spread in the resected sample. The timing of such therapy needs to be carefully considered so as to disrupt ongoing treatment as little as possible.

The main limitation of irradiation is its effect on normal tissues. Modern megavoltage therapy has a sharper beam edge, better depth of penetration and can give a more even dose distribution thus avoiding damage to skin and overlying tissues when administered to deep organs. When therapy is planned, careful clinical and radiological assessment of the tumor is undertaken so that radiation fields can be calculated to minimize the radiation dose to normal tissue. New radiation technology is facilitating much more focused therapy with sharp cutoff to minimize damage to surrounding normal tissues. When irradiation is

included with chemotherapy in treatment protocols there is a potential for additive toxicity as well as efficacy. In the short term, radiation recall especially with actinomycin, can be troubling. In the long term the combination of alkylating agents and irradiation leads to an increased risk of the development of secondary neoplasms.

### MONITORING TUMOR RESPONSE

Standardization of tumor response criteria is essential to facilitate comparison of treatment protocols. What constitutes each category of response is not always easy in any specific tumor.

1. *Complete regression* (CR): complete macroscopic regression of all apparent tumor.
2. *Partial regression* (PR): more than 50% reduction, but less than 100% of any single measurable lesion without any new lesions appearing or growth of other identifiable lesions. This category is sometimes split into good partial response and poor partial response.
3. *Stable disease*: no change in any tumor as defined by less than 50% reduction of any single measurable lesion without any new lesions appearing.
4. *Progressive disease*: enlargement of at least one measurable lesion and/or the development of new lesions while on therapy.

### SPECIFIC EFFECTS OF TREATMENT

#### Ionizing irradiation

Ionizing irradiation may kill or severely damage a cell. Sublethal cell damage, particularly to normal tissue surrounding a tumor, can cause tissue aging, malformation, growth impairment or induce carcinogenesis. Irradiation is generally given in daily fractions to facilitate normal cell recovery. As cells in the periphery of the tumor mass are killed, more centrally placed and hypoxic cells will undergo a reoxygenation process and will become susceptible to therapy, particularly if there is an interval between radiation exposures.

Multiple fractions of radiation produce the same effect as a single large dose, but are better tolerated and more efficacious for most tumors. Tolerance curves can be produced for normal and malignant tissues. It is sometimes possible to calculate split course therapy during the intervals of which normal tissues can repair and some tumor cells will be recruited into the proliferative phase where they will be more susceptible to therapy.

#### Chemotherapy

Table 24.8 shows some adverse drug effects. Most agents produce alopecia and varying degrees of myelosuppression and some gastrointestinal upset. Patients worry about the nausea and vomiting, physicians about infection risks and hemorrhage.

#### Hematological toxicity

The degree and duration of neutropenia increases the risk of sepsis. It is essential that patients and parents are aware of the need to urgently seek medical attention should they become febrile or unwell. Regular monitoring of counts and careful education of parents as to the risks are essential.<sup>117</sup>

#### Neutropenia and infection

Neutropenia leads to a significant risk of bacterial and fungal sepsis when the total neutrophil count is less than  $1.0 \times 10^9/L$ . Skin and gastrointestinal flora can rapidly produce septicemia. The commonest isolated organisms are Gram-positives especially *Staphylococcus aureus* and coagulase negative staphylococci, but the gravest threat to life comes from Gram-negative organisms including *Escherichia coli*, *Klebsiella* and *Pseudomonas*.<sup>118</sup>

Meticulous hand washing techniques by all staff can reduce nosocomial infection including colonization with some pathogens.<sup>119,120</sup> All rectal procedures should be prohibited during neutropenia unless absolutely unavoidable.

**Table 24.8** Specific drug toxicity effects of some commonly used chemotherapeutic agents

Drug	Myelo-suppression	Immuno-suppression	Tissue irritant	Nausea + vomiting	Cystitis	Nephrotoxicity	Cardiotoxicity	Neuropathic	Ototoxicity	Pulmonary	Hepatotoxicity
Anthracyclines (adriamycin + daunomycin)	++	+	+++	++	-	-	+++	-	-	-	Radiation recall effect
Actinomycin	++	+	+++	++	-	-	-	-	-	-	Radiation recall effect + VOD

Etoposide	++	+	+	+/- Mucositis	-	-	+/- (hypotension)	+ (mild peripheral)	-	-	+ (enzymes)
Steroids	-	+++	High dose pain	-	-	-	-	-	-	-	-
Asparaginase	++	++	-	-	-	-	-	Encephalopathy	-	-	++

In addition epipodophyllotoxins, asparaginases, bleomycin and rarely cytosine + cisplatin are associated with acute life threatening hypersensitivity reactions.

++-+++ denotes varying degree of toxicity.

- denotes no recorded toxicity of type.

VOD, veno-occlusive disease.

Any child who is neutropenic and febrile should rapidly receive broad spectrum antibiotics. Clinical signs of infection without fever necessitate a similar response.<sup>121</sup> The antibiotic regimen chosen should reflect local sensitivity profiles but must cover both Gram-negative and Gram-positive organisms (e.g. an aminoglycoside and a carbapenem). With more use of broad spectrum antibiotics fungal infection rates have increased. Failure of resolution of pyrexia after 96 hours of i.v. antibiotics or if there is clinical deterioration is an indication for systemic antifungal therapy. Fungal infections are particularly problematic in patients with prolonged neutropenia (> 10 days). There is no indication for prophylactic antiviral agents in the absence of clinical evidence of viral disease and no evidence for the routine use of granulocyte transfusions. Whilst granulocyte colony stimulating factor can reduce the duration of neutropenia there is no evidence of effectiveness in reducing duration of neutropenic fever. Current guidelines advise against its routine use.<sup>121</sup> There is no consensus on the use of prophylactic antibiotics in neutropenic patients.

Localizing signs are often absent in the face of profound neutropenia, but initial evaluation of these patients should include a thorough examination. Bacterial cultures should be taken from blood and any superficial lesion. Fungal and viral cultures plus serology should be performed if there is poor response. Chest X-ray is indicated in the presence of respiratory symptoms or lack of resolution of fever. Persistent fever indicates the need for further imaging to look for evidence of fungal infection. However in nearly two thirds of patients no initial focus of infection is identified. It is important that all medical and nursing staff are aware that these patients can become very ill very rapidly and it is essential that they are regularly monitored. Early intervention with aggressive fluid resuscitation and inotropic and ventilatory support can be life saving.

### Immunosuppression

Both chemotherapy and radiotherapy can induce lymphopenia and impaired T and B cell function. Viral infections may not be adequately cleared and common viruses may be excreted for months. Varicella and, increasingly, measles pose major risks. Varicella infection formerly carried a high mortality but zoster immune globulin (ZIG) given prophylactically within 96 hours of contact is effective at preventing primary infection.<sup>122</sup> Varicella infection (either primary or shingles) can be effectively managed with aciclovir 5–10 mg/kg i.v. 8-hourly for at least 5 days followed by at least 2 weeks of oral therapy to prevent recrudescence.<sup>123,124</sup> Immunosuppressed patients contracting measles and developing either immune encephalitis or giant cell pneumonitis have a near 100% mortality.<sup>125</sup> Prevention of measles in these patients is best achieved by high community uptake of measles vaccination and avoidance of close contact with cases. Although immunization programs have reduced measles prevalence, only uptake rates in excess of 90% will make epidemics a feature of the past.

*Pneumocystis carinii* pneumonitis may occur during periods of profound lymphopenia. It presents with intractable fever and tachypnea often with no clinically detectable chest signs despite florid radiographic changes. It can be effectively prevented by the use of prophylactic co-trimoxazole.<sup>126</sup> Treatment of the pneumonitis requires a higher dose (trimethoprim 20 mg/kg/day and sulfamethoxazole 100 mg/kg/day given in two divided doses daily). About 80% of patients respond, with some doing so only on the addition of steroids.<sup>127</sup> Nebulized pentamidine can be used in those hypersensitive to sulfonamides but has had disappointing results in leukemic patients. Cytomegalovirus may coexist with pneumocystis and can produce a similar pneumonitis. Ideally broncho-alveolar lavage should be performed to confirm the diagnosis, certainly if there is poor response to therapy. Disease infiltration, fungi and drug reactions can all mimic *Pneumocystis carinii* pneumonitis.

Live vaccines, including measles and polio, must be avoided during therapy but it is recommended that the normal schedule of childhood immunization should otherwise be followed. Patients should receive single booster doses of all vaccines that they have previously received 6

months after finishing chemotherapy, and 12 months after bone marrow transplant.<sup>128</sup>

### Blood product support

Children have more efficient platelets and good blood vessel wall support when compared with adults and only tend to bleed overtly at very low platelet counts (< 10 × 10<sup>9</sup>/L) except in the presence of severe infection. There is little evidence in favor of prophylactic platelets given at specific levels but most units will transfuse platelets once the count is < 10 × 10<sup>9</sup>/L in well patients. In those who are febrile and neutropenic it is usual to keep platelet counts > 20 × 10<sup>9</sup>/L. If invasive high risk procedures, such as lumbar punctures, are to be carried out, it is advisable to keep counts above 50 × 10<sup>9</sup>/L for 24 hours.<sup>129</sup> Frequent platelet transfusion can lead to antibody development with poor increases in platelet number. There is even less evidence for the use of prophylactic red cell transfusions but again most units have a hemoglobin limit at which they will transfuse patients regardless of symptoms; this is usually in the order of 8 g/dl.<sup>130</sup> The CMV immune status should be assessed for all patients at diagnosis and only CMV-negative donors used for those with no immunity. There is a significant risk of transfusion related graft versus host disease in patients with profoundly compromised cell mediated immunity. In oncological practice this includes all patients with Hodgkin disease, bone marrow transplant recipients and any patient who has received fludarabine. To minimize this risk, these patients should receive irradiated blood products at all times.

### Local tissue toxicity

Many cytotoxics will cause tissue damage if they extravasate (e.g. vincristine and anthracyclines). Use of central lines has decreased the risk. For both central and peripheral lines, only experienced fully trained staff should give cytotoxics and correct line placement should always be checked prior to injection (good blood flow back, easy flushing with saline and no pain).

### Nausea and vomiting

Many cytotoxics can produce profound nausea and vomiting. Symptom control has been greatly enhanced by use of the 5-HT<sub>3</sub> receptor antagonists. In the majority of patients vomiting can be controlled by regular ondansetron starting before chemotherapy.<sup>131</sup> The addition of i.v. dexamethasone is helpful in children receiving highly emetogenic regimens.<sup>132</sup> Metoclopramide and cyclizine can be used effectively with less emetogenic regimens and may also be useful in older patients with vomiting that is refractory to ondansetron and dexamethasone. Nabilone and levopromazine (nozinan) have also been effective in this setting.<sup>133</sup> Initial bad experiences with chemotherapy may induce anticipatory vomiting especially in teenagers, for which oral benzodiazepines (lorazepam) 12 hours prior to therapy can be effective. Lorazepam can also increase the effectiveness of dexamethasone.<sup>134</sup> Delayed vomiting can be a problem particularly with cisplatin but should also alert the physician to the possibilities of infection, hepatotoxicity or ongoing anxiety and psychological problems.

### Mucositis

Methotrexate, the anthracyclines and actinomycin all induce mucositis which is frequently complicated by secondary candida infection. There is some evidence that ice chips can prevent mucositis but none of the other currently used prophylactic agents are effective.<sup>135</sup> There is evidence that prophylactic antifungal agents can reduce the clinical signs of oral candidiasis.<sup>136</sup> Mucositis can be extremely painful and intravenous opiate analgesia should be used at an early stage.

### Bowel dysfunction

Myelo-ablative therapy regimens, high dose cytosine and irinotecan can all produce profound watery diarrhoea which can lead to significant (> 10% of body weight) weight loss for which parenteral nutrition is required. In the absence of diarrhoea such weight loss is usually due to tumor cachexia and loss of appetite is an indication for enteric feeding.

The vinca alkaloids can produce severe constipation and ileus. This autonomic neuropathy may be complicated by enterocolitis, bowel wall edema and even intussusception. Regular use of bowel softeners (e.g. lactulose) may decrease the risk but when established it may need more aggressive management. Prevention by attention to fluid intake, maximizing activity, avoidance of excess narcotics and stool softeners is preferable.

### Renal toxicity

Cisplatin causes progressive tubular and glomerular deterioration with increasing cumulative dosage and occasionally acute tubular necrosis. Vigorous hydration (saline and mannitol) can protect to some degree. Concomitant diuretics and aminoglycoside antibiotics should be avoided. Hydration should be continued for 24 hours after cisplatin. Glomerular function should be monitored regularly and no further cisplatin should normally be given if the GFR falls below 60 ml/min/1.73 m<sup>2</sup>. Profound tubular leakage of magnesium and calcium can produce weakness and tetany and require careful replacement. Methotrexate and melphelan can cause further nephrotoxicity in the face of renal impairment, delaying their own clearance and worsening myelosuppression.

Cyclophosphamide and ifosfamide can both cause hemorrhagic cystitis. Regular voiding and hydration for 24 hours after administration are essential. The metabolites can be inactivated by concomitant 2-mercaptoethane sulfonate sodium (Mesna).<sup>137</sup>

The alkylators and vincristine can have an antidiuretic hormone effect with resultant fluid overload and dilutional hyponatremia, sometimes resulting in seizures. Urinary flow must be maintained, if necessary with diuretics. Ifosfamide also can produce long-lasting renal tubular defects with hypophosphatemia, clinical rickets and reduction in glomerular filtration rate with cumulative dosage.

The nephrotoxicity of the commonly used antifungal agent amphotericin is an additive problem for these patients. Renal tubular damage can render them dependant upon electrolyte supplementation for prolonged periods. These problems can be largely avoided by the use of the liposomal formulations of this drug.<sup>117</sup>

### Cardiotoxicity

The anthracyclines produce cardiotoxicity. Acute toxicity with arrhythmias, conduction defects and fall in left ventricular output is relatively rare, transient and does not absolutely prevent future use of the drugs. Late cardiomyopathy is related to cumulative dosage with the incidence of congestive cardiac failure increasing steeply beyond 450 mg/m<sup>2</sup> of doxorubicin. Echocardiography and endomyocardial biopsies have, however, demonstrated functional abnormalities at much lower cumulative dosages.<sup>138</sup> Dose rate and infusion time both affect toxicity.<sup>139</sup> Studies have reported echocardiographic changes in children who have received only 200–250 mg/m<sup>2</sup> of doxorubicin.<sup>140</sup> Up to 5% of patients will develop anthracycline-induced clinical heart failure 15 years after treatment, and those receiving more than 300 mg/m<sup>2</sup> are at highest risk.<sup>141</sup> Careful monitoring of ventricular function is mandatory when using these agents.

### Neurotoxicity

Vincristine can produce peripheral neuropathy (ranging from loss of ankle jerks during therapy, through foot drop (5%), wrist drop (2%) to slapping gait and paresthesia of extremities), and rarely convulsions and encephalopathy.<sup>142</sup> The central effects may be complicated by an antidiuretic hormone effect with dilutional hyponatremia and seizures. The neuropathy can be very painful and is effectively treated with either amitriptyline<sup>143</sup> or gabapentin.<sup>144</sup> Encephalopathy has been recorded with leukemic induction therapy of weekly vincristine. However, such patients receive concomitant l-asparaginase and intrathecal methotrexate both of which can induce seizures and encephalopathic features.

CNS-directed therapy in leukemia can cause a leukoencephalopathy, most commonly if intrathecal or systemic methotrexate is administered after cranial irradiation. The least toxic modality is continuing

intrathecal methotrexate alone (see below); ifosfamide produces an encephalopathy more commonly in adults than children.<sup>145</sup>

### Ototoxicity

Platinum analogues, especially cisplatin, cause progressive high frequency hearing loss with increasing cumulative dosage. Tinnitus and, especially if combined with cranial irradiation, rapid deterioration of hearing can occur.<sup>146</sup>

### Hepatotoxicity

Oral methotrexate can induce a cirrhotic state and mercaptopurine can cause cholestatic jaundice. High dose methotrexate can induce florid hepatic disturbance with mucositis and severe myelosuppression (more likely if combined with other drugs cleared by the liver). Actinomycin and anthracyclines should be avoided if possible for the first 4–6 weeks following abdominal (liver encroachment) irradiation. These and busulphan/cyclophosphamide conditioning for transplantation have been associated with veno-occlusive disease (VOD). This condition presents with hepatomegaly, ascites, encephalopathy and thrombocytopenia 5–10 days after actinomycin treatment.<sup>147</sup> An incidence of 1.2% has been reported for this condition in patients treated on the IRS IV protocol,<sup>148</sup> and as high as 8% for children treated for Wilms tumor.<sup>149</sup> There is no effective treatment and it can be associated with multi-organ failure and death. A strong case can be made for the avoidance of actinomycin in patients who have even a mild episode of VOD.

### Biochemical disturbance

Rapid tumor cell breakdown, either after treatment or spontaneously, can result in tumor lysis syndrome, seen most commonly in T and B cell lymphoblastic disorders. Hyperkalemia, hyperphosphatemia, and consequent hypocalcemia, hyperuricemia, and urate nephropathy are seen. The risks can be reduced by gradual introduction of chemotherapy, often with a steroid pre-phase, hyperhydration (125 ml/m<sup>2</sup>/h), allopurinol (10 mg/kg/day in divided doses) and careful urinary alkalization with bicarbonate. In patients at greatest risk of tumor lysis syndrome recombinant urate oxidase (rasburicase) is highly effective at preventing its development.<sup>150</sup>

### Acute psychological effects

Painful procedures and toxic therapy can become intolerable for the child unless kept to a minimum. The family need to make the child realize the absolute need for such treatment and must expect and tolerate the natural reaction to it and show that they care for their child as a special individual. The pediatric oncologist must support and help the whole family. The parents must know and understand the diagnosis and the effect of treatment if the child is to come through emotionally intact. The initial shock at the diagnosis precludes 'real' hearing and, subsequently, phases of anger at the apparent injustice are often misdirected at the staff.<sup>151</sup> Excess optimism or pessimism must be avoided but if treatment is offered and accepted, some feeling of hope must be conveyed. Involvement in nursing their child often provides a sense of purpose for parents. As they come to terms with the shock of diagnosis, parents frequently ask more searching questions which must be answered truthfully. If more than one member of staff explains matters, it is essential to stress that words used may be different but the meaning is the same. The caring team must be coordinated, and unit meetings are essential for this purpose. There are a few genuine circumstances where the extent of disease or nature of tumor diagnosis precludes cure. For such a child where there is no realistic treatment option and if parents agree, support for the whole family is even more important. Parents must realize that they are always told the truth, 'good' means good and the converse is true about any bad news. Parents may wish their child to be protected from the facts of the disease and diagnosis, but for the majority of children this is a mistake. Children are usually much more resilient than adults and provided appropriate words are used, and they have confidence in the person conveying the problem, they can cope admirably with even the worst of news. Time is necessary to build up confidence for the child and

parents, and if such time is not spent at the beginning, management will become fraught with problems. Secrets about the disease within the family, especially keeping facts from siblings, is also unwise. When trust has developed, even if treatment fails and the patient becomes terminal, the team can usually support the patient and family through the final illness more adequately.

For teenagers the news of cancer and its necessary treatment can be particularly hard as it inevitably requires compliance with and dependence upon those from who they are striving to emotionally separate. They require great understanding and sometimes even a little support in their rebellion.

The involvement of a dedicated child psychiatrist in the team who can help staff to understand family interactions and can guide both staff and family through specific crises has proved very useful in many oncology centers. It may be that help is required by specific families where stress has become too great or where previous psychopathology is present. Cancer does not select specific families but affects the spectrum of the population independent of intelligence, insight and behavior.

## LONG TERM SEQUELAE

There are many potential long term sequelae of childhood cancer survivors and these are summarized in Table 24.9.

### Late recurrence

Hawkins<sup>152</sup> followed up over 11 000, 3-year cancer survivors, for at least 10 further years (Table 24.10). Overall 75% of late deaths were due to either treatment or recurrence of primary disease. No excess late deaths were seen in patients treated for non-Hodgkin lymphoma and nongenetic retinoblastoma, and were very rare in children treated for

**Table 24.9** Potential long term sequelae of childhood cancer

Late recurrence of primary cancer
Second malignancy
Impairment of normal growth
Endocrine dysfunction
Infertility
Educational and psychological dysfunction
Other organ toxicity, e.g. cardiac, pulmonary
Impairment of normal life, e.g. obtaining work, insurance, being allowed to adopt children

**Table 24.10** Long term survivors in childhood cancer. (Data derived from Hawkins 1989<sup>152</sup>)

Tumor type	% of survivors at 3 years still alive at +10 years	Excess deaths (per n survivors at +10 years)
Acute lymphoblastic leukemia	60	1 in 100
Hodgkin disease	74	< 1 in 100
Non-Hodgkin lymphoma	85	None
Neuroblastoma	89	< 1 in 200
Nephroblastoma	94	< 1 in 200
Retinoblastoma		
Genetic	93	1 in 200
Nongenetic	100	None

nephroblastoma and neuroblastoma. Late excess deaths in ALL were due to recurrent leukemia, which has been seen more than 10 years from diagnosis. Excess deaths in patients with genetic retinoblastoma and Hodgkin disease were due to second tumors rather than recurrence of primary disease.

### Second tumors

The incidence of second tumors has been reported as 8% at 20 years from diagnosis (15 times higher than the general population at this age range).<sup>153</sup> It is inevitable that this incidence reflects therapeutic strategies of the past, and not those which we currently employ. Whilst survival overall may be better than twenty years ago, and thus the number of treated patients at risk for second tumors may be increasing, it is also possible that the reduction in the use of some treatment modalities, such as craniospinal irradiation for ALL, may reduce the risk of second tumors. Patients with 'genetic' retinoblastoma and Hodgkin disease were most likely to develop second tumors and the risk factors were identified as genetic susceptibility (with an Rb1 gene mutation up to 30% of patients will develop a second tumor<sup>27</sup>) and the combination of irradiation with alkylating agents in Hodgkin disease.<sup>153,154</sup> Other genetic disorders predisposing to multiple malignancies in childhood include Li-Fraumeni syndrome, neurofibromatosis type 1 and Gorlin syndrome. Two thirds of all the second solid tumors occurred within radiation fields (30% being soft tissue or bony sarcomas). These tumors have a long latency with a median time to diagnosis of 10–15 years. Total dosage greater than 30 Gy, old-style orthovoltage treatment and young age at treatment all increased the risk.<sup>83,155</sup> Secondary leukemia was associated in a dose dependant fashion with previous treatment with alkylating agents.<sup>83</sup> Secondary acute nonlymphoblastic leukemia with a shorter latency period (median 30 months) than with alkylating agents (median 5–7 years) has been increasingly described in patients exposed to topoisomerase 2 inhibitors such as etoposide. The risk appears to be total dose and schedule dependent.<sup>84,156</sup> The risk of developing second tumors after treatment for acute lymphoblastic leukemia appears to be relatively low at 2.5–3% at 15–20 years from diagnosis and the commonest tumors seen are gliomas and meningiomas in cranial irradiation fields.<sup>157,158</sup> The risk continues to increase with time from treatment well beyond 20 years.<sup>159</sup>

### Growth impairment

Direct radiation damage to the hypothalamic–pituitary axis from cranial irradiation impairs growth hormone secretion and in higher dose also gonadotrophic and adrenocorticotrophic hormone secretion.<sup>160</sup> Precocious puberty can occur in children receiving cranial irradiation and young age at treatment increases the risk. Puberty may be both premature and foreshortened, further reducing final height and giving less time during which growth hormone replacement can be delivered. Growth hormone may need to be given in combination with gonadotrophin releasing hormone (GnRH) to attempt to arrest pubertal maturation. Growth hormone replacement may be less effective in gaining height for such patients than it is in idiopathic growth hormone deficiency. Growth hormone therapy appears totally safe to administer to patients with previous malignancies provided at least 1 year (but normally 2 years) have elapsed from treatment, and the patient is in full remission. To date there has been no convincing evidence of tumor reactivation or induction of second malignancies by growth hormone.<sup>161</sup>

The use of more intensive chemotherapy with cranial irradiation for childhood leukemia appears to increase the risk of growth impairment and there is increased likelihood of body disproportion with short spines in children treated with craniospinal irradiation and chemotherapy.<sup>162,163</sup> These children also have altered body composition with central obesity, hyperleptinemia<sup>164</sup> and reduced bone mineral density.<sup>165</sup> It is essential that all children who receive irradiation and intensive chemotherapy should be regularly assessed for linear growth, pubertal status and weight on a long term basis until they have reached maturity.

## Thyroid dysfunction

Radiation damage results in a rise in thyroid stimulating hormone (TSH) and then hypothyroidism. This follows total body, craniospinal and local neck irradiation. Low doses (100 cGy) may be sufficient. Thyroid adenomas and carcinomas have been reported.<sup>166</sup> Persistent TSH elevation on follow-up requires replacement even in the absence of clinical or biochemical hypothyroidism.

## Gonadal dysfunction and infertility

The germinal epithelium of the testis, from which the spermatozoa develop, is exquisitely sensitive to radiation and to cytotoxic drugs. Radiation doses as low as 1.2 Gy can result in permanent azoospermia.<sup>167</sup> The effects of cytotoxic agents are more variable but alkylating agents are particularly associated with poor sperm counts,<sup>168</sup> and procarbazine-containing regimens for Hodgkin disease can induce azoospermia in up to 97% of patients.<sup>169</sup> The gonadotoxicity of many chemotherapy regimens remains undefined and thus it is probably wise to recommend sperm banking for all post-pubertal boys, unless they are receiving a regimen which has been shown not to be gonadotoxic. Leydig cell function is far less sensitive than spermatogenesis, so many of these patients will develop normal secondary sexual characteristics and undergo a normal puberty.<sup>168</sup> Female gonadal dysfunction after treatment is much harder to predict than in males. Ovarian damage is related to both radiation and cytotoxic therapy, and to age at therapy; so that the younger the girl the more likely it is that she will recover ovarian function with time after treatment.<sup>168</sup> However procarbazine-containing regimens are still likely to impair female fertility; half of all pre-pubertal girls treated with 6 cycles of ChLVPP had elevated FSH, and 60% of these developed symptomatic ovarian failure requiring hormone replacement.<sup>169</sup> Irradiation decreases uterine volume, blood flow and endometrial thickness, and these changes are not usually reversible with androgen replacement. It is thus important to consider not just ovarian function when evaluating female fertility.<sup>170</sup> At present there are no nonexperimental techniques for the preservation of female fertility, but it is likely that these will become available reasonably soon.

Gonadal function is also affected by hypothalamic-pituitary damage from radiation and it is thus important to monitor FSH and LH levels in patients who have received cranial radiotherapy.<sup>168</sup> It is valuable to have an endocrinologist involved in the long term follow-up and management of childhood cancer survivors.

## Educational and psychosocial effects

Time lost from nursery and schooling at critical stages of learning may impair educational achievement. This may result from illness, sequelae of treatment and parental anxiety about allowing the child to mix in 'society'. CNS directed radiation therapy for leukemia and CNS tumors produces long standing neuropsychological sequelae including cognitive dysfunction, short term memory impairment and difficulties in problem solving. Young age at the time of treatment (especially under 3 years) increases the risk of damage.<sup>171</sup> The combined effect of cranial irradiation in leukemia patients on both growth and educational achievement has led to alternative CNS directed strategies being utilized. Such approaches are effective in controlling CNS disease but are not totally without effect on neuropsychological functioning.<sup>172</sup>

The incidence of long term overt psychological and psychiatric problems appears remarkably low among cancer survivors. However, many patients, particularly those who have received cranial irradiation, appear to be 'loners' with low self-esteem, working but in undemanding jobs and are much less likely than their peers to be in long term relationships. Child-parent relationships and life-long family coping does seem to influence psychological outcome. The impact of 'waiting for a relapse' is too much for some families to cope with.<sup>173</sup> Nevertheless the vast majority of childhood cancer patients complete normal education and have higher rates of employment than their matched peers.<sup>174</sup> Some face outdated prejudice from employers, some insurance and pension schemes (excessive weighting of premiums long term) and have difficulty in being considered as adoptees when rendered infertile by treatment.

## Cardiorespiratory

Acute cardiac effects after anthracycline drugs have been described above, but the extent of the long term effects on endocardial muscle remains controversial. There are reports of sudden death after strenuous exercise or during pregnancy, and deteriorating cardiac function only rescued by cardiac transplantation in others. Total anthracycline doses in excess of 200 mg/m<sup>2</sup> have been associated with long term echocardiographic changes but it is not clear how many progress to overt cardiac disease.<sup>175</sup>

Sixty-five per cent of 5-year leukemia survivors in one study showed one or more defects of low vital capacity, total lung capacity, residual volume or transfer factor<sup>176</sup> but very few were symptomatic. These features represent impairment of lung growth during the first 5–6 years of life. This may be of significance, especially among smokers, later in life. Amongst solid tumor survivors chest wall growth impairment, restriction defects and/or fibrosis are more frequently identified, especially where the lungs have been irradiated.<sup>177,178</sup>

## Conclusions on sequelae

Without intensive treatment most children with cancer died 30–40 years ago. Now approximately 70% survive long term and most have good quality of life. Some sequelae such as gonadal failure and infertility may be an acceptable, if regrettable, price for cure but second tumors and late cardiac deaths are not. It is essential that all childhood cancer patients are followed for life so that lessons can be learnt and therapy modified where appropriate without any loss of efficacy.

## CENTRAL NERVOUS SYSTEM TUMORS

Central nervous system tumors as a group are the commonest solid tumors of childhood, accounting for about 25% of all pediatric malignant disease.<sup>179</sup> Recognized etiologic factors are shown in Table 24.11, and Table 24.12 shows the incidence of different childhood brain tumors. The primary CNS tumors of childhood are a highly disparate group; application of the revised WHO classification is probably the best approach to their categorization.<sup>180</sup> The vast majority of childhood CNS tumors arise from neuroepithelial tissues (the principle exceptions are intracranial germ cell tumors and craniopharyngioma). The WHO classification divides neuroepithelial tumors into: 1) glial (which includes all gliomas, ependymomas and choroid plexus tumors); 2) neuronal; 3) mixed neuronal-glial; 4) embryonal (which includes primitive neuroectodermal tumor (PNET)) and 5) pineal cell tumors. With modern immunohistochemistry and molecular biological methods it is possible

**Table 24.11** Etiological factors for CNS tumors

Heritable syndromes
Neurofibromatosis (visual pathway tumors + gliomas)
Tuberous sclerosis (glial ependymomas)
Von Hippel–Lindau (cerebellar + retinal + pheochromocytomas)
Familial clustering without identifiable genetic factor (various tumors including pinealomas)
Familial with autosomal dominant inheritance: astrocytoma
Retinoblastoma and pinealoblastoma (13q-)
Rhabdoid renal tumors and primitive neuroectodermal tumors of brain
Monosomy 22: meningiomas + acoustic neuromas
Ionizing irradiation: after low dose scalp irradiation and possible dental investigations
Immunodeficiency (intracerebral lymphomas) especially:
a. Postrenal transplantation
b. Wiskott–Aldrich
c. Ataxia telangiectasia
Parental exposure to organic compounds such as nitrosamines and polycyclic hydrocarbons

**Table 24.12** Relative incidence of CNS neoplasms in childhood (1981–1990) with male/female ratio of each group of tumors. (Data from Parkin et al 1998<sup>3</sup>)

Tumor type	%	M/F ratio
Astrocytoma	38.3	1.1
Primitive neuroectodermal tumors	21.2	1.7
Ependymoma	10.8	1.4
Other gliomas	15.2	1.1
Other specified	8.6	1.1
Unspecified	5.9	0.9

to accurately identify the cells within CNS tumors. Commonly used neuronal antibodies such as glial fibrillary acidic protein (GFAP) and neurofilament protein (NFP) are coupled with non-neuronal markers such as smooth muscle actin (SMA), epithelial membrane antigen (EMA), keratin, vimentin, desmin and AFP to assign a diagnosis.

## SYMPTOMS AND SIGNS

The presenting symptoms and signs of brain tumors in childhood depend more on the site than on type of tumor. Neurological features are due to infiltration, compression of neuronal structures or raised intracranial pressure (ICP) secondary to obstruction of CSF pathways. Raised ICP presents early in the majority of the infratentorial tumors with the classic triad of morning headache, vomiting and visual disturbance. There may be more vague symptoms of tiredness, deteriorating school performance, personality change and nonlocalized headache for a variable period before this. Headaches in young children should always be taken seriously and investigated. Infants may present with irritability, loss of appetite and developmental delay or regression. Infants under 2 years may develop an increase in the occipitofrontal circumference (OFC) with springing of the sutures as intracranial pressure increases and in babies the 'setting sun' sign may be seen. Fundi are frequently pale with just the early signs of papilledema. Fundal examination can be very difficult and sedation and pupillary dilatation may be appropriate. Developmental assessment should be part of the full examination. Specific signs depend on the site of the tumor.

### Infratentorial lesions

Raised ICP and disturbance of balance (truncal and extremity) and specific cranial nerve dysfunction are the cardinal signs of the well-established tumor. Midline medulloblastomas may present only with raised intracranial pressure and truncal unsteadiness and without localizing features while cerebellar hemisphere lesions may present early with lateralizing features. It is, however, usually not possible to distinguish between astrocytoma and medulloblastoma clinically. VI nerve palsy may be a false localizing sign arising from raised intracranial pressure. When present bilaterally and especially when in combination with 5th, 7th or 9th nerve palsies, brainstem involvement is likely. Head tilt is frequently seen together with cochlear nerve palsy and vertical or horizontal diplopia when cerebellar tonsillar herniation occurs.

### Supratentorial lesions

Both the site and the size of the tumor determine the presenting signs. With these lesions nonspecific headaches, seizures of all types and long tract signs may predominate. Raised ICP may be the first sign of tumors in relatively silent areas of the cortex (frontal, parietal or occipital) and the tumor may be very large. Raised pressure may be an early feature in small third ventricular lesions. Visual field defects may help to localize tumors. In primitive neuroectodermal tumors dissemination throughout the CNS via the cerebrospinal fluid may lead to symptoms and signs far removed from the primary lesion with consequent diagnostic confusion. Careful documentation of all signs and symptoms in the order that they appear is important.

## DIAGNOSIS

Widespread availability of MR scanning has revolutionized the diagnosis of pediatric brain tumors. CT is useful for rapid identification of hydrocephalus and mass effect but MR is far better at defining tumor anatomy and extent.<sup>181</sup> Positron emission tomography (PET) may prove useful in detecting variations in metabolism between residual tumor and normal brain, and MR spectroscopy may also prove useful in noninvasive diagnosis.<sup>182</sup> For PNETs, exclusion of spinal deposits by MR scanning is essential.

## GENERAL PRINCIPLES OF TREATMENT

### Surgery

Preoperative steroids to reduce edema, external decompression of hydrocephalus and new scanning techniques have facilitated more complete surgical removal of visible tumor without increased morbidity. Extent of excision is a determinant of outcome for many tumor types.<sup>183,184</sup> Midline posterior fossa tumors more frequently require long term ventriculoperitoneal shunting. There is no evidence that this increases the likelihood of extracerebral metastases. Operative mortality for most tumors has been reduced to under 1%, although morbidity may be as high as 20%.

### Radiotherapy<sup>185</sup>

Fields and volumes treated should be limited to minimize normal tissue damage. High grade astrocytomas do require whole brain irradiation and ependymomas, PNETs and some germ cell tumors, craniospinal irradiation. Although local areas can tolerate total dosages as high as 50–55 Gy, whole brain dosages over 35 Gy are associated with significant sequelae. Fraction size, number of fractions and duration of treatment all influence toxicity.

Acute radiation side-effects include headache, vomiting, skin erythema, alopecia and otitis externa. Lymphopenia is universal and may persist for 6 months. Profound myelosuppression may follow spinal irradiation and make subsequent chemotherapy difficult to deliver. Five to ten weeks after cranial irradiation 'somnolence syndrome' can occur (profound sleepiness and mild pyrexia) owing to a temporary disturbance of myelination. A similar effect on the spine produces Lhermitte sign (shooting arm pains).

### Chemotherapy

The vulnerability of the developing CNS to radiation-induced damage, coupled with the poor survival for many types of tumor has resulted in considerable interest in the role of chemotherapy. The blood-brain barrier limits access to the brain of most drugs. At the margins of tumors, the tight capillary endothelial junctions persist, while neoplastic neovascularity makes the core of tumors more accessible. Lipid solubility, molecular size, protein binding and plasma concentration all determine the ability of a drug to penetrate the CNS. Lipophilic drugs (e.g. nitrosoureas) will penetrate tumor margins and water-soluble agents (e.g. cisplatin) the core. The initial goal of many of the early studies of chemotherapy for CNS tumors was to delay or avoid radiotherapy especially in the very young. A large number of such 'baby brain' studies have now been reported with varying degrees of success,<sup>186</sup> and such a strategy is now routinely adopted for most infants. The use of multiagent chemotherapy with curative intent is variable between tumor types and for most randomized prospective trials are only just beginning to be done to determine the role of chemotherapy in a multimodality treatment plan.

## GLIAL TUMORS

### ASTROCYTOMAS

Astrocytomas are by far the commonest pediatric brain tumor and the majority are low grade. Low grade and high grade astrocytomas are very different and are best considered as separate tumor types.

#### Low grade glioma (LGG)

This group contains a number of histologically different types of astrocyte or oligodendrocyte derived tumor, but all are WHO grade I or II.<sup>180</sup>

Between 30% and 40% of all pediatric primary CNS tumors are low grade gliomas. The commonest site is the cerebellar hemispheres (35%), and then the cerebral hemispheres (20%), hypothalamus (12%), thalamus (12%), brainstem (12%), spinal cord (4%) and optic nerve (3%). One third of children are less than 5 years at diagnosis<sup>187</sup> and the median age of presentation is around 7 years. The male to female ratio is approximately 1:1. Between 5% and 15% of patients with NF-1 will develop LGG of optic tract or hypothalamus.<sup>188</sup> Subependymal giant cell astrocytomas are seen in up to 15% of patients with tuberous sclerosis,<sup>189</sup> and LGG is also seen in patients with Li-Fraumeni syndrome.

### Presentation

This is dependent upon the tumor site. Posterior fossa tumors tend to present relatively early with signs of raised intracranial pressure; morning headache and vomiting, and with cerebellar signs such as ataxia. Supratentorial tumors may also present with signs of raised ICP but they are more likely to have seizures or motor symptoms. Optic tract tumors cause visual disturbance which can be difficult to detect in younger children, and hypothalamic tumors usually present with endocrinopathy. The presentation of spinal tumors is often insidious in onset with weakness, pain, sensory change, change in gait and eventually sphincter dysfunction.

### Diagnosis

Low grade gliomas are hypo- or iso-dense on MRI on T1 and hyperdense on T2. They may be solid or cystic and usually enhance with gadolinium. Histologically the juvenile pilocytic astrocytoma and the fibrillary astrocytoma are the commonest variants. The most frequent cytogenetic abnormality is gain of chromosome 7 and 8.<sup>190</sup> NF-1 is associated with optic tract gliomas, and up to a third of patients with these tumors may have NF-1.<sup>191</sup> Low grade gliomas are not usually metastatic and transformation to high grade tumors is rare.

### Management

The guiding principle for the management of these tumors is to achieve local control without inflicting major morbidity on the patient. The approach is thus dependent on the site of the tumor and the age of the patient. Cerebral hemisphere and cerebellar tumors can usually be fully resected without major morbidity; in series up to 90% of patients achieved gross total resection.<sup>187</sup> These patients have extremely good survival with most series giving 90–100%. Progression free survival (PFS) is significantly worse for patients with residual disease. Although there are no randomized trials comparing radiotherapy with no treatment

for these patients local radiotherapy for patients with gross residual disease in cerebral hemispheres or cerebellum has been traditionally given. There is however no evidence that it improves survival. Optic and hypothalamic tumors cannot usually be resected. For these patients radiotherapy is effective in controlling symptoms and disease progression.<sup>192</sup> The devastating late effects of radiotherapy on younger children have led to considerable interest in the use of chemotherapy for these patients with vincristine and carboplatin in various schedules being increasingly accepted as standard therapy. The success of such a strategy has been variable, some series report excellent PFS for younger children, while in others the PFS is worse in the younger age group.<sup>193,194</sup> The current SIOP strategy for low grade gliomas includes all low grade (WHO I–II) tumors anywhere in the CNS, except diffuse intrinsic pontine gliomas. The strategy is complex and takes into account extent of surgery, age, and presence of NF 1. The fundamental principle is to resect the tumor if possible. Patients with completely resected tumors are observed and only treated if they relapse or progress. Patients with incompletely resected or inoperable tumors are observed and treated according to progression of disease or severity of neurological symptoms; for example a patient with optic glioma with severe visual disturbance such that their eyesight is threatened. These patients receive radiotherapy only if older than 8 years, or chemotherapy with vincristine and carboplatin for 16 months if younger than 8. All children with NF1 receive chemo- rather than radiotherapy. For children less than 8 years without NF1 the study is evaluating the effectiveness of adding etoposide to the induction chemotherapy.

### High Grade Glioma (HGG)

These are WHO grade III–IV tumors and account for 7–11% of childhood brain tumors. Although the outlook is slightly better than for adults the overall survival remains extremely poor. Some may develop from previous LGG, and they are also seen after radiotherapy, and in the same tumor predisposing conditions as LGG.

### Presentation

Most HGG are thalamic or in the cerebral hemispheres and as such tend to present with seizures, motor symptoms or raised ICP.

### Diagnosis

HGG are usually infiltrative lesions and MRI will show an area of edema surrounding the tumor itself, which is often of heterogenous density and variable enhancement after gadolinium (Fig. 24.1). Metastatic

**Fig. 24.1** (a) T1-weighted coronal MR scan post gadolinium showing a high grade glioma of the right frontoparietal lobe, with cystic and solid components. (b) T2-weighted axial MR scan showing the same tumor with extensive signal change in the right frontoparietal lobe around the solid/cystic tumor.

(a)

(b)

disease and extensive local spread along neuronal pathways are both common. Histologically these are less differentiated, more cellular and pleomorphic tumors than LGG.

### Management

The mainstay of the treatment of HGG is extensive surgical resection and radiotherapy. Extensive resection does seem to improve survival for both anaplastic astrocytoma and glioblastoma.<sup>195</sup> Several randomized studies in adults have shown a significant benefit with radiotherapy, and there is evidence that doses up to 60 Gy improve survival compared to lower doses.<sup>196</sup> Given the poor outcome for these patients much work has been produced on the use of chemotherapy. Combinations of CCNU, vincristine and prednisolone have long been used in the US with evidence of improved survival in comparison to radiotherapy alone.<sup>197</sup> Intensification of chemotherapy has been tried by a number of groups and the combination of ifosfamide, etoposide, methotrexate, cisplatin and cytarabine preradiotherapy produced a highly significant survival benefit in comparison to radiotherapy followed by the European standard regimen procarbazine, CCNU and vincristine (PCV).<sup>198</sup> The current UK and French study for these patients is evaluating the use of the combination of cisplatin and temozolamide, which appeared promising in phase I studies.<sup>199</sup>

## BRAINSTEM TUMORS

Brainstem tumors collectively account for 10–15% of childhood CNS malignancies. The median age at presentation is between 5 and 10 years and there is no sex difference. Seventy-five per cent occur in the pons and the rest in the medulla and midbrain. About 50% are low grade gliomas, 35–40% are high grade astrocytomas, and 10% are ependymomas and PNETs.

### Presentation

Brainstem tumors can be considered in two groups, favorable and unfavorable. The favorable tumors are focal intrinsic, dorsal exophytic and cervicomedullary junction. These are usually pilocytic astrocytomas. Focal intrinsic tumors are usually found in the medulla and the midbrain. They are slow growing and present with either CSF obstruction or cranial nerve deficits according to site. Dorsal exophytic tumors arise from the floor of the fourth ventricle and do not usually invade the brainstem. Again they usually present with symptoms of CSF obstruction, and lesions of the IX–XII cranial nerves. Cervicomedullary junction tumors arise from the top of the spinal cord and grow up through the foramen magnum to compress the medulla. They usually present with lesions of IX–XII cranial nerves. Unfavorable brainstem tumors are diffuse intrinsic pontine tumors, PNETs and atypical teratoid/rhabdoid tumors. Diffuse intrinsic pontine gliomas account for 70% of brainstem tumors. These tumors present with a very short history of multiple bilateral cranial nerve defects.

### Diagnosis

MRI is the imaging modality of choice for patients with a suspected brainstem lesion. All the tumor types described above appear hypodense on T1-weighted images and hyperintense on T2-weighted images. Low grade gliomas usually enhance briskly after gadolinium, whilst intrinsic pontine tumors enhance poorly (Fig. 24.2).

### Management

For cervicomedullary junction tumors complete resection can be achieved in the majority of patients with excellent long term control.<sup>200</sup> For dorsal exophytic tumors it is always necessary to leave a layer of tumor on the floor of the fourth ventricle. However again most of these patients do well.<sup>201</sup> Resection of focal intrinsic tumors is difficult and should only be attempted on easily accessible tumors with the imaging characteristics of pilocytic astrocytomas. For diffuse pontine glioma the clinical and radiological appearances are so characteristic that even biopsy is unnecessary, and may worsen the patient's neurological

Fig. 24.2 T2-weighted axial MR scan showing a diffuse intrinsic pontine glioma.

condition.<sup>202</sup> Radiotherapy is indicated for favorable tumor types that cannot be safely surgically resected, or where there is progression after resection. 54 Gy delivered in 30 fractions results in tumor control in most patients.<sup>203</sup> Radiotherapy, again with 54 Gy in 30 fractions is indicated for patients with diffuse pontine tumors and will rapidly improve symptoms in most patients. However survival is extremely poor (20% at 2 years).<sup>204</sup> Hyperfractionated therapy (total dose up to 72 Gy) has proved disappointing.<sup>205</sup> To date no clear benefit has been shown from chemotherapy in either favorable or unfavorable brainstem tumors.<sup>206</sup>

## EPENDYMOMA

These arise from the lining of the ventricular system and central canal of the spinal cord (75% in the posterior fossa, 25% in the cord). Half the cases occur before the age of 5. There is considerable variation in anaplasia, pleomorphism and differentiation. The *subependymoma* is often silent and found coincidentally at autopsy. Spinal subarachnoid space involvement is much more likely with infratentorial tumors (20–30%) than with the supratentorial tumors (3–8%). High grade ependymomas may disseminate within the CNS through the CSF but systemic spread is rare.

### Presentation

Raised intracranial pressure is common in all posterior fossa tumors. There may be some cerebellar dysfunction. Local cranial nerve deficits are more commonly seen than in medulloblastoma because of local infiltration and invasion of the floor of the fourth ventricle and brainstem. Supratentorial ependymomas more commonly present with seizures and long tract signs. The duration of the history depends on the site and the grade of the tumor.

### Diagnosis

CT scans will show a hyperdense and contrast-enhancing tumor with hydrocephalus; MR scanning will delineate tumor relations and spinal CSF metastases (Fig. 24.3). CSF examination is needed operatively.

### Prognostic features

Spinal cord and especially myxopapillary cauda equina tumors fare better but otherwise site is not of prognostic significance. It is unclear for ependymomas whether histology (anaplasia) or degree of resection are of significance.<sup>207</sup> Young age (<5 years) and brainstem invasion do adversely affect outcome.

Fig. 24.3 T1-weighted sagittal MR scan post gadolinium showing a posterior fossa ependymoma.

## Management

Attempts at primary total resection are indicated and usually possible for supratentorial tumors, less so in the posterior fossa where brainstem infiltration increases perioperative morbidity (5–10%). With surgery alone 5-year survival is 15–20%. For supratentorial tumors extended local field irradiation to a total dose of 50–55 Gy and for posterior fossa lesions a field to extend down to C3–4 are indicated. Most relapses are local but 10–15% have subarachnoid spread. This may be greater in posterior fossa and anaplastic tumors; for them, craniospinal irradiation has been recommended. For low grade tumors, surgery and extended field radiotherapy yield 50% 5-year survival. Intramedullary spinal cord tumors may be cured by complete microsurgical resection. Chemotherapy has not been shown to significantly improve survival.<sup>208</sup> The current SIOP study gives vincristine, cyclophosphamide and etoposide to patients with residual disease after surgery, before radiotherapy.

## CHOROID PLEXUS NEOPLASMS

These are extremely rare tumors accounting for only about 0.5% of all childhood CNS tumors. Most occur before 2 years of age. Most occur in the lateral ventricles and are intraventricular papillomas which secrete CSF. About 15% are slow-growing carcinomas which can reach huge dimensions and can metastasize.

## Presentation

This is usually with raised intracranial pressure and hydrocephalus (they can produce CSF up to four times the normal rate) owing to ventricular obstruction with or without hemorrhage. CT scan will show hydrocephalus and an isodense to hyperdense intraventricular tumor with contrast enhancement and often with calcification, MRI will show where the fronds of the tumor extend into the ventricles.

## Management

Surgery is the treatment of choice but there is a high mortality and morbidity. For papillomas, curative complete resection appears to be possible in between 75 and 100%. Shunting may be necessary to relieve persistent hydrocephalus. For the papillomas there is no need for further therapy. For carcinomas degree of surgical resection seems to be a prognostic factor.<sup>209</sup> Radiotherapy seems to improve survival<sup>210</sup> and there are some reports of a role for chemotherapy.

## EMBRYONAL TUMORS

### MEDULLOBLASTOMA (PNET OF CEREBELLUM)

This is a midline PNET usually arising from the cerebellar vermis in the roof of the fourth ventricle. All PNETs tend to seed within the CSF, and up to 35% of medulloblastomas may have metastatic disease at presentation. The peak age incidence is 5 years. There is a male preponderance.

## Presentation

Obstruction of the fourth ventricle leads to raised intracranial pressure, progressive ataxia of the lower limbs, diplopia, and 5th, 7th and other cranial nerve deficits. Long tract signs appear rather later. Nuchal rigidity and/or head tilt suggests cerebellar tonsillar herniation and necessity for rapid relief. The differential diagnosis includes cerebellar astrocytoma, ependymoma, brainstem glioma, and infectious encephalitis (although the last is usually of more acute onset). CT scan shows a solid homogeneous, iso- or hyperdense lesion which is enhanced by contrast but these features are not unique to medulloblastoma (Fig. 24.4a). An MR scan may more easily differentiate a medulloblastoma from the other tumors by clearly showing the site of origin (Fig. 24.4b).<sup>211</sup> Lumbar CSF examination should *not* be performed before surgery.

## Prognostic features

Young children (under 3) have a poorer prognosis than older children and are generally considered unsuitable for craniospinal radiotherapy because of the profound neurodevelopmental sequelae. Meningeal enhancement on MR of brain or spine is sufficient evidence of metastatic disease (Chang stage M2/3) and is associated with worse prognosis. The presence of isolated tumor cells in the CSF (Chang stage M1) is now accepted to confer a poorer prognosis.<sup>212</sup> The prognostic significance of gross total resection is disputed with some studies showing a survival advantage<sup>212</sup> and others not (HIT 91). The commonest genetic abnormality in medulloblastoma is deletion of 17p, seen in 40–50% of tumors although the prognostic significance of this finding is debated.<sup>213</sup> High expression of ErbB2 and ErbB4 are associated with more aggressive tumors and worse prognosis.<sup>214</sup> MYC oncogene amplification is seen in only 6% of medulloblastomas but is associated with worse outcome.<sup>215</sup>

## Pathology

This is a highly cellular soft and friable tumor full of small round undifferentiated cells with hyperchromatic nuclei and abundant mitoses. There can be variable glial or neuroblast differentiation which may be of prognostic significance.

## Management

Complete macroscopic resection is achievable in about 50% of cases. These tumors are the most radiosensitive of the primary CNS childhood tumors and radiotherapy is required to the whole neuraxis (36 Gy) with at least 50 Gy to the posterior fossa. Three-year survival figures of up to 60% have been reported for surgical resection followed by craniospinal irradiation.<sup>216</sup> Medulloblastoma has been shown to be chemosensitive in relapse schedules and in vitro. Although early multicenter trials (SIOP I, II) were unable to confirm the survival advantage seen with adjuvant chemotherapy in single-center trials, SIOP PNET 3 showed a significant increase in event free survival (EFS) for patients treated with etoposide, vincristine, cyclophosphamide and carboplatin as opposed to those receiving radiotherapy alone (3-year EFS 78% vs. 65%).<sup>217</sup> Excellent results have also been reported using cisplatin, vincristine and CCNU (Packer chemotherapy)<sup>218,219</sup> and this combination is now the recommended treatment in most studies. These patients have high morbidity from whole CNS irradiation (intellectual impairment and growth) and as a result there has been an impetus toward reducing doses of craniospinal radiation. The current SIOP study for nonmetastatic patients compares reduced dose conventional radiotherapy with hyperfractionated radiotherapy (HFRT) with both groups receiving Packer chemotherapy. In contrast the UK strategy for patients with metastatic disease is to use hyperfractionated accelerated radiotherapy (HART) to deliver a

Fig. 24.4 (a) Noncontrast CT image of a left-sided medulloblastoma. (b) T2-weighted axial MR scan of the same tumor.

craniospinal dose of 40 Gy, with a total primary dose of 60 Gy to try to improve survival without worsening neurological sequelae.

### SUPRATENTORIAL PNETs

Eighty per cent of these tumors occur within the cerebral hemispheres and the remaining 20% in the midline, especially the pineal gland. Historically they have been treated in the same way as medulloblastoma, but there is now evidence that the nonpineal tumors have a significantly worse prognosis with 5-year PFS of 41% compared to 71% for pineal tumors and 78% for medulloblastoma.<sup>220</sup>

### Presentation

This is usually with raised intracranial pressure, seizures and motor signs. The time from symptom onset to diagnosis may be quite long (up to 10 months).

### Management

Despite adequate surgery, conventional chemotherapy and craniospinal radiotherapy the majority of nonpineal sPNETs recur locally (71% in German studies and 72% in SIOP PNET 3). The current UK strategy is to combine early HART with Packer chemotherapy.

### PINEAL TUMORS

Most pineal tumors are germ cell tumors, seen much more commonly in boys and girls in the second decade of life. 20–40% are pineal parenchymal tumors (pinealoblastomas or pinealocytomas) and occur in the first 10 years and more frequently in girls.

Pinealoblastomas are best categorized as PNETs, often showing some differentiation resembling retinoblastoma. Pinealocytomas are generally more differentiated. Pineal tumors spread locally and pinealoblastomas and germinomas may disseminate, but teratomas tend to remain localized.

### Presentation

Raised intracranial pressure from third ventricular outflow obstruction is the most common presenting feature. Other signs will depend on the site and the degree of extension of the tumor. The classic presentation of a pineal tumor is with failure of upward gaze (Parinaud syndrome) and pupils that react to accommodation but not to light. Imaging will identify the lesion but not differentiate the type since both teratomas

and parenchymal tumors tend to have irregular mixed density mass lesions with calcification but with a fairly uniform contrast enhancement. CSF examination is needed following decompression particularly in pinealoblastoma and germinoma.

### Management

Biopsy is recommended to clarify the diagnosis. It is associated with a high morbidity (though low mortality), with frequent impairment of vision. In well-circumscribed teratomas, excision may be possible but for the rest, where local infiltration is quite common, biopsy with some debulking and relief of hydrocephalus is all that can be achieved with surgery. The primary treatment for the majority is radiotherapy with whole brain irradiation in the region of 35–45 Gy and a boost of 10–15 Gy to the tumor area for germ cell tumors and pinealoblastomas. There is controversy as to who actually needs spinal irradiation. It should probably be judged by the presence or absence of cells in the CSF and MR appearances but some recommend routine whole neuraxis radiation in pinealoblastoma. There is no blood–brain barrier in the pineal region and drugs such as vinblastine, bleomycin, cisplatin and VP16 have all been shown to have some efficacy in pineal tumors.

### INTRACRANIAL GERM CELL TUMORS

These account for about 3% of childhood CNS tumors in the UK. They are most common in the second decade of life. Virtually all are either pineal or suprasellar in location. Up to 20% will present with concurrent primary tumors, and up to 15% will have CSF metastases at diagnosis. The majority of intracranial germ cell tumors are germinomas, the remainder are mature and immature teratomas and the secreting tumors; yolk sac tumors, choriocarcinoma and embryonal carcinoma.

### Presentation

The features of pineal tumors are described above. Suprasellar tumors usually present with raised ICP and endocrinopathy, ranging from isolated diabetes insipidus to panhypopituitarism. Visual field deficits related to chiasmal compression are also seen, and some will present with signs of hypothalamic compression, including anorexia. MR imaging of brain and spinal cord are needed because of the risk of CSF seeding. Germinomas are usually relatively homogenous and isodense to brain, with bright enhancement after gadolinium (Fig. 24.5). Teratomas usually contain calcification and are more heterogenous in

Fig. 24.5 T1-weighted sagittal MR scan showing a suprasellar intracranial germ cell tumor with CSF metastases.

signal intensity. Serum AFP and  $\beta$ HCG should be obtained before surgery and CSF should be examined for tumor cells and levels of AFP and  $\beta$ HCG either pre- or perioperatively. Tissue diagnosis is not mandatory for tumors with elevated serum or CSF markers.

### Management

Germinomas are radiosensitive and extensive surgical resection should not be attempted. Craniospinal radiotherapy results in greater than 90% survival in the most recent SIOP germ cell study. Mature teratomas need surgical resection for cure and 93% 10-year survival can be expected, while immature teratomas fare less well, with 75% 10-year survival.<sup>221</sup> In SIOP CNS GCT 96 secreting tumors received four courses of cisplatin, ifosfamide and etoposide, followed by focal or craniospinal radiation. Survival for both groups was around 70%.<sup>222</sup>

## CRANIOPHARYNGIOMA

Two thirds of these tumors occur before the age of 20 with a median age of 8 years. There is no sex difference. Craniopharyngioma arises either in the pituitary stalk or from the floor of the third ventricle. They may be solid, mixed or cystic with or without calcification. Although they are frequently well differentiated and benign histologically their close association with the hypothalamus, pituitary and optic chiasm makes their management challenging.

### Presentation

The usual presentation of these patients is with the combination of visual failure (secondary to compression of the optic chiasm), endocrinopathy (especially growth failure) and raised ICP (due to obstruction of the third ventricle). Classic diabetes insipidus is relatively rare, seen in only 15%.

### Diagnosis

CT scanning will show a cystic low density lesion with contrast enhancement and often considerable calcification. The MR scan may define the solid and cystic components of this tumor better and identify the surrounding anatomy (Fig. 24.6).

### Management<sup>223</sup>

For this low grade tumor with visual and neuropsychological disturbances the efficacy of treatment is often difficult to evaluate. With pre-operative steroids to reduce pressure and vasopressin to control diabetes insipidus, morbidity and mortality have decreased. Seventy-five to eighty per cent of tumors can be completely removed with recurrence rates of 20–25% (most in the first 2 years). Morbidity is high with secondary

Fig. 24.6 T1-weighted sagittal MR scan post gadolinium showing the typical location and appearance of a craniopharyngioma.

bleeding and local tissue damage. Periodic CT or MR scanning plus endocrine follow-up are essential. If scans show no disease and no calcification postsurgery there is a 70% 10-year event-free survival. If there is residual tumor or calcification, radiotherapy (50–55 Gy local field) is required. Many now recommend subtotal resection and radiotherapy rather than radical surgery.<sup>224</sup> Intracystic radiocolloid injection has been used successfully in recurrent cystic lesions. No role has yet been established for chemotherapy.

## LYMPHOMAS

Lymphoid malignancies in childhood arise from malignant transformation of lymphoid precursor cells at various stages of maturation. Lymphomas make up the third commonest group of childhood cancers. They are classified into Hodgkin's lymphoma or Hodgkin disease (HD) and Non-Hodgkin lymphoma (NHL) according to the WHO updated REAL (revised European-American Lymphoma) classification. This classification takes into account clinical and morphological as well as genetic and immunophenotypic features.<sup>225</sup>

The strong associations with congenital and acquired immunodeficiencies for NHL and to a lesser extent HD as well as the high incidence in geographical areas with high incidence of malaria and early EBV infection suggests a role for viral infections in the pathogenesis of these malignancies.<sup>226,227</sup> However, primary evidence of viral involvement in oncogenesis in other parts of the world is rare, and the precise role of EBV and other viruses is still unclear.

### NON-HODGKIN LYMPHOMA

Childhood non-Hodgkin lymphomas represent a heterogeneous group of high grade malignancies of immature T or B cell precursors. NHL in the pediatric age group can be divided into Burkitt, precursor B- and T cell lymphoblastic lymphomas, large B cell lymphomas and anaplastic large cell lymphomas. The characteristics that are important for the biology and the diagnosis of NHL are listed in Table 24.13. Typical nonrandom chromosomal rearrangements have been identified in Burkitt lymphoma, where the oncogene *c-myc* is translocated adjacent to the gene coding for heavy chain immunoglobulin, which leads to overactivation of *c-myc*, which is thought to play a crucial role in pathogenesis and malignant proliferation. Anaplastic large cell lymphoma (ALCL) carries a characteristic translocation between 2p23 and 5q35 that leads to activation of the ALK tyrosine kinase

Table 24.13 Common childhood non-Hodgkin lymphoma characteristics and frequency

	Burkitt	Precursor T/B lymphoblastic	Large B-cell	Anaplastic large cell
Stage of development	Germinal center	Immature	Germinal center	Mature T-cell
Immunophenotype	CD20+ CD79a+ S Ig+	TdT B-lineage T-lineage CD19+ CD7+ CD79a+ CD2+ S Ig- CD3+	CD20+ CD79+a	CD30+
Cytogenetics/molecular biology	t(8;14)(q24;q32) or variant resulting in transcriptional deregulation of c-MYC	No specific abnormalities	Occasional t(8;14)(q24;q32) der(3)(q27) resulting in deregulation of bcl6	t(2;5)(p23;q35) or variant Activation of NPM/ALK tyrosin kinase receptor
Frequency (UK)	45%	25%	5%	20%

receptor. Advances in the understanding of the cellular biology has contributed to clinical management of children with NHL, as these findings have not only made an important contribution to accurate diagnosis but have also been found to have prognostic implications. The uncommon ALCL without ALK expression appear to have a much worse prognosis.<sup>228</sup> There are promising data that also could lead to novel therapeutic strategies targeting deregulated genes, such as ALK in ALCL.<sup>229</sup>

### Presentation

The scope for presentation is wide and depends upon the site of the primary lymphoid mass and the presence of features of disseminated disease such as fatigue, pain and anemia.<sup>230,231</sup>

### Abdominal primary

The abdomen is the most common primary site. In Europe B cell lymphomas normally present as a diffuse abdominal tumor often involving the omentum and mesentery with infiltration into kidney, liver and spleen and ascites (Fig. 24.7). Frequently the bone marrow and central nervous system are also involved. Sometimes there are localized tumors of the bowel wall especially in the terminal ileum (thought to arise in Peyer's patches). These masses may lead to intussusception or bleeding and sometimes to perforation of the bowel. These tumors can resemble appendicitis or an appendix mass since they often present with a right iliac fossa mass and pain.

Fig. 24.7 Contrast-enhanced CT image of the pelvis showing the typical appearance of a diffuse abdominal B cell non-Hodgkin lymphoma.

### Mediastinal primary

In the UK approximately 20% of children with NHL present with a mediastinal mass with or without pleural effusions. Most T lymphoblastic lymphoma present in this way. There may be signs of superior vena caval obstruction, dysphagia, dyspnea and pericardial effusion. There may be associated neck and axillary lymphadenopathy. Hepatosplenomegaly and bone marrow involvement (present in more than 50% of cases) and central nervous system disease are common in these patients. These patients are at high risk of developing airway obstruction with general anesthesia.

### Other sites

In Europe jaw or neck masses are unusual, but in Africa this is the usual presentation. Fifty percent of African patients with jaw primaries also have abdominal disease but marrow disease is unusual.<sup>232</sup> Lymphoid swellings can occur anywhere but most commonly in the head and neck including Waldeyer's ring and the facial bones. Other sites of origin include the pharynx (usually B cell origin) and primary tumors of bone, skin, thyroid, testis (usually lymphoblastic), orbit, eyelid, kidney and epidural space have all been described. Bone lymphomas may be localized or disseminated and may be associated with hypercalcemia.

Anaplastic large cell lymphomas have additional distinct clinical features and can present with painful lymphadenopathy, skin involvement and a systemic inflammatory response with widely fluctuating fever.

### Central nervous system involvement

Primary intracranial lymphomas are rare although more frequent with postorgan transplantation and other forms of immunosuppression or immunodeficiency. However secondary CNS involvement is common in advanced lymphoblastic and Burkitt lymphoma. When present there are the characteristic features of headache, vomiting, papilledema, cranial nerve dysfunction and seizures.

### Diagnosis

A full history and examination usually gives a clue to the type of lymphoma and the extent of dissemination. All patients require a preliminary chest radiograph for assessment of the mediastinum. This must be performed prior to any anesthetic procedure. Imaging of lymphoid masses is best carried out by MRI particularly for tumors of the head and neck. Ultrasonography is the quickest and most efficient way to define liver, spleen and kidney involvement and extent of abdominal primaries without requiring sedation or anesthesia in young children. Either MRI or CT scanning can follow. All patients require bone marrow examination. The specimens should be examined cytogenetically and immunophenotyped as well as routine cytomorphology. All patients require examination of cerebrospinal fluid provided that there is no clinical evidence of raised intracranial pressure. If this is present then a CT or MRI scan should be carried out before lumbar puncture to exclude any focal deposit. Sometimes the diagnosis can be

made on cytological examination of pleural fluid or bone marrow. In the presence of any accessible localized disease excision biopsy should be carried out. If there is truly isolated mediastinal disease with no involvement of bone marrow or CSE, material will need to be obtained preferably by percutaneous needle or mediastinoscopy. For abdominal primaries diagnosis should be attempted by cytological examination of ascitic fluid or by percutaneous needle biopsy. Unless there is an acute abdominal emergency (such as gastrointestinal obstruction or intussusception) laparotomy should be avoided wherever possible to avoid sequelae of prolonged ileus and even ruptured abdominal wounds. Tumor material needs to be submitted for routine histological diagnosis, immunophenotyping and cytogenetics. Clinical patterns of presentation, histology, cytomorphology, immunophenotype and cytogenetics usually facilitate very precise definition of the tumor. Initial blood tests should include a full blood count, liver and renal function tests and an electrolyte profile to monitor for tumor lysis. Lactate dehydrogenase (LDH) serum levels which are thought to be prognostic, especially in B cell disease, should be assessed pretreatment.<sup>231</sup>

## Staging

Table 24.14 shows the most commonly used staging system for childhood NHL.<sup>233</sup> All primary mediastinal tumors and diffuse abdominal tumors are at least Stage III. The spread in NHL, unlike Hodgkin disease, is not orderly and contiguous from node to node. There is no place for routine staging laparotomy in NHL nor for lymphangiography. To what extent PET (positron emission tomography) is useful in staging and management of childhood NHL is currently under evaluation.

## Management

Many patients with lymphomas present with poor nutrition, concomitant infection and metabolic problems resulting from spontaneous tumor lysis. These require attention and, if possible, correction before

intensive therapy can be delivered. Prophylactic use of allopurinol or urate oxidase and more recently rasburicase has reduced the risks of therapeutic tumor lysis.<sup>234,235</sup>

Except for the diagnostic biopsy there is no routine role for surgery in childhood NHL. Radiotherapy can be helpful to control local disease and may be warranted in emergency situations such as spinal cord compression, and for the management of mediastinal masses. Chemotherapy is the preferred modality of treatment since all tumors have the potential to disseminate. Considerable improvement in survival from childhood NHL has been achieved with combination therapy, which has evolved over many national and international multicenter trials treating large numbers of patients.

In general chemotherapy in pediatric NHL is subtype specific. While B cell disease appears to be responsive to pulsed intensive treatment, T cell lymphomas and precursor B cell disease appears to benefit from prolonged and continuous treatment similar to that used in the treatment of lymphoblastic leukemia. Anaplastic large cell lymphoma is treated in Europe as an own identity with a more 'B cell like' approach.

## Localized lymphomas (Stage I and II)

Localized NHL is best treated with short course therapy of not more than 6 months' duration. For Stage I and abdominal Stage II disease there is no need for CNS directed therapy.<sup>236</sup> Over 80% event free survival can be achieved with short course pulsed therapy for low stage B cell lymphoma. Some groups have attempted to reduce the risk of late cardiotoxicity by limiting or omitting anthracyclines and reducing the risks of infertility or second tumor development by reducing anthracycline and alkylator dosages. Patte et al reported high cure rates with only two pulses of cyclophosphamide-based chemotherapy and Reiter et al very successfully treated Stage I and IIa B cell lymphomas using only three courses.<sup>236-238</sup> The only exceptions are localized lymphoblastic tumors which appear to require more intensive and sustained therapy similar to that used for advanced lymphoblastic leukemia and lymphoma.<sup>239</sup>

## Advanced stage B cell lymphomas

The best results are those reported by the SFOP and BFM groups.<sup>236-238</sup> Both groups used initial low dose cytoreductive therapy (cyclophosphamide, vincristine and prednisolone) in order to reduce tumor bulk before a more intensive induction regimen. The LMB protocol consists of high dose methotrexate, fractionated high dose cyclophosphamide, vincristine, prednisolone and doxorubicin followed by a consolidation phase using continuous infusion cytosine arabinoside. CNS-directed therapy is with high dose methotrexate and intrathecal therapy but not irradiation except for those with Stage IV disease involving the CNS at diagnosis. Event free survival has progressively improved over the last 20 years with therapy modified in duration and intensity. In recent times there has been a multinational protocol stratifying disease by stage attempting to reduce intensity and subsequent toxicity for lower risk patients and giving very intensive therapy for those with the highest risk, in particular those with bone marrow involvement of greater than 70% and those with CNS disease at diagnosis. The initial response to the cytoreductive therapy has also proven to be a significant prognostic indicator. Application of such therapy even in the most advanced disease now carries with it over 80% chance of 5-year event free survival.<sup>238</sup>

## Advanced stage non-B cell lymphoma

Since the mid-1970s patients with lymphoblastic lymphoma usually of T cell origin (but with a small percentage having precursor B cell disease) have been treated with leukemia type therapy.<sup>237,239</sup> The BFM Group have shown somewhat superior results because of their very sustained induction, consolidation and maintenance therapy similar to that used for acute lymphoblastic leukemia. With such intensive treatment there seems to be very little difference in survival between Stage III and IV disease. The most significant adverse prognostic feature appears to be failure to respond early (as defined by the BFM Group for acute lymphoblastic leukemia). Such slow responders may benefit from early intensification. The BFM 90 protocol has transformed the previously observed

Table 24.14 St Jude modified staging system for non-Hodgkin lymphoma

Stage		Approximate frequency by stage seen in UK
I	Single tumor (extranodal) or single anatomic area (nodal) (not mediastinum or abdomen)	5%
II	Single tumor (extranodal) with regional node involvement. Primary gastrointestinal tumor with or without involvement of associated mesenteric nodes only On the same side of diaphragm: a. two or more nodal areas b. two single (extranodal) tumors with or without regional node involvement	20%
III	On both sides of the diaphragm: a. two single tumors extranodal b. two or more nodal areas. All primary intrathoracic tumors (mediastinal, pleural, thymic); all extensive primary intra-abdominal disease; all primary paraspinal or epidural tumors regardless of other sites	50%
IV	Any of the above with initial CNS* or bone marrow involvement† (<25%)	25%

\* CNS disease = unequivocal blasts > 5/mm<sup>3</sup> in a cytocentrifugal cerebrospinal fluid specimen ± neurologic deficits, e.g. cranial nerve palsies ± intracranial nodal deposits

† Arbitrary cutoff of 25% to distinguish leukemia from lymphoma. This may not be useful for all, e.g. in B cell NHL no difference in outcome between Stage III and IV disease up to 70% bone marrow infiltration

pattern of ongoing relapses out beyond 4 years, to early relapses and virtually no late relapses.<sup>239</sup> A European wide international protocol is now in use.

### **Anaplastic large cell lymphoma**

Multi-agent chemotherapy as trialed by the SFOP and BFM groups results in an over 80% event free survival, with skin involvement and splenomegaly forming the most adverse features.<sup>240,241</sup> The duration of therapy is determined by stage and consists of short pulsed intensive treatment. As with T lymphoblastic leukemia there has been creation of a European Intergroup of investigators to create a trial using a prephase with vincristine, cyclophosphamide, and dexamethasone followed by a multi-agent BFM type regimen (ifosfamide, etoposide, cytosine arabinoside, dexamethasone and intrathecal therapy).

### **Immunosuppression/immunodeficiency related lymphoproliferative disease (LPD)**

There are increasing reports of patients developing what is thought to be an EBV driven lymphoproliferation of B cell phenotype following severe immunosuppression, especially after organ transplantation. The recognized strategy for dealing with them has first been to reduce immunosuppressive therapy. There is a clear correlation between the incidence of LPD and the severity of immunosuppression. It is not always possible to reduce immunosuppression in the post-transplant situation, and most appear to require some chemotherapy. Some respond to the use of cytoreductive therapy with cyclophosphamide, vincristine, and steroids. Some tumors require intensive B cell lymphoma type therapy. Numbers have been too small in the past to address some of the questions in clinical trials, but this might change with increasingly important international collaborations. Use of targeted anti-B cell monoclonal antibodies<sup>242</sup> and the production of cytotoxic T lymphocytes against EBV-infected cells have been reported.<sup>243</sup>

### **Alternative strategies**

Bone marrow transplantation has limited use in modern day therapy for NHL and should be reserved for those who have partial remission after intensive therapy, or those who relapse early but respond on re-induction with second line therapy. Specific targeted monoclonal antibody therapy has been used in adult high grade lymphomas but not systematically in children. Relapse in childhood NHL is still associated with a high mortality.

## **HODGKIN DISEASE**

Hodgkin's lymphoma or Hodgkin disease (HD) arises from malignant transformation of germinal center derived B-lineage precursors.<sup>244</sup> HD is characterized by the presence of giant multinuclear Hodgkin's and Reed–Sternberg cells, which are the malignant cells in this lymphoma. HD has a peak incidence in teenagers and is uncommon in children under five and rare in children under two. As for NHL, infection, in particular by EBV, is thought to contribute to the etiology. The Epstein–Barr virus genome has been detected in Reed–Sternberg cells in a significant percentage (at least 60%) of young cases especially boys and those with mixed cellularity subtype.<sup>91–93,245</sup> Although no typical recurrent nonrandom cytogenetic changes have been identified in HD, recurrently observed gains of material on chromosome 2p, which are found in approximately 50% of HD, point to deregulation of the REL gene, which is a putative oncogenic transcription factor in the pathogenesis of HD.<sup>246,247</sup>

### **Classification**

According to the WHO classification HD can be subdivided into four subtypes.<sup>225</sup>

1. *Lymphocyte predominance*: Reed–Sternberg cells may be quite scarce, fibrosis is rarely seen and the prognosis is very good.
2. *Mixed cellularity*: Reed–Sternberg cells are usually profuse (5–15 per high power field) often with fine fibrosis and focal necrosis.
3. *Lymphocyte depletion*: large abnormal mononuclear cells are often seen as well as Reed–Sternberg cells with few lymphocytes. Fibrosis

and necrosis are common and often quite diffuse. This form is rarer in children.

4. *Nodular sclerosis*: lacunar cells are a characteristic finding with a thickened capsule and bands which divide the tissue into nodules. This histology is especially common in lower cervical, supraclavicular and mediastinal HD of childhood.

The prognosis appears to be related to the proportion of lymphocytes present in types 1–3. Mixed cellularity is seen much more commonly in younger patients and in those from developing countries. Overall in the UK and Northern Europe nodular sclerosing and mixed cellularity types are seen in roughly equal proportions.

There is some correlation between patterns of presentation and histopathology with mixed cellularity and lymphocyte depleted forms usually presenting with more disseminated disease and nodular sclerosis classically presenting with mediastinal disease in adolescence. Lymphocyte predominant disease almost always presents with focal nodal disease characteristically in the neck or groin. Hodgkin disease generally follows an orderly pattern of spread from node to contiguous node. When the spleen is involved, infiltration usually starts as a small nodule. Liver infiltration is usually focal.

### **Clinical presentation**

In childhood most patients present with painless swelling of the cervical or supraclavicular nodes, which can feel firm or rubbery on palpation. Two thirds of children have mediastinal involvement, which may be found coincidentally on chest radiograph but may compromise the airway and cause respiratory distress (Fig. 24.8a). Involvement of the pleura or pericardium with effusions may worsen the chest symptoms. Axillary or inguinal node involvement is less common. The groin is involved in less than 5% of childhood cases. Hepatic and splenic involvement indicates advanced disease (Fig. 24.8b). Approximately 30% of young patients have nonspecific features of tiredness and anorexia but very specific symptoms of fever, weight loss (more than 10%) and night sweating. Other unspecific symptoms are generalized pruritus and unexplained pain on taking alcohol. These are designated as B symptoms and carry a worse prognosis and are therefore part of pretreatment staging.

### **Diagnosis**

Differential diagnosis includes infective causes of lymphadenopathy (e.g. infectious mononucleosis, atypical TB, and other viruses) and non-Hodgkin lymphoma particularly in lymphocyte-predominant disease. Usually NHL has a more rapid onset and rapid tumor growth. Diagnostic investigations which are essential include:

1. Clinical assessment for any node or organ enlargement and documentation of any symptoms.
2. Standard posteroanterior (PA) and lateral chest radiograph. It is important to document the extent of a mediastinal mass since its dimensions determine whether the patient may require subsequent radiotherapy (Fig. 24.8a).
3. CT scan of chest, neck and abdomen to define precise dimensions and extent of disease. Although MR scanning may be better for neck masses, CT is more commonly used enabling scanning from neck through to the abdomen (Fig. 24.8b,c).
4. Node biopsy to confirm diagnosis, subtype and to carry out molecular and EBV screening studies.
5. Bone marrow aspirates and trephine biopsy to exclude infiltration in patients with advanced disease and those with B symptoms.

In the past laparotomy and splenectomy have been part of the management of HD, but now the procedures are safely avoided wherever possible because of the risk of overwhelming sepsis associated with splenectomy. Table 24.15 shows the staging system most commonly used throughout the world.

### **Management**

Hodgkin disease is very responsive to treatment, in particular to radiotherapy, but universal use of radiotherapy was associated with

**Fig. 24.8** (a) PA chest radiograph showing right-sided hilar lymphadenopathy in Hodgkin disease. (b) Contrast-enhanced CT image of the abdomen showing the typical appearance of Hodgkin disease in the spleen. (c) Contrast-enhanced CT of the neck showing bilateral cervical lymphadenopathy in Hodgkin disease.

unacceptable local tissue growth problems in earlier trials. Combined modality therapy was adopted to minimize the toxicity of both radiation and chemotherapy but optimize cure. Newer evidence accrued that the combination of alkylating agents such as procarbazine and radiation increased the risk of some late toxicity, especially second tumor formation and infertility.<sup>248,249</sup> As a consequence modern therapy has contained radiotherapy in a dose range of 20–35 Gy only for those with localized Stage IA disease where an involved field was included. Since such tumors are primarily in the neck there still is the consequence of developing hypothyroidism.<sup>250</sup> Chemotherapy is now used for all stages including low stage disease. Positron emission tomography (PET) has become very important in assessing response to initial therapy in pediatric HD.<sup>251</sup> In lymphocyte predominant HD the approach today is surgery and resection only if the tumor is operable (mainly Stage IA and IIA). More extensive disease of this histology, which has an excellent prognosis, is treated with low intensity chemotherapy consisting of prednisolone, vinblastine and low dose cyclophosphamide. Response is assessed with PET scanning. For patients with Stage II and IIIA HD the aim of therapy is to achieve cure with least long term sequelae. The current

aim is to minimize the potential toxicity of alkylating agents and etoposide, which include infertility and second malignancies. The current approach in the UK has adapted the experiences from the GPOH trials and now uses two courses of OEPA chemotherapy consisting of prednisolone, vincristine, adriamycin and etoposide for patients with Stage I and IIA disease. If re-assessment with PET after the two courses indicates no active disease it is safe to give no further treatment.<sup>252</sup> Patients with Stage IIB, IIIA receive an additional two cycles of COPP (procarbazine, cyclophosphamide, vincristine, procarbazine and prednisolone) chemotherapy, if PET scanning after induction indicates no active disease. If the tumor is PET-positive after the initial OEPA involved field radiotherapy (IFRT) is delivered to sites of disease. Patients with Stage IIIB and IV disease require more therapy and receive four courses of COPP with IFRT if there is evidence of PET-positive residual disease after initial courses of OEPA, and without radiation if PET scanning indicates the absence of active disease. The responsiveness of HD to treatment has made it difficult now to run randomized trials with low stage Hodgkin disease, which has a 5-year event free survival greater than 95%. In Stage IV patients results have been less favorable (in the region of 50–60% 5-year survival in the past). Relapsed and progressive HD is still a problem, and no uniform strategy for second line treatment exists. In the UK EPIC chemotherapy, consisting of etoposide, prednisolone, ifosphamide and cisplatin is currently used for refractory or relapsed disease, which can be followed by high dose chemotherapy and stem cell rescue in high risk patients. A similar approach was reported by the GPOH, which conferred over 60% overall survival after relapse of HD, however early relapse after initial treatment and progressive disease remain difficult to cure.<sup>253,254</sup>

**Table 24.15** Ann Arbor staging system for Hodgkin disease

Stage I	Involvement of a single lymph node region (I) or of a single extralymphatic organ or site (I <sub>e</sub> )
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and one or more lymph node regions on the same side of the diaphragm (II <sub>e</sub> )
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III) which may be accompanied by involvement of the spleen (III <sub>s</sub> ) or localized involvement of extralymphatic organ or site (III <sub>e</sub> ) or both (III <sub>se</sub> ).
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node involvement

+B, presence of fever, night sweats or weight loss > 10% in previous 6 months; +A, none of above

## NEUROBLASTOMA

Although most frequently presenting as a large abdominal mass, this tumor is metastatic in 70% of patients at diagnosis. The commonest primary sites are the adrenal gland 40%, other abdominal sites 25%, chest 15%, pelvis 5% and neck 5%. The thorax is more frequently involved in those under 1 year. Neuroblastoma arises from primordial neural crest cells which form part of the sympathetic and rarely the parasympathetic nervous system. 1 in 250 neonates dying of other causes are found to have small foci of adrenal neuroblasts but disease

occurs only in 1 in 10 000 live births. These foci may represent tumors in situ or may be a reflection of a normal stage of adrenal development which regresses in health but persists in malignancy. Spontaneous regression of malignant neuroblastoma to benign ganglioneuroma has been recorded even in infants with quite widespread disease (see below).

### Epidemiology and etiology

Neuroblastoma occurs slightly more frequently in boys and occasional familial clusterings have been reported. Genetic rearrangement involving the short arm of chromosome 1 has been described and it is possible that up to 20–25% of cases may be heritable. Geographical variations may reflect genuine genetic or environmental factors or may be a reflection of low detection rates. Neuroblastoma occurs with increased frequency in Beckwith–Wiedemann syndrome, neurofibromatosis, nesidioblastosis and in fetal phenytoin syndrome.

### Presentation

The features of neuroblastoma are protean because of early dissemination and origin anywhere along the sympathetic chain. Superficial or abdominal lesions usually present as a mass, while pelvic or thoracic lesions often present with obstruction of bowel, bladder or airway. The classic presentation of Stage 4 disease is with an abdominal mass with the features of marrow infiltration including anemia, bruising, fever, lethargy and irritability. Anemia is present in approximately 90% of cases even in the absence of marrow infiltration. Bony disease gives characteristic deep-seated intractable pain in one or more limbs and often causes a limp. Proptosis with periorbital bruising is a characteristic but rare feature of Stage 4 disease due to infiltration either within the orbit or in the sphenoid bone. Local extension through an intervertebral foramen can produce cord compression at any level in some 5% of patients. These patients may need urgent treatment, either with radiotherapy, laminectomy or chemotherapy. Full neurological recovery can be expected in 50% of these patients, but recovery is unlikely if the presenting motor defect is severe.<sup>255</sup> Approximately 1–2% of tumors produce vasoactive intestinal peptide which produces intractable diarrhea associated with hypokalemia. Most (90%) tumors secrete catecholamines usually homovanillic acid (HVA) and vanillylmandelic acid (VMA), and although blood levels may be very high they do not normally cause hypertension. Hypertension does occur but is usually renovascular. Skin metastases present as nontender bluish, mobile subcutaneous nodules ('blueberry muffin') and are characteristically seen in Stage 4S disease.

A syndrome of opsochonus/myoclonus in which the patient has acute cerebellar and truncal ataxia with rapid eye movements may be seen (dancing eye syndrome). CNS disease is rare although increasingly described as length of survival improves.

### Investigations

The diagnosis must be confirmed and extent of disease evaluated.

#### Biopsy

All should have histological confirmation from the most easily accessible tumor deposit. In addition to histology fresh tumor material is needed for molecular diagnostics. Deletions of the short arm of chromosome 1 are found in 70–80% of near diploid cells and can assist in differentiation from other small round cell tumors. DNA content overall is of prognostic significance (pseudodiploidy is associated with advanced disease and poorer survival). MYCN amplification is associated with advanced disease and poor prognosis. Consequently, tumor cytogenetics, ploidy and MYCN amplification studies are all required. Histologically, neuroblastoma consists of small blue round cells with fibrillary bundles, hemorrhage, necrosis, calcification and attempts at rosette formation. Maturation to ganglion cells with fibrils may be diffuse (ganglioneuroma) or patchy (ganglioneuroblastoma). [Table 24.16](#) shows ways in which small round cell tumors of childhood may be distinguished.

#### Bone marrow

Multiple site aspirates and trephines are necessary to exclude involvement since it is the commonest metastatic site. When present, infiltration may be very heavy and mimic ALL or show patchy clumps or rosettes ([Fig. 24.9a](#)).

#### Diagnostic imaging

CT, MR and ultrasound scans can all be used to define primary tumor extent ([Fig. 24.9b](#)). It is essential to have three-dimensional assessment of tumor size to document response accurately. MR is optimal to determine any spinal extension ([Fig. 24.9c](#)). Iodine-123 metaiodobenzylguanidine (MIBG) scanning is needed to determine the extent of metastatic disease ([Fig. 24.9d](#)). If negative a technetium bone scan is needed to exclude bone metastases.

#### Urinary catecholamines

Between 85% and 95% of patients have detectable excess in their urine and the total levels of catecholamines and VMA and HVA can be used to monitor tumor response. Catecholamines should ideally be measured on 24-hour specimens but can be done on spot specimens in younger children.

#### Blood tests

In addition to the usual baseline investigations it is usual to measure lactate dehydrogenase (LDH), ferritin and neuron specific enolase (NSE) in patients with neuroblastoma.

#### Biology

The molecular biology of neuroblastoma has been extensively studied. It is well established that amplification of the proto-oncogene MYCN is associated with higher stage tumors and a worse prognosis.<sup>256</sup> Deletion of the short arm of chromosome 1 (1p deletion), with its loss of a putative tumor suppressor gene is similarly associated with more advanced disease and disease progression.<sup>257,258</sup> Gain of the long arm of chromosome 17 (17q gain) is also a powerful negative prognostic factor.<sup>259</sup> Expression of the high affinity nerve growth factor (NGF) receptor, TrkA, and to a lesser extent the low affinity NGF receptor (LINGFR/p75), correlates with good outcome.<sup>260,261</sup> Expression of TrkB, the receptor for brain derived neurotrophic factor (BDNF), correlates with MYCN amplification and poor prognosis<sup>262</sup> while expression of TrkC, the receptor for neurotrophin 3 (NT-3), is associated with good outcome.<sup>263</sup> These correlations suggest a difference in differentiation state between those tumors with a favorable prognosis and those which do badly. On the basis of these markers patients can be divided into three prognostic groups ([Table 24.17](#)). The first group consists of those whose tumors have a hyperdiploid or triploid karyotype, without MYCN amplification or 1p deletion and high expression of TrkA. These tend to be infants, less than 1 year of age, with Stage 1, 2, or 4s tumors who have an excellent prognosis. The second group contains those whose tumors have a diploid or tetraploid karyotype, no MYCN amplification, but deletion of 1p and low expression of TrkA. This group tends to contain children over the age of 1 year with Stage 3 and 4 disease who respond initially to chemotherapy but often relapse. They have an intermediate prognosis with 25–50% 5-year survival. The third group have tumors with diploid or tetraploid karyotypes, amplified MYCN, deletion of 1p, and absence of TrkA. These children have an appalling prognosis with a 5-year survival of 5%.<sup>261</sup>

#### Staging

Brodeur et al<sup>264</sup> published an international neuroblastoma staging system (INSS) ([Table 24.18](#)) which has been widely adopted. Standardization has enabled comparison of treatment results which was difficult in the past. All previous criteria were based on clinical, radiological and bone marrow examination but now staging includes the division of Stage 2 into those with and without lymph node involvement which alters prognosis and may indicate the need for a change in therapy. The overall distribution by stage is approximately 10–15% Stage 1, 8–10% Stage 2,

**Table 24.16** Useful markers in the differentiation of small round cell tumors of childhood

Tumor	Tdt	Cytoplasmic immunoglobulin	Markers now identified immunologically				Intermediate filament proteins			
			Actin	Myosin	Neuron-specific enolase	S100 protein	Desmin	Vimentin	Neurofilament	Cytokeratins
Rhabdomyosarcoma	-	-	+	+	+/- (rare)	+/-	+	+	-	+/-
Neuroblastoma	-	-	-	-	+	+	-	-	+	-
Askin tumor	-	-	-	-	+	-/+	-	+/-	?	+/-
Peripheral PNET	-	-	-/+	-	+	+	-/+	+/-	+/-	+/-
Ewing sarcoma 'typical'	-	-	-	-	- (+) (occasional)	- (+)*	-	+	-	+/-
Non-Hodgkin lymphoma	+T -B	In B cell	-	-	-	-	-	+	-	-
ALL	+ (95%)	In pre-B (10–15%)	-	-	-	-	-	-	-	-

This battery of markers should be combined with specific antibodies to detect surface antigens, e.g. UJ13A for neuroectodermally derived cells or UJ181A from fetal brain cell origin.  
 (+)\*,occasional in Ewing sarcoma. ALL, acute lymphoblastic leukemia; PNET, primitive neuroectodermal tumor; Tdt, terminal deoxynucleotidy transferase.

Fig. 24.9 (a) Bone marrow aspirate showing a clump of neuroblastoma cells. (b) Contrast-enhanced CT image of abdominal neuroblastoma – note the encased blood vessels displaced anteriorly. (c) Contrast-enhanced CT image of abdominal neuroblastoma – note the calcification anteriorly in the tumor and the intraspinal component. (d) MIBG scan of a patient with Stage 4 neuroblastoma. Note the uptake in the abdominal primary tumor and the extensive bony uptake.

Table 24.17 Prognostic features in neuroblastoma

Good	Intermediate	Adverse
Age < 1 year	Age > 1 year	Age > 1 year
INSS stage 1, 2, 4S	INSS stage 3, 4	INSS stage 3, 4
Single copy MYCN	Single copy MYCN	Amplified MYCN
Intact chromosome 1p	Deleted 1p	Deleted 1p
No gain of 17q	Gain of 17q	Gain of 17q
Hyperdiploid	Diploid/tetraploid	Diploid/tetraploid
High TrkA	Low TrkA	Low TrkA

15–20% Stage 3 and 60% Stage 4. In those under 1 year almost 30% have Stage 1 disease. Nearly 40% of infants (1 year) affected have localized disease compared with 20% of older children. Stage 4S (Stage 1 or 2 with dissemination limited to liver, skin and/or bone marrow) is almost exclusively seen in infants. Table 24.17 shows recognized prognostic features.

### Management

#### Low risk group

(INSS Stage 1, 2 and 3, Stage 4 without bone, lung, pleural, or CNS metastases in infants, and INSS Stage 4S disease, without MYCN amplification.)

**Table 24.18** International staging system for neuroblastoma

Stage 1	Localized tumor confined to the area of origin, complete gross excision, with or without microscopic residual disease, identifiable ipsilateral and contralateral lymph nodes negative microscopically
Stage 2A	Unilateral tumor with incomplete gross excision, identifiable ipsilateral and contralateral lymph nodes negative microscopically
Stage 2B	Unilateral tumor with complete or incomplete gross excision, with positive ipsilateral regional lymph nodes, identifiable contralateral lymph nodes negative microscopically
Stage 3	Tumor infiltrating across the midline with or without regional lymph node involvement; or unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral regional lymph node involvement
Stage 4	Dissemination of tumor to distant lymph node, bone, bone marrow, liver and/or other organs (except as defined in 4S)
Stage 4S	Localized primary tumor as defined for stages 1 and 2 but with dissemination limited to liver, skin and/or bone marrow

Surgery only is recommended for Stage 1 and 2 disease (99% and 98% overall survival respectively) and for resectable Stage 3 disease in infants, in the absence of MYCN amplification. Chemotherapy is reserved for any recurrence and may be needed in 10% of Stage 1 patients and 20% of Stage 2.<sup>265</sup> Unresectable Stage 2 or 3 disease in infants in the absence of MYCN amplification can be managed with short non-intensive combination chemotherapy based on cyclophosphamide/vincristine (CO), etoposide/carboplatin (VP-CARBO) and cyclophosphamide/doxorubicin/vincristine (CADO). A subset of Stage 2 patients with a poorer prognosis can be identified by MYCN amplification and age over 2 years.<sup>266</sup> These patients merit aggressive chemotherapy and should be regarded as high risk. Stage 4S disease is associated with spontaneous regression and good overall survival. However a group of infants who present at less than 2 months of age tend to have rapidly enlarging abdominal disease (either an abdominal primary or metastases in the liver) and a poorer prognosis. Whilst most patients with 4S neuroblastoma do not need treatment this group merit early combination chemotherapy<sup>267,268</sup> with VP-CARBO and CADO. A small group of infants with Stage 4 disease without bony metastases and without MYCN amplification, who would be categorized as 4S but for the presence of a large usually abdominal primary can also be treated with a similar expectant strategy and will regress spontaneously.

### Intermediate risk group

(Unresectable INSS Stage 2 and 3 without MYCN amplification and infants with Stage 4 with bone, lung, pleural, or CNS disease, but without MYCN amplification.)

This group of patients is relatively small, only 15% of cases of neuroblastoma are Stage 3, and 15% of these will be high risk due to MYCN amplification. Combination chemotherapy alternating VP-CARBO and CADO is recommended with surgical resection of any remaining tumor.

### High risk group

(Any child with INSS Stage 2 or 3 with MYCN amplification, infants with Stage 4 or 4S disease with MYCN amplification, Stage 4 disease over the age of 1.)

Infants with disease above Stage 1 with amplification of MYCN do not do well in the absence of intensive therapy. Current European guidelines for this group of patients include chemotherapy with VP-CARBO and CADO followed by radiotherapy to the tumor site and myeloablative therapy with autologous bone marrow transplantation (ABMT).

Children over the age of 1 year with Stage 4 disease constitute 40–50% of all patients with neuroblastoma. Without intensive chemotherapy the survival for this group of patients is < 5%. With intensive induction chemotherapy, high dose myeloablative therapy with stem cell transplantation and maintenance therapy with 13-*cis* retinoic acid the survival for this group has improved dramatically, but remains stubbornly stuck at around 30%.<sup>269</sup> Many different induction regimens have been utilized for high risk neuroblastoma; most involve cisplatin/carboplatin in combination with cyclophosphamide, etoposide and vincristine. In the US doxorubicin has usually been included. No schedule has been convincingly shown to be superior, although the best European results to date have been with the Rapid COJEC schedule (vincristine/cisplatin alternating with vincristine/carboplatin/ etoposide and vincristine/cyclophosphamide/ etoposide every 10 days for eight cycles) on ENSG 5 (5-year overall survival, 39.6%). The current European cooperative trial uses Rapid COJEC as induction therapy, followed by surgical resection of the primary tumor, ABMT with either busulfan/melphalan or carboplatin/etoposide/melphalan as myeloablative therapy, 21 Gy of radiotherapy to the primary site, and 6 monthly cycles of 13-*cis*-retinoic acid. The use of immunological approaches including anti-G2 ganglioside antibodies and/or interferon are now under investigation as adjuvant therapy.

Since neuroblastoma is radiosensitive, a place for total body irradiation or targeted radiotherapy with MIBG in the above plan has been suggested. The optimal timing of such therapy remains unclear.

### Screening

Since the prognosis for localized disease is good and that for advanced disease is so very poor and there is a readily obtainable marker for disease (urinary catecholamines) attempts have been made to carry out urinary screening of infants. Studies of screening in Japan and Canada have convincingly shown that it fails to detect Stage 4 disease in children over 1 year, and merely increases the number of previously asymptomatic and presumably spontaneously resolving cases detected.<sup>270-274</sup> Mass screening for neuroblastoma with urinary catecholamines thus cannot currently be recommended.

## NEPHROBLASTOMA (WILMS TUMOR)

The incidence of Wilms tumor is approximately 1 in 10 000 live births with a very slight female preponderance (Tables 24.1, 24.2). The complex genetic picture is covered in the etiology section and Table 24.4. About 1% of patients have a family history of such tumors and it is possible that all bilateral (5% of all cases) and up to 20% of unilateral forms might be predominantly genetic in origin.

### Presentation

Presentation is usually with an abdominal mass in a well child, often found coincidentally on routine examination. Fever is present in about 25%, hematuria in 25%, abdominal pain in 40% and hypertension in 5–10% of patients. It is important to examine specifically for aniridia, hemi-hypertrophy and genitourinary tract abnormalities.

### Investigations

Ultrasound examination will define the mass and enable assessment of the contralateral kidney and patency of the inferior vena cava. Cross-sectional imaging with CT usually provides convincing evidence of the renal origin of the tumor, with the remaining renal parenchyma spread around the tumor (the so-called 'claw sign') as well as visualizing the contralateral kidney (Fig. 24.10a). Chest CT is needed to exclude pulmonary metastases (the usual site for Wilms tumor metastases) (Fig. 24.10b). If histology reveals a clear cell sarcoma then isotope bone scan is needed to exclude bone metastases, and if the histology is of a rhabdoid tumor then CT of brain is needed to exclude intracranial metastases.

Fig. 24.10 (a) Contrast-enhanced CT of abdomen showing the typical appearance of an intrinsic renal tumor stretching the renal parenchyma around it (the 'claw sign'). (b) CT of thorax showing multiple pulmonary metastases of Wilms tumor.

## Histology

The current SIOP working classification of renal tumors defines low, intermediate and high risk groups. Mesoblastic nephroma (see below) is classified as low risk, while clear cell sarcoma and rhabdoid tumors are considered high risk. The risk classification of Wilms tumor varies according to whether the patient has received chemotherapy before nephrectomy. The SIOP approach to Wilms tumor treatment with pre-nephrectomy chemotherapy for all patients means that the diagnostic needle biopsy is really only to confirm the diagnosis of Wilms tumor and the risk classification and tumor stage are defined by the post-chemotherapy nephrectomy specimen. In post-chemotherapy nephrectomy specimens only cystic partially differentiated nephroblastoma (CPDN) or completely necrotic tumors are classified as low risk. Blastemal type and diffuse anaplasia are classified as high risk, while all other histological types constitute intermediate risk.

Clear cell sarcoma comprises 5% of childhood renal tumors. It is always unilateral and is usually seen between 2 and 3 years of age. The most useful diagnostic feature is a trabecular pattern of blood vessels, and the clear cytoplasm is only present in a minority of tumors. Rhabdoid tumors comprise just 2% of childhood renal tumors, and have a poor prognosis. Eighty percent of patients are younger than 2 years. These patients often have hypercalcemia. Histologically the tumor cells have large eccentric nuclei with prominent eosinophilic nucleoli and are vimentin and cytokeratin positive. Wilms tumor with diffuse anaplasia, clear cell sarcoma and rhabdoid tumors account for more than 50% of deaths from renal tumors.<sup>274</sup>

## Prognosis

Stage and tumor histology (see Table 24.19 and above) influence outcome.<sup>275</sup> In the second UK Wilms tumor study (UKW2) 32% of patients were Stage I, 14% were Stage II, 29% Stage III, 15% Stage IV and 5% Stage V. In this study 4-year overall survival was 94% for Stage I, 91% for Stage II, 84% for Stage III, 75% for Stage IV and 78% for Stage V.<sup>276</sup>

## Management

The aims of therapy are to cure without excessive toxicity in Stage I to III and improve long term disease control in Stage IV disease. The International Society of Pediatric Oncology Studies have shown that pre-operative chemotherapy reduces the risk of tumor rupture, down-stages tumors and consequently reduces the numbers requiring flank irradiation.<sup>277,278</sup> As a result the current European practice is for all children over the age of 6 months to have pre-operative chemotherapy after needle biopsy confirmation of diagnosis. SIOP studies have also shown that for selected subgroups therapy can be

Table 24.19 Staging system for nephroblastoma

Stage I	Tumor limited to one kidney and totally excised. The renal capsule intact with no rupture pre- or during surgery. No residual tumor is apparent beyond the margins of excision. Tumor may have been biopsied
Stage II	Tumor extension beyond the kidney but totally excised. The extension is regional referring to renal vessels outside kidney, infiltrated or containing thrombus. There may be penetration through the capsule to the outer surface and into the perirenal soft tissue. Biopsy may have been performed with local flank spillage. No residual tumor beyond margins of excision
Stage III	Residual nonhematogenous tumor confined to abdomen. Any one or more of the following may be present: <ol style="list-style-type: none"> <li>1. Extension beyond surgical margins micro- or macroscopically</li> <li>2. Diffuse peritoneal contamination by spread or spillage</li> <li>3. Involved nodes (renal hilar nodes previously)</li> <li>4. Tumor not fully resectable because of local infiltration into vital organs, e.g. liver</li> </ol>
Stage IV	Blood-borne metastases, e.g. lung, liver, bone and/or brain
Stage V	Bilateral kidney tumors initially or subsequently

reduced without compromising cure.<sup>279</sup> Primary nephrectomy is only recommended for children less than 6 months of age with localized intrarenal tumors.

### Pre-operative chemotherapy

For localized tumors vincristine weekly for 4 doses with actinomycin in weeks 1 and 3, followed by nephrectomy in week 5.

For metastatic tumors vincristine weekly for 6 doses with actinomycin weeks 1, 3 and 5 and doxorubicin in weeks 1 and 5, followed by nephrectomy in week 6.

### Postoperative chemotherapy

This is determined by the combination of local stage and histological classification at nephrectomy for localized disease, and by this and the response of pulmonary metastases for those with metastatic disease. Stage I tumors are limited to the kidney, without involvement of the vessels of the renal sinus, and are completely resected. Stage II tumors extend beyond the kidney, infiltrate the renal sinus or adjacent organs or vena cava, but have been completely resected. Stage III tumors extend

beyond the resection margins or involve abdominal lymph nodes, including post-chemotherapy changes in resected lymph nodes.

### Localized tumors

Histological low risk, Stage I tumors do not need any further treatment. Stage II and III tumors receive 27 weeks of vincristine (20 doses) and actinomycin (9 doses)(AV-2). Intermediate risk, Stage I tumors receive 4 doses of vincristine and 1 of actinomycin (AV-1). Intermediate risk Stage II and III patients are randomized between actinomycin, vincristine and doxorubicin (AVD) and AV-2, Stage III patients receive local flank radiotherapy. High risk patients with Stage I disease receive AVD, Stage II and III patients receive the high risk strategy described below and local radiotherapy.

### Metastatic tumors

Patients with complete radiological clearance of their pulmonary metastases pre-nephrectomy receive AVD with flank radiotherapy if they have local Stage III disease, unless they have histological high risk disease at nephrectomy. Patients with persistent metastases that cannot be surgically removed receive the high risk strategy with flank radiotherapy for local Stage III tumors and pulmonary radiation. Patients with high risk tumors of any stage receive the high risk strategy, etoposide and carboplatin alternating with cyclophosphamide and doxorubicin for 34 weeks with flank radiotherapy for Stage II and II tumors and pulmonary radiotherapy for all.

### Specific late effects

Long term renal problems are uncommon in Wilms tumor patients these days. The small group of patients with Denys–Drash syndrome are at risk of nephritis in the remaining kidney. Flank radiation fields including the full vertebral width have reduced bony anomalies and lower dosages have reduced abdominal wall muscle atrophy. An acute veno-occlusive syndrome is occasionally seen when right-sided flank irradiation is combined with actinomycin D or adriamycin (both should be avoided for 6 weeks postradiation). Lung irradiation for residual pulmonary metastases can cause an acute pneumonitis, fibrosis and impairment of lung function.<sup>177</sup> Meadows et al<sup>153</sup> described 24 second tumors among Wilms tumor patients, with 22/24 having received radiotherapy and 10/24 chemotherapy and radiotherapy. As with Hodgkin disease, increasingly attempts are made to avoid radiation combined with chemotherapy wherever possible, hence the use of presurgical chemotherapy to reduce tumor rupture and the subsequent need for radiotherapy.

## MESOBLASTIC NEPHROMA

This tumor forms only a small percentage of childhood renal tumors but it is the commonest in the neonatal period with a mean age at diagnosis of 3–4 months. It is a quite distinct entity from Wilms tumor. The kidney may be large with no pseudocapsule. Hemorrhage, cysts and necrosis are rare but the tumor may appear to infiltrate into the normal kidney and into the perinephric connective tissue. The mass is most commonly felt coincidentally at the time of an examination for other reasons. Occasionally there is hematuria, hypertension secondary to a rise in renin and even congestive cardiac failure. Babies with this tumor can have increased risk of preterm delivery due to polyhydramnios. Prenatal diagnosis has been made using ultrasound. The differential diagnosis is between hydronephrosis and multicystic kidney. Ultrasound can distinguish between these but cannot distinguish a nephroma from nephroblastoma. The treatment of choice is nephrectomy; recurrence is rare and usually only in children presenting beyond 3 months of life. Adjuvant treatment is only required for recurrent disease or significant but rare renal rupture or if the patient is older than 3 months with marked cellular mitosis on histology.

## SOFT TISSUE SARCOMAS (STS)<sup>280</sup>

Sarcomas can arise from primitive mesenchymal cells anywhere in the body. They are the sixth most common form of childhood cancer.

## RHABDOMYOSARCOMA (RMS)

The vast majority (75%) of soft tissue sarcomas are rhabdomyosarcomas. Bladder and vaginal rhabdomyosarcomas are more common in the young and are most often embryonal or botryoid in type. Truncal and extremity lesions are more common in older patients and are more likely to have alveolar histology.

### Specific etiologic factors

Most cases of RMS are sporadic and of unknown etiology. However STS in children is associated with a significant increase in risk of breast cancer in their mothers due to germline mutations of the p53 tumor suppressor gene on chromosome 17.<sup>282,281</sup> RMS has also been associated with the nevoid basal cell carcinoma syndrome (Gorlin) which results from a germline mutation of the human homologue of the *Drosophila* segment polarity gene, patched (*ptc*).<sup>282,283</sup> The protein product of *ptc* is a membrane receptor that is involved in the regulation of sonic hedgehog (*shh*) and *wnt-1* signaling. *Shh* and *wnt-1* are very important in the induction of embryonal myogenesis, via expression of the developmental transcription factors Pax-3 and Pax-7.<sup>284</sup> Chromosomal translocations involving either Pax-3 (t(2;13)) or Pax-7 (t(1;13)) and the Forkhead (FKHR) transcription factor are seen commonly in alveolar RMS.<sup>285</sup> Thus a model is beginning to emerge in which abnormalities in the *ptc/shh/Pax* signaling pathway contribute to the development of RMS.<sup>286</sup>

### Clinical presentation

Rhabdomyosarcomas can arise at any site in the body as mass lesions. They are usually nontender and the presentation depends on the site of the tumor.

### Head and neck (40% of all rhabdomyosarcomas)

About 10% of tumors arise in the orbit producing proptosis and ophthalmoplegia. These are usually small, localized tumors with good prognosis (Fig. 24.11). Parameningeal tumors (about 20%) arise from the nasopharynx, paranasal sinuses, middle ear, mastoid and pterygopalatine fossa, producing nasal airway and ear symptoms often with purulent or bloody discharge. There is a high risk of cranial nerve or meningeal involvement and raised intracranial pressure may be the presenting feature. Other head and neck sites including scalp, face, oral mucosa, oropharynx, larynx and neck do not carry the same risk of CNS spread and present as mass lesions; they tend to be of low stage and nonmetastatic.

Fig. 24.11 Contrast-enhanced CT of orbit showing a rhabdomyosarcoma of the medial rectus muscle.

### Genitourinary tract (20%)

These usually arise in the bladder and prostate (12%) presenting as a polypoid mass inside the bladder leading to hematuria, urinary obstruction or even extrusion of the tumor into the urethra in females. They tend to be localized. Prostatic tumors lead to bladder outlet obstruction. Constipation may arise from obstruction of the rectum. Bladder tumors tend to occur in younger patients. Prostatic tumors have a higher risk of dissemination. Vaginal and uterine rhabdomyosarcomas make up 2% of the total. Most are botryoid (grape-like) and present with a mucosal or bloody discharge. Paratesticular tumors make up about 6% of the total and usually present as painless swellings in the scrotum or inguinal canal. The genitourinary tract tumors tend to have embryonal histology.

### Extremity lesions (20%)

The majority have alveolar histology. Nodal and metastatic involvement is common.

### Truncal (10%)

On the trunk the mass may reach massive proportions before diagnosis. Local recurrence and distant spread is more likely than lymphatic or nodal involvement.

### Other sites (10%)

Intrathoracic and retroperitoneal tumors may reach large dimensions before diagnosis. Intrathoracic primaries may present with airway obstruction or other respiratory symptoms and abdominal tumors with gastrointestinal obstruction. Perineal lesions are rare but can present like an abscess or a polyp. They often have alveolar histology and nodal spread.

### Diagnosis

Careful assessment of primary tumor extent and regional node involvement (clinical and radiological) is required as a baseline. A truly localized lesion should have a full excision biopsy attempted but most will have diagnostic biopsy. In parameningeal sites, investigations should include full CNS visualization by CT or MR plus CSF examination if there is no evidence of an intracerebral mass lesion. CT scan of the chest and isotope bone scan to exclude lung and bone metastases are needed. Bilateral marrow trephines and aspirates are required to exclude marrow involvement.

### Histological classification

Traditionally several forms of rhabdomyosarcoma were recognized.<sup>287</sup> Differences in classification of these tumors existed between North American and European pathologists and an attempt to produce a unifying classification based upon prognostic categories (International Classification of RMS) has been proposed.<sup>288</sup> This divides these tumors into three groups:

1. *Superior prognosis*: This consists of the botryoid and spindle cell subtypes of embryonal RMS. Both of these variants are uncommon, botryoid accounting for 6% of STS and spindle cell 3%. However both have an excellent prognosis; 95% 5-year overall survival (OS) for botryoid and 88% for spindle cell reported in the second Intergroup study (IRS II). Botryoid lesions are usually found at sites that allow growth into a cavity, normally in the genitourinary tract. They tend to have a distinctive macroscopic 'bunch of grapes' appearance, and microscopically a subepithelial layer of condensed tumor cells. Spindle cell RMS is of low cellularity and is almost exclusively formed of spindle-shaped cells. These tumors are normally paratesticular in site.
2. *Intermediate prognosis*: This group contains embryonal RMS. Histologically these consist of blastemal mesenchymal cells which tend to differentiate into cross-striated muscle cells. Considerable cytologic variation can exist. These tumors tend to be found in children less than the age of 10 years and in sites including head and neck, pelvis and retroperitoneum. In IRS II these patients accounted for 49% of STS and had a 66% 5-year OS.

3. *Poor prognosis*: This group contains alveolar RMS and the undifferentiated sarcomas. Alveolar RMS features a connective tissue stroma lined with tumor cells giving rise to the so-called alveolar pattern. This may not be present throughout the tumor, but any amount of alveolar tumor even within a predominantly embryonal RMS carries a worse prognosis and the tumor should be regarded as alveolar. Alveolar RMS tends to present in older patients in association with skeletal muscle, usually involving the extremities or the trunk. Undifferentiated sarcomas are usually diffuse and contain primitive mesenchymal cells which are negative for the antigenic markers of RMS. In IRS II, 31% of tumors were alveolar and 10% undifferentiated sarcoma; alveolar RMS had a 5-year OS of 54% and undifferentiated sarcoma 40%.

Although rhabdomyosarcoma is the commonest STS of childhood, other tumors including extrasosseous Ewing sarcoma, fibrosarcoma and peripheral primitive neuroectodermal tumors may need to be considered in the differential. Identification on light and electron microscopy of cross-striations will facilitate a specific diagnosis. Immunocytochemistry as outlined in Table 24.16 has enabled easier differentiation of rhabdomyosarcoma from other tumors.<sup>289</sup> Desmin is the most useful marker but caution is required for its interpretation. Multiple monoclonal antibodies may help to confirm the diagnosis. It is the pattern of positivity rather than any single marker which determines the diagnosis.

### Staging

The system used by the Intergroup collaborators (IRS) is the most widely accepted (Table 24.20) but attempts are now being made to adapt the TNM system<sup>290</sup> and relate it to site and extent of disease. A new grouping system is being tested in most recent trials.

### Prognostic variables

RMS is a heterogeneous condition and several prognostic factors have been identified, in addition to the histological groupings described above. Both pre-operative stage and postsurgical extent of disease are important. For those with localized tumors, complete excision (Group I) yields better survival than those with microscopic residual tumor or regional extension (Group II). Even poorer survival is seen for those with macroscopic (Group III) residual tumor and the worst for those with metastatic disease (Group IV). In IRS III 5-year OS for Group I disease was 93%, while for Group IV disease it was only 30%.<sup>291</sup> The site of the primary influences the lag time between first symptoms and diagnosis, the likelihood of metastatic spread and the possibility of surgical excision, and is also related to histological type. Orbital tumors had a 5-year OS of 95% in IRS III, while 5-year OS for parameningeal tumors was only 70%, a difference that was still seen in IRS IV.<sup>292</sup> In all trials to date, alveolar histology confers a worse prognosis than embryonal (see above). Tumor size

**Table 24.20** Intergroup rhabdomyosarcoma study clinical grouping system

Clinical group	Definition
I	A. Localized, completely resected, confined to site of origin B. Localized, completely resected, infiltrated beyond site of origin
II	A. Localized, grossly resected, microscopic residual B. Regional disease, involved lymph nodes, completely resected C. Regional disease, involved lymph nodes, grossly resected with microscopic residual
III	A. Local or regional grossly visible disease after biopsy only B. Grossly visible disease after >50% resection of primary tumor
IV	Distant metastases present at diagnosis

(< 5 cm) and patient age (< 10 years) are also important prognostic features. Some data also exist to suggest that different molecular abnormalities may confer different prognoses. Event free survival among a group of patients with alveolar RMS having the Pax7-FKHR gene fusion was significantly better than for a group containing the Pax3-FKHR translocation.<sup>293</sup> Rate of response to treatment and achievement of complete response also closely predict for outcome.

## Management

The outcome of treatment for RMS has improved steadily over the last 30 years. Overall survival was only 25% in 1970 but was 70% by 1991. This improvement in outcome has been achieved through cooperative studies; Intergroup Rhabdomyosarcoma Study Group (IRSG) in North America, and the SIOP Malignant Mesenchymal Tumor (MMT) studies in Europe. The major differences between these two groups' strategies lie in the intensity of initial therapy and the use of radiotherapy. IRSG studies tend to give radiotherapy earlier and to a greater proportion of patients than MMT studies with the result that although overall survival is not significantly different, event free survival is better in IRS studies.<sup>292</sup> The focus in the current European collaborative study (EpSSG RMS 2005) is on increasingly sophisticated risk group stratification.<sup>294</sup>

### Low risk

A. This contains nonalveolar, localized tumors  $\leq 5$  cm in maximum diameter in patients < 10 years of age in any site which have been fully resected (IRS Group I). These patients receive vincristine and actinomycin alone for 22 weeks, a strategy that has been effective in all previous European studies, with a 5-year EFS in these patients of > 90%.<sup>295</sup>

### Standard risk

This contains three subgroups of patients all with nonalveolar, localized tumors:

- B. Fully resected (IRS I) tumors that were > 5 cm or in patients  $\geq 10$  years. This is effectively an upstaging of older patients who seem to do worse.<sup>296</sup> These patients receive 4 cycles of IVA and then 5 of VA.
- C. This contains those patients with micro- or macroscopic residual disease (IRS II/III) after surgery for localized tumors in special sites (orbit, nonparameningeal head and neck, nonbladder/prostate genitourinary tract). This group contains most of the patients who have not received radiotherapy in MMT studies. IRS IV treated these patients with VA and radiotherapy with very good results.<sup>292</sup> The aim of the EpSSG study is to reduce chemotherapy for this group, so they receive 4 cycles of IVA and 5 of VA, and to use response to 3 cycles of IVA to determine need for radiotherapy.
- D. Localized,  $\leq 5$  cm, non-alveolar tumors with residual disease in all other sites in patients < 10 years. These patients receive 9 cycles of IVA and local radiotherapy with or without surgery.

### High risk

This again contains three subgroups:

- E. Those patients with localized, non-alveolar tumors with residual disease in other sites who either have tumors > 5 cm or are  $\geq 10$  years.
- F. Non-alveolar,  $\leq 5$  cm tumors in any site with nodal disease in patients < 10 years.
- G. Localized alveolar tumors of any size, in any site, in any age of patient. All three of these subgroups will be randomized between 9 cycles of IVA and 4 cycles of IVA with doxorubicin followed by 5 cycles of IVA (IVADo). Those patients in CR at the end of 9 cycles are randomized between stopping and 24 weeks of vinorelbine and cyclophosphamide.<sup>297,298</sup>

### Very high risk

Those patients with alveolar disease with nodal spread. These patients have a very poor prognosis in previous European studies with survival comparable to that for metastatic disease. They will

thus be treated with the intensive IVADo and vinorelbine/cyclophosphamide arm.

## Metastatic disease

In IRS III the survival for patients with metastatic disease was only 30%<sup>291</sup> and in MMT 89 was only 29%. Both groups have used the up-front window study as a means of evaluating the effectiveness of novel agents. In the IRS IV study single agents found to be effective when used alone were subsequently incorporated into the continuation chemotherapy regimen. Topotecan was shown to be highly effective in the treatment of newly diagnosed metastatic RMS<sup>299</sup> and IRS V is using a similar approach with irinotecan. However despite the activity of topotecan the overall survival for patients receiving the topotecan-based regimen was still only 20% at 3 years.<sup>300</sup> MMT 98 used the up-front window approach described above and followed this with a six drug regimen of IVA and carboplatin, epirubicin and etoposide, the combination having been previously shown to be effective in this setting,<sup>301</sup> followed by 9 cycles of maintenance chemotherapy with VAC. However MMT 98 also defined a high risk group of patients older than 10 years or those with bone or bone marrow disease who were treated with high dose sequential monotherapy (cyclophosphamide, etoposide, carboplatin) and nine courses of VAC as maintenance. Pooled analysis of the results from five up-front IRS window studies suggests that future strategies for metastatic RMS should include ifosfamide, etoposide, doxorubicin and topotecan/irinotecan.<sup>302</sup>

## OSTEOSARCOMA

The age-standardized incidence of osteosarcoma in Europe is 5.5 per million for boys and girls aged 0–14 years. However it is commoner in the second decade of life when the incidence rises to 19.3 per million for boys and 10.7 per million for girls aged 14–19 years. Between 51% and 55% of bone tumors in children are osteosarcomas.<sup>303</sup>

### Etiology

The peak age incidence is at the time of maximum bone growth and osteosarcoma usually occurs at the metaphyses of rapidly growing long bones (distal femur, proximal tibia, proximal humerus). It has a slightly younger peak age for girls, corresponding to earlier onset of puberty. These features all point toward malignant transformation of rapidly proliferating bone forming cells. The question then is whether transformation is a spontaneous event or induced by other environmental factors. Trauma frequently draws attention to the tumor but is almost certainly not causative. About 3% of all osteosarcomas are secondary to therapeutic irradiation. Latency between initial treatment and onset of a secondary osteosarcoma can be 10–15 years. Osteochondromas and chronic osteomyelitis can predispose to tumor formation. There is a strong association with retinoblastoma and 50% of the second tumors in heritable retinoblastoma are osteosarcomas. The same chromosome 13 defect has been demonstrated in both tumors. It has been speculated that rapidly proliferating bone forming cells may be particularly susceptible to mitotic errors and lead to loss of heterozygosity at the Rb locus. A number of other familial clusterings have also been described, including in families with demonstrated p53 germline mutations. Many osteosarcomas show somatic rearrangements of p53.

### Presentation

Most osteosarcomas present as a mass. Symptom duration is usually about 2–3 months. A more delayed presentation is commoner in periosteal sarcomas when symptoms may be present for many months or even years. Distal femur (33–35%), proximal tibia (15%), proximal humerus (9–10%), mid-femur (5%) and proximal femur (4–5%) are the commonest sites. Axial flat bones can be affected, especially in the pelvis, and constitute 15–20% of all tumors. These sites tend to occur in older patients. Up to 20% of patients have metastases at diagnosis, most commonly in the lungs. Occasionally multifocal osteosarcoma is seen and this carries a very poor prognosis.

## Diagnosis

Plain radiographs of the primary tumor site usually show destruction of the normal trabecular pattern with irregular margins and no endosteal bone reaction. There is usually surrounding soft tissue swelling. Periosteal elevation and new bone formation is common, producing the classic radiographic appearances of Codman's triangle (Fig. 24.12a). The appearances are characteristic in about two thirds of cases, particularly in association with a metaphyseal site. The lesions are sclerotic in 45% of cases, lytic in 30% and mixed in 25%. By contrast, Ewing sarcoma are usually diaphyseal, lytic and more often involve flat bones.

MRI is essential to define the extent accurately, especially within the medullary cavity (Fig. 24.12b). CT scanning of the chest is essential as plain radiographs may miss as many as 10–20% of small metastases (Fig. 24.12c). Ninety per cent of all metastases are within the lungs. Bone scanning identifies any multifocal lesions or metastases within bone (10% of metastases).

Once the extent of the disease has been assessed a biopsy should be performed in a specialist bone tumor center. A frozen section should be performed at the time of biopsy to ensure the adequacy of the tissue material obtained.

## Pathology

The characteristic features of osteosarcoma are a malignant sarcomatous stroma with variable tumor osteoid and bone formation. A number of pathological types of osteosarcoma exist.<sup>304</sup> Amongst the commonest type in childhood is conventional osteosarcoma of which 50% are osteoblastic with active osteoid and 25% are chondroblastic with some differentiation to cartilage. Twenty-five percent of tumors are fibroblastic and can be confused with fibrosarcoma but again osteoid is present. All of these tumors are of high grade malignancy.

Parosteal tumors occur in older patients most frequently in the distal femur and often have a long history. They slowly encircle the whole bone with a risk of local recurrence. Periosteal tumors do not extend into the medulla and occur most commonly in the age group 10–15 years especially in the upper tibia and are of high grade. Again local recurrence is common but metastases are rare. Finally there is a low grade intraosseous osteosarcoma which shows slow growth, local infiltration and a low metastatic rate.

## Staging

The usual scheme for bone tumor staging is to divide the tumors into: 1) low grade, 2) high grade, and 3) metastatic with intramedullary or extramedullary primary.<sup>305</sup> However it is not of great use in children where almost all cases are high grade and extramedullary or metastatic. Osteosarcoma can rarely metastasize to the pleura, pericardium, kidneys, adrenal and brain. Lymph node involvement is rare. Pulmonary disease is the commonest cause of death.

## Prognosis

Analysis of more than 1700 patients treated in German/Swiss/Austrian COSS studies showed the most important negative prognostic factor to be inadequate surgical resection, followed by poor histological response to chemotherapy, metastatic disease and axial location.<sup>306</sup> Inherent favorable histological features include parosteal, periosteal and intraosseous well-differentiated tumors.<sup>307</sup>

## Management

With surgery alone survival in osteosarcoma is poor, with only 15–20% of patients surviving until 3 years from end of treatment. With chemotherapy the 3-year disease free survival is 60–70%. The most effective

Fig. 24.12 (a) Plain radiograph of the humerus with a metaphyseal osteosarcoma. Note the destruction of the normal trabecular pattern, extensive new bone formation and associated soft tissue swelling. (b) T1-weighted coronal MR scan of the same tumor. (c) CT of thorax showing pulmonary metastases of osteosarcoma.

agents in osteosarcoma are cisplatin, doxorubicin and methotrexate. Ifosfamide has been shown to be a promising agent with greater than 20% single drug efficacy in relapsed patients and is often used in combination with etoposide. The amount of tumor necrosis after presurgical therapy relates to outcome with those with <10% viable tumor having 75% 5-year survival compared to 45% for poor responders.<sup>306</sup> The current collaborative European and North American trial (EURAMOS 1) compares cisplatin, doxorubicin and methotrexate (MAP) with MAP and ifosfamide and etoposide (MAPIE) in those with poor response to pre-surgery chemotherapy, and MAP with MAP and pegylated interferon  $\alpha_{2b}$  for good responders. Importantly this study includes patients with axial primary tumors, primary metastatic disease, and those with secondary tumors who may all have comparable survival to those with localized extremity tumors, with complete surgical excision.<sup>308,309</sup>

Modern surgical practice avoids amputation if possible. However this is not always the case and it is probably best discussed as an option at the time of diagnosis. Both endoprosthetic replacement and amputation can have very good functional outcomes, but high quality physiotherapy is important in achieving the maximum function after surgery.<sup>310</sup>

Previously patients relapsing with pulmonary metastases have been salvaged with the use of second line intensive therapy, e.g. using ifosfamide and etoposide plus high dose methotrexate when they have initially received just cisplatin and doxorubicin followed by thoracotomies to remove metastases. With these aggressive approaches to pulmonary metastases 30–40% of such patients may be alive 5 years from the time of relapse. The therapy for such patients who have already received all of these agents before relapse remains to be clarified.

## EWING SARCOMA

This is the second most common malignant bone tumor of childhood with a peak age at 10–15 years. Worldwide variations are seen in [Tables 24.1 and 22.2](#) with a low risk especially among black Americans and the Chinese. Ewing, Askin and peripheral neuroectodermal tumors are all included in this group. These tumors consist of small round blue cells and more than 95% show re-arrangements of chromosome 22, usually an 11;22 translocation resulting in an EWS-FLI1 fusion oncogene.<sup>311</sup>

### Presentation

The commonest presentation is with a painful swelling of an affected bone and adjacent soft tissue. Around 20–25% of patients will have metastatic disease at presentation and tiredness, anorexia, weight loss and fever can be expected. Radiological appearances and the presence of fever may lead to the diagnosis of osteomyelitis and delay appropriate therapy ([Fig. 24.13a](#)). The most common sites are the pelvis, proximal humerus and femur but any bone can be involved. The axial skeleton is more frequently involved than with osteosarcoma. In long bones, metaphyseal and diaphyseal sites are the rule. Rib primaries often present with pleural effusions and respiratory difficulties. Sacral tumors may present with sacral nerve compression and either limb or bladder signs and symptoms.

### Diagnosis

The differential diagnosis includes osteomyelitis, arthritis, traumatic injury to bone, osteosarcoma, neuroblastoma, lymphomas and even leukemia. MR imaging is required to determine the local extent of tumor within bone and soft tissue ([Fig. 24.13b](#)). CT is necessary to exclude pulmonary metastases and bone scan to exclude bony metastases ([Fig. 24.13c,d](#)). At biopsy

**Fig. 24.13** (a) Plain radiograph of the leg showing a Ewing sarcoma of the proximal fibula. Note the 'moth-eaten' appearance of the upper fibula, extensive periosteal reaction and associated soft tissue swelling. (b) T2-weighted sagittal MR scan of the leg in Ewing sarcoma showing an extensive soft tissue component surrounding the fibula and signal change affecting the upper half of the fibula. Contrast this with relatively discrete changes on plain radiography. (c) CT of chest showing pulmonary metastases of Ewing sarcoma.

(Continued)

(d)

Fig. 24.13 Continued (d) Technetium isotope bone scan showing extensive bony metastases in Ewing sarcoma.

adequate material must be obtained. Incision for biopsy must be in a place where if further definitive surgery is to take place the scar can be excised, as with osteosarcoma. Diagnostic biopsy is best performed in a supraregional unit specializing in bone tumors. Two bone marrow aspirations and trephines from different sites should be performed to exclude marrow infiltration.

### Pathology

Typical Ewing sarcoma consists of sheets of small round cells with minimal stroma. These cells are usually strongly vimentin positive and negative for neural markers, although in PNET NSE and S100 are often positive. Most Ewing sarcomas and PNETs will be strongly positive for MIC2. Identification of the EWS-FLI1 translocation by FISH is often useful in confirming the diagnosis.

### Prognostic features

Metastatic disease at presentation is the strongest adverse prognostic feature in Ewing sarcoma. In CESS 81–EICESS 92 the 10-year disease free survival for patients with localized disease was 55%, for those with pulmonary metastases alone 30% and for those with bone or bone marrow metastases only 18%.<sup>312</sup> The structural type of EWS-FLI1 fusion transcript has also been reported to be an independent prognostic factor, patients with the type 1 transcript having a better prognosis than those without.<sup>313</sup> Tumor volume greater than 200 ml is associated with worse outcome in patients with localized disease.<sup>314</sup> The histological response to chemotherapy correlated with prognosis in both the French EW88 and CESS 86 studies.<sup>314,315</sup> Pelvic and spinal tumors are usually bigger at presentation and less amenable to surgical resection than distal limb tumors and thus tend to have a worse prognosis.

### Management

#### Chemotherapy

The role of chemotherapy in Ewing sarcoma is both to treat systemic disease and to shrink local tumor to allow for easier or less mutilating surgery.

Chemotherapy based on vincristine, cyclophosphamide and doxorubicin has been effective and replacement of cyclophosphamide with ifosfamide resulted in an improvement in 5-year overall survival from 44% to 62% in UK studies,<sup>316</sup> and was associated with improved outcome in CESS 86.<sup>314</sup> Further intensification with ifosfamide and etoposide in CCG/POG studies resulted in improved overall survival for localized, but not metastatic, disease.<sup>317,318</sup> To improve survival for patients with primary metastatic disease further dose intensification and up-front windows studies of new agents have been tried. Whilst topotecan alone did not seem to be active, the combination of topotecan and cyclophosphamide is promising.<sup>319</sup> Myeloablative therapy with peripheral blood stem cell support does not seem to improve survival for this group of patients.<sup>320</sup> The current European study (Euro-Ewing 99) gives six courses of vincristine, ifosfamide, doxorubicin and etoposide (VIDE) before local therapy, and then maintenance therapy with vincristine, actinomycin and cyclophosphamide (VAC) or vincristine, actinomycin and ifosfamide (VAI) for patients with localized disease and good histological response to VIDE. Patients with poor response to VIDE or pulmonary metastases at diagnosis are randomized between VAI and MAT with PBSC support. Patients with nonpulmonary metastatic disease are eligible for an up-front windows study of irinotecan and receive MAT with PBSC support after local therapy.

#### Surgery

Definitive local therapy to achieve complete clearance of tumor is required for Ewing sarcoma. The increasing sophistication of prosthetic surgery means that this can now be achieved in many patients without amputation. However the primary consideration in deciding upon surgical approach remains the need to achieve good margins of tumor clearance. Evidence from EICESS 92 suggests that a more aggressive surgical approach, and even the use of pre-operative radiotherapy to improve operability, have a significant effect on both overall survival and on local recurrence rates. In EICESS 92 75% of German patients received surgery compared to 51% of UK patients, and 45% received pre-operative radiotherapy compared to 3% of UK patients. Overall survival for these groups was 66% versus 54% and local recurrence rates were 7% versus 21%.<sup>321</sup>

#### Radiotherapy

Whilst surgery should be considered the primary mode of local control in Ewing sarcoma there will be many patients, particularly those with pelvic or other axial tumors, for whom this is not possible. In the EICESS 92 study even in the German patient group 25% of patients had inoperable tumors. Whilst Ewing sarcoma is radiosensitive the EICESS 92 patients receiving radiotherapy alone as local therapy had the worst overall survival<sup>321</sup> and the same differential survival has been seen in POG studies.<sup>322</sup> Despite this radiotherapy is effective for local control; in the POG 8346 study local control rates were 88% for patients receiving surgery with or without radiotherapy, but still 65% for those receiving radiotherapy alone, and among patients receiving appropriate treatment volumes the local control rate was 80%.<sup>322</sup> The majority of treatment failures with this disease are systemic rather than local.

## GERM CELL TUMORS

These tumors are derived from primordial germ cells and arise within the gonads and at a number of other midline sites in the sacrococcygeal, retroperitoneal, mediastinal, neck or pineal regions. Malignant germ cell tumors account for 3% of all childhood cancers. A number of structural chromosomal changes have been detected in germ cell tumors, most consistently an isochromosome 12p, in about 80% of patients with testicular lesions.<sup>323</sup> Klinefelter syndrome is strongly associated with mediastinal tumors (20% of males so affected). 46XY gonadal dysgenesis is frequently complicated by germ cell tumors.

## TERATOMAS

These are tumors with tissue arising from all three germinal layers, with a lack of organization and variable maturation. They may be

solid or cystic and are most often found in the sacrococcygeal region. Teratomas can contain three types of tissue; mature, with well-differentiated tissues; immature, with embryonic components; and malignant with disorganized embryonic tissue and malignant germ cell elements.

### GERMINOMA<sup>324</sup>

The commonest sites for these tumors in childhood are the ovary (dysgerminoma), anterior mediastinum and pineal region (Fig. 24.14). Ten percent of all ovarian and 15% of all germ cell tumors are germinomas and they are the commonest in undescended testicles (seminoma). There is a characteristic histological appearance of large round cells, vesicular nuclei and clear eosinophilic cytoplasm. Serum levels of AFP and HCG levels are not elevated in pure germinoma.

### EMBRYONAL CARCINOMA

This is a poorly differentiated tumor usually with an epithelial appearance. Apparent pathological maturation to teratoma has been noted after chemotherapy. These tumors stain markedly for AFP and HCG. In pediatric practice it is rare to see pure embryonal carcinoma, but it may be found as a component of other germ cell tumors. In young males, the commonest site is the testis.

### YOLK SAC TUMOR

This tumor occurring alone or in combination with teratoma is the most common malignant germ cell tumor in childhood. The sacrococcygeal region is the usual site in infancy but later the ovary and testes are more frequently affected, although it can occur elsewhere. The tumors are often soft and friable with a papillary, reticular or a solid pattern.

### CHORIOCARCINOMA

This highly malignant tumor is rare in childhood and arises from non-gestational extraplacental tissue. The commonest sites are the mediastinum, ovary and pineal region.  $\beta$ HCG but not AFP is markedly elevated in serum. Histology shows large round cells with vesicular nuclei (cytotrophoblasts) and large, usually vacuolated, cells which form syncytia (syncytiotrophoblasts). Hemorrhage and necrosis are common.

### GONADOBLASTOMA

This tumor is most frequently found in dysgenetic gonads. Thirty percent of patients with gonadal dysgenesis develop gonadoblastoma (bilateral in 40% of cases). Local invasion is seen within the gonads but if elements of germinoma are present it is more likely to spread. AFP and HCG are not produced by this tumor.

Fig. 24.14 Contrast-enhanced CT of pelvis showing a large ovarian dysgerminoma.

### POLYEMBRYOMA

This is a rare tumor of the ovary or anterior mediastinum. Both AFP and HCG are elevated. The tumor contains elements resembling small embryos.

### Biochemical markers

Three markers may help with diagnosis and monitoring of therapy.

#### *Alpha-fetoprotein*

Alpha-fetoprotein (AFP) production from the yolk sac is maximal at about 12–15 weeks of gestation. Normal adult blood levels are not reached until 6–12 months postpartum. Tumors arising from the pluripotential germ cells of the yolk sac secrete AFP with the exception of pure dysgerminoma, pure choriocarcinoma, mature teratomas and gonadoblastoma. Monitoring of serum levels can be useful, especially for evidence of resistant or recurrent disease. Staining of tumor for AFP is a useful diagnostic tool.

#### *Beta-human chorionic gonadotrophin*

This glycoprotein is produced by specialized placental cells so that tumor with trophoblastic elements (choriocarcinoma and hydatidiform moles) have high levels. The half-life is extremely short (45 minutes) so rapid normalization occurs with tumor kill.

#### *Lactate dehydrogenase isoenzyme 1*

Elevation of this isoenzyme is seen in tumor derived from the yolk sac. It can be used to monitor response to therapy.

### SACROCCYGEAL TERATOMAS

The incidence is 1 in 35 000 live births with 65% being benign, 30% malignant and 5–10% having an immature appearance. Approximately 40% of all germ cell tumors occur in this area. There is a marked female sex preponderance (70%). The mode of presentation will depend on the precise site of the tumor:

1. The buttocks with a minimal presacral component. This is the commonest site in the newborn (186 out of 398 in one series<sup>325</sup>).
2. External but with a significant intrapelvic component (138 out of 398).
3. External but with most of the mass intrapelvic and extending into the abdomen (35 out of 398). This is the group most likely to be malignant de novo.
4. Entirely presacral with no external component or significant pelvic extension (39 out of 398). These are more difficult to detect and may lead to constipation, urinary frequency or lower limb weakness from sacral nerve compression.

### Diagnosis

The early detection and surgical removal of even a benign tumor is necessary because of the risk of subsequent malignant change. If the diagnosis is made before 2 months of age the chance of malignancy is low (10% in boys and 7% in girls). After 2 months, the risk of malignancy is over 60% in boys and 45–50% in girls. The estimation of AFP and HCG levels is mandatory. CT or MRI scanning will delineate the tumor extent, and determine the presence of any intraspinal component. Pulmonary metastases must be excluded.

### MEDIASTINAL TERATOMAS

These almost always arise in the anterior superior mediastinum along the urogenital ridge which extends from C6 to L4. They are sometimes found coincidentally on chest X-ray or they may present with airway obstruction, cough, wheeze and dyspnea. Many histological types have been reported, ranging from pure teratoma to embryonal carcinoma and yolk sac tumor. Radiological appearances are of a rounded mass often with calcification. Sometimes teeth may be identified in a mature teratoma. Cross-sectional imaging is essential to determine tumor

extent. AFP, HCG levels and urinary catecholamines should be measured. It is important to exclude other diagnoses because, for a mediastinal teratoma, complete surgical excision is necessary for cure whereas in other tumors (especially lymphomas) chemotherapy is the treatment of choice.

## ABDOMINAL GERM CELL TUMOR

Most arise in the retroperitoneum but they can occur within the gastrointestinal tract, omentum or liver. In the stomach they may present as obstruction or hemorrhage and in the liver as a mass or jaundice. The retroperitoneum is the third commonest site after the sacrococcygeal and mediastinal regions in those under 2 years. Pressure from the mass causes pain, constipation or urinary difficulties. Cross-sectional imaging and measurement of urinary catecholamines and serum AFP levels will aid diagnosis.

## INTRACRANIAL TERATOMAS

These account for about 6% of germ cell tumors. Most arise in the pineal region but they can also arise in the suprasellar and infrasellar regions, more frequently leading to CSF pathway obstruction at third ventricular level. A wide variety of histological types including germinomas, embryonal carcinoma and pure teratoma are reported and it is important to distinguish between them since the treatment will be different. For teratoma, surgical excision is the treatment of choice; for embryonal carcinoma, which is more likely to be highly malignant, intensive chemotherapy and radiotherapy will be needed.

Other sites for extragonadal germ cell tumors are the oral cavity, the pharynx, the orbit and the neck, collectively making up about 6% of germ cell tumors. These are mostly found at birth and are of benign histology though they can cause death from airway obstruction. Vaginal tumors, mostly of the endodermal sinus tumor type, usually present with bloody discharge.

## GONADAL TUMORS

### Ovarian tumor

These account for about 30% of all germ cell tumors; 65% are benign teratomas, 5% are immature teratomas and about 30% are malignant. In children epithelial carcinoma of the ovary is rare. Most malignant ovarian germ cell tumors occur around the time of puberty. Presentation is usually with acute or chronic pain associated with nausea and vomiting. There may be fever. These tumors are not infrequently misdiagnosed as appendicitis and found at laparotomy. The mass may be large with omental seeding before presentation. If  $\beta$ HCG secretion is marked, pregnancy may be misdiagnosed. The tumor can spread locally to the adnexae, throughout the abdomen (with ascites), to nodes or via the blood. Cross-sectional imaging is needed to define site and extent of tumor (Fig. 24.14). Pulmonary metastases should be excluded. AFP levels will be elevated if the tumor contains yolk sac elements or immature teratoma and  $\beta$ HCG if it is an embryonal carcinoma or choriocarcinoma.

### Testicular tumors<sup>326</sup>

These comprise about 7% of all germ cell tumors and about 70% of all testicular tumors in childhood. Eighty percent are malignant and nearly 20% are pure teratomas. The most common malignant tumor is yolk sac tumor. The presentation is with a slowly growing painless testicular mass, with or without accompanying hydrocele (25%) and/or inguinal hernia (20%). These tumors may be misdiagnosed as either epididymitis or hydrocele. If the testis is undescended the risk of malignancy is 20–40 times greater. The risk of malignant change is also higher in the contralateral descended testis in a patient with unilateral cryptorchidism. Ultrasound of the testis with CT scanning of abdomen, pelvis and chest, and measurement of AFP and HCG levels will help diagnosis and staging.

## MANAGEMENT

### Benign germ cell tumors

The optimal treatment for mature teratomas is complete surgical excision. In the UKCCSG study 123 of 125 patients with mature or immature germ cell tumors had primary surgical resection and 114 of these needed no further treatment.<sup>327</sup> Six of these patients developed yolk sac recurrence which was successfully treated with combination chemotherapy. The AFP should be followed long term to identify any recurrence. External sacrococcygeal tumors require a transsacral approach but if the pelvis is involved an abdominal combined approach is needed. Removal of the coccyx is essential if recurrence is to be avoided. Spillage from cysts must be avoided and the surgeon should ensure that there is no intraspinal extension of the tumor.

### Immature germ cell tumors

Controversy exists about the ideal treatment of immature teratomas. For localized but immature forms, most authorities still recommend surgery and follow-up, as the diagnosis is often only made after tumor removal. The UK and US practice is to treat recurrence with chemotherapy if it arises; the POG experience in 68 children receiving surgery alone was of three recurrences, all salvaged with chemotherapy<sup>328</sup> and a 3-year disease free survival of 96.7%; the UK experience is of four recurrences out of 41 patients, three salvaged with chemotherapy.<sup>327</sup>

### Malignant germ cell tumor

Einhorn et al<sup>329</sup> showed that cisplatin, bleomycin and vinblastine (BVP) were superior to all previous chemotherapy for malignant ovarian and testicular germ cell tumors. More recently the UKCCSG has demonstrated that pulsed carboplatin, etoposide and bleomycin (JEB) is as effective and less toxic for all malignant extracranial nongonadal tumors. Five-year event free survival was 87% and overall survival 91% in GCII with JEB as compared with 46% and 63% respectively with the previous regimen (GCI). Rates of renal toxicity and deafness in children treated on GCI were 20% and 35% respectively, while on GCII they were 0% and 10%.<sup>330</sup> The current UK GCIII study attempts to use a risk group strategy to reduce the chemotherapy exposure for many of these patients.<sup>331</sup> All those with gonadal Stage 1 tumors are considered low risk and need no therapy beyond surgical resection. Stage 4 tumors, other than those of the testes in children < 5 years and pure germinomas, thoracic tumors (other than Stage 1), and tumors with AFP  $\geq 10$  000kU/l (except Stage 1 tumors and testicular tumors in children < 5 years) are considered high risk and receive 6 cycles of JEB. All other tumors are considered intermediate risk and receive 4 courses of JEB. For relapsing adult patients cisplatin and ifosfamide have been effective<sup>332</sup> and high dose chemotherapy with autologous bone marrow rescue have also been used successfully but there are few published pediatric data.<sup>333</sup>

## RETINOBLASTOMA<sup>334</sup>

This malignant embryonal tumor occurs predominantly in the first 2 years of life (75% are diagnosed before 3 years). Its relative incidence varies considerably around the world (see Table 24.1). The increase in Africa and India is of nongenetic retinoblastoma and strongly suggests an environmental factor may be involved in etiology. The age-standardized incidence rate in the UK is 7.5 per million children which amounts to between 40 and 50 new cases diagnosed per annum in the UK. There is no obvious sex difference in incidence. There is a family history in about 10% of cases, the remaining 90% appearing sporadic. However 20–30% of all tumors are bilateral and clearly 'genetic' (even if there is no family history) and about 10–12% of unilateral cases are also inherited. This means that overall about 40% are genetic or 'heritable' from an affected, surviving parent, from a non-affected carrier parent or as the result of a new mutation in the patient. Sixty percent are 'nonhereditary' and result from spontaneous somatic cell mutations within retinal cells. They are always unilateral and have no family history. Knudson<sup>335</sup> proposed that in the 'genetic' form the first mutation occurred prezygotically, while a second somatic event triggered the tumor in the retina or elsewhere in the body.

In nongenetic tumors both events occur within the retinal cells. Carriers of the retinoblastoma gene (13q14) mutation can develop single or multiple retinal tumors and/or neoplasms at other sites. Indeed germline Rb mutations have been implicated in the development of osteosarcoma, small cell lung carcinoma, bladder and breast carcinoma and various soft tissue sarcomas. Abnormalities of the p53 gene often occur concurrently with the inactivation of the retinoblastoma susceptibility gene.<sup>336</sup> The retinoblastoma gene encodes for a 928 amino acid protein, which is a nuclear phosphoprotein with DNA-binding activity, that plays a critical role in cell cycle regulation. Very accurate genetic counseling is possible from the mode of presentation, family history and search for evidence of the Rb gene mutation in the parents. Any child of a surviving parent who had retinoblastoma has a 50% chance of developing a tumor. If normal parents have one affected child, the next one has a 1% risk if the first child had unilateral disease and 6% if it was bilateral. As with all tumor suppressor genes, sequencing has demonstrated heterozygous point mutations along the 27 exons of the Rb gene. Prenatal and postnatal prediction using such sequencing of this large gene, although cumbersome at present, clearly enables even more accuracy in terms of risk assessment.

Despite much research we do not know what causes the initial germline mutation in genetic retinoblastoma but such mutations may arise merely as a result of spontaneous mutations at a 'background' mutation rate.<sup>337</sup> New mutations appear to more frequently derive from the paternal allele, i.e. arise during spermatogenesis.<sup>338,339</sup> About 5% of retinoblastoma patients carry a constitutional deletion on the long arm of chromosome 13.<sup>337</sup> Sporadic nonhereditary retinoblastoma risk factors include older maternal and paternal age and paternal employment in the 'metal' industries.<sup>340</sup>

## Presentation

Nowadays most children are identified with the tumor still intraocular. The commonest presenting feature is leukocoria or loss of the red reflex. The tumor shows as a creamy to pinkish mass through the iris. Strabismus is common if the tumor arises in the macula. Occasionally, patients may show inflammatory changes or even a fixed pupil. A common reason for delay in diagnosis is a mistaken diagnosis of uveitis or endophthalmitis. The tumor is not painful unless there is secondary glaucoma or inflammation. If the involvement is unilateral the child will probably not complain of visual loss. Most often parents note the eye abnormality and seek help. A full ophthalmological examination under general anesthetic is required. Ultrasonography, CT and MR scanning have enabled better visualization of the tumor. Bone marrow aspiration and lumbar puncture should also be performed under general anesthetic to exclude dissemination. Hemorrhage and calcification are quite common and pieces of tumor may break off and seed either into the vitreous or elsewhere on to the retina. External layer disruption can lead to choroid involvement and a greater risk of blood-borne metastases. The iris may be pushed forward by a mass effect or the trabecular network infiltrated leading to glaucoma. Spread can occur along the optic nerve to invade the brain and CSF. Blood-borne spread commonly goes to bone and brain. Lymphatic spread to the preauricular and submandibular nodes is rare. A staging system based on size of tumor, site of tumor on the retina, extension to involve the choroid, optic nerve or vitreous and presence/absence of metastases is now employed.

## Management

All patients require treatment in highly specialized multidisciplinary centers. For those patients with unilateral nongenetic tumors near 100% cure is possible by enucleation.

There is clear benefit of adjuvant chemotherapy for patients with deep choroidal or optic nerve infiltration.<sup>341</sup> Limited dosage JOE (carboplatin, vincristine and etoposide) has been used successfully with the least toxicity and lowest rate of secondary tumors to date, from any chemotherapy regimen. The UK approach is to give 4 cycles of JOE post enucleation to those patients with deep choroidal invasion and 6 cycles with intrathecal therapy, and local radiotherapy to those with involvement of the cut end of the optic nerve at enucleation. For those with small

unilateral lesions (less than 4 disk diameters) cryotherapy and photocoagulation offer an alternative to enucleation, but very careful expert follow-up is required to ensure that the tumor is sterilized.<sup>342</sup> For 'genetic' disease, enucleation in unilateral disease, and the worse eye in bilateral disease, is usually performed. With the high risk of tumors developing in the other eye with such genetic tumors, if not already present, radiotherapy and/or chemotherapy is used as well to try to conserve some vision in both eyes. Careful attention must be paid to scheduling and total dosage.<sup>343</sup> Even with bilateral disease, event free survival at 5 years can be 90% unless there is orbital or CNS invasion, but with germline Rb carriage it would appear that the development of secondary neoplasia is a very high risk over the ensuing 30–40 years.<sup>27</sup> All planned combined modality therapy should attempt to minimize the risk by avoiding for example combinations of irradiation and alkylators and careful attention to the dose and scheduling of drugs such as the topoisomerase 2 inhibitors.

## LIVER TUMORS

### Presentation

#### *Hepatoblastoma*

This tumor usually presents as an abdominal mass in a child under 2 years. Weight loss, anorexia, vomiting and pain can be seen but symptoms are less prominent than in hepatocellular carcinoma. Occasionally the tumor ruptures and presents as an acute abdomen. Abdominal distention with an enlarged liver is the most common finding. Jaundice is rare but the patient may be anemic.

#### *Hepatocellular carcinoma (HCC)*

These tumors usually present as painful right-sided abdominal masses, often with features of underlying liver disease. Splenomegaly with finger clubbing and spider nevi is often seen. Nausea, vomiting, fever, weight loss and anorexia are more common than in hepatoblastoma. These tumors may also rupture. Jaundice is reported in up to 25% of cases. There may also be associated thrombocytosis and polycythemia due to raised erythropoietin and probably thrombopoietin levels.

### Diagnosis

Ultrasound examination will define the liver mass, up to 10% of which may show calcification, and the inferior vena cava, hepatic and portal veins. Hepatoblastoma and HCC are deeply infiltrative and may be multicentric. MR scanning is superior to CT for definition of tumor margins. Hepatoblastoma occurs most commonly in the right lobe of the liver. Cooperation between radiologist and surgeon is likely to result in more reliable anatomical information (Fig. 24.15). CT of chest is needed to exclude pulmonary metastases. Blood tests should include a full blood

Fig. 24.15 Contrast-enhanced CT of abdomen showing a hepatoblastoma arising from the right lobe of the liver.

count. Mild normochromic normocytic anemia is quite common but, particularly in HCC, increased erythropoietin production may lead to polycythemia. The platelets may be elevated in excess of  $1000 \times 10^9/L$  in childhood liver tumors. The most useful marker is AFP, produced exclusively in the liver in postnatal life. AFP is raised in about two thirds of patients with hepatoblastoma and in about 50% of patients with HCC and is useful for monitoring the course of the disease. Failure to fall along the usual gradient or a late rise suggests persistent or recurrent disease, often prior to any clinical evidence of relapse. Liver function should be evaluated and monitoring of calcium, phosphate and alkaline phosphatase levels are necessary particularly if there is any significant osteopenia. Hepatitis B serology is often positive in hepatocellular carcinoma but rarely in hepatoblastoma.

### Staging and histology

Staging in Europe is based on the relationship between the tumor and the anatomy of the liver (the PRETEXT classification). Surgical resection is crucial for cure of hepatoblastoma and HCC, and this staging system aims to predict the anatomy of the healthy liver that will remain after resection and describes the number (out of four) of sections of the liver involved. The presence of tumor beyond the liver, either local spread to vena cava and/or portal vein or distant pulmonary metastases is sufficient to categorize the disease as high risk. Biopsy is usually necessary, although in children between 6 months and 3 years with a raised AFP it is not mandatory. Hepatoblastoma most often metastasizes to lungs and nodes at the porta hepatis and rarely to bone. HCC similarly metastasizes to the lungs, nodes and later to bone.

### Management Hepatoblastoma

Hepatoblastoma requires total surgical excision for cure. Preoperative chemotherapy, with doxorubicin and cisplatin, produces tumor shrinkage and increases the number of patients whose tumors can be fully resected. Between 80% and 100% of hepatoblastomas are chemoresponsive, and 67–80% will be resectable after this treatment.<sup>344</sup> In the first SIOP liver tumor trial, SIOPEL-1, all patients received pre-operative chemotherapy regardless of initial resectability. The 3-year overall survival in this trial was 79%.<sup>345</sup> The presence of pulmonary metastases at diagnosis has been consistently found to be an adverse prognostic factor.<sup>346</sup> SIOPEL-1 also identified tumor affecting all four liver sections, extrahepatic tumor and multifocal tumor as poor prognostic factors. In the current SIOP trial (SIOPEL-3) this group of patients are regarded as high risk and receive an intensive chemotherapy regimen alternating cisplatin with carboplatin/doxorubicin (SuperPLADO). This regimen was piloted in SIOPEL-2 and produced a 67% resection rate and a 3-year overall survival of 53%.<sup>347</sup> The remaining patients are standard risk and receive either cisplatin as a single agent or cisplatin/doxorubicin, as cisplatin single agent therapy was effective for standard risk patients in SIOPEL-2, with a 97% resection rate and a 3-year overall survival of 91%. In SIOPEL-1 10 patients had liver transplantation because of unresectable disease, all but 1 of these patients were alive without evidence of disease at median 3-year follow up. The presence of pulmonary metastases at diagnosis is not a contraindication to transplantation, providing that these are no longer visible at the time of surgery; 4 of the successfully transplanted patients in SIOPEL-1 had pulmonary metastases at diagnosis.

### Hepatocellular carcinoma

In the SIOPEL-1 study, pre-operative therapy (cisplatin, doxorubicin) was given to 40 patients of whom 12 had complete resection, and 2 incomplete. Seven of these patients were alive without disease at 10- to 46-month follow-up while 22 were still unresectable. Overall survival for these patients on SIOPEL-1 was 28% at 5 years, the presence of metastases and the PRETEXT stage were both predictive of survival. In SIOPEL-2 these patients received SuperPLADO but there was no improvement in survival. In the American Pediatric Intergroup Study there were 46 patients with HCC. Seventeen percent had Stage 1 disease (complete

resection with clear margins) and for these patients the survival was 88%. Survival for the whole patient group was 19% and, as in SIOPEL-1, no patients with metastatic disease survived.<sup>348</sup> In the current HCC specific study SIOPEL-5 those patients with localized respectable tumors will undergo primary surgery. Those patients with unresectable, extrahepatic or metastatic tumors receive PLADO in combination with thalidomide as an anti-angiogenic agent pre-operatively, surgery if possible, and then 12 months of metronomic therapy with cyclophosphamide and thalidomide. In multifocal nonresectable HCC in childhood, liver transplantation may also have a place; two patients were transplanted on SIOPEL-1, both were alive and disease free at 40 and 55 months follow up.

### LANGERHANS CELL HISTIOCYTOSES

Histiocytoses are a heterogeneous group of uncommon proliferative diseases involving bone marrow derived immature histiocytic cells, which can have more reactive than malignant features. The classification of histiocytic disorders by the Writing Group of the Histiocyte Society includes hematological malignancies and hemophagocytic lymphohistiocytosis (HLH), which are discussed elsewhere in this book.<sup>349</sup> Relevant in the context of pediatric oncology are dendritic cell related class 1 disorders as these manifest mainly as nonhematopoietic organ dysfunction (see below) and are treated with antineoplastic agents (Table 24.21).

To understand Langerhans Cell Histiocytosis (LCH) it is useful to look at the development of the histiocyte. The hematopoietic bone marrow stem cell develops into committed granulocyte and macrophage precursors, which divide and differentiate producing myelocytes and monocytes. When these migrate into the peripheral circulation they undergo terminal differentiation into macrophages and histiocytes in many tissues determined by the local microenvironment, e.g. Kupffer cells in the liver and Langerhans cells (LCs) in the skin, which are involved in antigen-processing or antigen presentation to the circulating T cells. All of the antigen-presenting cells, and in particular LCs, have a strong affinity for class 2 antigens which the T4 or helper T cells recognize. LCs contain

Table 24.21 Classification of histiocytosis syndromes in children

Class I	Class II	Class III
Langerhans' cell histiocytosis	1. Primary hemophagocytic lymphohistiocytosis (FHLH ± family history)	Malignant histiocytic disorders: 1. Acute monocytic leukemia 2. Malignant histiocytosis 3. True histiocytic lymphoma
I Single bone	2. Secondary HLH (infection, malignancy, etc.)	
II Multiple bone	3. Other mononuclear phagocytosis (not Langerhans' cell)	
IIIA Bone + soft tissue		
IIIB Soft tissue only	4. Sinus histiocytosis + massive lymphadenopathy (Rosai–Dorfman) 5. Juvenile xanthogranuloma 6. Reticulocytoma	
(Birbeck granules CD1A antigen positive S100 morphology)		

structured organelles called Birbeck granules (these are rod-like structures with central striations and a terminal vesical expansion which looks like a tennis racket under electron microscopy) and express the CD1a surface antigen. Normal LCs make up not more than 2% of all epidermal cells and play an important role in immunosurveillance.

In LCH the normal LCs are stimulated to proliferate and accumulate in affected tissues with a variable mixture of other cells to form granulomas with locally destructive behavior, which interfere with normal organ function. Although features of clonality have been described in LCH it is regarded as reactive rather than malignant.<sup>350</sup> This atypical immunological response is thought to be triggered by a pathological response to infection, but no infectious agent has been identified as responsible.

### Clinical features and staging

The generic name 'Langerhans cell histiocytosis' is used to encompass historical terms like eosinophilic granuloma, Hand-Schuller-Christian triad and Letterer-Siwe disease, which were descriptions of different stages

of LCH (Table 24.21). Pathological staging includes breakdown of bony lesions into those with or without contiguous soft tissue involvement and/or involvement of immediately adjacent lymph nodes. Stage I is a single lytic bone lesion; Stage II are multiple lytic bone lesions, which were formerly called eosinophilic granulomata. Bone lesions most commonly affect the skull, long bones and vertebrae, where these lesions can lead to vertebral collapse, mandible or maxilla and can lead to gingival disease with even loss of teeth. Bone scans may identify such lesions but sometimes they can be missed but picked up preferentially by plain X-rays (Fig. 24.16a,b). Magnetic resonance imaging has identified lesions not seen either by X-rays or bone scans. Almost every bone in the body has at sometime been reported to show such lytic lesions. The skull is involved in nearly 50% of cases. Stage IIIA, bone plus soft tissue lesions, is often associated with diabetes insipidus if the pituitary is involved or proptosis of the orbit (previously termed Hand-Schuller-Christian triad); Stage IIIB, soft tissue only, is the disseminated form previously termed Letterer-Siwe disease. The absence of bone disease carries worse prognostic implications.<sup>351</sup> Stage IIIB typically

(a)

(b)

(c)

affects young infants and although overall LCH has a low mortality, those aged under 6 months with disseminated soft tissue disease have a mortality of 50–60%. They often have failure to thrive, lymphadenopathy, hepatosplenomegaly, anemia and pancytopenia with red to purple skin lesions, a high incidence of seborrheic dermatitis and multiple organ involvement. A wide range of skin lesions have been identified, ranging from patterns similar to seborrheic dermatitis through nodular lesions, bronzing of the skin, and xanthomatous lesions (Fig. 24.16c). Skin involvement carries adverse prognostic features.<sup>351</sup> Over 70% of all patients with LCH have bone lesions, while 30–45% have skin and mucous membrane involvement, 25–30% pulmonary involvement, 25–30% hepatosplenomegaly, 30% lymphadenopathy and 30% hemopoietic disorders. The pituitary is involved in about 15–20% of cases. CNS involvement and protein losing enteropathy are less common. CNS involvement is rare apart from pituitary disease but can present with space occupying lesions and neurological dysfunction and is an unfavorable feature. These patients usually have multisystem disease and a high mortality.<sup>352,353</sup> Definitive diagnosis of LCH depends on the characteristic pathological appearances with Birbeck granules and CD1a antigen positivity in the cells on biopsy specimen from skin, lymph node, bone or soft tissue.

## Management

For Stage I and II bone disease excision biopsy or curettage for diagnosis with the intra-lesional injection of steroids is the treatment of choice.<sup>354</sup> Local low dosage irradiation has been used for deposits which cannot

easily be treated by curettage but require treatment. For more advanced disease systemic chemotherapy with prednisolone, vinblastine and etoposide has been subjected to evaluation by clinical trials.<sup>355,356</sup> For the approximately 15% patients with extensive dysfunction particularly of liver, lung or hemopoietic system, more aggressive chemotherapy has been used including the use of moderate dose systemic methotrexate and cytosine arabinoside in addition to prednisolone, mercaptopurine and vinblastine.<sup>355,356</sup> Response to initial chemotherapy appears to be of prognostic significance.<sup>357</sup> In the Japanese trial from 1996 poor responders were allocated much more intensive treatment including anthracyclines, cytosine arabinoside, methotrexate and cyclophosphamide, which resulted in improved overall survival.<sup>358</sup> The role of high dose therapy including etoposide, cyclophosphamide and busulfan prior to allogeneic marrow transplantation or alternatively antithymocyte globulin, prednisolone and ciclosporin where there is no donor for high risk patients has not been established, but such treatment as used for hemophagocytic lymphohistiocytosis (HLH) could be an option for high risk patients.<sup>359</sup> Recent pilot data from France which addressed the role of 2-chlorodeoxyadenosine in combination with cytosine arabinoside have shown promising response rates but also treatment related mortality from bone marrow suppression.<sup>360</sup> The small patient numbers with relapsing and severe multisystem LCH necessitate continuing international collaboration in order to further improve the outlook of children affected by this disorder, which carries considerable long term morbidity in survivors.<sup>361</sup>

## INTRODUCTION

The awareness of gynecological problems in children and adolescents has increased in recent years. Some children's hospitals have dedicated gynecological and multidisciplinary clinics but the majority of girls and teenagers seen are still seen by general practitioners, pediatricians or gynecologists with no particular expertise.

There is a need for such a service. Gynecologists do not always appreciate that girls are not miniature women but have specific anatomy and physiology, and psychology. Pediatricians often feel inadequate dealing with sexual and hormonal problems. A report that 30% of males and 26% of females under the age of 16 are sexually active<sup>1</sup> is not always remembered in pediatric practice. Additionally, while all our patients deserve to be treated with sensitivity, this is especially true for girls with gynecological problems. A painful, inappropriate examination may cause fears and phobias in young girls that stay with them during their teenage years – and even into adulthood, with unfortunate effects on their future reproductive health.

## PHYSIOLOGY

Prior to birth, high levels of estrogens produced by the placenta inhibit gonadotrophin release from the fetal pituitary. Following delivery and the loss of maternal estrogens a transient rise in neonatal gonadotrophin levels may result in neonatal ovarian activity. Such activity, however, is short-lived and both gonadotrophin and estrogen levels drop within a short time of delivery and remain so throughout childhood until just before puberty.

The high levels of circulating estrogens may cause secretion of milk from the neonatal breast and a white vaginal discharge to be present. The loss of the estrogens after delivery may result in a vaginal bleed due to breakdown of the endometrium.

The high levels of circulating estrogens affect the appearance of the neonatal genitalia. The labia majora and minora are large and rounded and the hymen appears edematous. These changes disappear with the loss of maternal hormones – the labia majora becoming flattened, the labia minora thin and attenuated and the hymen less prominent. The hymenal changes are often the last to regress with the result that for the first year of life the hymen can appear quite

prominent; the appearance of the external genitalia then remain unchanged until puberty.

Gonadotrophin-releasing hormone begins to be released in a pulsatile fashion between the ages of 6 and 9 years, initially during sleep. This results in release of gonadotrophins, initially luteinizing hormone (LH) but later also follicle-stimulating hormone (FSH) from the pituitary. As the duration of gonadotrophin release becomes prolonged, the ovary responds with the production of estrogens.

Estrogen production, along with adrenal androgen production, causes the physical changes of pubertal development that were classically described by Tanner and his colleagues in the 1960s and 1970s. The first sign of puberty is the appearance of the subareolar breast bud at the mean age of 10.8 years (range 8.8–12.8 years). Pubic hair growth occurs approximately 6 months later, although in approximately one third of girls it occurs before breast development.<sup>2</sup> Thereafter, pubertal development proceeds in a recognized sequence of events – increase in growth velocity, pubic and axillary hair development to Tanner Stage 4, breast development to Tanner stage 3–4, menstruation.<sup>3</sup> The median age of menarche in British teenagers is 13 years<sup>4</sup> with little geographic, social or ethnic variation. In the UK 95% will reach menarche by the age of 15 and one in eight while still in primary school.

## PROBLEMS AT BIRTH

### DISORDERS OF SEXUAL DIFFERENTIATION

The diagnosis, investigation and management of girls with disorders of sexual differentiation (DSD) have been dealt with in Chapter 15. Surgical correction of the genital abnormalities has traditionally been performed soon after birth, with the belief that it is important to correct the appearance of the genitalia as soon as possible – and certainly before the girl reached her adolescent years. More recently clinicians have been questioning this management. Delaying corrective surgery until later years allows the girl to be involved in the decision-making. Additionally, the growth of the structures and the estrogenization of the tissues make the surgery easier, allowing, for instance, better dissection of the neural bundle during clitoridectomy, thus preserving function. Recent articles showing poor sexual function in later life in women who had surgery performed in childhood have strengthened the argument that corrective surgery should be delayed until adolescence.<sup>5,6</sup>

## HYDROCOLPOS

Hydrocolpos presents at birth with a bulging membrane visible at the introitus, less commonly as an abdominal mass rising out of the pelvis. It is caused by the failure of breakdown of the membrane at the junction of the Mullerian duct and the urogenital sinus, allowing the collection of fluid. Treatment is by excision of the membrane. Failure to recognize that an abdominal/pelvic mass may be due to hydrocolpos may have serious consequences. In the only published series, 35% of neonates died after an unnecessary laparotomy for hydrocolpos.<sup>7</sup> Although the paper is old it emphasizes the importance of making the correct diagnosis.

## PROBLEMS IN EARLY CHILDHOOD

### VULVOVAGINITIS

Vulvovaginitis is without doubt the commonest condition seen at a pediatric gynecology clinic – and has almost always been misdiagnosed and mismanaged before being referred.

Vulvovaginitis occurs because the anatomy and physiology of the genitalia of the prepubescent girl do not provide the resistance to bacterial infections found in the adult woman. In the pre-pubescent girl, the labia minora are thin and attenuated. The changes in vaginal secretion that occur at puberty, under the influence of estrogen (acidic vaginal secretions and the presence of Doderlein's bacilli), and which help prevent infection, are not present. This results in the girl being prone to bacterial infection. The common age of presentation, between the ages of 3 and 8, may be due to the girl being more responsible for her own personal hygiene at this age. The common organisms involved are fecal flora and nasopharyngeal organisms (*Haemophilus influenzae* and Group A beta-hemolytic streptococci),<sup>8</sup> although the significance of these organisms is uncertain because of the lack of information about normal vaginal flora in pre-pubertal girls.<sup>9</sup> Other organisms, particularly *Candida*, are much less common.

Girls with vulvovaginitis present with symptoms of vaginal irritation or pain, which can be severe and vaginal discharge, which can be profuse and often described as 'green' or 'brown'. Dysuria may also be present and the girl may well have been investigated for urinary tract infection before the correct diagnosis is made. Examination shows the labia to be inflamed and often excoriated. Careful inspection should also be undertaken to exclude dermatological conditions.

The differential diagnosis of vulvovaginitis includes other conditions that cause vulvar irritation or vaginal discharge that are mentioned later.

Management is usually limited to treatment for the relief of symptoms. The role of investigation is a vexed one. It is impossible to take an uncontaminated high vaginal swab in a young girl without a general anesthetic and no attempt should be made to do so. An introital swab may be helpful but interpretation may be difficult because of the presence of contaminants. The use of antibiotics in response to a specific swab result is limited as subsequent attacks are likely to be due to different organisms. Antibiotics should only be used if a pure growth of a pathogen is identified.<sup>9</sup>

The mainstay of treatment should be advice regarding personal hygiene and clothing. The use of an emollient cream such as E45 or Sudocrem may relieve symptoms and provide a barrier, especially to relieve pain on micturition. There is no place for antifungal therapy unless a *proven* candidal infection is present.

It is essential to explain to the mother why the condition has occurred along with reassurance that it will improve as the girl approaches puberty. It is also important to stress that the girl will not have any long-term gynecological consequences.

### BLOODSTAINED VAGINAL DISCHARGE

Bloodstained vaginal discharge is relatively uncommon. It may be due to infection but a foreign body or tumor must be excluded.

Foreign bodies in the vagina in this age group are not unusual, resulting from the normal practice of girls exploring their own bodies. Examination under anesthesia is mandatory. Imaging with ultrasound or X-rays will not pick up foreign bodies such as pieces of toilet paper or sponge. In any case, general anesthesia will be required for removal.

Genital rhabdomyosarcoma is an unusual tumor that may present with bloodstained discharge. It is dealt with more fully later.

### VULVAR IRRITATION

Other common causes of vulvar irritation in this age group are:

- dermatological conditions;
- threadworms;
- nonspecific vulvitis.

### Dermatological conditions

Any dermatological condition such as eczema or psoriasis may occur on the vulva just as in any other part of the body.

A dermatological condition that is not uncommon in prepubertal girls is lichen sclerosus. This condition may occur anywhere on the body but is found on the vulva at the extremes of reproductive life – in the prepubertal girl and the postmenopausal woman. The etiology is unknown, although genetic susceptibility and an autoimmune basis have both been suggested.<sup>10</sup> It presents with extreme irritation. Examination shows characteristic appearances of shiny white ('pearly white') macules or papules that may coalesce into larger plaques. There are often associated hemorrhagic areas that may appear as bruising. Ulcerated areas may also be present (Fig. 25.1). To the unaware, the condition may be suggestive of sexual abuse<sup>11</sup> and it has been suggested that lichen sclerosus is more common in girls who have been sexually abused.<sup>12</sup>

Treatment depends on the severity of the symptoms. If the irritation is severe, treatment is with high-potency steroids, most commonly clobetasol propionate 0.05%. In less severe cases or when the disease is asymptomatic, an emollient cream is all that is required. As the condition may also involve the perianal skin ('figure of eight appearance'), constipation is often a feature and laxative therapy may also be required. Most girls have complete remission of symptoms after 2 or 3 months<sup>13</sup> and the condition usually resolves completely before puberty. There is no risk of malignancy with lichen sclerosus in this age group, unlike that debated in the postmenopausal group, and it may be worth emphasizing that to parents, who in this age of the Internet may be alarmed by the information they find there.

### Threadworms

Threadworms (*Enterobius vermicularis*) are common in this age group and although the most common presentation is with anal irritation, vulvar irritation may also be present or may be the only presenting symptom. Diagnosis is by a Sellotape test, the tape being applied to the perianal region overnight, removed in the morning and fixed to a glass slide. Examination of the slide will reveal ova and adult worms. Treatment is with mebendazole 100 mg as a single dose to all members of the family over the age of 2 years.

### Nonspecific vulvitis

Nonspecific vulvitis is common but difficult to treat. Common precipitating factors are washing powder, fabric conditioners and bubble bath. Treatment is by identifying and removing the cause.

## OTHER VULVAR DISORDERS

### Vulvar warts

Vulvar or perianal warts (Fig. 25.2) present the dilemma of whether or not they are indicative of sexual abuse. They may well have been transferred quite innocently from the hands of a parent or childminder, or the child herself, and the situation requires sensitive handling. It has been suggested that DNA typing of the virus may be helpful but this is debatable except in cases of child abuse, where a matching to genital warts

Fig. 25.1 Lichen sclerosus on the vulva of a prepubertal girl showing the classical appearances of pearly white areas with hemorrhage and ulceration.

from the alleged abuser will provide confirmation. Warts on the hymen are always significant.

Treatment is by cauterization under general anesthesia or, in the older girl, by using podophyllin, taking care not to damage the surrounding skin.

Fig. 25.2 Perianal warts in a young girl (reproduced by kind permission of Edward Arnold).

Fig. 25.3 Labial adhesions in a child of 18 months. Note the completely flat appearance of the perineum.

### LABIAL ADHESIONS

Labial adhesions are seen most commonly in girls under the age of 3 years and are thought to be secondary to chronic irritation. It is important to make the correct diagnosis. The child is commonly brought up by parents, who are panic-stricken, having been told that their child has a congenital abnormality that will require major reconstructive surgery.

The difference between labial adhesions and congenital absence of the vagina is quite straightforward. In a girl with labial adhesions, the perineum is quite flat, with the fused labia preventing visualization of the urethra, clitoris or hymen (Fig. 25.3). The line of the fused labia can often be clearly seen. In a girl with congenital absence of the vagina, separation of the labia shows clearly the introital structures.

Labial adhesions are usually asymptomatic, a chance finding by the mother or a health worker. Occasionally, the presentation may be that of incontinence, urine being trapped behind the adhesion when the girl is squatting on the toilet but being expelled when she stands up.

Treatment, if required, is with estrogen cream. There is debate that treatment should be restricted to those girls who are symptomatic as the condition is a self-limiting one and resolves spontaneously as the child becomes older. There is no place for surgical separation.

The debate as to whether labial adhesions are diagnostic of, or more common in, girls who have been sexually abused is unresolved.

### PROBLEMS OF PUBERTY

#### PRIMARY AMENORRHEA

Amenorrhea is considered as 'primary' when the girl has never menstruated and 'secondary' if she has not had a period for 6 months or more. Primary amenorrhea is usually subdivided into two groups – girls who have no pubertal development in whom the problem is most likely due to a hormonal cause and girls who have normal pubertal development in whom the cause is most likely an anatomical one. The causes of primary amenorrhea are shown in Table 25.1.

It is standard practice to advise investigation of girls with primary amenorrhea without pubertal development by the age of 14 and girls with normal pubertal development by the age of 16. It is equally important to remember that pubertal development is a continuum and that a break in the continuum is as significant as arbitrary cut-offs of age.

#### Primary amenorrhea without sexual development *Constitutional delay*

Girls with constitutional delay may have a family history of the condition. Investigations show low estrogen and low gonadotrophin levels.

Table 25.1 Causes of primary amenorrhea

<b>Without pubertal development</b>
Constitutional delay
Chronic systemic disease
Absent ovarian function
Hypothalamic pituitary dysfunction (Polycystic ovarian syndrome)
<b>With pubertal development</b>
Absent uterus (Absent or imperforate vagina)

Bone age is delayed compared to chronological age. Reassurance is all that is required although girls in whom puberty is significantly delayed should be considered for induction of puberty.

### **Chronic systemic disease**

Chronic diseases such as poorly controlled diabetes or hypothyroidism are not usually a diagnostic problem. Estrogen and gonadotrophin levels are low. Puberty follows control of the disease.

### **Absent ovarian function**

Absent ovarian function may be due to primary or premature ovarian failure or to gonadal dysgenesis. The characteristic findings on investigation are high follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels and low estrogen. Ovarian failure may also present as secondary amenorrhea depending on the stage of development at which the failure occurred. It is a devastating diagnosis to have to give any woman of reproductive years but worse for an adolescent girl and it requires sensitive handling.

The most common identified cause of premature ovarian failure in modern practice is subsequent to chemotherapy or irradiation for childhood or adolescent malignancy. Recent advances in techniques of ovarian tissue cryopreservation suggest that it may be possible in the future to preserve fertility in some patients whose gonadal function is threatened by premature menopause, or by treatments such as radiotherapy, chemotherapy or surgical castration.<sup>14</sup> While most cases are idiopathic, identified causes of ovarian failure in this age group are autoimmune, chromosomal (e.g. 46XXX, fragile X), metabolic (e.g. galactosemia).

Gonadal dysgenesis most commonly is associated with a 45X or variant karyotype (Turner syndrome) but may also be found in girls with a 46XY karyotype (Swyer syndrome or pure gonadal dysgenesis). Turner syndrome is found in 1:2000 to 1:3000 of the female population. It is characterized by short stature and ovarian failure, the ovaries being only streaks of tissue (streak ovaries). However, only approximately 50% of girls with Turner syndrome have the 45X karyotype on lymphocyte culture, the remainder being due to abnormal X chromosomes or mosaic karyotypes. Because of this, the phenotype varies greatly, but the main additional features include web neck, shield chest with wide-spaced nipples and wide carrying angle (Fig. 25.4). Delay in the diagnosis is often due to the failure to appreciate the variation in phenotype.

### **Hypothalamic pituitary dysfunction**

Hypothalamic or pituitary disorders, such as craniopharyngiomas, hydrocephaly or Kallmann syndrome may result in primary amenorrhea.

### **Treatment**

Treatment involves hormone replacement in such a way as to mimic the normal physiological response of the ovary. Obviously in girls with constitutional delay or those with chronic illness, development may proceed normally given time. However, while waiting for spontaneous development, adolescents may experience psychological stress or even bullying at school so induction of puberty should be considered and discussed.

Estrogen replacement should begin around the age of 10 or 11, unless it is wished to delay it for the administration of growth hormone

Fig. 25.4 Classical appearance of a girl with Turner syndrome showing web neck, wide-spaced nipples and wide carrying angle. Mosaic conditions are common so that a wide variation in phenotype is seen.

in girls with Turner syndrome. The initial dose should be 1 mcg ethinyl estradiol increasing every 6 months to 2 mcg, 5 mcg and 10 mcg. After this period of time a cyclical preparation of estrogen and progestogen should be introduced, either in the form of the combined oral contraceptive or, preferably, hormone replacement therapy. Girls on long-term oestrogen replacement should be monitored for dosage and compliance to reduce the long-term risks of estrogen lack such as osteoporosis.

### **Primary amenorrhea with sexual development**

Primary amenorrhea with normal development is usually due to an anatomical cause, either absence of the uterus (or more correctly the endometrium) or absence or blockage of the vagina, which more correctly causes cryptomenorrhea.

### **Absence of the uterus**

Failure of development of the Mullerian duct causing congenital absence of the uterus may be found in Rokitansky–Kuster–Hauser syndrome or as part of complete androgen insensitivity syndrome (CAIS).

**Rokitansky–Kuster–Hauser syndrome.** Girls with this condition are phenotypically normal, with a 46XX karyotype and normal ovaries. Associated renal tract abnormalities are found in 40% of patients and vertebral column abnormalities such as hemivertebrae or fused vertebrae in 12%. The degree of failure of development (Fig. 25.5) varies from total absence of Mullerian duct structures to varying degrees of uterine

Fig. 25.5 Rudimentary uterine horns in a girl with Rokitansky-Kuster-Hauser syndrome (adhesions surrounding the left horn).

horn development, very occasionally including endometrium within a small blind uterine horn causing cryptomenorrhea. It is not necessary to remove the rudimentary uterine horn unless there is cryptomenorrhea. Vaginal reconstruction with dilators or surgically is required.

**Complete androgen insensitivity syndrome (CAIS).** Girls with CAIS have a 46XY karyotype. They are often slightly taller than average, have good breast development and sparse pubic and axillary hair. The condition arises as a result of the cells of the mesonephric duct and genital tubercle failing to respond to circulating androgens with the resulting failure of development of male external genitalia. The condition is an X-linked disorder and a history of a sister or aunt with the condition may be obtained.

Treatment is by removal of the testes because of the 5% risk of malignancy<sup>15</sup> and vaginal reconstruction. Long-term estrogen replacement is required to protect against osteoporosis.

Girls with CAIS and their families require sensitive management, particularly in regard to their sexual identity.<sup>16</sup>

### Cryptomenorrhea

Cryptomenorrhea or 'hidden menstruation' presents with amenorrhea in the presence of increasingly severe cyclical lower abdominal pain. The common blockage occurs at the lower end of the vagina, but higher lesions may occur.

In severe cases, the girl may present with acute urinary retention due to blockage of the urethra by the vaginal mass. Examination of the abdomen reveals a mass arising out of the pelvis, the size being dependent on the duration of menstruation. With a low blockage, examination shows the classical bulging blue membrane at the introitus on separation of the labia (Fig. 25.6). Treatment is by cruciate incision of the membrane.

More rarely, cryptomenorrhea may occur in the presence of menstruation when there is a blockage of a duplex genital tract, in which case presentation is with severe dysmenorrhea.

## PROBLEMS OF ADOLESCENCE

### HEAVY PERIODS

A complaint of heavy periods is the commonest reason for seeing a teenager at a gynecological clinic. It is essential when seeing these patients that an accurate history is taken. In practice, it is difficult to assess a girl's menstrual loss objectively in the absence of evidence such as anemia. Information about cycle length and duration is subjective and rarely helpful, although the use of a menstrual diary or a pictorial chart<sup>17</sup> may help. A history of how her periods affect activities such as attendance at school, having to get up at night to change sanitary protection or

Fig. 25.6 Bulging membrane at the introitus of an adolescent with cryptomenorrhea due to a low transverse vaginal septum.

nightwear may be more helpful. However, a study in adult women with a complaint of heavy periods that showed that in 68% the blood loss was less than 80 ml and in 42% it was less than 50 ml<sup>18</sup> illustrates the difficulty in making an accurate assessment of the problem through history. It is essential however that an objective assessment is made as acceptance that a problem exists may affect a girl's perception of her menstruation into adulthood.

### Pathophysiology

Girls with heavy, irregular periods are unlikely to be ovulating. Whereas in their early twenties, 95% of women are having ovulatory cycles, regular ovulation only occurs in 15% of girls in the first year after menarche.<sup>19</sup> In the absence of progesterone produced as a result of ovulation, the endometrium continues to proliferate under the action of unopposed estrogen until the endometrium breaks down irregularly with resultant extremely heavy loss. Girls with regular heavy periods are more likely to be ovulating and the mechanism for the heavy loss is thought to be due to increased endometrial fibrinolysis<sup>20</sup> and an alteration in prostaglandin balance.<sup>21</sup>

### Management

There is no place for bimanual vaginal or rectal examination of these girls. It is unlikely that there will be any pelvic pathology causing these symptoms and such an examination is only likely to cause distress and deter them from attending future gynecological examination. If it is essential that an assessment is made of the pelvic organs, then pelvic ultrasound should be performed.

Full blood count should be performed. Thyroid function should only be assessed if there are features in the history or examination suggestive of thyroid dysfunction.<sup>22</sup> There is no indication in this age group for hysteroscopy or dilatation and curettage.

Girls who are not anemic and whose periods are not disrupting their school or personal life require reassurance only. Girls with heavy regular periods should be treated with tranexamic acid 1 g 6 hourly and mefenamic acid 500 mg 8 hourly.<sup>23</sup> Tranexamic acid has been shown to reduce menstrual flow by 54% and mefenamic acid to reduce menstrual flow by 20%.

In girls with irregular periods, treatment should be with cyclical progestogens, such as dydrogesterone, norethisterone or medroxyprogesterone, or the combined oral contraceptive pill. Treatment should continue for 6–12 months in the first instance before stopping, with the information that the medication is not curing anything, merely controlling symptoms until ovulatory cycles occur. Treatment should therefore be continued in the long term until the symptoms have settled.

Concerns about giving the combined oral contraceptive pill to adolescents are largely unfounded. The most commonly expressed are premature closure of epiphyses, which is unfounded as a girl producing enough estrogen to have heavy periods will already have closed epiphyses, and an increased risk of developing breast cancer. The risk of the latter has been defined by the Collaborative Group on Hormonal Factors in Breast Cancer<sup>24</sup> as being 0.5 excess cancers per 100 000 women when used in the ages 16–19.

### PAINFUL PERIODS

Dysmenorrhea affects 60% of adolescents – 14% of them having symptoms severe enough to cause them to miss school.<sup>25</sup> Dysmenorrhea occurs in ovulatory cycles and is caused by increased levels of prostaglandins being released by the menstrual endometrium. The pain starts with the onset of menstruation, or just before, and lasts 24–48 h. It may be accompanied by nausea, vomiting, diarrhea, backache and pain in the thighs. Treatment is with one of the prostaglandin synthetase inhibitors, usually mefenamic acid 500 mg 8 hourly.<sup>26</sup> Although good-quality trials are lacking,<sup>27</sup> the combined oral contraceptive pill is the treatment of choice for those girls who fail to respond to the prostaglandin synthetase inhibitors and has the added advantage of reducing menstrual flow and providing contraception.

In girls who fail to respond to the combined oral contraceptive pill, underlying pathology should be excluded. The commonest underlying cause is endometriosis (Fig. 25.7), found in approximately 40% of adolescent girls investigated.<sup>28</sup> Treatment is with the combined oral contraceptive pill, progestogens, danazol and gonadotrophin-releasing hormone (GnRH) agonists, the choice being made principally on the basis of the side effects as they are equally effective in relieving pain.<sup>29</sup>

Fig. 25.7 Extensive endometriosis involving the right uterosacral ligament and pouch of Douglas in an adolescent girl.

Loss of bone mass is the main limiting side effect of the use of GnRH agonists but has been shown to be reversible in adolescents.<sup>30</sup> GnRH agonists may be used with add-back estrogen/progestogen to prevent bone loss without apparent loss of effective therapy.<sup>31</sup>

The other condition that should be considered in girls who fail to respond to the combined oral contraceptive pill is cryptomenorrhea in a patient with a duplex system. Ultrasound examination in such girls may show an 'ovarian cyst', which is, of course, the blind uterine horn filled with menstrual blood. Depending on the level of the blockage, treatment is either by removing the vaginal septum blocking the uterus or removing the uterine horn. Endometriosis is often additionally present. Imaging of the renal tract should be performed as 47% of girls with Mullerian duct abnormalities have renal tract anomalies.<sup>32</sup>

### SECONDARY AMENORRHEA

Secondary amenorrhea is defined as the cessation of periods for 6 months or more. The main causes are listed in Table 25.2.

#### Polycystic ovarian disease

Polycystic ovarian syndrome (PCO) presents with irregular periods or secondary amenorrhea and is associated with obesity, hirsutism, acne and anovulation. Endocrinologically it is characterized by LH hypersecretion and insulin resistance, and a finding of an LH:FSH ratio of greater than three with slightly raised testosterone levels and low sex hormone-binding globulin (SHBG). Ultrasound examination reveals a slightly enlarged ovary with hyperechoic stroma and 10 or more follicles of no greater than 10 mm around the circumference (Fig. 25.8). These ultrasound appearances are found in up to one third of women and diagnosis should not be made on these appearances alone.

Treatment should emphasize the importance of weight loss through exercise and diet<sup>33</sup> as this reduces insulin resistance and is associated with improved regularity of menstruation, hirsutism and ovulation. It is also important as women with PCO have an increased risk of developing diabetes mellitus, or having a stroke or a transient ischemic attack.<sup>34</sup> Treatment otherwise is aimed at controlling the symptoms. In the case of secondary amenorrhea or irregular periods, this is achieved with the

Table 25.2 Causes of secondary amenorrhea

Pregnancy
Premature ovarian failure
Polycystic ovary syndrome
Pituitary disorders
Hypothalamic disorders

Fig. 25.8 Ultrasound appearances of polycystic ovarian syndrome.

combined oral contraceptive pill. Metformin has been shown to reduce hyperinsulinemia and hyperandrogenemia<sup>35</sup> although there is no literature about the safety of long-term use in young women.<sup>36</sup>

### Pituitary disorders

Pituitary disorders as a cause of secondary amenorrhea in adolescents are very rare.

### Hypothalamic disorders

Girls who have a low body mass index (BMI) due to dieting, anorexia nervosa or excessive exercising will have amenorrhea secondary to hypothalamic dysfunction and low levels of gonadotrophin. Investigation reveals low levels of FSH, LH and estrogen. Menstrual cycles will normally resume when, or just after, the girl achieves normal weight. Management in the meantime, however, can be difficult as such girls often refuse replacement hormones as they fear putting on weight.

### HIRSUTISM AND VIRILISM

Hirsutism is defined as the presence of excessive hair in a female in a distribution that is characteristic of an adult male. It is an extremely embarrassing and distressing condition for a teenager. Causes include ovarian disorders, adrenal disorders, drugs and hypothyroidism; polycystic ovarian syndrome is the most common.

Examination should include careful recording of the extent of the abnormal hair growth as a baseline prior to treatment. Initial investigation is by hormone profile including FSH, LH, testosterone, SHBG, 17 $\alpha$ hydroxyprogesterone and the specific adrenal androgen dehydroepiandrosterone sulfate (DHEAS). Cortisol levels and thyroid function tests should also be assessed.

Treatment should be started as soon as possible as terminal hair growth can be difficult to stop once stimulated. Cosmetic treatments such as waxing, laser therapy or electrolysis should be used. Specific treatment depends on the cause. Ovarian or adrenal androgen-secreting tumors should be removed. Late-onset congenital adrenal hyperplasia is treated with dexamethasone.

Hirsutism due to polycystic ovarian syndrome is treated with the antiandrogen cyproterone acetate in conjunction with estrogen. Low-dose cyproterone acetate may be given in the form of the combined oral contraceptive Dianette (Schering). Higher doses may be given.

Spironolactone and finasteride have also been used for the treatment of hirsutism although neither is licensed for the treatment of hyperandrogenism.

### FEMALE GENITAL MUTILATION

Female genital mutilation is a complex issue that raises concerns about competing cultural backgrounds, autonomy, health education and sexuality. It is practiced in many cultures but most widely in northern Africa and in the Arab peninsula. The age at which it is performed varies with culture but most commonly around the ages of 7–9.

Immigration figures show that the number of women from communities that traditionally practice female genital mutilation is rising in the UK.<sup>37</sup> Girls from cultures where it is the practice for the procedure to be performed but who live in Britain probably have the operation performed in the country of their family.

Four main types are recognized:

1. **Circumcision.** This is the least extensive and involves cutting of the prepuce of the hood of the clitoris. In some countries this is known as 'Sunna'.
2. **Excision.** This involves removal of the clitoris and all or part of the labia minora with the remainder of the labia minora being stitched together, leaving a small opening to allow urine and menstrual blood to be passed (Fig. 25.9).
3. **Infibulation.** This is the most extensive. It involves removal of the clitoris, labia minora and a substantial part of the medial aspect

Fig. 25.9 Appearance of the external genitalia in an adolescent girl who has had excision of the genitalia (reproduced by kind permission of Edward Arnold).

of the labia majora. The remainder of the labia majora are then pinned together to leave a small opening.

4. **Intermediate.** This involves removal of the clitoris and varying amounts of the labia minora and majora.

The most common problems likely to be seen by pediatricians in girls who have had circumcision performed are recurrent urinary tract infection and dysmenorrhea.

In Britain, female genital mutilation is illegal (Prohibition of Female Circumcision Act 1985); it is regarded as a form of abuse<sup>38</sup> and raises child protection issues. It differs from other forms of abuse in that it may be done with the best intentions for the future welfare of the child, there is no possibility of its repetition during childhood and it is approved by sections of the communities in which it is practiced.

### GYNECOLOGICAL TUMORS

Gynecological tumors are rare in childhood and adolescence – and malignant tumors particularly so. The commonest are ovarian lesions with tumors of the vagina and cervix being the next most common. Late presentation is a major problem, partly due in the case of ovarian lesions to the nonspecific presenting symptoms, and partly due to the rarity of the tumors resulting in a low index of suspicion. The main presenting symptoms are nonspecific lower abdominal pain, occasionally with vomiting. Vaginal bleeding may be the presenting symptom in estrogen-secreting tumors.

## BENIGN OVARIAN TUMORS

*Follicular cysts* are the most common, frequently being found incidentally as part of an ultrasound examination. Management for lesions less than 5 cm is simply by follow-up ultrasound examination to ensure that the cysts resolve. Larger cysts should be aspirated, either under ultrasound control or laparoscopically. If surgical removal is required, care should be taken to preserve as much of the normal ovarian tissue as possible.

*Teratomas* are the most common neoplasm. They arise from totipotential primordial cells and may contain tissue derived from all three tissue layers. The predominant tissue is usually ectodermal – i.e. sebum and hair – earning the common term ‘dermoid cyst’. Treatment is by surgical removal, with conservation of as much ovarian tissue as possible, and close examination of the other ovary as 10–15% of these tumors are bilateral.

## MALIGNANT OVARIAN TUMORS

Dysgerminomas are the most common malignant ovarian tumor in childhood and adolescence; 60% of these tumors are found in females under the age of 20. They are bilateral in 10–15% of cases. As they are usually of low malignant potential unilateral oophorectomy may be carried out, unless the girl has a Y chromosome – or part of one – in her karyotype, when bilateral oophorectomy should be performed.

Other malignant tumors of the ovary such as immature teratomas, endodermal sinus tumors, embryonal carcinoma, mixed germ-cell tumors and granulosa cell tumors are less common.

## OTHER MALIGNANT TUMORS

Genital rhabdomyosarcoma (previously known as sarcoma botryoides) is the most common genital tract neoplasm in children under the age of 16. The tumor occurs most commonly in the vagina, less commonly in the cervix and uterus. Vaginal lesions occur most commonly in girls under the age of 2 years, with lesions of the cervix and vagina being found most commonly in older girls and young adults.

The tumor presents with vaginal bleeding and bloodstained discharge and such symptoms should always be assessed by examination under

anesthesia and should include cystoscopy and proctoscopy. Treatment is with multimodal regimes using triple chemotherapy (vincristine, actinomycin D and cyclophosphamide), with or without radiotherapy. The use of this regime has reduced the need for surgical resection from 100% in the initial Intergroup Rhabdomyosarcoma Study Group (IRSG) to only 13% in the most recent study.<sup>39</sup>

## TEENAGE PREGNANCY

The problems associated with teenage pregnancy are those associated with social deprivation rather than specifically related to young maternal age. The incidence of teenage pregnancies varies between countries and within countries. The Guttmacher Institute recently reported trend data on adolescent birth rates for 46 countries over the period 1970–1995. Lowest rates were reported from the Netherlands (12/1000 adolescents/year) with the highest among resource rich countries being the Russian Federation (> 100/1000 adolescents/year). Japan and most western European countries had rates of < 40/1000 adolescents/year.<sup>40</sup> Within the Netherlands, four times as many pregnant teenagers had non-Dutch ethnicity compared to all pregnant women.<sup>41</sup> Psychosocial problems, and the consumption of alcohol, cigarettes, marijuana, heroin and solvents are higher among pregnant teenagers than in the general teenage population.<sup>42</sup> Pregnant teenagers with higher levels of education are more likely to undergo termination of pregnancy than continue with the pregnancy.<sup>43</sup> There is some evidence that, in some areas, the difference in teenage pregnancy rates between more affluent and more deprived areas has widened over the last 2 decades.<sup>44</sup>

Antenatal problems reported in pregnant teenagers include pregnancy-induced hypertension, anemia,<sup>45</sup> premature labor and low birth weight,<sup>46</sup> although some of these are also associated with social factors such as smoking and deprivation. There are no specific intrapartum problems faced by pregnant teenagers, high rates of spontaneous delivery with low rates of prolonged labor and cesarean section being consistently reported.<sup>46</sup> While no differences have been reported in outcome of first teenage pregnancy, a second teenage pregnancy is associated with three times the average risk of stillbirth.<sup>47</sup>

*"Nature is no where accustomed more openly to display her secret mysteries than in cases where she shows traces of her workings apart from the beaten path; nor is there any better way to advance the proper practice of medicine than to give our minds to the discovery of the usual law of nature, by careful investigation of cases of rarer forms of disease. For it has been found in almost all things that what they contain of useful or applicable, is hardly perceived unless we are deprived of them, or they become deranged in some way." (William Harvey 1642: letter to John Vlackveld)*

## INTRODUCTION

### THE EVIDENCE BASE

Randomized, controlled, clinical trials are the basis of evidence-based medicine. However, for rare disorders, there are so few subjects, even with multicenter studies, that they are very difficult or impossible to conduct. In addition, wide clinical and genetic heterogeneity can render the generalizing results of such trials invalid. For rare diseases, treatment is often based on anecdote, empiric data and theory that can lead to a perception of treatment efficacy, as happened with the use of Lorenzo's oil for adrenoleukodystrophy and supplemental cholesterol for Smith-Lemli-Opitz syndrome. Recent successful trials of enzyme replacement therapy for several lysosomal storage diseases have been funded by the pharmaceutical industry without which they would have been difficult, if not impossible, to perform.

### USEFUL REFERENCES

The major reference on biochemical genetics is the four-volume textbook edited by Scriver et al.<sup>1</sup> Additional sources for clinicians are Nyhan et al.<sup>2</sup> Gilbert-Barness and Barness<sup>3</sup> and Fernandes et al.<sup>4</sup> Other useful texts are by Holton,<sup>5</sup> Blau and Blaskovics,<sup>6</sup> Hommes,<sup>7</sup> Lyon et al<sup>8</sup> and Clarke.<sup>9</sup>

On-line Mendelian Inheritance In Man (OMIM), accessed through Pubmed on the Internet (<http://www3.ncbi.nlm.nih.gov/omim/>), provides invaluable information about all known human genetic conditions. Other sites include <http://www.genetests.org>, which is a listing of laboratories providing specific DNA tests, and links to GeneReviews which provides online chapters on many inborn errors of metabolism (IEM). Other good sites are <http://www.kumc.edu/gec/geneinfo.html>, 'Children Living with Inherited Metabolic Disease' (<http://www.climb.org.uk/>) and the National Organization for Rare Disorders (NORD), New Fairfield, CT, USA (<http://www.rarediseases.org/>).

### BIOCHEMICAL AND GENETIC CONSIDERATIONS

For 80 years after the term 'inborn errors of metabolism' was coined,<sup>10</sup> metabolic disorders were viewed as mostly involving amino acids. The field now includes over 600 disorders in almost every metabolic pathway and including defects of subcellular organelles, membrane structure and function, and disorders of protein processing, ion channeling, signal transduction, etc. The boundaries between environmental, genetic and metabolic conditions, never very clear, have increasingly merged. Over 400 conditions are discussed in this chapter; others, such as the metabolic endocrinopathies (Ch. 15), genetic defects of digestion and

absorption (Ch. 19) and the metabolic defects of erythrocytes and leukocytes (Ch. 23) are discussed elsewhere.

### Biochemical considerations

Expression of an enzyme activity usually represents the sum of the effect of two alleles. In Figure 26.1 the contribution of each allele (0–50%) and the total enzyme activity as a percentage are shown. The mother (I-2) is heterozygous for an allele producing a nonfunctional protein and I-1 is heterozygous for a mild mutation. Individuals such as I-3, who is a compound heterozygote with 11% of residual function, might be totally asymptomatic, be mildly affected or may only exhibit problems when the enzyme is stressed. Such heterogeneity results in 0–100% of normal activity, giving rise to severe or mild cases of a disorder even within a single pedigree.

Readers should always be mindful of the artificial nature of enzyme assays that usually involve highly unphysiological conditions, including high substrate levels and the use of artificial substrates. Some mutant enzymes require high in vivo levels of substrates to work adequately, as seen in some vitamin-dependent diseases. Occasionally healthy people have no activity against an artificial substrate in vitro. Conversely, it is possible to have normal in vitro activity but none in vivo. Similarly, in immunological assays, the epitope of the antibody may not involve the active site of the enzyme; immunological cross-reactivity can therefore be present even though a mutant protein is functionally defective.

Many enzymes exist in different forms in different tissues. Such *isoenzymes* may share some subunits while others are under separate genetic control. It is thus possible for a defect to occur in one tissue while normal activity is present in others. This must be remembered when leukocytes or surrogate tissues are used to diagnose an enzyme defect that is suspected to exist in other organs. A further confounding fact is that some isozymes derive from a single gene but are matured to different forms in different tissues; in an unusual form of acute intermittent porphyria, the erythrocyte isoform is normal but the enzyme is deficient in liver.

The potential consequences of an enzyme deficiency are illustrated in Figure 26.2. In phenylketonuria (PKU), for example, the metabolic

Fig. 26.1 Hypothetical pedigree showing the contribution of different mutant alleles to the total activity of an enzyme that is indicated as a percentage of the normal. Each normal allele contributes 50% of total normal function as seen in II-1. The index case II-3 has only 1% of normal activity. Case I-3 and even case II-2 might, under some circumstances, show evidence of the defect.

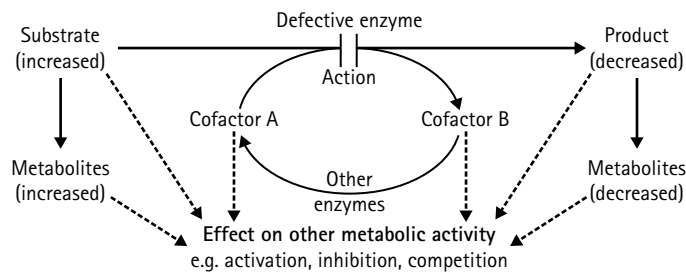

Fig. 26.2 Theoretical consequences of an enzyme deficiency.

derangements include inhibition of amino acid transport into brain cells, diminished synthesis of myelin and aromatic amines and inhibition of pyruvate metabolism, but it is not known how the brain damage is actually caused. Phenotypic variations even within a single family are presumed to be due to different environmental exposures or to inherited differences in the other metabolic steps that are affected by the biochemical upset (*epigenetics*). Genotype–phenotype correlations are proving to be very difficult to predict.<sup>11</sup>

### Genetic considerations

The rapid advances fostered by the Human Genome Project have radically changed the specialty of genetics and are ever more impinging upon all branches of medicine. While some disorders are caused by one or only a few mutations, most are caused by many, sometimes numbering over 1000. New genes and new mutations make it almost obligatory to check the Internet before consulting on almost any genetic condition.

Some mutations are common in certain populations and rare in others, often due to founder effects or closed populations, but the high incidences of Tay–Sachs, Gaucher disease and mild congenital adrenal hyperplasia in Ashkenazim, which are caused by several different mutations, raise questions not only of founder effects but also of selective advantages.

Most heterozygotes can be identified if a specific test can be devised. For example, carriers of maple syrup urine disease have normal plasma amino acid levels and amino acid tolerance tests, but reduced enzyme activity in leukocytes. On the other hand, 80% of carriers for PKU can be identified by the phenylalanine:tyrosine ratio in fasting plasma or a phenylalanine tolerance test, though DNA analysis is now preferred. However, even *in vitro* enzyme assays may not clearly differentiate between carriers and affected or normal subjects. If available, DNA analysis is the optimum way to detect heterozygotes.

When a known metabolic disease is associated with other unrelated problems such as dysmorphic features, consideration should always be given either to the possibility of a microdeletion syndrome (e.g. glycerol kinase; see p. 1070), incest or the possibility of two conditions coexisting.

Most metabolic defects are recessively inherited. In this chapter, the genetics of each condition will not necessarily be discussed unless they vary from this pattern. Gene loci are not routinely provided in this chapter; they can be found on OMIM.

## CLINICAL CONSIDERATIONS

### Incidences

At least 1–2% of individuals have a pathogenic metabolic disorder of which most, such as hyperuricemia and the hyperlipidemias, are of minor clinical importance in childhood. Almost all of the conditions in this chapter are rare (~1 in 100 000–250 000); many are extremely rare (1 in  $10^6$ – $10^7$ ). However, if there are 1000 diseases each with an incidence of only one in a million, 1 in 1000 people will have one of them and for *each* of these conditions, 1 in 500 is a carrier! This rarity constitutes a major diagnostic stumbling block for clinicians.<sup>12–15</sup>

Some of the commonest reasons for referral to a metabolic clinic are:

- disorders detected by expanded newborn screening;
- suspected or confirmed lactic acidosis;
- suspected or confirmed metabolic neurological disorders; including nonspecific developmental delay;
- metabolic bone diseases such as nutritional or hereditary rickets;
- failure to thrive;
- hypercholesterolemia;
- suspected porphyria;
- visceromegaly.

### Clinical features

Metabolic disorders should always be considered when patients present with puzzling or unexplained problems, whether of growth, development or specific organ pathology. They can disrupt the function of any organ and may present at any age to specialists in any clinical discipline. Review of Tables 26.7, 26.10, 26.11, 26.26 and 26.28, which list common symptoms in various classes of disease, show the enormous diversity of presentations. Superb diagnostic algorithms are given in Chapter 66 of Scriver et al.<sup>1</sup>

### Metabolic screening

Because the symptoms of metabolic disorders mimic nongenetic disease, some kind of ‘metabolic screen’ is frequently done on blood and/or urine of potential cases in the hope that an abnormality may assist in the diagnosis. This screening is different from the newborn screen and varies in different centers but may include rather insensitive tests for sugars, mucopolysaccharides, amino acids and a variety of other compounds. Quantitative assay of plasma amino acids, carnitine derivatives and urine organic acids are increasingly available and used for screening.<sup>16</sup> Such screening of ‘at risk’ children reveals an IEM in about 10% of cases.<sup>17,18</sup> It must always be remembered that many disorders are not associated with abnormal metabolite levels and thus cannot be detected by such assays. In most centers, the cost of such testing is less than that of a computed tomography (CT) or magnetic resonance imaging (MRI) scan. Increased number and availability of specific metabolic tests is improving the possibility of accurate diagnosis (Table 26.1).<sup>19</sup>

Large-scale metabolic screening in subjects with neurodevelopmental delay has led to the discovery of many new defects; most are rare. When an unusual defect is associated with clinical symptoms it is tempting to assume that they are causally related; however, this is often not the case. Amino acid disorders once thought to cause neurodevelopmental delay but now considered benign include cystathioninuria, methionine adenosyl transferase deficiency, some hyperlysinemias, saccharopinuria, 2-ketoadipic aciduria, sarcosinemia, hyperprolinemia, hydroxyprolinemia, histidinemia, carnosinemia, urocanic aciduria and beta-aminoisobutyricaciduria.

Routine newborn metabolic screening (including tandem mass spectrometry [MS/MS]) has entered a new phase with as many as 40 different conditions being detectable. Interpretation of the results requires considerable biochemical knowledge and is outside the scope of this chapter (see Appendix 1). It remains to be seen how radically expanded screening will alter our understanding of these diseases and reveal as yet unknown biological diversity.

## THERAPEUTIC CONSIDERATIONS

Roughly 12% of metabolic diseases are markedly ameliorated by therapy; in about 50% treatment is partially effective, but treatment has little effect in the remainder.<sup>20</sup> For most, the approach is still to try and induce activity, as in the vitamin-responsive conditions, or to counteract the biochemical disturbance by diet or drug therapy. However, even total correction of a biochemical defect may not improve the symptoms (see Fig. 26.2). For example, in the Lesch–Nyhan syndrome, the blood urate is easily controlled with allopurinol, but the neurological symptoms are unchanged.

Table 26.1 Specialized investigations used in biochemical genetics

Test	Disorders detected
<i>Blood</i>	
Carnitine	Defects of amino, organic and fatty acid metabolism
Acyl-carnitines	Defects of amino, organic and fatty acid metabolism
Amino acids	All the aminoacidopathies
Very long chain fatty acids	Screening for peroxisomal defects
Plasmalogens	Screening for peroxisomal defects
Fatty acids	Several disorders, including the Smith–Lemli–Opitz syndrome
White blood cells/skin lysosomal enzymes	Lysosomal storage diseases
Transferrin (isoelectric focusing)	Congenital disorders of glycosylation
Creatine	Defects of creatine synthesis
Total homocysteine	Defects of folate and clotting abnormalities
Biotinidase	Biotinidase deficiency
Prolactin	Used to assess neurotransmitter dysfunction
<i>Urine</i>	
Organic acids	This is a primary test for many different disorders
Sulfate	For defects of trans-sulfuration and sulfite oxidase deficiency
Glycine conjugates	For derivatives of many organic and amino acids
Purines and pyrimidines	Several defects in these pathways
Pterins	Cofactors for synthesis of several neurotransmitters
Creatine	Low in defects of creatine synthesis
Guanidinoacetic acid	Abnormal in defects of creatine synthesis
Glycosaminoglycans	Mucopolysaccharidoses
Oligosaccharides	Oligosaccharidoses
<i>Cerebrospinal fluid</i>	
Neurotransmitters (biogenic amines)	Several synthetic defects
Pterins	Cofactors for synthesis of several neurotransmitters
$\gamma$ -Aminobutyric acid	Specific defect
S-Adenosyl methionine	Defect of methionine metabolism
Folate	Several defects
Amino acids	Nonketotic hyperglycinemia (with simultaneous blood)

Adapted from Buist et al.<sup>19</sup>

Transplantation of bone marrow, liver, kidney, as well as stem cells offers the possibility of 'cure' for a variety of disorders. Increasingly, enzyme replacement therapy is being deployed, especially for lysosomal storage disorders, since problems of delivery of stable, active enzyme to the appropriate organelle are being solved. However, these treatments are very costly; enzyme replacement for Gaucher disease is dramatically effective but can cost more than £100 000/year. Similar therapy for other lysosomal disorders costs even more.<sup>21</sup>

Substrate inhibitors as used in tyrosinemia type I, if available, can be very effective. Chaperones are a class of proteins that are essential for the proper tertiary folding of proteins. Studies on chaperone treatment, especially for lysosomal storage diseases, are being initiated to improve the structural configuration of mutant enzymes.

## DISORDERS OF AMINO ACID METABOLISM

### GENERAL CONSIDERATIONS

Of the disorders of amino acid metabolism, defects of catabolism represent the largest group, but abnormalities also exist in amino acid biosynthesis and transport. The clinical manifestations vary widely and involve many different organs. Systemic manifestations are common because of the presence of high levels of circulating small molecules, many of which are toxic to different tissues.

Pyridoxine dependent transamination of an amino acid to the corresponding keto acid is an early step in amino acid catabolism. Therefore, the accumulation of abnormal organic acids and systemic acidosis are the primary biochemical manifestation of many disorders of amino acid metabolism. Collectively, these conditions are a subgroup of the 'organic

acidemias'. This has important implications for the diagnosis of these disorders. While many can be diagnosed by quantitative analysis of plasma amino acids, examination of urine organic acids is often the single most valuable diagnostic test. The more distal the enzyme deficiency lies in the degradation pathway, the more likely plasma amino acid levels will be normal and urine organic acid analysis abnormal. Usually, if one of these disorders is suspected, both plasma amino acids and urine organic acids should be analyzed.

The nutritional characteristics of proteins and amino acids are discussed in Chapter 16. Hydrolysis of protein to oligopeptides and free amino acids in the gut is controlled by enzymes that may be defective as a result of a hereditary disorder (Ch. 19).

Figure 26.3 shows the possible metabolic fate of plasma amino acids that are normally maintained within narrow limits, although they are affected by nutrition, systemic diseases and hormones. Insulin and glucagon usually lower the plasma levels; conversely, many amino acids stimulate the release of insulin and other hormones. In obesity and early in fasting, the branched chain amino acids may be elevated. In starvation the essential amino acids are low and the non-essential amino acids may be elevated, although alanine, a major gluconeogenic substrate, is usually low. In sepsis, stress, renal failure and liver disease, there may be considerable changes, liver disease often causing marked elevation of methionine, phenylalanine and tyrosine. In early life, high protein intake and immature regulatory systems may cause major elevations of many amino acids. The level of most free amino acids in intracellular fluid is about 10 times higher than in plasma.

In PKU, the blood phenylalanine concentration may be 20–60 times normal. Conversely, a rise of alanine of only 10–20% above normal may be the first indication of serious lactic acidosis or hyperammonemia.

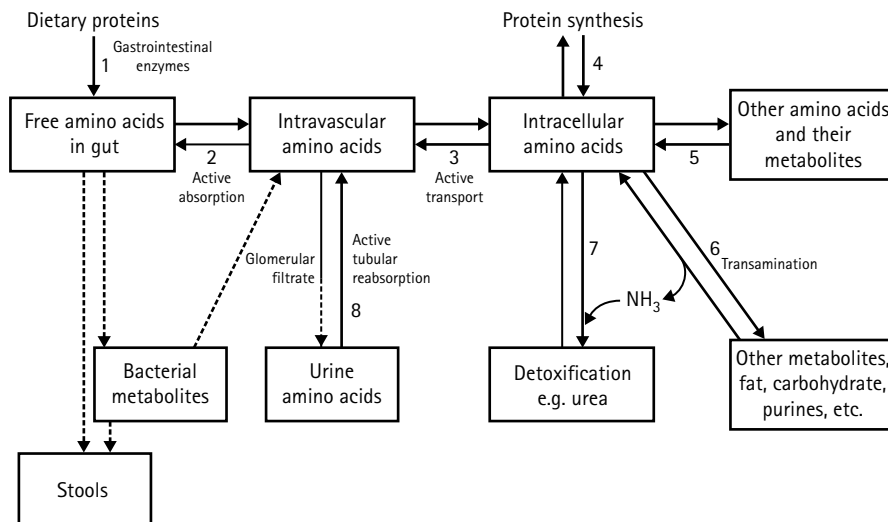

Fig. 26.3 Potential metabolic fate of amino acids. Numbers represent processes requiring active metabolism where congenital defects could occur. Dotted lines represent processes independent of metabolic activity.

In some conditions, such as argininosuccinic aciduria and nonketotic hyperglycinemia, the amino acid is excreted readily in the urine and blood levels may be only mildly abnormal, although in both these conditions the levels are markedly increased in the cerebrospinal fluid (CSF).

The quantity of amino acids in normal urine can vary over 10-fold and depends greatly upon age and nutrition; the levels are higher in infants. Values expressed per unit volume are worthless and even when calculated per milligram creatinine or per square meter, may be misleading. The predominant amino acids in urine (% of total in parentheses) are glycine (20–25%), taurine (5–15%), histidine (10–20%) and glutamine (7–10%). Normally, renal tubular reabsorption is nearly 100%, notable exceptions being histidine and glycine. In early infancy, amino acids may be reabsorbed poorly, adult rates being reached by 3–6 months. Normal urine contains many metabolites arising from the diet, drugs or bacterial action in the gut; these compounds often pose diagnostic problems since many are detected on amino acid or organic acid analyses. Increased urinary excretion is termed *aminoaciduria*; it can be due to increased filtration from raised plasma levels or defective reabsorption by the renal tubular cells. Amino acids are transported across cell membranes in specific groups. Excess of a single amino acid may saturate the renal absorption mechanism for others that share the same transport site and cause a competitive aminoaciduria.

## DESIGNING AN AMINO ACID RESTRICTED DIET

When dietary restriction of amino acids is required to treat aminoacidopathies, certain basic nutritional principles apply. These include:

1. The basal nutritional requirements of the patients are similar if not identical to those of normal infants. This includes the need for enough of the restricted amino acid(s) to allow for normal growth and development.
2. The diet must be adequate in every respect, nutritionally, acceptability and palatability for the patient.
3. It is critical to recognize the catabolic effects of even minor illness or emotional upset upon normal metabolic homeostasis.
4. A normal diet provides only about 25% of the daily amino acid pool; the remainder comes from endogenous turnover; illness can increase catabolism many fold. For each gram of protein catabolized for energy (~4 calories), 65 000 mcg of ammonia is generated.
5. Unlike in normal people, deficiency of any essential nutrient (such as phenylalanine in PKU), causes increased catabolism that will raise the blood level of the limiting amino acid. This is particularly difficult in maple syrup urine disease since all three of the

branched chain amino acids (leucine, isoleucine and valine) must be present in adequate amounts.

6. Diet therapy is very challenging and requires detailed knowledge of the food options available, their nutritional compositions and limitations and how they can be optimally combined.
7. With few exceptions, the amino acid profile of most foods is relatively similar, e.g. all proteins, animal or vegetable, contain about 4–5% phenylalanine; what is different is the actual protein content.
8. The essential principle is to reduce natural protein sources as far as necessary while maintaining the energy intake as high as possible. With this as a base, additional medical foods and normal low-protein, high-energy foods are added to develop a complete intake.
9. Special low-protein, high-energy foods are becoming more available and should be freely used in designing these diets.
10. It is hard to overemphasize the effect of these diets upon patients as well as their families. Every effort must be made to make the diet as 'normal' and as varied as possible.

## PHENYLALANINE–TYROSINE GROUP

### Phenylketonuria and hyperphenylalaninemia

The term phenylketonuria (PKU) was coined in 1930 to describe patients with severe neurodevelopmental delay and high blood phenylalanine levels. It is now clear that it represents only one end of a spectrum of hyperphenylalaninemia (HPA) in which 30–40% of infants, detected by newborn screening, never develop high enough blood phenylalanine levels to cause brain damage. Such clinical heterogeneity is now apparent for virtually all IEMs but for the PKU/HPA spectrum, the central debate is over what level of phenylalanine requires treatment, what the treatment goals should be, and what constitutes PKU and what HPA. All are recessively inherited disorders. In all of them, phenylalanine cannot be converted to tyrosine. Blood phenylalanine is elevated and, when high, phenylpyruvic acid is excreted in the urine.

### Clinical findings

Almost all classic, untreated PKU patients exhibit severe brain damage with an IQ < 30 because persistently elevated phenylalanine is toxic to the central nervous system (CNS). This damage begins to become irreversible within 3–6 weeks of birth and therefore early screening and treatment are important. Phenylketonuric infants appear normal at birth, but some show nonspecific feeding problems. In the early months, vomiting, irritability, an eczematoid rash, developmental slowing and a mousy, musty odor, derived from phenylacetic acid (the same metabolite that is frequent in chronically incontinent patients), usually emerge.

General physical development is usually normal. Over 90% of untreated patients are fair haired, fair skinned and blue eyed, but dark skin, hair or irises do not exclude the diagnosis. Peripheral neurological findings are usually not prominent, but one third have minimal upper motor neuron signs. Seizures occur in about 25%, predominantly in the most severely retarded. Electroencephalographic (EEG) abnormalities can be seen in approximately 80% and brain CT or MRI scan may reveal cortical atrophy and white matter abnormalities.

Behavioral problems, including restlessness, aggression, learning difficulties and sleep disturbances, are common in patients treated early in life but in whom the restriction diet was later discontinued.

### Diagnosis and screening

Phenylalanine is converted to tyrosine by hepatic phenylalanine hydroxylase (PAH). In the absence of PAH, tyrosine becomes an essential amino acid, and phenylalanine is diverted to other pathways producing phenylpyruvic acid and phenylacetic acid, which are normally only present in trace amounts. Untreated patients with classic PKU usually have plasma concentrations over 1200 mcM ([20 mg/dl]; normal ~60 mcM, [-1 mg/dl]). Throughout infancy, levels as high as 3600 mcM (60 mg/dl) can be seen.

Where newborn screening is available, PKU should always be diagnosed in the neonatal period (see Ch. 12). Initial abnormal screening results require urgent quantitation of plasma phenylalanine and tyrosine. Transient HPA can take as long as 2 months to resolve, and even in mild HPA, the plasma phenylalanine can be very high in the first weeks of life. In classic PKU the plasma phenylalanine generally rises over 1–2 weeks to levels well over 1200 mcM; the concentration of tyrosine is low.

About 1–2% of patients with HPA do not have a defect in PAH, but in synthesis or recycling of the cofactor tetrahydrobiopterin (see below). Every infant with persistently raised blood phenylalanine should be tested for this group of disorders since treatment and prognosis of these disorders is radically different (see p. 1120).

HPA occurs in 1 in 10000–20000 persons but is more frequent in some countries such as Ireland. The carrier frequency in most populations is ~1–2%. Over 500 mutations have been defined, but none accounts for a majority of patients (<http://www.pahdb.mcgill.ca/>). Carrier detection and prenatal diagnosis are possible with molecular genetic methods.

### Treatment (also see above)

Clinical manifestations of classic PKU can be completely prevented by early and continued restriction of dietary phenylalanine to maintain blood levels at 120–360 mmol/L (2–6 mg/dl) in infancy and childhood; values up to 600–750 mmol/L (10–12 mg/dl) are often unavoidable in adolescence and adulthood.

Infants generally require ~60–80 mg/kg/d phenylalanine but the phenylalanine tolerance must be individually established and falls to ~7–15 mg/kg by 5 years. The blood levels should be tightly monitored (two to three times weekly for 2–3 months, falling to once a week by 3–4 years). Breast milk is relatively low in phenylalanine and breastfeeding should be encouraged, usually supplemented with a phenylalanine-free formula as needed. Over-restriction of phenylalanine results in tissue breakdown, increasing levels of phenylalanine and, if prolonged, growth problems, seizures, mental retardation and death are reported sequelae.

There is still debate about when treatment of HPA is indicated. We believe treatment should be started for blood levels over 360–500 mcM (6–8 mg/dl) or if phenylalanine metabolites are detected in the urine.

It was formerly common to discontinue dietary restriction of phenylalanine by school age but it is now clear that this leads to IQ loss and behavioral disturbances.<sup>22</sup> The diet is now recommended to be continued for life at least for classic cases. Even severely affected adult PKU patients who were not treated in childhood usually benefit from phenylalanine restriction in terms of psychiatric manifestations of the disease.

It is now clear that blood phenylalanine levels in many cases of HPA, particularly those running at < 1000 µmol/L, can be substantially reduced or even normalized by treatment with tetrahydrobiopterin. While this drug is not yet widely available, it offers the possibility that for as many as 50% of cases, the diet can be relaxed or even stopped.<sup>23</sup> In addition, recent studies on the use of large neutral amino acids (NeoPhe, Prekulab, Korsor, Denmark) 0.5–1.0 g/kg/d have shown that, by competitive inhibition of absorption of phenylalanine, they too can reduce the blood levels by as much as 50%.<sup>24</sup>

### Maternal phenylketonuria

High phenylalanine levels are exquisitely toxic to the developing fetal brain and thus offspring of mothers with HPA can be severely damaged. All offspring are obligatory heterozygotes and ~1 in 100 are homozygotes.<sup>25</sup> The miscarriage rate is high and affected children have prenatal microcephaly typically with severe, mental retardation and sometimes congenital heart defects. This outcome can be prevented if the maternal phenylalanine levels are maintained in the range 0.15–0.25 mmol/L from conception. Table 26.2 indicates the risk of damage to the fetus depending on maternal phenylalanine levels.

### Defects in the synthesis or recycling of biopterin (malignant PKU) (see also p. 1120)

Tetrahydrobiopterin (BH<sub>4</sub>) is an essential cofactor for phenylalanine, tyrosine and tryptophan hydroxylases. At least five defects in the synthesis or recycling of BH<sub>4</sub> are the cause of ~1% of HPA diagnosed by newborn screening. If, however, the true nature of the defect is not recognized, and treatment is limited to dietary restriction of phenylalanine, patients show severe and progressive neurological symptoms in spite of normal phenylalanine levels.<sup>26</sup> All these defects result in deficient conversion of phenylalanine to tyrosine, even though the PAH apoenzyme itself is normal. Severe neurological disease may occur with only mild hyperphenylalaninemia, suggesting that BH<sub>4</sub> levels may be relatively more adequate for phenylalanine hydroxylation than for that of tryptophan or tyrosine. Affected patients have marked hypotonia, parkinsonism, as well as spasticity and dystonic posturing. Some have seizures, myoclonus and EEG abnormalities. Drooling is common. The delay in psychomotor development is usually profound.

Testing for these defects by blood and urine biopterin profiling should be done routinely in all patients with hyperphenylalaninemia, because early treatment is vital. CSF neurotransmitter and biopterin levels and phenylalanine loading tests are often useful in diagnostic confirmation. The diagnosis of specific enzyme deficiency can be confirmed in many cases in cultured fibroblasts.

The treatment for this group of patients consists of administration of biogenic amine precursors, such as 5-hydroxytryptophan (5-HT) and L-dopa that do not require hydroxylation. Carbidopa is a necessary adjunct to prevent decarboxylation of these precursors before they reach the CNS. BH<sub>4</sub> is used in patients with synthesis defects, but if not sufficient by itself it should be supplemented by phenylalanine restriction. In order to optimize the drug dosages, monitoring of neurotransmitter levels in CSF is often indicated. Unfortunately, however, even early

Table 26.2 Maternal phenylalaninemia: percentage risk of damage to fetus according to maternal phenylalanine level

	Blood phenylalanine (mmol/L)		
	> 1.25	0.65–1.2	< 0.625
Spontaneous abortion	24	22	8
Mental retardation	92	53	21
Microcephaly	73	57	24
Congenital heart disease	12	11	0
Low birth weight	40	52	13

and aggressive therapy does not always prevent neurological deterioration and eventual death.

Inherited isolated deficiency of tyrosine hydroxylase causes severe parkinsonism in infancy. It and other disorders affecting aromatic acid neurotransmitters are discussed on p. 1120.

## Tyrosinemia

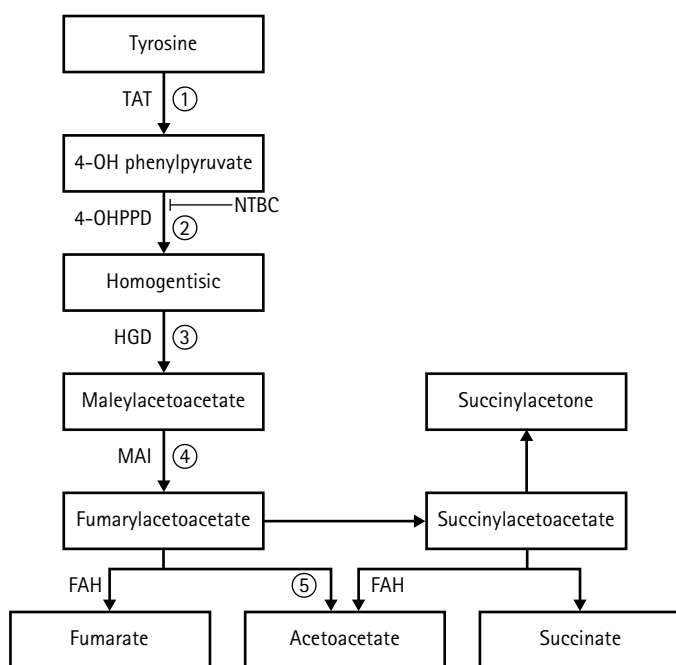

The tyrosinemias are a group of disorders in which tyrosine is elevated (Fig. 26.4). The commonest, most often seen in premature infants, is transient tyrosinemia of the newborn resulting from delayed maturation of tyrosine-metabolizing enzymes. Tyrosinemia can also occur in scurvy and many forms of liver disease.

### Hepatorenal tyrosinemia (hereditary tyrosinemia type 1)

**Clinical features.** The liver and kidney are the primary organs affected in this disorder. Symptoms may begin early in infancy with an acute rapid course to demise, or they may progress more chronically. Most patients present with failure to thrive and liver dysfunction. Untreated, the liver disease is progressive, causing cirrhosis and liver failure. Renal tubular damage results in the Fanconi syndrome with tubular acidosis and rickets. Neurodevelopmental delay is not a feature. Surviving patients have a high risk for hepatocarcinoma.

#### Diagnosis

This disease is caused by deficiency of fumarylacetoacetate hydrolase, the last enzyme in tyrosine catabolism. Biochemical alterations include elevated plasma concentrations of tyrosine and methionine and the excretion of tyrosyl compounds in the urine. The presence of succinylacetone in urine is diagnostic. Highly elevated blood concentrations of alpha-fetoprotein (AFP) are seen, even before the elevation in tyrosine

- 1= Tyrosinemia type II-> corneal ulcers, hyperkeratosis
- 2= Tyrosinemia type III-> mental retardation
- 3= Alkaptonuria-> ochronosis, black urine
- 4= Maleylacetoacetate isomerase deficiency-> phenotype?
- 5= Tyrosinemia type I-> liver failure, renal damage

**Fig. 26.4** The tyrosine catabolic pathway. The enzymes for each reaction are given on the left, the disease corresponding to its deficiency on the right. TAT, tyrosine aminotransferase; HPD, 4-PH phenylpyruvate dioxygenase; HGD, homogentisic acid dioxygenase; MAI, maleylacetoacetate isomerase; FAH, fumarylacetoacetate hydrolase.

(note that AFP can be falsely high in infants). Hypoglycemia may occur, and coagulation defects are common.

Mutation analysis can be used for prenatal diagnosis and carrier detection. Hepatorenal tyrosinemia is common in the Canadian province of Quebec, where a single founder mutation is responsible for most cases.

#### Treatment

The liver failure and renal Fanconi syndrome of hepatorenal tyrosinemia can be effectively treated with 2(2-nitro-4-trifluoromethylbenzoyl)-1,3 cyclohexanedione (NTBC) which blocks tyrosine metabolism by inhibiting its second step (Fig. 26.4), thus preventing the accumulation of toxic metabolites. NTBC raises blood tyrosine levels and thus needs to be combined with a dietary restriction of phenylalanine and tyrosine. The prognosis of patients with this disease has vastly improved with this new therapy.<sup>27,28</sup>

### Oculocutaneous tyrosinemia (tyrosinemia type 2)

Tyrosine aminotransferase is deficient in oculocutaneous tyrosinemia. The characteristic features of this disease are corneal ulcers or dendritic keratitis early in life and erythematous papular or keratotic lesions on the palms and soles. About 50% of patients display mental retardation, but this may be due in part to ascertainment bias or gene deletions. Tyrosine itself is not toxic and the liver and kidney are unaffected. Plasma concentrations of tyrosine are higher than in other forms of tyrosinemia, and the urine contains large amounts of tyrosine metabolites generated by other transaminases. The lesions on the palms and soles and in the eyes relate directly to the accumulation and crystallization of tyrosine. Both respond rapidly to treatment with diets low in tyrosine.

### Tyrosinemia type 3

The second step in tyrosine catabolism is catalyzed by 4-hydroxyphenylpyruvate dioxygenase. Several patients lacking this enzyme have been identified and all suffer from mild psychomotor retardation, but no other organ systems are involved. Plasma tyrosine levels are elevated, but usually not to levels that cause corneal ulcers or hyperkeratosis. Treatment consists of a low tyrosine diet.

### Alkaptonuria

Garrod's suggestion that the disorder results from absence in the liver of the enzyme that catalyzes the oxidation of homogentisic acid (Fig. 26.4) gave rise to the one-gene, one-enzyme hypothesis, the notion of IEM and the field of biochemical genetics.<sup>10</sup>

Alkaptonuria results from defective activity of the enzyme homogentisic acid dioxygenase. Blood tyrosine is not elevated and the disorder is characterized by the excretion of homogentisic acid in urine. Urine appears normal when fresh but on standing, and particularly after alkalization, homogentisic acid is oxidized forming a dark brown or black pigment. This can be seen in diapers (nappies) and should permit the condition to be recognized in infancy, but the diagnosis is usually first made in adulthood during routine urinalysis or during investigation of arthritis. Alkaptonuria is usually asymptomatic in childhood. After the third decade, deposition of brownish or bluish pigment is seen, particularly in the ears and sclerae, and is extensive in fibrous tissues. This is referred to as ochronosis. It leads to progressive arthritis, produces symptoms resembling rheumatoid arthritis or osteoarthritis, with limitation of motion; complete ankylosis is common with a characteristic appearance on X-ray. NTBC should also be useful.

### SULFUR-CONTAINING AMINO ACIDS (Fig. 26.5)

Methionine plays an important role in methylation reactions. Some is resynthesized from homocysteine by two separate pathways, one of which interdigitates with folate metabolism, the 1-carbon pool and with vitamin B<sub>12</sub>. Some defects of folate or vitamin B<sub>12</sub> metabolism can therefore cause accumulation of homocysteine. The disulfides, homocystine and cystine, are formed from two molecules of homocysteine and cysteine, respectively. In proteins, two molecules of cysteine condense to form

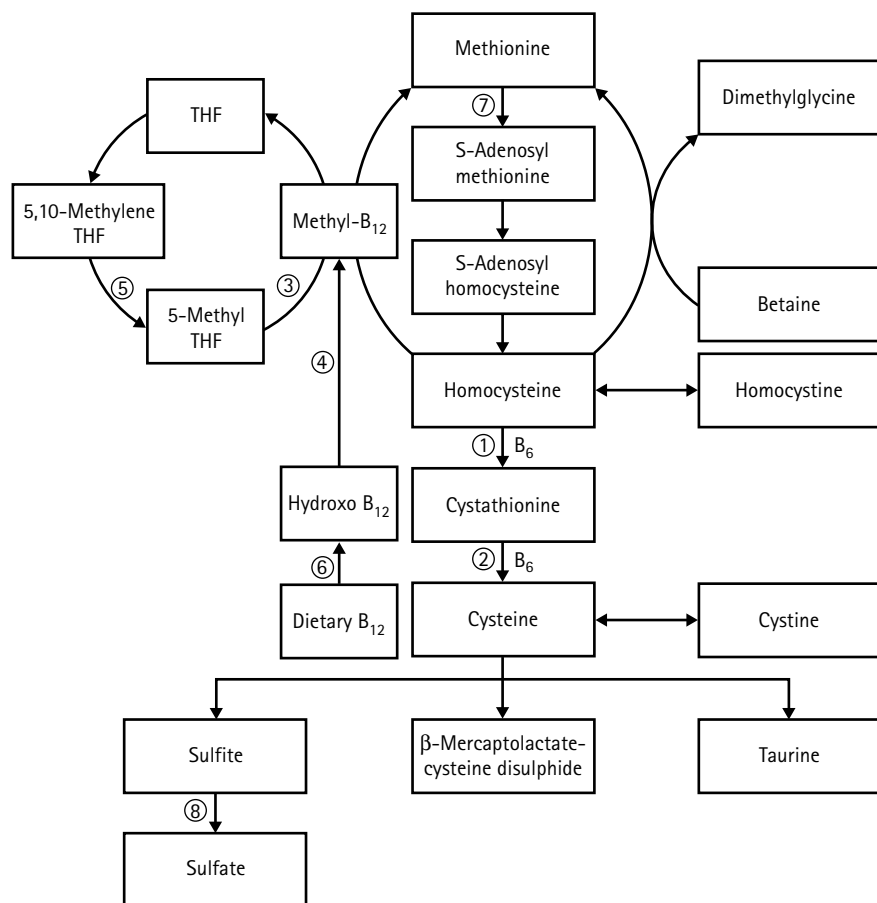

Fig. 26.5 Metabolism of the sulfur-containing amino acids. 1, Cystathionine synthase (homocystinuria); 2, cystathioninase (cystathioninuria); 3, 5-methyltetrahydrofolate-homocysteine methyl transferase; 4, cobalamin-activating system (homocystinuria and methylmalonic aciduria); 5, 5,10-methylenetetrahydrofolate reductase (homocystinuria); 6, gut absorption and reduction of vitamin B<sub>12</sub> (homocystinuria and methylmalonic aciduria); 7, methionine adenosyltransferase (hypermethioninemia); 8, sulfite oxidase (sulfite oxidase deficiency). THF, tetrahydrofolic acid.

disulfide bonds that help to maintain the three-dimensional shape of the protein. Homocysteine is not present in protein. Cystinosis is discussed on p. 1112 and in Chapter 18 (p. 550). Breast milk contains the sulfur-containing amino acid taurine which is also present in high levels in muscle, leukocytes and other tissues; it is frequently excreted in large quantities as a result of liver disease, a high protein intake, leukemia or endogenous protein catabolism. No primary defect of taurine metabolism is known and its role in metabolism is unclear.

## Homocystinuria

The term homocystinuria is sometimes used to indicate one specific form of the disease caused by defective activity of the enzyme cystathionine beta-synthetase (CBS). However, several other enzyme defects can also cause elevated homocysteine, including defects of folate and B<sub>12</sub> metabolism. Therefore, homocystinuria refers to a heterogeneous group of disorders. Plasma methionine, cystine and B<sub>12</sub> levels, as well as urine organic acids, should be measured in all patients with elevated plasma homocysteine. Biosynthesis of the sulfur amino acid cysteine involves the demethylation of methionine to homocysteine, followed by its reaction with serine to form cystathionine. This latter step is catalyzed by the pyridoxine-requiring enzyme cystathionine beta-synthetase.

### *Homocystinuria due to cystathionine beta-synthetase deficiency*

#### *Clinical findings*

This autosomal recessive defect is the most common cause of homocystinuria. The most characteristic feature of this disorder is subluxation of the ocular lens. Most patients have a marfanoid habitus, with skeletal abnormalities similar to those seen in Marfan syndrome. In homocystinuria, however, the joints tend to be limited in mobility rather than hypermobile. There is also lenticular subluxation in both conditions; however,

in Marfan syndrome the lens is usually displaced upwards, whereas in homocystinuria it is displaced downwards and medially. Additional features include developmental delay, osteopenia and predisposition for thrombosis. Presentation is usually in the first decade with the exception of thromboembolism that may occur at any age. Homocystinuria is one of the few amino acid disorders in which manifestations tend to progress in adulthood, because many clinical manifestations result from thrombotic complications. Classic tests of clotting function are normal, but elevated homocysteine levels cause increased platelet adhesiveness.

#### *Diagnosis*

Homocysteine is not normally detected in the usual assays of amino acids in body fluids. In CBS deficiency, elevated homocysteine can be detected in both urine and blood. Levels of methionine are usually also elevated and levels of cystine are reduced. Because homocysteine is unstable, testing should be done on fresh urine and measurement of blood total homocysteine is also essential. Because homocystinuria can be caused by several genetic defects, it is important to confirm the diagnosis of CBS deficiency by DNA mutation analysis or enzyme assay. DNA based diagnosis can theoretically be used for prenatal detection.

#### *Treatment*

Since CBS is a pyridoxine-dependent enzyme, some activity may be restored by pharmacological doses of pyridoxine. Seven days of 100–500 mg/d should always be tried to determine any degree of vitamin responsiveness. (Prolonged high doses can be associated with peripheral neuropathy.) If the homocysteine levels normalize, no additional therapy may be needed. Those who do not respond should be treated with a low-methionine diet supplemented with L-cystine. All patients should probably receive high doses (5 mg)/day of folic acid. In addition, the compound betaine may be used to aid in the reconversion of homocysteine to methionine.<sup>29,30</sup> Medications to reduce platelet adhesiveness can be prescribed, but do not abolish all thromboembolic events.

Oral contraceptives may be contraindicated in women due to the increased risk of thrombosis.

### Other causes of homocystinuria

The second most important cause of homocystinuria is *N5,10-methyl-entetrahydrofolate reductase (MTHFR) deficiency* which is involved in the recycling of homocysteine to methionine. It is associated with low rather than high plasma methionine levels. Neurological features and a clotting propensity predominate this rare condition but eye and skeletal involvement are lacking. The specific enzyme diagnosis can be made on cultured skin fibroblasts. For treatment, no pyridoxine is given and methionine may be supplemented rather than restricted in the diet. Folate administration may also be beneficial.

A mild form of MTHFR deficiency associated with a thermolabile variant of the MTHFR gene is found in 5–7% of people. It can be easily diagnosed by DNA mutation analysis. Homozygous individuals are prone to develop thromboembolic and arteriosclerotic disease and there is a minor degree of hyperhomocysteinemia. In addition to screening for individuals at risk for atherosclerosis who might benefit from administration of folate, B<sub>6</sub> and/or B<sub>12</sub>, measurement of blood free and total homocysteine levels can detect true inborn errors of sulfur amino acid metabolism in those who have very high levels, and is a valuable test for monitoring response to therapy.

Methylcobalamin is required for resynthesis of methionine from homocysteine and defects in the vitamin B<sub>12</sub> pathway can cause varying mixes of megaloblastic anemia, homocystinuria and/or methylmalonic aciduria. At least eight different complementation groups that involve vitamin B<sub>12</sub> metabolism are known (see Fig. 26.43). There may be more since not all cases appear to have a demonstrable defect. These conditions are often associated with neurological deficits and have a guarded prognosis. For this reason it is important that every patient with homocystinuria has a urine organic acid analysis to assay for the presence of methylmalonic acid. If a vitamin B<sub>12</sub> synthetic defect is found, B<sub>12</sub> injections (usually hydroxycobalamin) are used in addition to the usual treatments for homocystinuria.

### Sulfite oxidase and molybdenum cofactor deficiency

The terminal step in the oxidative degradation of cysteine, the conversion of sulfite to sulfate, is catalyzed by the molybdenum-containing enzyme sulfite oxidase. Severe neurological diseases are associated with deficiency of the oxidase or the cofactor. Molybdenum cofactor deficiency is discussed on p. 1123 and 1126.

#### Clinical findings

Most patients present with neonatal neurological disease including severe hypotonia, seizures and myoclonic spasms. Symptoms are progressive and usually lead to early death. Patients with milder forms of the disease have progressive cerebral palsy and choreiform movements. Infantile hemiplegia has been reported and lens dislocation is frequent even in neonates.

#### Diagnosis and treatment

Deficiency of sulfite results in increased amounts of sulfite, thiosulfate and S-sulfocysteine in the urine. These compounds require special analyses for their detection. Sulfite oxidase deficiency can be caused by a defect in the gene for this protein or by defects in the synthesis of the molybdenum cofactor required for its function. In molybdenum cofactor deficiency the serum uric acid is very low and urinary hypoxanthine and xanthine are markedly elevated. Prenatal diagnosis is available. Ophthalmologic examination is indicated in all suspected cases.

Currently, no effective therapy is available.

### Other disorders of S-containing amino acids

*Cystathioninuria*, an inborn error of amino acid metabolism in which there is a deficiency of the activity of cystathionase, was first reported in two adults with mental deficiency. Subsequently, however, cystathioninuria has been found in a number of individuals with no clinical signs and is currently considered a benign variant.

Persistent hypermethioninemia occurs in *methionine adenosyl transferase deficiency* which, in most cases, appears to be benign.

Transient neonatal hypermethioninemia occurs in a small number of infants, most of whom are receiving a high protein intake. Although there are no known toxic sequelae, modest protein restriction seems warranted in view of the toxicity of methionine in laboratory animals. It is also frequent in tyrosinemia type 1 and in hepatocellular damage.

A defect of *S-adenosylhomocysteine hydrolase* causes hypermethioninemia and is associated with developmental delay and a severe destructive myopathy accompanied by high plasma creatine kinase.<sup>31</sup>

### DISORDERS OF THE GAMMA-GLUTAMYL CYCLE

The synthesis and recycling of the sulfur-containing tripeptide glutathione involves a series of six enzymatic reactions termed the gamma-glutamyl cycle (Fig. 26.6). Six disorders causing disease are known; pyroglutamic aciduria is discussed below.

#### Pyroglutamic aciduria (5-oxoprolinuria)

Pyroglutamic aciduria, or 5-oxoprolinuria, is caused by autosomal recessive deficiency of glutathione synthetase. Pyroglutamic acid is 2-pyrrolidone-5-carboxylic acid, a condensation product of glutamic acid or glutamine. It can be readily detected by urine organic acid analysis. Acquired, nongenetic pyroglutamic aciduria is due to glutathione depletion, most often caused by acetaminophen.

In the newborn, marked nonketotic acidosis without accompanying coma and massive hemolysis are usual and may recur. The disease is often characterized later by neurological symptoms, including spasticity, ataxia and mental retardation. Therapeutic attempts have been aimed at increasing cellular glutathione concentrations and antioxidant activity. However, this does not eliminate neurological problems in severely affected patients. Drugs such as acetaminophen that require glutathione for detoxification should be avoided.

Treatment involves providing antioxidants, vitamin E, vitamin C and Bicitra or bicarbonate in large enough amounts to control the acidosis. The prognosis is variable. Mild cases may have a normal outcome; severe cases may be partially helped by therapy.

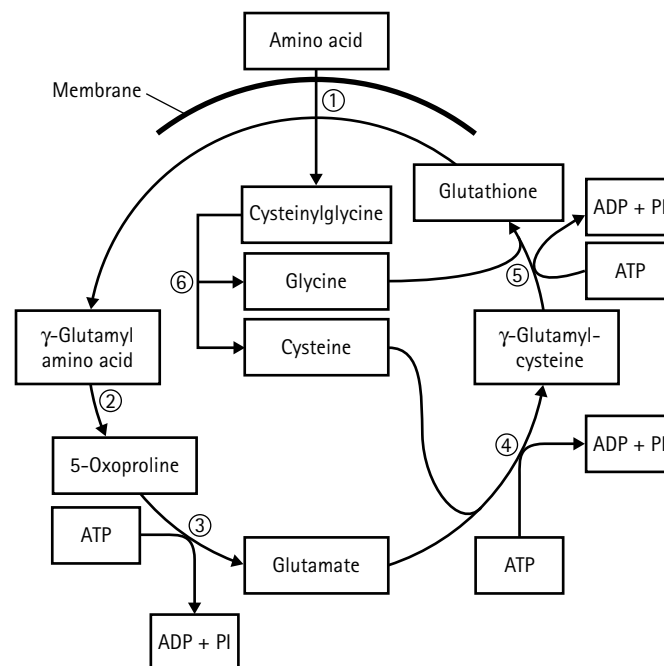

Fig. 26.6  $\gamma$ -Glutamyl cycle. 1,  $\gamma$ -Glutamyl transpeptidase; 2,  $\gamma$ -glutamyl cyclotransferase; 3, 5-oxoprolinase; 4,  $\gamma$ -glutamyl-cysteine synthase; 5, glutathione synthase; 6, peptidase.

## DISORDERS ASSOCIATED WITH HYPERAMMONEMIA

Most diets contain excess amino acids, the nitrogen of which is mostly excreted as urea. The enzymes of the urea cycle are active before birth. The first three steps of the pathway are mitochondrial so the full cycle requires the transport of ornithine into and the transport of citrulline out of mitochondria. Arginine is an important regulator of the cycle since it induces N-acetylglutamate synthetase. N-acetylglutamate, in turn, activates carbamyl phosphate synthetase.

The urea cycle is only complete in the liver where urea is synthesized. Defects at all steps of the urea cycle have been described, the common feature of which is hyperammonemia, although it may not occur in argininemia. Some of the enzymes are present in other tissues where the enzymes must have other roles. In severe liver damage, hyperammonemia is sometimes found and may contribute to the cerebral symptoms of liver failure.

### Clinical features

The clinical features of the different disorders associated with hyperammonemia are similar and therefore will be discussed as a group. Patients with severe defects in the urea cycle present in the newborn period with coma and acute metabolic crisis. Postnatal catabolic events and protein intake contribute to the metabolic derangement. In infancy, the symptoms include episodes of poor feeding, vomiting, failure to thrive, lethargy, irritability or other neurological symptoms, all of which are aggravated by any metabolic stress or formula changes that increase protein intake, and may be alleviated by reducing the protein content of the diet. Respiratory alkalosis is not uncommon.

Most babies with hyperammonemia are initially thought to be septic and therefore ammonia measurements are essential in any infant with suspected sepsis, especially if accompanied by lethargy or CNS depression. Elevated blood ammonia levels can cause an increased respiratory rate resulting in some degree of respiratory alkalosis. In older children with, presumably, less severe mutations, symptoms often develop for the first time during weaning. Food intolerance or distaste for protein may be evident; some have failure to thrive, developmental or neurological problems with seizures, migraine, ataxia and abnormal EEG. Even adults may present with new onset of hyperammonemic symptoms, particularly during times of high catabolic stress such as the postpartum period, dieting or during intercurrent illnesses such as infections, dehydration, surgery or chemotherapy.

### Transient neonatal hyperammonemia

Hyperammonemia is sometimes seen in infants receiving intravenous alimentation. In these cases it may be due to an inappropriately high nitrogen intake. Other infants with profound, but transient, hyperammonemia have mostly been preterm; respiratory distress is usual. Rapid

development of neurological damage with apnea, loss of reflexes and coma ensues within 12–48 h of birth. Ammonia levels may be as high as 5000  $\mu\text{mol/L}$ . Liver function tests and plasma amino acids, including glutamine, may be normal. If the condition is treated early and vigorously the babies rapidly improve, the protein tolerance becomes normal, liver enzyme assays show no abnormality and the prognosis is excellent. The cause is unknown but rapid protein catabolism, mitochondrial dysfunction, maternal carnitine deficiency and/or portocaval shunting may play a role.

### Enzyme defects of the urea cycle (Fig. 26.7)

With the exception of ornithine transcarbamylase deficiency which is X-linked, all these disorders are autosomal recessive traits. All have both severe (neonatal) forms and milder, later onset forms that may not even present until adulthood.

#### N-Acetylglutamate synthetase deficiency (step 1)

This disorder usually presents in the first weeks of life. N-Acetylglutamate does not participate directly in the urea cycle, but is an allosteric activator of carbamyl phosphate synthetase (CPS). Thus, the absence of this compound results in secondary CPS deficiency. Several acyl-CoA derivatives of organic acids such as methylmalonyl-CoA, propionyl-CoA or valproyl-CoA can inhibit N-acetylglutamate synthesis, which explains the profound hyperammonemia that can occur in the 'ketotic hyperglycinemias' and valproic acid toxicity.

Treatment of this disease differs from that for the other urea cycle disorders<sup>32</sup> in that carbamylglutamate, which is structurally similar to N-acetylglutamate, can stimulate CPS activity. Arginine (1 mmol/kg/d) and carbamylglutamate (1.7 mmol/kg/d) are effective in controlling hyperammonemia.<sup>33,34</sup>

#### Carbamyl phosphate synthetase I deficiency (step 2)

This enzyme is mitochondrial and provides carbamyl phosphate for the synthesis of urea. Deficiency (step 2) usually presents with severe neonatal hyperammonemia, although later onset is possible. Prenatal detection is possible. CPS II is a separate cytoplasmic enzyme involved in the synthesis of pyrimidines (p. 1123).

#### Ornithine transcarbamylase deficiency (step 3)

This is the most common urea cycle defect; the only one inherited as an X-linked trait. Most affected males present as newborns in severe hyperammonemic crisis. About 20–30% are less severely affected and some have normal mental development and almost normal tolerance for protein, except during stress. Some female carriers are totally asymptomatic, others have mild aversion or intolerance to protein and some have recurrent hyperammonemic crises, e.g. during dieting, that can be fatal. Plasma amino acids are never grossly distorted; citrulline is low,

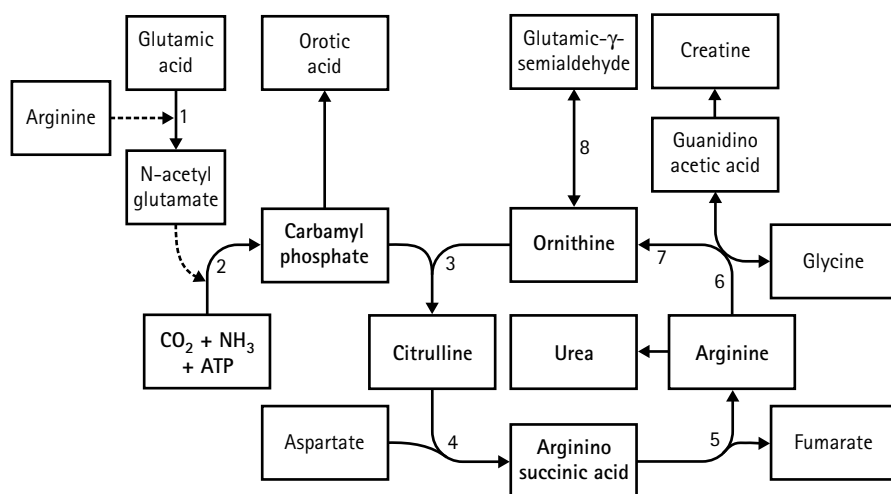

Fig. 26.7 Urea cycle. 1, N-acetylglutamate synthetase; 2, carbamyl phosphate synthetase; 3, ornithine transcarbamylase; 4, argininosuccinate synthetase; 5, argininosuccinate lyase; 6, arginase; 7, ornithine uptake into mitochondria; 8, ornithine ketoacid aminotransferase.

ornithine is normal but glutamine, alanine and sometimes lysine are increased in blood and sometimes in urine; during stress, orotic acid is usually increased in the urine. The combination of the clinical presentation, elevated urine orotic acid, normal urine organic acids and blood amino acids showing only elevated glutamine and alanine is diagnostic.

The enzyme can be assayed in liver or duodenal mucosa but not in fibroblasts. Enzyme activity from multiple liver biopsies from a female carrier may vary widely, representing different degrees of inactivation of the mutant X chromosome in different areas. Most carriers can be detected by increased urine orotic acid from 0 to 8 and 8 to 16 h after a provocative challenge of allopurinol (100 mg/kg p.o.) either alone or together with 1.0 g protein/kg or L-alanine 0.5 g/kg p.o. DNA analysis, when possible, is best for prenatal diagnosis and carrier detection since, when informative, it obviates the need for liver biopsy.

#### Citrullinemia (step 4)

Citrullinemia is caused by argininosuccinate synthetase deficiency. The presentation varies greatly from death in the neonatal period to being asymptomatic. Many patients who have suffered severe hyperammonemia become mentally retarded. Hepatic function is occasionally impaired. The etiology of this hepatocellular dysfunction is unknown. Plasma and urine citrulline levels are markedly elevated, even between crises. The enzyme can be assayed in fibroblasts; prenatal diagnosis is possible.

#### Argininosuccinic aciduria (step 5)

Argininosuccinic aciduria is caused by deficiency of argininosuccinic acid lyase. Death in infancy is not rare and even mild cases tend to have developmental delay, even when they have never had prolonged coma or overt hyperammonemia. Trichorrhexis nodosa, an abnormal fragility of the hair, is found in some cases. Hepatocellular dysfunction and hepatic enlargement are common findings. Plasma citrulline is elevated, but to a much lesser degree than in citrullinemia. This, along with the presence of argininosuccinic acid and its anhydrides in plasma, urine and CSF, are diagnostic. The enzyme defect can be shown in several tissues, including red blood cells. Prenatal diagnosis is available. Large supplements of arginine are added to the normal treatment since urinary argininosuccinic acid provides a major pathway for waste nitrogen disposal.

#### Argininemia (step 6)

Argininemia is caused by arginase I deficiency; it has a different presentation from the other urea cycle disorders in that profound hyperammonemia is unusual. This disease usually presents with increasingly severe pyramidal tract signs starting within the first 2 years of life. It may mimic cerebral palsy. The plasma arginine is markedly raised. The urinary amino acid pattern may be similar to that seen in cystinuria, caused by arginine saturating the group reabsorptive site in the proximal renal tubules. Alternatively, urine amino acids may be normal or there may be a generalized aminoaciduria. Deficient arginase activity can be shown in the red blood cells of both patients and heterozygotes.

#### Hyperammonemia–hyperinsulinism

This autosomal dominant disorder is caused by specific mutations in the glutamate dehydrogenase (GLUD1) gene. Glutamate dehydrogenase enzyme activity in pancreatic beta cells is allosterically regulated by intracellular leucine levels. Thus, it acts as sensor that couples insulin secretion to amino acid levels just as glucokinase links glucose levels to insulin production. In the liver GLUD1 activity negatively modulates the urea cycle and hence ammonia metabolism. The mutations that cause hyperammonemia–insulinism result in constitutive activation of GLUD1, independent of intracellular amino acid levels. This results in simultaneous hyperinsulinism (beta cell) and hyperammonemia (hepatocyte).

Clinically, the hyperinsulinism is more significant and can present as severe (usually leucine sensitive) hypoglycemia in infancy. The hyperammonemia is typically mild with levels elevated only 3–5-fold.

Hyperammonemic crises are very rare. Treatment includes inhibition of insulin release with drugs such as diazoxide and avoidance of fasting; pancreatectomy, which reveals nesidioblastosis, may be necessary. The hyperammonemia is usually mild enough not to require specific therapy. Diagnosis is confirmed by molecular analysis. (see also Ch. 15)

#### Citrullinemia, type II (citrin deficiency)

Both neonatal and adult forms of type II citrullinemia are becoming increasingly recognized. Neonatal cases typically present with severe cholestasis and hepatic dysfunction. Plasma levels of citrulline, methionine and galactose are markedly elevated and often detected by newborn screening but hyperammonemia is not typical. Most patients respond to a low-protein, lactose-free diet with improved hepatic function.

The adult-onset form is characterized mainly by psychiatric symptoms and/or delayed development. Hyperammonemia is frequent. Drowsiness and coma occur and several patients have died from cerebral edema during these neurological episodes.

This disorder is caused by mutations in a transporter responsible for shuttling aspartate and glutamate across the mitochondrial membrane. Citrin deficiency is associated with decreased hepatic activity of argininosuccinate synthetase deficiency and thus causes elevated blood citrulline levels. The disease is most common in Japan and may be rare elsewhere. Arginine supplementation and ammonia scavenger therapy are thought to be beneficial.

#### Lysinuric protein intolerance

This condition is caused by a defect in the uptake of arginine and other amino acids in several tissues. The result is deficiency of urea cycle substrates in the liver (see p. 1067).

#### Hyperornithinemia

##### Hyperornithinemia with hyperammonemia and homocitrullinuria

Two distinct disorders of elevated plasma ornithine levels exist, but only the hyperornithinemia with hyperammonemia and homocitrullinuria (HHH) syndrome has associated hyperammonemia. Most reported patients have a history of developmental delay and older patients tend to have spasticity. Symptoms may develop at any age. Excretion of ornithine, polyamines, orotic acid and glutamine may be increased. The primary defect is in the mitochondrial uptake of ornithine. Large, bizarre mitochondria may be present in the liver. Oral ornithine supplements have been reported to be beneficial. Homocitrulline can also be formed during pasteurization of milk and, if ingested, is excreted in the urine.

##### Gyrate atrophy of the retina

Hyperornithinemia in the absence of hyperammonemia also occurs in gyrate atrophy of the choroid and retina, caused by deficiency of ornithine K aminotransferase. The disease presents in adults with a characteristic retinopathy, subcapsular cataract and progressive loss of peripheral vision leading to blindness by middle age. In children, small discrete circular patches of degeneration may be seen in the periphery of the retina; later these coalesce to form a characteristic lobular appearance that gives rise to the name. The electroretinogram (ERG) dark adaptation is abnormal. Plasma and CSF ornithine levels are markedly elevated. The enzyme is deficient in several tissues, including cultured skin fibroblasts. Heterozygotes may be detected by oral ornithine loading tests (100 mg/kg) or by enzyme assay. Abnormal inclusions have been reported in muscle and bizarre, elongated mitochondria are present in liver. Direct toxicity of ornithine and low proline, lysine or creatine have all been suggested as a cause of the retinal damage.

Pharmacological doses of vitamin B<sub>6</sub>, the cofactor of the mutant enzyme, may improve the biochemical and ERG findings in some cases. Ornithine is not contained in protein and hence cannot be restricted in the diet. Instead, long term arginine restriction may result in improved visual function but such treatment is very hard to maintain.

## Secondary hyperammonemias

Other causes of hyperammonemia include:

- liver disease (Ch. 19);
- Reye syndrome (Chs 19 and 22);
- the ketotic hyperglycinemias (p. 1065);
- methylmalonic aciduria (p. 1065);
- propionic aciduria (p. 1065);
- 3-ketothiolase deficiency (p. 1071);
- 3-hydroxy-3-methylglutaric aciduria (p. 1070);
- familial lysinuric protein intolerance (p. 1067);
- neonatal glutaric aciduria type II (p. 1070 and Ch. 12);
- defects of fatty acid oxidation (p. 1068);
- valproic acid toxicity;
- ureterostomy;
- shock and after surgery.

## Diagnostic approaches

Blood ammonia should be routinely assayed in any acutely sick child with neurological findings and in patients with mild, episodic symptoms. Hyperammonemia may be present in the fasting state but is sometimes induced only by a protein load. Hyperammonemia up to 2–3 times the normal limit is sometimes seen in severely ill infants, especially those with impaired hepatic function. In contrast, the ammonia levels in patients with primary hyperammonemia may exceed 1000  $\mu\text{mol/L}$ .

Great care must be taken in handling samples and in the assays – erroneously high values are common. When hyperammonemia is confirmed, immediate assay of blood amino acids and urine organic acids is indicated. Raised levels of glutamine and alanine reflect increased transamination and should always suggest this possibility. Defect at steps 3–6 of the urea cycle (see Fig. 26.7) may cause orotic aciduria due to diversion of carbamyl phosphate to the overproduction of pyrimidines.

An algorithm for the work-up of hyperammonemia is provided in Figure 26.8.<sup>35</sup>

## Treatment<sup>36,37</sup>

Every effort must be made to minimize catabolism for energy needs. Management of acute, severe hyperammonemic crises includes the following steps:

1. Maximal hydration p.o. or i.v. to enhance renal excretion.
2. Maximum tolerable nonprotein caloric intake p.o. or i.v. Central venous access may be necessary to administer high concentrations and quantities of glucose (D20–D30); often an insulin drip is added to enhance amino acid synthesis and to control hyperglycemia.
3. Hemodialysis is the most effective method to remove ammonia rapidly and should be considered in any comatose hyperammonemic patient. Dialysis should not be delayed to await the effects of alternate pathway drugs (see below). Peritoneal dialysis is less effective.
4. Administer i.v. ammonia scavenging drugs. For sodium benzoate and sodium phenylacetate, usually given together, the loading dose of each is 250 mg/kg (or 5.5 g/m<sup>2</sup>) given in 25–30 ml/kg of 10% dextrose solution over 90 min. The maintenance dose is 250 mg/kg/d (or 5.5 g/m<sup>2</sup>/d) for each drug given as a 24 h infusion. Great care in dosing, administration and monitoring is essential.
5. Administer L-arginine-HCl i.v. The loading dose is 600 mg/kg (or 12 g/m<sup>2</sup>) given along with the sodium benzoate and sodium phenylacetate. The maintenance dose is 250 mg/kg/d (or 5.5 g/m<sup>2</sup>/d). The HCl derivative can produce serious acidosis.

The doses stated above are for acute hyperammonemia without a known enzyme defect. Arginine is very effective in reducing blood ammonia in citrullinemia and argininosuccinic aciduria and the high dose is aimed at these disorders. In patients with known CPS or ornithine transcarbamylase (OTC) deficiency, a lower dose is used for loading (200 mg/kg or 4 g/m<sup>2</sup>) and maintenance (200 mg/kg/d or 4 g/m<sup>2</sup>/d). In argininemia, neither arginine nor the ammonia scavenging drugs are indicated.

## Maintenance therapy<sup>37–39</sup>

After the acute crisis, dietary protein is cautiously introduced at 0.5–0.75 g/kg/d and increased as tolerated. A mix of essential amino acids may be added. The protein intake is increased to the minimum daily requirement as tolerated. The ammonia scavenging drugs are gradually switched from i.v. to p.o. For chronic oral therapy sodium phenylbutyrate is preferred.<sup>40</sup> The dose is 450–600 mg/kg/d if the patient weighs < 20 kg and 10–13 g/m<sup>2</sup>/d in larger patients. Arginine is used in patients with citrullinemia or argininosuccinic aciduria at 400–600 mg/kg/d (10–13 g/m<sup>2</sup>/d). For CPS and OTC deficiency oral L-citrulline is preferred and is given at a dose of 170 mg/kg/d (3.3 g/m<sup>2</sup>/d).

Liver transplantation has been successful in correcting the metabolic disease and preventing hyperammonemic brain damage in many patients.<sup>41</sup>

## GLYCINE

### Nonketotic hyperglycinemia

#### Clinical findings

Nonketotic hyperglycinemia (NKH) usually presents with intractable seizures in the neonatal period. Hypotonia, lethargy, hyperreflexia, hiccups and myoclonic jerks are frequent. Many patients require assisted ventilation and death is a common outcome. The EEG shows a typical burst-suppression pattern. Most patients who survive have profound mental retardation.

Rarer forms of NKH include an infantile form in which there is a symptom-free interval and apparently normal development for several months. Patients then present with seizures with various degrees of mental retardation. In an even milder form, patients present in childhood with mild mental retardation and episodes of delirium, chorea and vertical gaze palsy during febrile illness. There is a late-onset form that presents in childhood with progressive spastic diplegia and optic atrophy, but intellectual function may be preserved and seizures are not common. Rare infants have presented with symptoms and laboratory tests consistent with classic NKH, but then had complete, spontaneous reversal of both hyperglycinemia and neurological problems.

#### Diagnosis

Glycine levels are usually elevated in all body fluids including blood, urine and CSF. However, the blood levels may be normal, although they are always elevated in the CNS and an abnormal ratio of CSF: blood glycine is considered diagnostic except in the presence of valproate which can interfere with this ratio. Urine glycine is virtually always markedly elevated but should not be relied upon since physiological hyperglycinuria is common in neonates. Atypical cases, and cases where prenatal diagnosis may later be requested, may necessitate liver biopsy for enzyme analysis and/or mutation analysis.

The basic defect is in the glycine cleavage system that catalyzes the conversion of glycine to CO<sub>2</sub> and hydroxymethyltetrahydrofolic acid. The enzyme is multimeric with four distinct protein components designated P, H, T and L. Mutations in the P and T genes have been found with the P protein being most commonly affected. Prenatal diagnosis can be performed by biochemical analysis of chorionic villus sample biopsies.

#### Treatment

There has been modest success in treatment, particularly in late-onset cases. Sodium benzoate combines with glycine to form hippurate which is readily excreted; large doses may reduce CSF glycine and decrease seizures. Glycine is a neurotransmitter and anticonvulsants that block the N-methyl-D-aspartate (NMDA) receptor may be beneficial. Dextromethorphan has resulted in some improved outcome.<sup>42,43</sup> Similarly, imipramine has had some beneficial effects. For infants with classic severe neonatal NKH, consideration should be given towards allowing the lethal form to take its natural course.

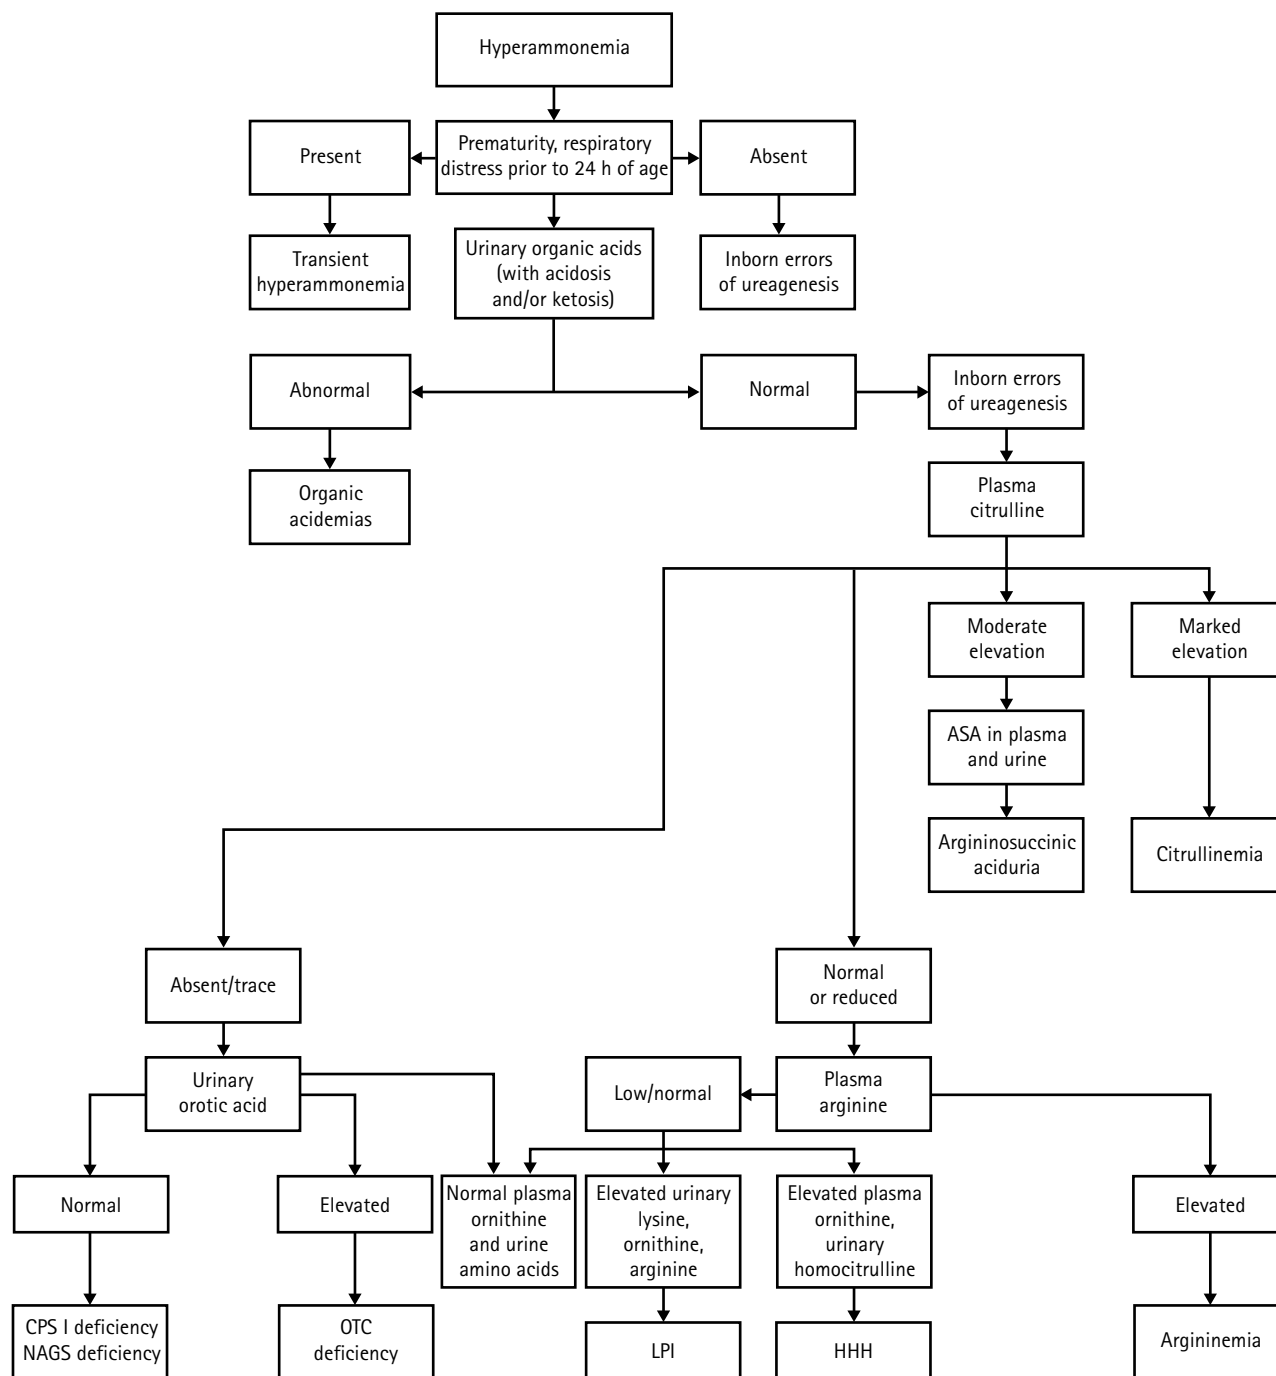

Fig. 26.8 Diagnostic flow chart for hyperammonemia. ASA, argininosuccinic acid; CPS I, carbamyl phosphate synthetase I; HHH, hyperornithinemia with hyperammonemia and homocitrullinuria; LPI, lysinuric protein intolerance; NAGS, N-acetylglutamate synthetase deficiency; OTC, ornithine transcarbamylase.

### Hyperoxaluria (oxalosis)

#### Clinical findings

In primary hyperoxaluria large amounts of oxalate are excreted in the urine, leading to calcium oxalate lithiasis and nephrocalcinosis and massive extrarenal deposits of oxalate (oxalosis). Two distinct types are known with type 1 generally being more severe than type 2. Renal failure is common and first signs or symptoms are often before age 5 years (see Ch. 18).

#### Diagnosis

Primary hyperoxaluria type 1 is caused by deficiency of the hepatic enzyme alanine:glyoxylate aminotransferase and type 2 by D-glycerate/

glyoxylate reductase. In addition to hyperoxaluria, there is additional excretion of glycolic acid in type I and of L-glycerate in type 2.

Oxalic acid is a dicarboxylic acid that forms a calcium salt of very low solubility. Oxalate in the urine is clearly of endogenous origin, and glycine is a precursor. Patients with hyperoxaluria may excrete 30 times as much oxalate as normal. Genes for both types have been identified; prenatal diagnosis is available.

#### Treatment

This is aimed at reducing the intake of oxalate and calcium as far as possible with only minimal intake of vitamin C. The urine should be alkalinized and the volume should be kept as high as possible. Some type 1

patients respond to oral pyridoxine (200–500 mg/d), possibly by increasing conversion of glyoxylate to glycine. However, dietary and pharmacological treatment is often ineffective in the long term. Combined hepatorenal transplantation is usually successful,<sup>44</sup> but renal transplantation alone is not because systemically generated oxalate is deposited in the transplanted kidney.

### Creatine deficiency

Two autosomal recessive diseases affect the biosynthesis of creatine from glycine and arginine via the intermediate metabolite guanidinoacetate. The deficient enzymes are arginine:glycine amidinotransferase (AGAT) and guanidinoacetate methyltransferase (GAMT). The resulting lack of phosphocreatine is most damaging to the CNS and is associated with major neurological problems including hypotonia, developmental delay, progressive movement disorder and seizures. A third, X-linked disorder associated with creatine deficiency is caused by mutations in a creatine transporter (SLC6A8). The clinical symptoms consist of developmental delay and hypotonia.

#### Diagnosis and treatment

The diagnosis of AGAT and GAMT deficiency is made by measuring creatine, creatinine and guanidinoacetate in blood or urine. Creatine is very low in both disorders. Guanidinoacetate is low in AGAT and elevated in GAMT deficiency. Plasma and urine creatinine levels may be low but normal levels do not rule out the diagnosis. Importantly, treatment with creatine monohydrate has been reported to reverse neurological symptoms.<sup>45,46</sup> Disease-causing mutations have been found in both types.

In the transporter defect, plasma creatine levels are not decreased and the diagnosis is made by measuring phosphocreatine levels in brain using proton magnetic resonance spectroscopy (MRS). The urinary creatine:creatinine ratio is high and supplementation with creatine is not clinically beneficial. The diagnosis is confirmed by mutation analysis.

### Sarcosinemia

Sarcosine is formed from dimethylglycine, which may be a product of betaine or choline. It is not normally detectable in blood or urine although sarcosinuria may occur after the ingestion of lobster and some other foods. Sarcosine dehydrogenase deficiency has been found in individuals with short stature and mental retardation, but a causal relationship is unclear.

## LYSINE, HYDROXYLYSINE AND TRYPTOPHAN

Glutaric aciduria type I is caused by a defect in the catabolic pathway of lysine, hydroxylysine and tryptophan. Alpha-ketoadipic acid, the common product of all three amino acids, is oxidatively decarboxylated to form glutaryl-CoA in a reaction catalyzed by alpha-ketoadipic acid dehydrogenase. Glutaryl-CoA dehydrogenase, the enzyme deficient in glutaric aciduria type I, is a mitochondrial flavin adenine dinucleotide (FAD)-dependent enzyme, which converts glutaryl-CoA to crotonyl-CoA.

Glutaric aciduria type II is a very different disease with deficiency in the activity of many acyl-CoA dehydrogenases. It is also known as multiple acyl-CoA dehydrogenase deficiency (MADD; see p. 1070).

### Glutaric aciduria type I (GA<sub>1</sub>)

#### Clinical findings

Glutaric aciduria type I is usually asymptomatic for some months after birth. Symptoms usually develop during an intercurrent illness with lethargy followed by the sudden onset of severe extrapyramidal neurological signs, after which the patient is left with dystonia and choreoathetosis. Mild macrocephaly may be found in early infancy. Metabolic stress such as intercurrent infections can trigger ketosis, acidosis, liver dysfunction, vomiting and acute neurological symptoms such as seizures and coma. The biochemical reason for the sudden emergence of catastrophic CNS damage is not known. The neurological deficits can probably be prevented if the disorder is effectively treated before the first metabolic crisis.

### Diagnosis

This disorder is readily detected by expanded newborn screening. The cardinal characteristic is massive glutaric aciduria together with increased 3-hydroxyglutaric acid (see Appendix 1). Prenatal diagnosis can be performed on cultured amniocytes and by DNA based diagnosis.

### Treatment

Therapy consists of protein restriction, especially lysine and tryptophan. In addition L-carnitine (100–300 mg/kg/d) and often riboflavin (100 mg/d) are used, starting at the time of diagnosis. Some success has been reported with the use of anticonvulsants that stimulate gamma-aminobutyric acid (GABA) receptors. Early treatment can significantly improve or prevent the neurological outcome. Aggressive management of intercurrent illness is critical. Young children with GA1 should be hospitalized and receive i.v. glucose (D10W at twice maintenance) and i.v. L-carnitine (150–300 mg/kg/d) very early in any situation that could result in metabolic decompensation, including febrile illnesses, decreased food intake, vomiting and diarrhea.

### Other disorders of lysine metabolism

Deficiency of the bifunctional protein alpha-aminoadipic semialdehyde synthase causes familial hyperlysinemia. The clinical significance of this enzyme deficiency is controversial. Psychomotor retardation has been reported in many but not all affected individuals.

Individuals who lack 2-ketoadipic acid dehydrogenase excrete large amounts of 2-ketoadipic acid and 2-hydroxyadipic acid in their urine. The disorder is termed *2-ketoadipic acidemia*. Although there are some case reports of neurological disease in this condition, other patients have been clinically normal.

*Hydroxylysinemia* has been found in several mentally retarded patients. The amino acid comes solely from collagen, where lysine is hydroxylated after incorporation into procollagen. However, collagen metabolism was normal and the disorder was due to a defect in the metabolism of free hydroxylysine. An X-linked disorder in lysine hydroxylation is found in Ehlers–Danlos syndrome type VI (see Ch. 29, p. 1398).

### Hyperprolinemia, hydroxyprolinemia and prolidase deficiency

Hyperprolinemia and hydroxyprolinemia are defects of the imino acids. Three distinct metabolic defects have been identified: proline oxidase is deficient in type I hyperprolinemia; 1-pyrroline-5-carboxylate dehydrogenase is deficient in type II hyperprolinemia; and hydroxyproline oxidase is deficient in hydroxyprolinemia. Although some patients with hyperprolinemia type II have been normal into adult life, it may be responsible for seizures in some patients.

Prolidase is an enzyme that cleaves X-pro linkages. Deficiency is associated with developmental delay, minor dysmorphic features and recalcitrant skin lesions that appear anywhere on the body from infancy to adult life. Massive amounts of many X-pro dipeptides are found in the urine. There is no specific treatment.

## BRANCHED CHAIN AMINO ACIDS

Defects in the degradation of the branched chain amino acids valine, leucine and isoleucine result in the accumulation of organic acid intermediates (Fig. 26.9). High levels of leucine are toxic, particularly to the CNS. These diseases are most readily detected by analysis of urine organic acids and in many cases there is a characteristic odor. There are many different enzymes involved in this pathway, all of which are autosomal recessive traits.

Several of the disorders of branched chain amino acid metabolism are associated with elevated plasma glycine levels and/or hyperammonemia. These disorders were historically termed 'ketotic hyperglycinemias'. They are discussed as a group in this section.

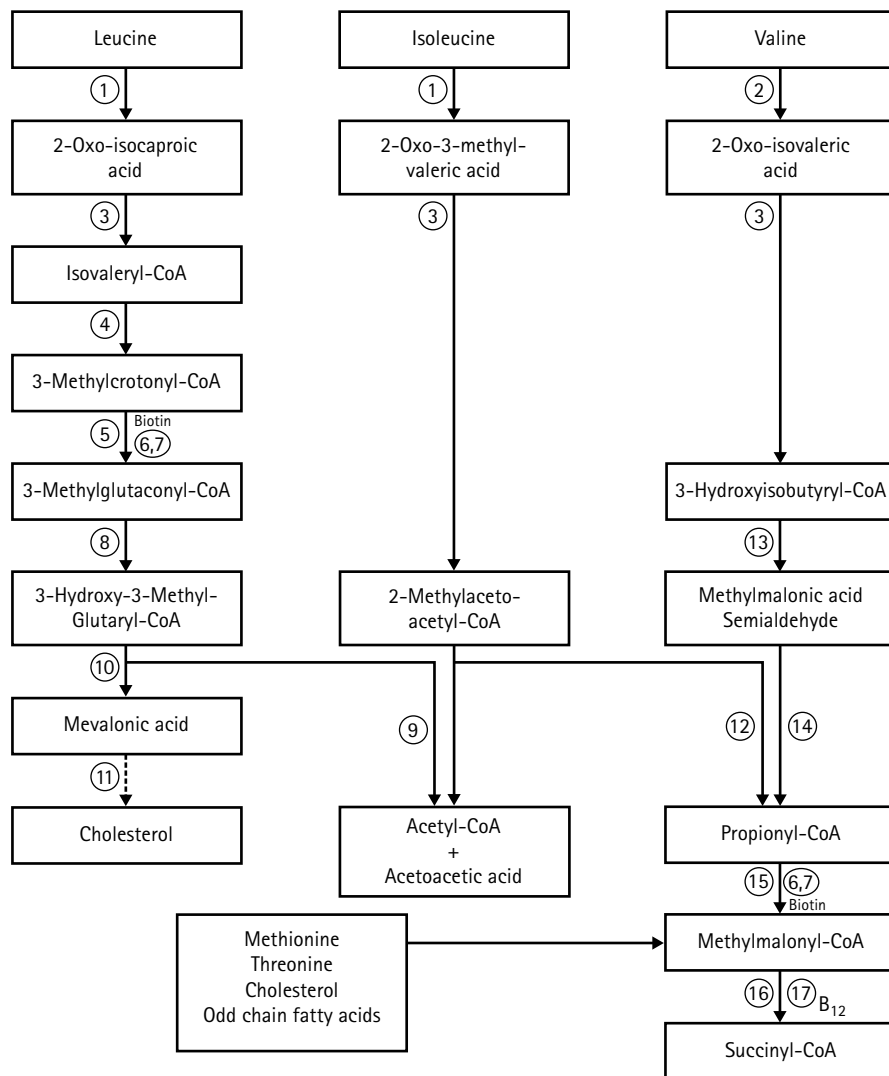

Fig. 26.9 Branched chain amino acid metabolism: numbers indicate known metabolic errors. 1, Leucine aminotransferase; 2, valine aminotransferase; 3, branched chain keto acid decarboxylase (maple syrup urine disease); 4, isovaleryl-CoA dehydrogenase; 5, 3-methylcrotonyl-CoA carboxylase; 6, biotinidase; 7, holocarboxylase synthetase; 8, 3-methylglutaconyl-CoA hydrolase; 9, 3-hydroxy-3-methylglutaryl-CoA lyase; 10, 3-hydroxy-3-methylglutaryl-CoA reductase; 11, mevalonate kinase; 12, 2-methylacetoacetyl-CoA thiolase ( $\beta$ -ketothiolase); 13, 3-hydroxyisobutyryl-CoA deacylase; 14, methylmalonic semialdehyde dehydrogenase; 15, propionyl-CoA carboxylase; 16, methylmalonyl-CoA mutase; 17, cobalamin defects.

## AMINO ACID RELATED ORGANIC ACIDEMIAS

Many of the disorders of branched chain amino acids present with acidosis that is sometimes severe; they are an important subgroup of the organic acidemias. Diagnostic and therapeutic approaches to metabolic acidosis will be discussed first, followed by the description of individual disorders. Table 26.3 lists disorders associated with metabolic acidosis.

### Diagnostic approaches (see also lactic acidosis, p. 1080)

Unexplained metabolic acidosis, with or without ketosis, should always suggest the possibility of an organic acidemia and demands urgent evaluation. The blood pH may be normal or low, and an anion gap or base deficit is to be expected. In some disorders, hypoglycemia is frequent and hyperammonemia or lactic acidosis reflect disturbed mitochondrial function. Hyperuricemia can be caused by inhibition of renal tubular secretion of uric acid by other organic acids. In the 'ketotic hyperglycinemia' syndromes (methylmalonic acidemia, propionic acidemia, isovaleric acidemia and 2-methyl-3-hydroxybutyric aciduria) the blood glycine is often raised; an elevated plasma glycine:alanine ratio is more consistent. In contrast, in lactic acidosis, hyperalaninemia reflects increased transamination of pyruvate. The urine pH is low and the Acetest (Ames), Ketostix (Ames) or dinitrophenylhydrazine tests may be abnormal depending upon which metabolites are being excreted. Diagnosis can usually be made by identification of the organic acid pattern, or their glycine and carnitine conjugates, in blood or urine and can be confirmed by specific enzyme assays (see also Appendix 1).

In milder cases, the diagnosis may be easily missed unless samples are obtained during an acidotic episode. Provocative tests with precursor amino acids have proved fatal and should not be used. *Blood and urine samples for metabolite identification should be taken from any child with unexplained acidosis.*

A number of organic acids may occur in the urine of sick, ketotic or acidotic children without IEM, presumably reflecting secondary metabolic disturbances. Lactate can reflect poor tissue perfusion. The *dicarboxylic acids* adipic, suberic and sebacic acids, 3-hydroxyisobutyric acid, 2-methyl-3-hydroxybutyric acid and 3-hydroxyisovaleric acid, as well as the ketone bodies, can all accumulate when lipolysis is increased, making it difficult to distinguish between primary or secondary effects on fatty acid breakdown (see also p. 1067). Many of these disorders are detected by expanded newborn screening (see Ch. 10).

### Treatment

Since dehydration is associated with endogenous protein catabolism, it must be avoided; a urine output of 150–200 ml/kg/d or more, if tolerated, may help in the elimination of the metabolites. Although sodium bicarbonate is not a mainstay of therapy, and does not treat the cause of acidosis, it may be required along with definitive therapy to help correct the base deficit. Before the abnormal metabolites are identified, protein and fat should be restricted with as many calories from carbohydrate as can be tolerated, i.v. or p.o. If carbohydrate aggravates a lactic acidosis, the defect may be in pyruvate dehydrogenase (see Fig. 26.17) for which protein and fat are given and glucose

**Table 26.3** Disorders associated with metabolic acidosis and/or organic aciduria. The major metabolite excreted is indicated either by the name of the disorder or by the compounds in parentheses (see also Table 26.8 and 9)

<b>Branched chain amino acid disorders</b>
Maple syrup urine disease (branched chain keto acids)
Methylmalonic acidemia
Propionic acid acidemia
Isovaleric acidemia
3-Methylcrotonylglycinuria
3-Methylglutaconic aciduria
3-Hydroxy-3-methylglutaryl-CoA lyase deficiency
Mevalonic acidemia
2-Methylacetoacetyl-CoA thiolase deficiency
3-Ketothiolase deficiency (3-hydroxybutyrate)
3-Hydroxyisobutyryl-CoA deacylase deficiency
Methylmalonic semialdehyde dehydrogenase deficiency (3-hydroxypropionate)
<b>Other disorders</b>
2-Ketoadipic aciduria
Glutaric aciduria types I and II
Crotonic acidemia
5-Oxoprolinuria
Succinic semialdehyde dehydrogenase deficiency (4-hydroxybutyrate)
Succinyl-CoA:3-ketoacid CoA transferase deficiency
Threonine sensitive acidosis
2-Hydroxyglutaric aciduria
Barth syndrome (3-methylglutaconic acid)
Fanconi syndrome
The tyrosinemias (tyrosyluria) (succinyl acetone)
Renal tubular acidosis
Lactic/pyruvic acidosis
Multiple carboxylase and biotinidase deficiencies
Mitochondrial disorders
Krebs cycle disorders
Fructose 1,6-diphosphatase deficiency (lactate)
Glycogen storage disease type 1 (lactate)
Ketoacidosis as in diabetes mellitus
Carnitine depletion
Disorders of fatty acid catabolism
Disorders of ketone body utilization
<b>Other disorders in which pathological organic aciduria can occur</b>
Urea cycle disorders (orotic acid)
Canavan disease (N-acetylaspartate)
Phenylketonuria (phenylpyruvate)
<b>Other acquired causes of acidosis</b>
Poisoning: salicylate, methanol, benzyl alcohol, antifreeze, etc
Ethanol
Starvation
Dehydration
Diarrhea
Reye syndrome

is minimized. Once the abnormal metabolites are identified, their precursors are restricted in the diet to the limits of metabolic tolerance. Calories are then supplied from all other available sources. Thus in maple syrup urine disease, all three branched chain amino acids are restricted, whereas in isovaleric acidemia only leucine needs to be controlled. Before the diagnosis is established, large doses of vitamin B<sub>12</sub> (1–2 mg), pyridoxine (150–500 mg), thiamin (200–500 mg), folic acid (10–20 mg), biotin (10–20 mg), nicotinamide (100–500 mg) and riboflavin (100–500 mg) should be given in case the disorder is vitamin responsive. Once the definitive diagnosis is known, those unlikely to be useful can be stopped.

Abnormal quantities of any CoA derivative combines with carnitine to make acylcarnitine derivatives that are then excreted. This frequently causes profound carnitine depletion that in turn aggravates the metabolic acidosis and may induce muscle weakness, hypoglycemia,

hepatocellular damage and cardiomyopathy. Initial treatment should include L-carnitine 100–300 mg/kg/d in divided doses.

In extreme cases, hemodialysis or continuous extra corporal hemoperfusion should be used; peritoneal dialysis is less effective. A glucose/insulin drip may help to reverse endogenous protein catabolism. Once the crisis is over, a diet appropriate to the particular disorder is cautiously re-introduced over several days.

### Maple syrup urine disease

In maple syrup urine disease (MSUD; branched chain ketoaciduria), major cerebral symptoms typically appear early in the newborn period, and the urine has an odor reminiscent of maple syrup. The branched chain amino acids – leucine, isoleucine and valine – are present in high concentration in the blood and urine, and the ketoacid analogues are found in the urine. The catabolic pathway is initiated by a transamination reaction to the respective ketoacids. The defect in MSUD is in the next step, namely oxidative decarboxylation of the ketoacids to their CoA derivatives. This is catalyzed by a mitochondrial multienzyme complex similar to pyruvate dehydrogenase and alpha-ketoglutarate dehydrogenase. For this reason autosomal recessive mutations in four different genes can cause MSUD. Patients have been identified with defects in the E1alpha, E1beta, E2 and E3 subunits of the complex. The E3 subunit is shared by all three complexes and defects in this gene cause simultaneous deficiency of all three dehydrogenases. MSUD is rare in most populations with an incidence of ~1:150 000.

### Clinical findings

Infants with MSUD appear well at birth. Typically, symptoms begin after 3–5 d and progress rapidly. Early manifestations include feeding difficulty, irregular respirations and progressive CNS depression. Severe hypoglycemia may occur. Characteristically these patients develop convulsions, opisthotonos and generalized muscular rigidity with or without intermittent flaccidity. Death usually occurs within a few weeks after decerebrate rigidity develops. Cortical atrophy may be seen on CT or MRI, and the myelin is usually hypodense. This is consistent with defective myelination as has been observed at autopsy. “A characteristic odor of maple syrup, caramel or fenugreek is present in urine sweat and cerumen. A similar odor is sometimes reported in normal infant’s diapers”

Milder forms of the disease due to different mutations occur. There is an intermittent form with repeated episodes of ataxia and lethargy progressing to coma, but without neurodevelopmental sequelae. Episodes are usually precipitated by infection or anesthesia.

### Diagnosis

Any traces of odor should be sought in all infants with such a presentation. Increased quantities of leucine, isoleucine and valine, and their keto acids are found in the plasma and urine. The presence of an abnormal amino acid, alloisoleucine, is diagnostic for MSUD.

### Treatment

Treatment demands a diet with strict control of leucine which is acutely neurotoxic. Isoleucine and valine are normally restricted as well but they are not actually neurotoxic and, since all three are essential nutrients, they are sometimes *added* back to the diet to reduce the possibility that deficiency of one of them may be contributing to poor biochemical control (see p. 1064). With care, the plasma amino acids can be maintained near normal limits but this must be continued for life. A normal IQ may be achieved in those treated early and well. In a severe crisis, special intravenous solutions of amino acids can be used. Rare patients have a thiamine responsive form of MSUD and therefore this vitamin should be tried in all cases.

### KETOTIC HYPERGLYCINEMIAS

Secondary elevation of plasma glycine is found in some defects of branched chain amino acid metabolism, particularly in propionic

acidemia, methylmalonic acidemia and 3-ketothiolase deficiency. Because these conditions are also associated with ketoacidosis, they were originally termed the ketotic hyperglycinemias in contrast to nonketotic hyperglycinemia (see above). Urine organic acids should be analyzed in any patient with elevated plasma glycine.

## Propionic acidemia

### *Clinical findings*

This disease is characterized by recurrent episodes of lethargy, coma and metabolic acidosis with severe ketosis, similar to those observed in diabetic coma. There may be symptomatic hyperammonemia due to secondary inhibition of the urea cycle. Neutropenia, thrombocytopenia and osteoporosis severe enough to lead to pathological fracture may occur. Mental retardation, seizures and cerebral palsy are common in older patients, with the basal ganglia often involved. Symptoms begin within 24 h after birth, with vomiting, lethargy, acidosis and ketonuria. Death can occur with intractable acidosis. Surviving patients are susceptible to metabolic strokes, cardiomyopathy, progressive renal dysfunction and recurrent pancreatitis, any of which may prove fatal. The cause of these later complications is not known.

### *Diagnosis*

The defect is in the enzyme propionyl CoA carboxylase, a multimeric enzyme with non-identical alpha and beta subunits; it catalyzes the formation of methylmalonyl CoA from propionyl CoA (see Fig. 26.9). Mutations in both genes have been identified.

Propionyl CoA is formed in the catabolism of several precursors (valine, isoleucine, methionine and threonine, odd-chain fatty acids and cholesterol, which creates a memorable mnemonic, "VOMIT"). Propionic acidemia is most readily diagnosed by organic acid analysis of the urine for methylcitrate, 3-OH propionate, propionyl-glycine and others. Elevated quantities of glycine in the blood and urine may be suggestive. Patients frequently have an abnormal plasma carnitine profile with low free carnitine levels and an elevated fraction of short chain acyl-CoA carnitine. The defect can be demonstrated in leukocytes and in cultured fibroblasts: prenatal diagnosis is possible using molecular techniques as well as analysis of amniotic fluid for abnormal metabolites.

### *Treatment*

Restricting the intake of the precursor amino acids reduces the frequency and severity of attacks of ketosis and acidosis (see p. 1070). Treatment with L-carnitine serves to reduce toxic quantities of propionyl CoA as well as reversing secondary deficiency of carnitine.<sup>47</sup> With bone marrow suppression, intercurrent illness and infection readily occur and must be treated vigorously with large amounts of glucose, fluids and electrolyte, often including sodium bicarbonate and L-carnitine. The acidosis or hyperammonemia can be life threatening and dialysis may be needed during acute decompensation. Patients diagnosed early in infancy and raised according to these principles clearly have improved survival and a more favorable developmental outcome. However, even when treated from birth, and in the absence of any known metabolic decompensation, the outcome can be very poor. Milder cases are sometimes not even detected until adult life. Liver transplantation has been used in this disorder, but has not been completely curative and in particular has not prevented neurological deterioration.

## Methylmalonic acidemias

The methylmalonic acidemias are a genetically heterogeneous family of disorders in which methylmalonic acid accumulates in body fluids. The most severe disorders have a primary defect in the same pathway as propionic acidemia (see above) and the same compounds are toxic. Methylmalonic acid is normally formed from methylmalonyl-CoA, which is a product of the propionyl-CoA carboxylase reaction (see Fig. 26.9). Methylmalonyl-CoA mutase, a dimer of identical subunits, converts

methylmalonyl-CoA to succinyl-CoA, which can then be metabolized through the citric acid cycle. The mutase enzyme requires a vitamin B<sub>12</sub> coenzyme, deoxyadenosylcobalamin (AdoCbl).

Impaired methylmalonyl CoA mutase activity can also be caused by several primary defects in vitamin B<sub>12</sub> metabolism (styled Cbl A-G), all of which are autosomal recessive (see p. 1079 and Fig. 26.43). These defects affect the transport or synthesis of both methylcobalamin (MeCbl) and AdoCbl and thus can cause both abnormalities in both pathways at the same time. These patients tend to have lower plasma levels of methylmalonic acid than those with mutase mutations; they may not become ketotic and may also have megaloblastic anemia. High plasma homocysteine levels may be present.

### *Clinical findings*

The clinical manifestations, complications and outcome of the severe forms are similar to those of propionic acidemia, patients usually presenting in the first weeks after birth. Hyperammonemia, hypoglycemia and ketosis are prominent. Growth retardation may be striking. Convulsions and abnormalities of the EEG have been observed. Failure to thrive may be extreme and death can occur in early infancy. However, later presentations, including serendipitous diagnosis in adults, have been reported. The cobalamin defects are somewhat different.

### *Diagnosis*

Methylmalonic acid is elevated in plasma or urine, where it is normally present only in trace quantities. The urine also contains methylcitrate and plasma glycine may be elevated. Because plasma homocysteine levels may be elevated with defects in B<sub>12</sub> metabolism, this compound should be measured in every patient with methylmalonic acidemia. Blood concentrations of vitamin B<sub>12</sub> are normal, except when B<sub>12</sub> deficiency is the cause of elevated methylmalonic acid. The activity of methylmalonyl CoA mutase is defective in leukocytes, cultured fibroblasts and amniotic fluid cells.

Several of the involved genes have been cloned and some mutations identified. In order to provide accurate prognostic information and genetic counseling, the exact cause of the methylmalonic acidemia needs to be determined, if feasible.

### *Treatment*

The treatment for patients defective in the mutase structural gene is similar to that of propionic acidemia. It includes L-carnitine supplementation as well as dietary protein restriction.<sup>48</sup> Liver transplantation has been shown to be partially beneficial.

Some patients with Cbl defects are responsive to injection of high doses of specific isoforms of vitamin B<sub>12</sub>. Those that do not respond may require specialized pharmacological and dietary management to control the elevated plasma homocysteine.

## Isovaleric acidemia

Isovaleryl-CoA is the product of the branched chain decarboxylation of the ketoacid analogue of leucine that normally converts isovaleryl-CoA to 3-methylcrotonyl-CoA. Isovaleryl-CoA dehydrogenase is deficient in this disorder.

### *Clinical findings*

Isovaleric acidemia normally presents within days of birth with lethargy, vomiting, coma, acidosis, ketosis and symptomatic hyperammonemia. The most distinguishing feature is a characteristic pungent odor, reminiscent of sweaty feet, which is that of isovaleric acid. Many patients die within a few weeks after birth.

In infants who survive the initial attack but remain untreated, there are recurrent episodes of vomiting, acidosis and ataxia, progressing to lethargy and coma. Acute episodes often occur with infections or after surgery. The odor is more likely to be appreciated during an episode of acute illness, but it may be absent. Mental retardation can be seen, especially among those diagnosed late, but normal IQ and good health are not uncommon. Patients with isovaleric acidemia also may have leukopenia, thrombocytopenia and anemia.

### Diagnosis

During acute episodes, concentrations of isovaleric acid in the serum and urine may be enormous. Increased urinary isovalerylglycine is the most reliable biochemical indicator, and this compound is easily identified in routine organic acid analysis.

### Treatment

Acute episodes are treated by vigorous use of parenteral fluids that contain glucose and electrolytes. The acidosis may require sodium bicarbonate. Hemodialysis or peritoneal dialysis may be indicated to treat hyperammonemia and/or acidosis. Long term treatment requires restricting the dietary intake of protein until the amount of leucine ingested is that necessary for growth. The conjugation of isovaleric acid with glycine (250 mg/kg/d) permits the possibility of adjunctive treatment with exogenous glycine. Additionally L-carnitine 100–200 mg/kg/d is administered.<sup>49</sup> If treatment is begun early, the prognosis is good.

## OTHER BRANCHED CHAIN ORGANIC ACIDURIAS

*3-Methylcrotonylglycinuria*, due to isolated deficiency of 3-methylcrotonyl-CoA carboxylase, is similar to isovaleric acidemia except there may be an odor similar to cats' urine. 3-Methylcrotonylglycine and 3-hydroxyisovaleric acid are excreted in large amounts in the urine but are not elevated in blood. A trial of biotin (10–20 mg/d) is indicated because most cases who excrete these metabolites have multiple carboxylase deficiency. Most of these cases are asymptomatic.

A defect of *3-methylglutaconyl-CoA hydratase* (step 8, see Fig. 26.9) causes excretion of 3-methylglutaconic acid and 3-methylglutaric acid. The usual symptoms are progressive neurological deterioration in infancy, *without obvious metabolic acidosis*. However, hypoglycemia, metabolic acidosis and cardiomyopathy have also been reported although these could have been due to carnitine depletion. Other patients with 3-methylglutaconic aciduria but normal enzyme studies have presented with various symptoms of neurological deterioration, including choreoathetosis, spasticity, optic atrophy, tapetoretinal degeneration and nerve deafness. Metabolic acidosis may be absent or marked and most such cases die. Some cases are associated with defects of the respiratory chain but in most, the primary enzyme defect is not known. Barth syndrome is discussed on p. 1098.

*2-Methylbutyryl-CoA dehydrogenase* deficiency is a defect of isoleucine metabolism. The presentation includes neurological symptoms in the newborn period along with mild acidosis and hypoglycemia. Most cases are asymptomatic. The abnormal metabolites included 2-methylbutyrylglycine and 2-methylbutyrylcarnitine.

The last step in leucine catabolism, *3-hydroxy-3-methylglutaryl-CoA lyase*, commits leucine to ketogenesis and is discussed on p. 1070.

## MULTIPLE CARBOXYLASE AND BIOTINIDASE DEFICIENCIES

Biotin is an essential cofactor for many carboxylases, including several involved in branched chain amino acid metabolism. For this reason perturbations of its association with these enzymes affect multiple different carboxylases. There are two distinct causes of multiple carboxylase deficiency. One is a deficiency of holocarboxylase synthetase and the other a deficiency of biotinidase. Holocarboxylase synthase catalyzes the association of biotin with the various carboxylases to form functional holoenzymes. Defects in this protein usually cause a severe, neonatal form of the disease. Biotinidase is involved in recycling of the vitamin and deficiency is usually clinically milder.

### Clinical findings

Neonatal and infantile forms of the disease are distinguished. The former generally presents with life threatening acidotic illness in the newborn period, like that of propionic acidemia. Symptoms include severe

ketosis, acidosis, dehydration and coma. Death can occur unless vigorous treatment is instituted. Patients who survive the first days of life have alopecia totalis and an impressive red, scaly total body eruption. The infantile form presents later with periorificial dermatitis resembling acrodermatitis enteropathica, partial alopecia and neurological abnormalities such as ataxia, delayed mental development and convulsions. These patients too may develop life threatening acidotic episodes. Immunodeficiency may be found in either form of the disease and may involve T- and B-cell function. Mild deficiency of biotinidase may be asymptomatic.

### Diagnosis and treatment

Urine organic acid analysis is characteristic with excretion of 3-methylcrotonylglycine, 3-hydroxyisovaleric, methylcitric, 3-hydroxypropionic and lactic acids. Tiglylglycine may also be found. The two forms of the disease can be distinguished by mutation analysis or by enzyme measurement in cultured fibroblasts.

Newborn screening for biotinidase deficiency is employed in several programs because the disorder is readily treated and sequelae can be completely avoided. The incidence of complete deficiency is ~1 in 100 000.

Both genes for holocarboxylase synthetase and biotinidase have been identified. Two alleles for biotinidase account for ~50% of all mutations. Holocarboxylase synthetase deficiency is rarer than biotinidase deficiency and there are also two mutations that are more frequent. Prenatal diagnosis and successful prenatal treatment of affected fetuses has been reported.

All cases of biotinidase deficiency and most patients with multiple carboxylase deficiency are responsive to exogenous biotin.<sup>50</sup> Doses of 10 mg/d are usually sufficient to reverse all of the findings, but some patients require more. Carnitine may be a useful adjunct to therapy.

## AMINO ACID TRANSPORT DISORDERS

In the kidney and gut, amino acids are actively transported across cell membranes in five major groups (Table 26.4). In addition, there are other separate, but minor, transport systems.

Disorders of both group-specific and individual amino acid transport systems exist. In tissues other than the kidney and gut there are similar, but not identical, active transport processes, but only in lysinuric protein intolerance is any other tissue known to be involved. Renal transport defects result in specific patterns of aminoaciduria, when, if anything, the plasma levels of the same amino acids are lower than normal. Plasma elevation of a single amino acid usually causes a single aminoaciduria, as in PKU, but a single amino acid may saturate the transport mechanism for all the others in the group, causing a group aminoaciduria. For example, in hyperglycinemia, the imino acids (group 2) may also be excreted.

Inherited defects of four group transport systems are known but they probably do not affect all cells. For example, the two types of iminoglycinuria imply that several genes must be required for amino acid transport in different tissues. *Dicarboxylic aminoaciduria* is a benign trait.

### Cystinuria (see also Ch. 18)

Although the disorder bears the name of only one amino acid, cystinuria is a disorder of transport of cystine and all of the dibasic amino acids – cysteine, ornithine, lysine and arginine ('COLA'). The defect is in the SLC7A9 gene, which encodes a subunit of a family of amino acid transporters expressed in kidney, liver, small intestine and placenta. The condition is mainly important because cystine is very insoluble in normal urine and patients tend to develop renal calculi at any age. About 1–5% of patients with renal stones have cystinuria. Cystine crystals, which are flat and hexagonal, may be found in the urine. The diagnosis is based upon the nitroprusside test, amino acid chromatography or stone analysis. The aim of treatment is to keep urine cystine levels in the range of maximum solubility (approx. 0.1 mmol/mmol creatinine). It consists of maintaining a urine flow of 2–3 L/m<sup>2</sup>/24 h or more; 25%

Table 26.4 Group systems of amino acid transport in kidney and gut and their disorders

Group	Disorder
1. a. Cystine, lysine, ornithine, arginine b. Lysine, ornithine, arginine	Cystinuria type I, II and III Dibasic aminoaciduria: • Lysinuric protein intolerance • Without protein intolerance
2. Glycine, proline, hydroxyproline	Iminoglycinuria
3. $\beta$ -Amino acids, taurine	None known
4. Aspartic and glutamic acid	Dicarboxylic aminoaciduria
5. Neutral amino acids (e.g. glycine, alanine, valine, leucine, isoleucine, serine, threonine, cysteine, cystine, phenylalanine, tyrosine, methionine, histidine, tryptophan)	Hartnup disease

of the fluid intake should be taken during the night. Maximum alkalinization of the urine to around pH 7.5 is important, since the solubility of cystine decreases markedly below that.

Isolated cystinuria, isolated dibasic aminoaciduria (lysine, ornithine, arginine) and isolated lysinuria have been reported, showing that partial transport defects within the group can also occur.

### Lysinuric protein intolerance

#### Clinical features

In this disorder, most common in Finland, symptoms of hyperammonemia become evident following weaning, when food intolerance, diarrhea, vomiting, hypotonia, hepatosplenomegaly, sparse hair, osteoporosis and marked failure to thrive develop. Interstitial pulmonary fibrosis is a late feature and may prove lethal. Mental development may be normal.

#### Diagnosis and treatment

There is a defect in the renal, liver and intestinal transport of lysine, arginine and ornithine, resulting in increased excretion in the urine and low levels in plasma. Cysteine transport is normal. The hyperammonemia is explained by deficient transport of urea cycle substrates into liver cells. In addition to other treatment for hyperammonemia, supplementation with citrulline (2–10 g/d) is very beneficial.

### Iminoglycinuria

Free imino acids are normally present in urine in the first 6 months but they fall to very low levels thereafter. A defect of proline, hydroxyproline and glycine transport appears to be benign. Gastrointestinal transport may be either normal or defective. Hyperglycinuria is usually marked but glycine normally varies within wide limits, accounting for up to 25% of the urinary amino acids. It is common in iminoglycinuria heterozygotes, the ketotic and nonketotic hyperglycinemias and in valproate therapy. Glycinuria with glucosuria can occur either alone or with vitamin D-resistant rickets, although the reason for this is not known.

### Hartnup disease

Hartnup disease is caused by defective transport in the kidney, and usually the gut, of amino acids in group 5 (see Table 26.4). The only constant feature is a characteristic aminoaciduria. The symptoms, if they occur, are those of pellagra caused by malabsorption of tryptophan. They include photodermatitis, ataxia, psychiatric changes and mental deterioration, but these are usually intermittent and are only precipitated during protein deprivation or periods of stress. Symptoms usually lessen with age. Patients on a normal protein or niacin-supplemented diet are symptomless. Deficiency of the other amino acids causes no problem. Treatment with oral nicotinic acid (25 mg/d) is effective.

### Other amino acid transport defects

Methionine malabsorption in gut and kidney has been associated with mental retardation, convulsions, diarrhea and white hair. 2-Hydroxybutyric acid produced by gut bacteria has a peculiar, beer-like body odor that gives rise to the name oast-house syndrome. No treatment is known.

The blue diaper (nappy) syndrome is a rare isolated defect in gut absorption of tryptophan; gut bacteria degrade tryptophan to indoles that are then absorbed, metabolized in the liver and excreted in the urine as the blue pigment indican. The defect may be associated with mental retardation, hypercalcemia and nephrocalcinosis.

## MISCELLANEOUS AMINO ACID DISORDERS

A number of patients with *carosinemia* have been reported. Most have had abnormalities of the CNS, but others with the same defect are completely normal, so this defect is probably benign.

*Histidinemia* is a disorder in which large amounts of histidine are found in blood, urine and CSF. Deficiency of histidase (histidine-ammonia-lyase) has been demonstrated by direct assay of the enzyme in skin. More than half of these patients have had speech, mental and growth retardation; however, prospective studies have shown conclusively that histidinemia does not cause disease.

Histidine is normally converted by histidase to urocanic acid, which is ultimately metabolized to glutamic acid. Rare case reports have associated urocanase with severe mental retardation and neurological deterioration.

## FATTY ACID OXIDATION DISORDERS (Fig. 26.10)

(in aggregate ~1 in 10,000–20,000)

### GENERAL CONSIDERATIONS

After birth, fatty acids are the major fuel for cardiac and skeletal muscle, both at rest and during aerobic exercise. Following release from circulating or stored triglycerides by lipoprotein lipase (step 1), free fatty acids are bound to albumin in the plasma. After diffusing across the cell membrane, the long chain fatty acids, primarily palmitic and oleic acids, are converted to fatty acyl-CoA esters by an acyl-CoA synthase (step 3). Neither this step nor the transport systems into mitochondria seems to be required for medium or short chain fatty acids but these are usually minor metabolic pathways.

Transport into mitochondria requires L-carnitine, which is both endogenously produced and also comes from animal sources in the diet. Carnitine palmitoyl transferase (CPT)-I (step 4) forms fatty acyl-carnitine conjugates that are transported into the mitochondria by a translocase (step 5). Once inside the matrix, the reaction is reversed by CPT-II and free carnitine and long chain fatty acyl-CoA are reformed (step 6).

Fatty acid beta-oxidation occurs in a repeating four-reaction cycle, each 'spiral' of the cycle releasing one molecule of acetyl-CoA (steps 7–12). The first reaction is performed by one of four acyl-CoA dehydrogenases, the choice of enzyme dependent upon the structure and chain length of the fatty acid substrate. Straight chain  $C_{12-18}$  fatty acids are metabolized by very long chain acyl-CoA dehydrogenase (VLCAD), which is bound to the inner mitochondrial membrane. Long chain branched or desaturated fatty acids are probably substrates for long chain acyl-CoA dehydrogenase (LCAD), an enzyme within the mitochondrial matrix. Shortened fatty acids become substrates for either medium chain ( $C_{6-12}$ ) or short chain ( $C_{4-6}$ ) acyl-CoA dehydrogenases (MCAD or SCAD). All these reactions provide reducing equivalents and are coupled directly through electron transfer flavoprotein (ETF) and ETF:coenzyme Q (CoQ) oxidoreductase (ETF:QO) (steps 13–15) to CoQ of the electron transport chain. Three further enzymes (steps 10–12) complete one cycle leaving a fatty acyl-CoA two carbons shorter for further beta-oxidation.

For long chain fatty acids, steps 10–12 are all catalyzed by a single membrane bound enzyme complex called the trifunctional protein. For

shorter fatty acids, three distinct mitochondrial matrix proteins are required. Reducing equivalents generated in step 11 (3-hydroxyacyl-CoA dehydrogenase) are coupled to complex I of the electron transport chain. Fatty acid oxidation in the liver produces the ketone bodies, acetoacetate and beta-hydroxybutyrate, which, under homeostatic conditions, are recycled to fatty acids for use in other tissues, although they can be directly metabolized by the brain for energy during prolonged fasting. In liver and muscle, acetyl-CoA generated through fatty acid oxidation is a substrate for the citric acid cycle, sparing glycogen and preventing glucose depletion.

Transition from the continuous supply of glucose in fetal life to a mixed fuel system after birth requires efficient beta-oxidation, which is not usually stressed by the normal frequent feeding schedules of newborn infants. It is often only when breast milk let-down is insufficient, when the time between feeding increases, or during a catabolic illness, that these disorders tend to cause symptoms.

When beta-oxidation is increased or disrupted, the dicarboxylic acids adipic (C<sub>6</sub>), suberic (C<sub>8</sub>) and sebacic (C<sub>10</sub>) are produced by omega-oxidation of the excess intermediates. Thus they are seen in fasting and in ketoacidosis from any cause, as well as in the disorders of fatty acid catabolism or ketone utilization.

Isolated deficiencies of most of the enzymes involved in fatty acid oxidation have been described, and collectively these disorders appear to be relatively common. All are inherited in an autosomal recessive pattern, and specific gene defects have been identified for most of the disorders.

The role of carnitine is discussed below.

### Clinical features

Disorders of fatty acid metabolism commonly present with one of three phenotypes:

1. sudden infant death;
2. hypoketotic hypoglycemia in association with recurrent vomiting and hepatic encephalopathy;
3. recurrent rhabdomyolysis and myoglobinuria.

The expected phenotypes associated with the known disorders of fatty acid oxidation are presented in Table 26.5. Sudden infant death due to occult hypoglycemia often occurs in the setting of fasting or intercurrent illness, but sudden death may also occur in nonfasting neonates (particularly in infants with long chain fatty acid metabolism

defects such as VLCAD deficiency) due to cardiac arrhythmia or cardiomyopathy.

More commonly, disorders of fatty acid metabolism cause episodes of lethargy with nausea and vomiting, hypoketotic hypoglycemia, progressive somnolence and hepatic encephalopathy. As many as one third of the initial episodes may be fatal, the diagnosis not being established unless appropriate perimortem metabolic studies are performed.<sup>51</sup> Some children may have recurrent episodes of decompensation prior to diagnosis and may exhibit muscle weakness, hypotonia and developmental delay. Dysmorphic features and cardiomyopathy may occur in some of the disorders and CNS symptoms, when they occur, may be life threatening. Fatty acid metabolism defects may also

**Table 26.5** Clinical presentations of fatty acid oxidation disorders

Enzyme deficiency	Hepatic	Myopathic

SCHAD	X	X
Ketolytic defects	X	

Hepatic presentation – recurrent Reye-like syndrome, hypoglycemia, acidosis; myopathic presentation – hypotonia, recurrent rhabdomyolysis.

LCHAD, long chain 3-hydroxyacyl-CoA dehydrogenase; MCAD, medium chain acyl-CoA dehydrogenase; MTP, microsomal triglyceride transfer protein; SCAD, short chain acyl-CoA dehydrogenase; SCHAD, short chain 3-hydroxyacyl-CoA dehydrogenase; VLCAD, very long chain acyl-CoA dehydrogenase.

present as exercise intolerance and recurrent episodes of rhabdomyolysis and myoglobinuria, often with initial onset during adolescence or adulthood. It is now clear from newborn screening that asymptomatic adults are not uncommon.

### Diagnosis

Hypoketotic hypoglycemia is discussed below. Fatty acid oxidation defects should be sought by studies of urine organic acids and plasma carnitine status in patients with encephalopathy, myopathy, cardiomyopathy, unexplained liver disease or hypoglycemia. These patterns may be diagnostic at all times or only abnormal during metabolic stress. Plasma acylcarnitine or urine acylglycine profiles should also be assessed.

Histologically, microvesicular fat in the liver and myocytes are characteristic of carnitine depletion. Enzyme assays can usually be done on peripheral blood lymphocytes or cultured skin fibroblasts. Some of the defects, such as MCAD or LCHAD deficiency, are associated with common, specific disease-causing mutations. However, negative findings on specific mutation analysis does not rule out these disorders.

### Treatment

Optimal therapy for disorders of fatty acid oxidation is generally based upon anecdotal experience. Avoidance of fasting and the ready provision of nonfat calories during stress, either orally or parenterally, are critical. L-Carnitine (50–300 mg/kg/d orally or 50–100 mg/kg/d i.v.) is given to reverse deficiency and to enhance urinary excretion of toxic acyl-CoA intermediates as carnitine conjugates,<sup>52</sup> but no controlled trials of carnitine supplementation have been published to prove its clinical efficacy. The safety and efficacy of L-carnitine therapy in disorders of long chain fatty acid metabolism remain anecdotal. Carnitine supplementation in acute carnitine deficiency syndromes, such as cardiomyopathy secondary to a defect in the cellular carnitine transporter, can be life saving.<sup>53</sup>

For defects in long chain fatty acid oxidation, dietary long chain fat restriction under the guidance of an experienced nutritionist may be useful, and medium chain triglyceride (MCT) oil is an effective alternative fuel source.<sup>54</sup> Specific nutritional deficiencies, including essential fatty acid deficiency (associated with hair loss, eczema and poor growth), fat soluble vitamin deficiency, vitamin B<sub>12</sub> and iron deficiency, may complicate extreme dietary fat restriction (total energy from fat < 20% of total energy intake); these parameters must be carefully and repeatedly monitored during such dietary therapy.

## SPECIFIC DISORDERS

### Defects in the carnitine cycle

Carnitine derives mostly from the diet and partly from endogenous synthesis. It can be depleted in liver or kidney disease, malnutrition and malabsorption. Low blood levels are usual in premature and neonatal infants and in pregnancy, in which lowered values are probably physiologically normal.

Marked depletion occurs either from renal loss (e.g. Fanconi syndrome – see Ch. 18, p. 550) or increased utilization (e.g. the organic acidemias or valproate therapy). The latter occurs because carnitine accepts any acyl-CoA ester and the resulting acylcarnitine is then excreted. In removing the toxic acyl-CoA esters, the carnitine is lost. In addition, acylcarnitines inhibit the renal reabsorption of free carnitine, aggravating the depletion. In such cases, free carnitine levels are reduced but the acylcarnitine (bound) values are high. It is important to assay both fractions in plasma; an acyl:free ratio above 0.5 is abnormal. All the disorders of carnitine metabolism can be detected by newborn screening (see Appendix 1) and those with liver damage may develop hyperammonemia.

### Carnitine transporter deficiency ('primary carnitine deficiency')

No primary defect of carnitine synthesis is currently known. The term 'primary deficiency' is reserved for a defect in the uptake of

carnitine into cells. Such defects may be pancellular or tissue specific in myocytes, renal tubular cells or, rarely, hepatocytes. Renal tubular losses produce very low plasma values and very high urine levels, resulting in systemic deficiency involving all tissues. Muscle depletion presents with hypotonia or weakness; cardiac depletion causes acute or chronic cardiomyopathy and hepatocellular depletion can cause hepatic steatosis or fulminant Reye syndrome, any of which can be precipitated during stress or minor starvation. In other cases, the plasma levels may be normal but the involved tissues are deficient. L-Carnitine (250–350 mg/kg/d) should be used as replacement therapy.<sup>53</sup>

### Carnitine palmitoyl transferase deficiency I and II

(steps 4 and 5) (~1:500 000)

Deficiency of the liver isoform of CPT-I causes symptomatic fasting hypoketotic hypoglycemia and occasionally hepatocellular damage. Recurrent rhabdomyolysis is the hallmark of deficiency of muscle CPT-I deficiency. In either form, total and free plasma carnitine are characteristically elevated; this observation is unique among all known fatty acid oxidation defects and is otherwise seen only with carnitine supplementation, renal insufficiency or cardiac muscle damage.

In CPT-II deficiency, an infantile form presents with severe hypoglycemia, myopathy and cardiomyopathy leading to death. Plasma carnitine is low with elevated acylcarnitines. A milder form presents with lipid myopathy, recurrent rhabdomyolysis and myoglobinuria in young adults.

*Carnitine/acylcarnitine translocase deficiency* is clinically similar to infantile CPT-II deficiency.

Treatment of these disorders is frequent intake of dextrose or sugary snacks to diminish the need for fat during exercise or stress.

### Medium chain acyl-CoA dehydrogenase deficiency

(MCADD) (step 8) (1:10–20 000)

#### Clinical features

This is the most common defect in fatty acid oxidation. The typical acute presentation includes fasting- or illness-induced hypoketotic hypoglycemia, often associated with metabolic acidosis and hepatocellular dysfunction that can progress to full-blown Reye syndrome. Chronically, cardiomyopathy and/or signs of muscle carnitine depletion such as fatigue, lethargy, weakness or hypotonia can also occur. As with all disorders of fuel-related pathways, these problems are produced or aggravated by poor nutrition or the stress of even a minor illness, and may be recurrent.

The most severe presentation is of sudden death in the first days or months of life, presumably due to occult hypoglycemia. These cases may be mislabeled as sudden infant death syndrome (SIDS), especially if a detailed postmortem examination including metabolic testing is not performed.<sup>55</sup> The risk of sudden infant death can be prevented through avoidance of prolonged fasting, making medium chain acyl-CoA dehydrogenase deficiency an ideal candidate for newborn screening (see Ch. 4), although death can occur soon after birth before screening results are available.

Some individuals with MCADD may never become symptomatic, presumably because they never develop carnitine depletion under sufficient stress or because they carry mutations with relatively mild physiological effects. It is important to note however that the initial presentation of MCADD may occur in adolescence or even adulthood.

#### Diagnosis

Characteristic medium chain fatty acid metabolites, acylglycine and acylcarnitine conjugates, are present in urine or blood. Fatty acid metabolites are often detected by urine organic acid analysis, especially during acute crises, but may be normal between episodes. Analysis of acylcarnitine conjugates is more sensitive and is often diagnostic even between clinical episodes. Newborn screening using tandem mass spectrometry is now being increasingly used.

Of patients presenting clinically, 80–90% are homozygous for an A985G mutation in the MCAD gene, but the frequency of this mutation is lower in cases detected by newborn screening, suggesting that other mutations may be associated with mild or subclinical disease.<sup>56</sup> Whether phenotype can be accurately predicted from genotype is still under evaluation.

### Defects of long chain fatty acid oxidation

A trifunctional enzyme comprises *long-chain 3-hydroxy-acyl-CoA dehydrogenase (LCHAD)*, enoyl-CoA hydratase and thiolase activities, the so-called trifunctional protein (TFP). LCHAD deficiency (step 11) appears to be the second most common fatty acid oxidation defect and is frequently caused by homozygosity for a G1528C mutation in the TFP alpha subunit gene. Cases with other mutations in either the alpha or beta TFP subunit genes often exhibit deficiency of all three enzymatic activities; this may alter both the pattern of diagnostic metabolites and the clinical presentation. Long chain hydroxy acids may be detectable by urine organic acid analysis during acute metabolic crises, but as in MCADD, analysis to detect long chain 3-hydroxylated carnitine esters is often more sensitive.

In LCHAD/TFP deficiency and in *very long chain acyl-CoA dehydrogenase deficiency (VLCADD)* (step 7), the clinical features are often similar to, but more severe than, MCADD. Older patients may develop late-onset cardiomyopathy or myopathy with recurrent myoglobinuria, and patients are generally carnitine deficient. Pigmentary retinopathy and vision loss during childhood is a complication specific to LCHAD/TFP deficiency. In addition to fasting avoidance and ingestion of a fat-restricted diet, treatment with dietary MCT oil and L-carnitine may be beneficial.<sup>54</sup> Acute fatty liver of pregnancy or the 'HELLP' syndrome occurs in many women who carry LCHAD deficient fetuses;<sup>57</sup> the pathophysiological mechanism of this complication is currently unknown.

### Defects of short chain fatty acid oxidation

These include defects of *short chain acyl-CoA dehydrogenase (SCADD)* (step 9), *short chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD)*<sup>58</sup> and *malonyl-CoA decarboxylase*. These disorders tend to cause failure to thrive, recurrent vomiting with or without hypoglycemia and/or ketosis, hypotonia, marked developmental delay, seizures and early demise. The urine organic acid profiles tend to suggest the site of the defects but confirmation requires detailed studies in fibroblasts or other tissues.

Many individuals with clinical symptoms and biochemical evidence of SCADD have inherited variations in the SCAD gene that are also common in the normal population. In one study, 69% of 133 patients with biochemical findings of SCADD were either homozygous for a single mutation or were compound heterozygous for two different SCAD polymorphisms (G625C or C511T); yet 14% of the general population also carry these polymorphisms.<sup>59</sup> So, the exact pathophysiological relationship between the presence of these polymorphisms and clinical disease is not clear. All of these disorders are detectable by expanded newborn screening (see Appendix 1).

### Glycerol kinase deficiency

Glycerol derives from hydrolysis of fats and, reversibly, from glycolysis, making it available for gluconeogenesis. Glycerol kinase deficiency causes recurrent attacks of a Reye-like syndrome with vomiting, acidemia, CNS depression and hypotonia that are precipitated by a high fat intake or fasting. Milder cases are found by chance with pseudohypertriglyceridemia on routine multichannel blood testing. It also can be part of an X chromosome microdeletion syndrome that can include Duchenne muscular dystrophy, retinopathy and adrenal hypoplasia, which usually dominates the clinical picture; note that glycerol in urine may derive from body lotions or suppositories. Frequent high carbohydrate feeding with mild fat restriction is indicated.

*Glycerol intolerance* is a different condition associated with recurrent hypoglycemia and Reye-like attacks that may actually be a manifestation of fructose-1, 6-diphosphatase deficiency.<sup>60</sup>

### Multiple acyl-CoA dehydrogenase deficiency

This comprises several different disorders that are all associated with a defect in the entry of electrons into the electron transport chain (see Fig. 26.19). All affect the handling of reducing equivalents generated from the catabolism of several amino acids and by numerous different acyl-CoA dehydrogenases, hence the name multiple acyl-CoA dehydrogenase deficiency. Defects of transport, processing or binding of FAD (Fig. 26.10) (step 13), ETF (step 14) or the ETF:QO (step 15) are all possible. Three forms are generally recognized with clinical overlap between groups and genetic heterogeneity within each group.

The severe form (MAD:S), also called *glutaric aciduria type II*, is often lethal in the newborn period, secondary to profound acidosis, hypoglycemia, coma and multiple organ system involvement. A subgroup of these patients exhibits dysmorphic facial and other features, characteristic subependymal brain cysts, dysmyelination of brain and polycystic kidneys. Milder cases lack dysmorphism but usually exhibit severe failure to thrive, hypotonia, cardiomyopathy and liver damage. An unusual 'acid' odor and the 'sweaty feet' odor of isovaleric acid are often described. The biochemical profile on urine organic acid analysis is generally diagnostic, with accumulation of ethylmalonic, glutaric, 2-hydroxyglutaric, adipic, suberic and sebacic acids, isovaleryl-, isobutyryl- and 2-methylbutyrylglycines, with sarcosine often detected by urine amino acid screen.

A milder form of the disorder termed MAD:M (sometimes called *ethylmalonic-adipic aciduria*) may not present until adulthood; the presentation being similar to other acyl-CoA dehydrogenase deficiencies. The urine organic acid profile is simpler than in MAD:S, usually containing only ethylmalonic, adipic and methylsuccinic acids and hexanoyl and butyrylglycines. Dicarboxylic acids are abundant and sometimes disappear following riboflavin supplementation, giving rise to the original term riboflavin-responsive dicarboxylic aciduria. A similar metabolite pattern may also be seen in isolated SCADD and is often detected by newborn screening (Ch. 4).

Defects of both ETF and ETF:QO dehydrogenase have been found in both forms of MAD. Generally, the severity of the enzyme deficiency correlates with the severity or type of disorder. Some of these patients improve on riboflavin (100–300 mg/d) and carnitine (100–200 mg/kg/d).<sup>61</sup>

### Disorders of ketone metabolism

#### 3-Hydroxy-3-methylglutaric aciduria

The last steps of leucine catabolism are mitochondrial *3-hydroxy-3-methylglutaryl-CoA synthase* and *lyase* which are essential to the formation of the ketone bodies acetoacetyl-CoA and acetyl-CoA. Defective function of these enzymes is characterized by *hypoketotic hypoglycemia* as well as metabolic acidosis. The disease is particularly likely to be mistaken for Reye syndrome (Ch. 22, p. 875).

In the cytosol, *3-hydroxy-3-methylglutaryl-CoA synthase* reverses this reaction and *3-hydroxy-3-methylglutaryl-CoA reductase*, the enzyme inhibited by statin drugs, is the next and rate-limiting step in cholesterol synthesis (see p. 1090).

#### Clinical findings

Patients deficient in the mitochondrial synthase or the lyase have acute episodes of life threatening illness in early infancy, often with persistent vomiting as the first symptom. Coma and dehydration may lead to apnea and death. Seizures, hepatomegaly, elevated liver enzymes, metabolic acidosis, hypoglycemia and hyperammonemia can occur. Acute episodes, reminiscent of Reye syndrome, are likely to follow an acute infectious illness and may be followed by mental retardation, neurological abnormalities and cerebral atrophy.

#### Diagnosis

Concentrations of glucose may be strikingly low, but ketonuria is absent, and this distinguishes these patients from most others with organic acidemias. Liver function tests may be abnormal at times of acute illness. The organic aciduria is characteristic; in addition to large quantities of 3-hydroxy-3-methylglutaric acid, the urine contains 3-methylglutamic acid, 3-methylglutaric acid and 3-hydroxyisovaleric acid. During illness, the urine may also contain large amounts of lactic acid.

**Treatment.** Parents should be alerted to the need for early, vigorous management of the acute crises, especially when the oral route is compromised by fasting or anorexia. Long term management depends on the avoidance of fasting and hypoglycemia. A high carbohydrate diet is useful, and the intake of both fat (ketone precursors) and protein should be limited. L-Carnitine has limited usefulness, because 3-hydroxy-3-methylglutaric acid does not form carnitine conjugates.

## Defects of ketone utilization

### 3-Ketothiolase deficiency

Defects of ketone utilization cause facile hyperketosis; they include deficiencies of *succinyl-CoA:3-ketoacid-CoA transferase*, *2-methylacetoacetyl-CoA thiolase* or of several different enzymes with *3-ketothiolase* activity (step 12). *Mitochondrial acetoacetyl-CoA thiolase* is an enzyme in the isoleucine pathway that converts 2-methylacetoacetyl-CoA to propionyl-CoA and acetyl-CoA.

All can present with severe neonatal acidosis, intermittent episodes of ketoacidosis with lethargy and coma, or may be asymptomatic. Developmental delay and episodes of diarrhea may occur. Mitochondrial acetoacetyl-CoA thiolase is associated with progressive neurological deterioration, neuropathy and an extrapyramidal movement disorder. Hypoglycemia, ketotic hyperglycinemia and hyperammonemia are reported.

The urine contains 2-methyl-3-hydroxybutyric acid, tiglylglycine, 2-methylacetoacetic acid and other organic acids and butanone. Acetoacetic and beta-hydroxybutyric acids can be greatly elevated, and the differential diagnosis must include acquired ketotic hypoglycemia (see below), as well as salicylism. Lactic acidosis with abnormal lactate:pyruvate ratios and increased ketone body levels are usual. Continued elevation of diagnostic metabolites between ketotic episodes strongly suggests the diagnosis. The enzyme defect can be demonstrated in cultured skin fibroblasts.

Treatment for these disorders is again based primarily upon avoidance of fasting.

## Hypoglycemia as a presenting feature of metabolic disorders

Hypoglycemia is often considered the purview of endocrinologists since changing rates of glucose consumption are balanced by intricate hormonal controls and the coordinated release of fuels from glycogen, fat or protein. Metabolic causes should never be forgotten; often, hepatomegaly or acidosis suggests a metabolic diagnosis but evaluation of hypoglycemia may require extensive metabolic testing. The half-life of metabolic fuels in the plasma is about 100 secs, so, as with hormone assays, tests for high or low levels of ketones, free fatty acids, amino acids, carnitine and its conjugates, and possibly glycerol *must be obtained during hypoglycemia (< 2.2 mmol/L [40 mg/dl]) and before any treatment has been given.* Urine organic acids and acylcarnitine analyses can be diagnostic. Hyper- or hypo-ketosis is often not recognized because quantitative assays are not readily available. If these tests are not diagnostic, then starvation/fasting stress tests can be used to recreate an acute hypoglycemic episode but should only be performed in hospital with full emergency support and expert consultation available.<sup>62</sup>

## Hypoglycemia with ketosis and/or acidosis

Ketotic hypoglycemia occurs frequently in small undergrown infants and children. Most cases are due to poor growth, poor nutrition with inadequate and/or infrequent feeding, but symptoms can sometimes occur even in apparently healthy, well fed infants. Lack of glycogen stores and of muscle protein for gluconeogenesis necessitates increased lipolysis. As a result, fatty acid intermediates and ketones readily accumulate in patterns that mimic hereditary defects of fuel homeostasis. In nutritional deprivation or hormonal problems, plasma alanine and lactate are low and there is no response to intramuscular glucagon. The differential diagnosis includes glycogen storage disorders and defects of ketone utilization, pyruvate, the citric acid cycle and organic acid metabolism.

## Hypoketotic hypoglycemia

Hypoglycemia with inappropriately low levels of blood ketones suggests a defect of fatty acid oxidation or of ketone production; it is also typical in hyperinsulinism. Quantitation of serum free fatty acids during a hypoglycemic episode assists with the differential diagnosis; free fatty acid levels are suppressed in hyperinsulinism while they are elevated in fatty acid oxidation disorders.

## DISORDERS OF CARBOHYDRATE METABOLISM

The hereditary disorders of digestion and absorption, including *lactase*, *sucrose-isomaltase*, *trehalase* and *glucose-galactose malabsorption* are addressed in Chapter 19 (p. 621).

In the kidneys, renal glycosuria is caused by a defect in glucose reabsorption. Pentosuria is a benign condition, most common in Jewish people due to deficient *L-xylulose reductase* activity; xylulose is excreted in the urine where it reacts with Benedict's solution or Clinitest to give a false positive test for glucose.

## DEFECTS OF GLYCOLYSIS (FIG. 26.11)

### In erythrocytes

Severe defects of glycolysis in erythrocytes are usually associated with hemolytic anemia (Ch. 23). Such conditions include defects of *glucose-6-phosphate dehydrogenase*, *hexokinase* (step 2), *glucosephosphate isomerase* (step 4), *phosphofructokinase* (step 5), *aldolase triose phosphate isomerase (TPI)* (step 7), *phosphoglycerate kinase (PGK)* (step 9), *diphosphoglycerate mutase* (step 10), *pyruvate kinase* (step 12) and *lactate dehydrogenase*. In contrast, deficiency of either *2,3-diphosphoglycerate (DPG) mutase* or *diphosphoglycerate phosphatase* causes mild erythrocytosis. Hemolysis can also be caused by defects of glutathione metabolism (see p. 1057) and certain steps in purine and pyrimidine metabolism (see p. 1122) and *adenosine triphosphatase*. Another red cell enzymopathy is a deficiency of *6-phosphogluconate dehydrogenase* in the pentose monophosphate shunt. Finally, *cytochrome b<sub>5</sub> reductase* deficiency is often associated with methemoglobinemia and developmental delay.

### In the nervous system

Several of these disorders also cause neurological or muscular disease. Severe TPI deficiency is associated with severe, progressive neurological disease with both upper and lower motor neurone damage. The intellect is relatively well preserved but there is a tendency to sudden death and increased susceptibility to infection. Severe PGK deficiency can cause developmental delay and attacks of behavioral and emotional abnormalities, movement disorders including hemiplegia and even coma that develop during hemolytic crises. *Glutathione reductase* deficiency can also cause a variety of neurological abnormalities, including myelopathy. About 15% of cases with cytochrome b<sub>5</sub> reductase deficiency have severe progressive neurological deterioration with microcephaly, athetosis and hypertonia in addition to methemoglobinemia. In all of these disorders, management of these neurological symptoms is unsatisfactory but should include avoidance of oxidant drugs.

### In muscle – the metabolic myopathies (see also p. 1088)

There is a large and growing number of metabolic myopathies, almost all of which involve energy metabolism. Since several are glycolytic disorders, the whole group is summarized here (Table 26.6).

### Clinical features

The usual symptoms are muscle weakness, lack of endurance and post-exercise muscle pain or cramps. Infants are often hypotonic. Muscle wasting, when present, is often due to disuse rather than to the intrinsic muscle disease. Disorders associated with lactic acidosis are characterized by exercise-induced dyspnea. In glycolytic or fatty acid defects, excessive exercise leads to severe cramping and rhabdomyolysis with increased serum creatine phosphokinase (CPK) levels and recurrent myoglobinuria that can cause severe renal damage. These diseases may

Fig. 26.11 Embden-Meyerhof glycolytic pathway. 1, Hexokinase; 2, glucose-6-phosphatase; 3, phosphoglucomutase; 4, phosphohexose isomerase; 5, phosphofruktokinase; 6, fructose-1,6-bisphosphatase; 7, triose phosphate isomerase; 8, glyceraldehyde-3-phosphate dehydrogenase; 9, phosphoglycerate kinase; 10, phosphoglyceromutase; 11, enolase; 12, pyruvate kinase; 13, pyruvate carboxylase; 14, phosphoenolpyruvate carboxykinase.

be aggravated by fasting or a high fat diet and tend to present in adolescence or later. Curiously, the disorders of the electron transport chain, which may occur at any age, are rarely associated with myoglobinuria, perhaps because the dyspnea from lactic acidosis is so marked that exercise capacity is too limited to result in much muscle cell damage.

*Myoadenylate deaminase* is an enzyme of the purine pathway (p. 1123). Deficiency is found by histochemical staining in 1–2% of muscle biopsies. It is frequently asymptomatic but can cause a variety of muscular symptoms.

### Diagnosis

Nonspecific complaints of muscle weakness, lack of endurance or muscle cramps are very common and only 10–20% of such cases prove to have a real muscle disorder. Real cases are often not detected or evaluated for years or until a crisis such as rhabdomyolysis develops. The differential diagnosis includes both cardiovascular and respiratory disease as well as a psychogenic disorder. The key to the diagnosis is in the history and consideration of its veracity regarding the symptoms and their effects upon daily life. Physical signs including muscle wasting or hypertrophy and muscle weakness are supportive of the diagnosis, but their absence does not preclude a metabolic defect. Elevation of serum CPK levels and myoglobinuria indicate ongoing rhabdomyolysis; blood electrolyte abnormalities or lactic acidosis may suggest specific defects.

Table 26.6 Metabolic myopathies

#### Glycogen storage diseases (GSDs)

- Acid maltase deficiency (GSD type II)
- Glycogen debrancher deficiency (III)
- Glycogen brancher deficiency (IV)
- Phosphorylase deficiency (V)

#### Glycolytic defects

- Phosphofruktokinase
- Phosphoglycerate kinase
- Phosphoglycerate mutase
- Glucosephosphate isomerase
- Lactate dehydrogenase
- Lactate transporter

#### Fatty acid oxidation disorders

- Long chain fatty acid oxidation disorders (VLCAD, LCHAD/TFP deficiency)
- Carnitine palmitoyl transferase deficiency
- Secondary carnitine depletion

#### Purine disorders

- Myoadenylate deaminase deficiency

#### Mitochondrial defects

- Defects in respiratory chain complexes I–IV
- Luft syndrome (complex V – ATPase deficiency)
- Krebs cycle defects
- Adenine nucleotide translocase defect
- Pyruvate dehydrogenase deficiency
- Defect in the malate–aspartate shuttle

#### Others

- Ion channelopathies
- Periodic paralyses (hypo- or hyper-kalemic)
- Malignant hyperthermia

LCHAD, long chain 3-hydroxyacyl-CoA dehydrogenase; TFP, trifunctional protein; VLCAD, very long chain acyl-CoA dehydrogenase.

Metabolic screening with plasma amino acid analysis, plasma carnitine levels, plasma acylcarnitine profile and urine organic acid analysis may also yield the diagnosis.

Blood lactate and ammonia, inosine and hypoxanthine (from the purine nucleotide cycle) normally rise after exercise but in many metabolic myopathies this is not so. A semi-ischemic forearm exercise test may provide useful information. In some of the glycogen storage diseases and mitochondrial defects, the lactate rises very fast and limits the duration of the test. In glycogenolytic defects, lactate and ammonia should rise abnormally and in glycolytic lesions, ammonia and purines rise but the lactate does not; in myoadenylate deaminase deficiency, the ammonia, inosine and hypoxanthine do not rise normally.

The test is carried out as follows: a blood pressure cuff is inflated above systolic pressure. A handgrip is formed and opened every second for 1 min. Prior to and for eight 1 min intervals after starting the exercise, venous blood is collected for assay of lactate, ammonia and hypoxanthine. Other physiological measurements of muscle function including electromyography (EMG), or treadmill exercise test, may assist with the diagnosis and help assess exercise tolerance but should be done with caution in these patients.

Before a muscle biopsy is performed, it is essential to plan for the tests that might be required, including histochemistry, electron microscopy, isolation of mitochondria, biochemical analyses, immunohistochemistry and DNA studies, because processing of the tissue varies for different studies and in different laboratories. For example, immediate flash freezing is essential for glycogen quantitation, enzyme assays require fresh tissue or flash freezing while preparation for histochemistry and electron microscopy varies upon the laboratory. Glycogen content is often increased in the glycogen storage diseases, the glycolytic defects and frequently in electron transport defects. The lipid content is usually increased in the lipid disorders and often in electron transport

chain defects. Muscle biopsy for mitochondrial disease is discussed on p. 1088.

In some research laboratories, intracellular levels of ATP, phosphocreatine and phosphate are measured *in vivo* by  $^{31}\text{P}$ -NMR spectroscopy; this technique may be used to detect defects of energy generation and to monitor the effects of treatment

### Treatment

This is usually restricted to limiting exercise which should be stopped before symptoms are provoked. Mild aerobic exercise can be encouraged<sup>63</sup> but rigorous training may be dangerous. In glycolytic and fatty acid disorders, 'carbo loading' may be useful and continuous intake of glucose during exercise is helpful; fasting and high fat diets should be avoided, especially before exercise. Anecdotal reports suggest that carnitine therapy (50–100 mg/kg/d) may help prevent rhabdomyolysis in certain fatty acid oxidation defects such as VLCAD deficiency. Dietary supplementation with MCT oil provides a fuel source that bypasses the block in long chain fatty acid oxidation disorders and may also improve exercise intolerance.<sup>64</sup>

## DEFECTS IN GALACTOSE METABOLISM

The main source of dietary galactose is lactose (glucose–galactose disaccharide), the predominant carbohydrate in milk and most milk-based infant formulae, in which it provides a considerable amount of energy. Galactose is metabolized for energy mainly in the liver, but must first be converted to glucose. Other tissues, such as erythrocytes, can metabolize galactose too, which provides a means to screen for galactose problems in the newborn. The metabolic pathway of galactose is depicted in Figure 26.12. Three metabolic errors are known.

### Galactose-1-phosphate uridyltransferase deficiency (galactosemia) (step 2)

#### Clinical features

Infants with severe transferase deficiency become sick soon after beginning to ingest milk. The severity of the presentation depends on the quantity of milk ingested (breast milk contains more lactose than milk-based formulae) and the presence of residual transferase activity in liver. Severe cases mimic sepsis and many do develop Gram negative (especially *Escherichia coli*) or beta-streptococcal sepsis. Prior to the availability of newborn screening and in areas where newborn screening for galactosemia is not routine, many transferase-deficient infants die from sepsis and/or liver failure without the diagnosis being entertained, with the true cause of the infant's death not being revealed until the disease recurs in a subsequent sibling.

Typically, transferase-deficient infants present within a few days after birth with vomiting, diarrhea, failure to thrive and persistent jaundice. Hepatosplenomegaly, progressive liver dysfunction, hypoglycemia, anemia, coagulopathy with purpura and deficient clotting factors, and the biochemical findings of the renal Fanconi syndrome (see Ch. 18, p. 550) are typical. Cataracts may be evident at birth or appear

soon after. Edema, ascites, malnutrition, cachexia and septicemia usually presage a fatal outcome from hepatic failure within a few weeks if the condition is not treated. Mental retardation and behavioral abnormalities develop in the absence of treatment if the disease has a more protracted course. When residual enzyme activity is present, or with poor control, the course is less catastrophic, with failure to thrive and cataracts being the major features.

The acute abnormalities are rapidly corrected by complete elimination of galactose from the diet.<sup>65</sup> With treatment, the cataracts and even the cirrhosis reverse. However, long term complications are frequent, regardless of how early or how well the infant is treated. Overall, there is a slight reduction in intelligence and visual perceptual skills; 50% have dyspraxic speech, and hypergonadotrophic hypogonadism with ovarian failure and often sterility occurs in approximately 80% of females. The causes of these late complications are unknown but probably prenatal.<sup>65</sup> Testicular function is unaffected.

### Diagnosis

The simplest screening test is examination of the urine for reducing sugars (Clinitest) performed 24–36 h after the start of lactose-containing feeds. This test, however, is neither completely sensitive nor specific. If the infant is feeding poorly, there may be no galactose in the urine. In addition, other reducing substances, such as antibiotics, may cause a false positive Clinitest reaction. It must be noted that dipstick tests for 'sugar' in urine specifically detect glucose and do not react with galactose.

Newborn screening tests (see Ch. 4) for blood galactose, galactose metabolites or erythrocyte transferase enzyme activity (Beutler test) are in wide use, but often the results are only available after symptoms have already developed. The metabolite galactose-1-phosphate (gal-1-P) is markedly elevated even in cord blood, enabling early detection in high-risk infants. Vomiting or the use of nonlactose formulae may obscure the diagnosis and blood transfusion or exchange transfusion negate the erythrocyte assays for gal-1-P and the enzyme. Clinical suspicion, even without supporting lab results, is enough reason to initiate treatment and for quantitative assays of erythrocyte galactose metabolites, enzyme assays or mutation analysis. Galactose tolerance tests should never be undertaken if the diagnosis is suspected.

The most obvious histological changes occur in the liver. There is fatty infiltration, fibrosis, bile duct proliferation and pseudoacinar arrangement of hepatic cells. The renal changes consist of widening of the proximal tubules and alterations of the tubular epithelium.

Transferase activity can be assayed in erythrocytes, cultured fibroblasts and chorionic villi.

### Variants

There are many variants with lesser deficiencies of enzyme activity. The commonest is the Duarte mutation; 1 in 25 people are carriers and they have about 75% of normal enzyme activity. Duarte homozygotes have about 50% and Duarte/classical compound heterozygotes (who carry one Duarte and one galactosemia allele) have about 10–25% activity. Such cases often, but not invariably, have elevated blood gal-1-P and are often detected by routine newborn screening. If they drink lactose-containing formula or breast milk, gal-1-P remains high for months but gradually falls to normal as lactose becomes a smaller portion of total energy intake.

There is no evidence that the gal-1-P or other galactose metabolites are toxic in these cases or that there is any risk for any of the long or short term complications of classical galactosemia, and opinion is divided as to whether galactose restriction should be recommended. Some authorities recommend nonlactose formula for the first year; others allow partial breast-feeding, while still others allow lactose intake to continue unrestricted. Often, clinical practice in this matter seems to be guided by medicolegal concerns.

Several other known mutations cause partial transferase deficiency and are associated either with mild galactosemia or are entirely asymptomatic. A specific mutation common to blacks is associated with complete transferase deficiency in erythrocytes but 10% normal activity in the liver and intestine and a mild phenotype.

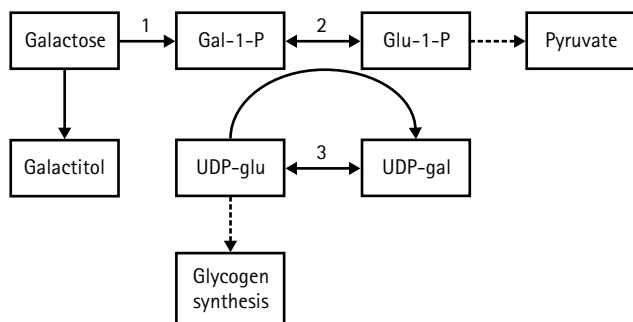

Fig. 26.12 Galactose metabolism. 1, galactokinase; 2, galactose 1-phosphate uridyltransferase; 3, uridine diphosphate galactose 4-epimerase.

### Treatment

In infants with the full-blown disease (i.e. complete transferase deficiency), elimination of dietary galactose corrects all of the acute problems within a few days if treatment is begun soon enough to prevent irreversible complications. Soy milk (which contains galactose but in a nonbioavailable form) or synthetic formulae, which do not contain lactose, are used. On the diet, weight gain ensues, residual liver damage is rare and usually the cataracts resolve.<sup>64</sup>

Without question, the diet should be strictly followed for the first several years. It is less clear how important strict galactose restriction is for older children. Some authorities believe that the diet requires life-long meticulous attention to detail, but the occurrence of long term complications from galactosemia, including speech dyspraxia, tremor, ataxia and seizures, does not correlate with dietary galactose exposure.<sup>66</sup> Once solid foods are introduced, it becomes more difficult to offer a truly galactose-free diet. Many foods contain unlabeled lactose and even many fruits and vegetables contain galactose largely in the form of complex saccharides (fiber) that, for the most part, are not bioavailable; the overall contribution of galactose from these sources is unknown. In general, the list of foods to be avoided includes dairy products, some breads, sausage and candies which contain lactose, and other food products that list whey, casein or caseinates, or milk solids as ingredients. Also, some medications may contain lactose. Such diets are very restrictive and can lead to eating disorders and serious parental anxiety.

With the evidence that individuals with galactosemia synthesize significant quantities of galactose metabolites (see below), other authorities now believe that, after childhood, obsessive adherence is unnecessary and small quantities of galactose are safe, although deliberate and continuous high exposure is clearly contraindicated. Adults can tolerate small quantities of galactose without acute symptoms or obvious biochemical abnormalities; the long term safety of this is not known and some restrictions are clearly needed until further studies have been performed. Some children on a relaxed regimen show deteriorating school performance and behavior problems. Life-long galactose restriction remains the standard of care.

Because cataracts may be present at birth, cord blood gal-1-P is often markedly elevated and because gal-1-P may also be increased in the mother's blood, prenatal restriction of galactose has been attempted. However, this seems to have no effect upon the long term outcome.<sup>67</sup> Heterozygote offspring of properly treated homozygous mothers appear to be completely normal.

### Self-intoxication

About 12–24 mg/kg/d galactose is synthesized by these patients;<sup>68</sup> some galactose is essential for the synthesis of galactolipids and galactoproteins. Moreover, lactose is synthesized normally in the milk of a lactating galactosemic mother. It is not surprising that, even with the use of strict galactose-free diets or parenteral nutrition, gal-1-P remains elevated in the blood of classical galactosemics. Galactose ingestion certainly raises the erythrocyte gal-1-P further and this test is still used to monitor diet compliance; in view of the dual sources, elevated values may be misinterpreted.

Galactitol from free galactose is the likely cause of cataracts. The cause of the acute and long term complications is not known; they have been attributed to gal-1-P toxicity but, by inference from the variants, this seems unlikely. It appears likely that they are largely determined prenatally.

### Galactokinase deficiency

As soon as galactose is consumed by individuals with galactokinase deficiency, it accumulates in the blood and urine; some is reduced to the polyol galactitol that causes cataracts because of osmotic swelling and disruption of lens fibers. Gal-1-P and UDP-galactose (UDP-gal) levels are normal and cataract is the only clinical abnormality directly related to the enzyme defect. Fetuses of affected females may also develop cataracts, as may heterozygotes in later life. A galactose-free diet is indicated and should be continued for life. Early treatment prevents cataracts or

arrests their further increase. A similar diet has been proposed for heterozygotes but no long term studies have been reported. Prenatal diagnosis is possible

### Uridine diphosphate galactose-4-epimerase deficiency

This disorder occurs in two forms: one confined only to erythrocytes, the second being generalized, affecting the liver as well. The former is completely symptomless and needs no treatment. Generalized epimerase deficiency is clinically similar to transferase deficiency and galactose, gal-1-P and UDP-gal increase after galactose consumption. Dietary galactose restriction is followed by a drop of all three metabolites in the blood. UDP-gal is a critical substrate for the production of sphingolipids for the brain and dietary intake of approximately 1.5–2 g galactose/d is thought to be necessary to meet the requirement of UDP-gal while simultaneously preventing gal-1-P accumulation.

### DEFECTS IN FRUCTOSE METABOLISM (FIG. 26.13)

The main dietary sources of fructose are fruits, fruit juices, vegetables, potatoes, honey and all products that contain sucrose (fructose–glucose). Sorbitol, an artificial sweetener, is oxidized by the enzyme sorbitol dehydrogenase to fructose.

### Fructose-1-phosphate aldolase deficiency (hereditary fructose intolerance) (step 2)

There are three aldolase isozymes, A, B and C, each with specific properties and tissue localization. In this condition, aldolase B is deficient; it is localized in liver, intestine and kidneys and normally cleaves fructose-1-phosphate (F-1-P) and fructose-1,6-diphosphate (F-1,6-P) into two trioses. These trioses are then substrates either for glycolysis or

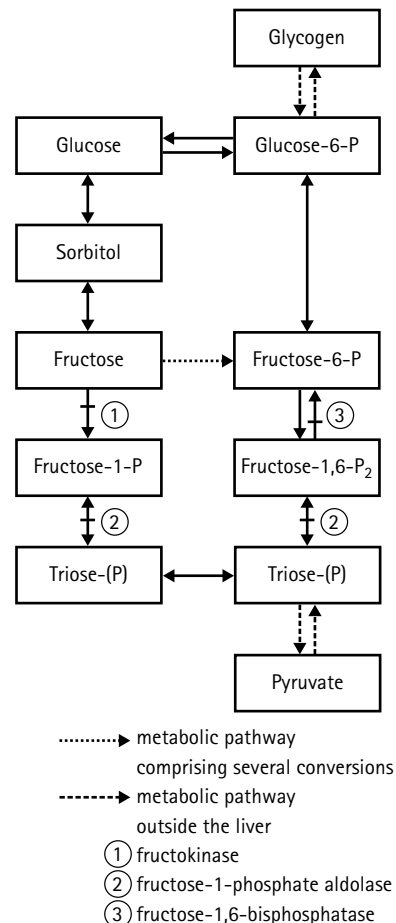

Fig. 26.13 Metabolism of fructose.

gluconeogenesis. In hereditary fructose intolerance, F-1-P accumulates as soon as the patient ingests fructose; it is very toxic and it inhibits several enzymes of glycogenolysis and gluconeogenesis, causing rapid and profound hypoglycemia. Furthermore, the intracellular supply of phosphate is sequestered as F-1-P which prevents the regeneration of ATP from ADP. Under these conditions, ADP is dephosphorylated to AMP and then further metabolized to uric acid.

### Clinical features

Symptoms develop at the very first introduction of fruit or fructose containing infant formula (some soy formulae contain fructose), or when honey is misused as a pacifier. This usually occurs during weaning, since breast milk and most infant formulae do not contain fructose. Acute symptoms include vomiting, diaphoresis, tremor, lethargy, convulsions and other manifestations associated with hypoglycemia. Chronic exposure to fructose leads to progressive liver damage with anorexia, failure to thrive, jaundice, hepatomegaly, splenomegaly, ascites, edema and hemorrhage. Aversion to sweets develops early in life and, by avoiding sweetened foods, most patients, if they survive infancy, unknowingly protect themselves from the toxic effects of fructose. Occasionally the condition is only diagnosed in adult life. Remarkably, the teeth often remain free of caries.

### Diagnosis

Fructosemia is easy to diagnose if the feeding history is carefully obtained. Metabolic abnormalities following acute fructose ingestion include hypoglycemia, hypophosphatemia, hyperuricemia and hypermagnesemia. Chronic ingestion is associated with all the manifestations of renal Fanconi syndrome (see Ch. 18) and markedly abnormal liver function tests often with increased levels of some amino acids such as tyrosine and methionine. Absence of these findings in a patient with fructose avoidance behavior does not eliminate the diagnosis. Liver biopsy, during acute or chronic fructose ingestion, shows extensive abnormalities, including focal areas of necrosis, fatty degeneration, proliferation of bile ducts, formation of pseudoacini and ultimately biliary cirrhosis.

The presence of a reducing sugar in urine following fructose ingestion is an important clue. When the diagnosis is suspected but not proven, DNA analysis can be definitive. More than 80% of individuals of European descent with hereditary fructose intolerance can be identified by DNA analysis for a small set of common mutations.<sup>69</sup> However, most laboratories only test for specific mutations.

In this disease, a fructose tolerance test can be dangerous and even fatal. If it is deemed absolutely necessary, the test should be executed in hospital with full medical support available, under the guidance of a metabolic specialist and only when the patient is clinically stable. A positive test is signaled by a rise of at least 50% in serum uric acid and a drop of 40–50% in the serum glucose and phosphate. In unclear cases, enzymatic assay of a liver biopsy may be necessary.

### Treatment

All dietary sources of fructose must be strictly eliminated; this includes fruits, fruit juices, vegetables, potatoes, honey and all products that contain sucrose (fructose–glucose) or sorbitol. This diet prevents all abnormalities and restores liver and kidney function to normal, except in cases of severe liver failure. The effects of the treatment are influenced by the age of the patient, the amount and duration of fructose ingestion and the residual aldolase B activity. Young infants are most susceptible to life threatening fructose toxicity. In older children, even small amounts of fructose can elicit symptoms, and continued exposure to small amounts, although insufficient to cause acute symptoms, may cause growth retardation. Successful treatment requires detailed knowledge of the fructose content of all foods.

### Fructose-1,6-diphosphatase deficiency (step 3)

This enzyme is one of the unidirectional enzymes in the pathway of gluconeogenesis and is also important for the conversion of fructose into

glucose. Fasting, fructose ingestion or metabolic stress lead to hypoglycemia and increased protein and fat catabolism, resulting in the accumulation of lactate, pyruvate, alanine, ketone bodies and glycerol.

### Clinical features

The symptoms of this disorder are similar to those of fructosemia or type 1 glycogen storage disease. They may develop in the neonatal period or later, provoked by insufficient food intake. Dietary sugar ingestion is usually not the inciting event precipitating metabolic crisis, as these patients are not nearly as sensitive to fructose as are those with hereditary fructose intolerance. Fulminating lactic acidosis and hypoglycemia can lead to hyperventilation, hypotonia, hepatomegaly, nausea, vomiting, lethargy and convulsions. Liver and kidney function may deteriorate and the course may be either severe and rapidly fatal or episodic, being exacerbated during acute metabolic stress. Hepatomegaly is often present.

### Diagnosis

Hypoglycemia and lactic acidosis together with or without evidence of liver dysfunction demand metabolic investigation. Characteristically, glycerol and glycerol-3-phosphate accumulate during hypoglycemia and are excreted in the urine. These metabolites derive from excessive proteolysis and fatty acid oxidation that increase to compensate for the lack of glucose. The lactic acidosis can be profound and recalcitrant to therapy. Liver histology may show fatty degeneration and fibrosis and the renal Fanconi syndrome may be apparent. All these are reminiscent of type 1 glycogen storage disease. A fasting test might elicit the above symptoms. Fasting fructose or glycerol stress tests are not without risk, and should be avoided in most cases. Definitive diagnosis requires enzyme assay of leukocytes or liver biopsy tissue but the leukocyte assay is fraught with difficulties.

### Treatment

Treatment consists of frequent meals and the restriction, but not total elimination, of fructose, sucrose and sorbitol intake. Prolonged fasting must be avoided and early and aggressive treatment with i.v. glucose and bicarbonate may be necessary during infections.

### Other disorders of fructose metabolism

In *fructokinase* deficiency (essential fructosuria) (step 1), fructose metabolism is blocked in the liver, intestine and kidney, and fructose levels in blood and urine rise if the patient consumes fructose. The condition is benign. Fructose malabsorption is reasonably common and is associated with fermentative diarrhea following quite modest fructose ingestion.

A defect of *aldolase A*, detectable in fibroblasts, is associated with nonspherocytic hemolytic anemia; some cases have had microcephaly and dysmorphic features.

## DEFECTS IN GLYCOGEN METABOLISM: GLYCOGEN STORAGE DISORDERS AND ALLIED DISEASES

Several inherited enzyme defects interfere with the metabolism of glycogen. Defects in glycogen synthesis severely limit glycogen storage and are associated with postprandial hyperglycemia followed by rebound fasting hypoglycemia. Defects in degradation often raise the glycogen content of the organ in which the enzyme is normally localized, causing local tissue dysfunction. Glycogen is a giant polysaccharide that is stored mainly in liver and muscle. Around 90% of the glucose molecules are linked in straight chains through alpha-1,4 bonds; about 8% are linked through alpha-1,6 bonds that form branching points. The usual glycogen concentration of the liver is 5–7 g/100 g wet weight and in muscle < 2 g/100 g wet weight, these concentrations being influenced by factors such as the nutritional status, the pre- or post-prandial condition of the patient and hormones. Therefore, quantitative glycogen analyses on tissue biopsies, while often done, may be difficult to interpret.

The major function of glycogen in liver is to provide reserve glucose for export to other organs, mainly the brain. In contrast, muscle glycogen is only used as a fuel for ATP synthesis during muscle contraction. It

follows that a glycogen storage disorder (GSD) involving the liver is usually characterized by fasting hypoglycemia, whereas the muscle defects are characterized by myopathy.

For the synthesis of glycogen (Fig. 26.14), glucose is phosphorylated to glucose-6-phosphate, then converted to glucose-1-phosphate. The enzyme glycogen synthase (enzyme 1) then catalyzes the polymerization of glucose-1-phosphate molecules into straight chain glycogen. Branching enzyme (enzyme 2) adds glucose-1-phosphate in alpha-1,6 linkages to form branch points.

In the initial step of glycogenolysis, whether in liver or muscle, a phosphorylase cleaves glucose-1-phosphate molecules from the alpha-1,4 linkages of the outer chains. Liver phosphorylase (enzyme 3) is distinct from muscle phosphorylase (enzyme 4). The activity of both enzymes is influenced by hormones, mainly glucagon, insulin and epinephrine (adrenaline). Phosphorylase activity ceases as it nears a branch point; further degradation of the glucose polymer and removal of the branch point is mediated by debranching enzyme (enzyme 5). The product of glycogenolysis, glucose-1-phosphate, is converted to glucose-6-phosphate. In the liver, glucose-6-phosphate is predominantly dephosphorylated to glucose by glucose-6-phosphatase (enzyme 6). In muscle, glucose-6-phosphate is consumed as a substrate for glycolysis and ATP production.

This main pathway of glycogen degradation by phosphorylation and dephosphorylation in the cytoplasm is different from that in lysosomes. Pompe disease (GSD II), a lysosomal GSD, results from deficiency of lysosomal alpha-1,4-glucosidase. The severity of this disorder illustrates the importance of lysosome-mediated glycogen degradation (see p. 1112).

Traditionally, the GSDs have been classified numerically or by eponym. However, different numbers have been assigned to the same enzymatic defect and the specific enzyme nomenclature is now preferable (Table 26.7). For historical reasons, all three systems are used in this chapter.

Two defects of glycogen synthesis are known, glycogen synthase (enzyme 1) deficiency and branching enzyme (enzyme 2) deficiency. The

Fig. 26.14 Glycogen metabolism. 1, glycogen synthase; 2, branching enzyme; 3, liver phosphorylase; 4, muscle phosphorylase; 5, debranching enzyme; 6, glucose-6-phosphatase.

Table 26.7 Glycogen storage diseases, classification

Type	Deficient enzyme	Tissue involved	Main clinical findings
IA	Glucose-6-phosphatase	Liver, kidney	Hepatomegaly, hypoglycemia, lactic acidosis
IB	Glucose-6-phosphatase-related transport	Liver, leukocytes	Same as IA + immunological abnormalities
IC			Same as IA
ID			Same as IA
II	Acid $\alpha$ -glucosidase (lysosomal)	Generalized	Infant form: cardiorespiratory failure. Later forms: myopathy
III	Debranching enzyme	Liver, muscle, heart	Hepatomegaly, hypoglycemia, myopathy
IV	Branching enzyme	Liver	Hepatosplenomegaly, cirrhosis
V	Phosphorylase	Muscle	Myopathy, exercise intolerance
VI	Phosphorylase system	Liver (muscle)	Hepatomegaly (myopathy)
VII	Phosphofructokinase and other defects of glycolysis	Muscle (erythrocytes)	Myopathy, exercise intolerance (hemolysis)
0	Glycogen synthase	Liver	Hypoglycemia

disorders of glycogenolysis can generally be separated into two groups, hepatic dysfunction and hypoglycemia or skeletal myopathy, depending upon the normal location of the missing enzyme.

## Glycogen synthase deficiency (GSD type 0)

### Clinical features

This defect is usually grouped with the GSDs since it involves the same metabolic pathway. Failure to synthesize glycogen results in rapid and profound hyperglycemia after even quite modest meals. This is followed by a rapid and profound fall of the blood glucose when postprandial events normally turn to glycogenolysis to maintain blood glucose. Facile ketosis and postprandial hyperlactacidemia can be seen. The liver is not enlarged and its glycogen content is low.

### Diagnosis and treatment

The enzyme defect can only be demonstrated in the liver. Mutation analysis may also be helpful. The differential diagnosis can include Munchausen-by-proxy (see Ch. 5, p. 50) from occult insulin administration.

Treatment consists of small, frequent protein-rich meals and regular uncooked cornstarch feedings to prevent hypoglycemia and ketosis.

## Branching enzyme deficiency (GSD type IV)

### Clinical features

The main features of this disorder are marked hepatomegaly with progressive cirrhosis, splenomegaly, muscle hypotonia and weakness, hypo- or areflexia, retarded motor milestones, growth retardation and normal mental development. Death usually occurs in the first years of life, although liver transplant may prolong survival, and milder forms exist. Rarely, milder variants with myopathy are observed in adults and cardiomyopathy with heart failure may be the only presentation.

### Diagnosis and treatment

The metabolic derangements are hypoglycemia, usually mild, increased transaminases and decreased clotting factors. The enzyme defect causes insufficient branching of the glycogen molecule and its prolonged inner and outer chains give it the appearance and properties of amylopectin. Apparently this abnormal glycogen is difficult to mobilize. It acts as a foreign body and glucose release from it is hampered. In contrast to the liver, muscle histology is usually normal in spite of absent enzyme activity in that tissue. The enzyme defect is expressed in many tissues including fibroblasts; antenatal diagnosis is feasible.

Treatment is symptomatic and consists of frequent high carbohydrate feedings and, eventually, gastric drip feeding. This treatment, however, does not prevent liver failure. Liver transplantation has been successful but does not address the myopathy.

### Glucose-6-phosphatase deficiency (GSD type IA, von Gierke disease)

#### Clinical features

The most conspicuous clinical findings are a protruding abdomen because of marked hepatomegaly, hypotrophic muscles, truncal obesity, a rounded 'doll face' and short stature (Fig. 26.15). Because glucose-6-phosphatase activity is required for both glycogenolysis and gluconeogenesis, severe symptomatic hypoglycemia is frequent, often occurring during the night or after even short periods of reduced caloric intake. Even minor delays or reduction of carbohydrate intake may provoke hypoglycemic attacks that are accompanied by lactic acidosis. The liver may be enlarged at birth; its size increases gradually and it may achieve a total span of 15–20 cm. Initially, the liver is smooth with a normal consistency, but by 10–20 years age, it becomes firmer and nodular due to the development of benign adenomas. Cirrhosis, however, does not typically develop. Severe hypertriglyceridemia is caused by poor glycaemic control and can be associated with acute pancreatitis. The spleen is normal in size, but the kidneys are moderately enlarged. Easy bruising, epistaxis and even frank hemorrhage after surgery or other event, may be troublesome due to impaired platelet function. Linear growth is retarded but truncal obesity is obvious; both are improved through

Fig. 26.15 Typical features of a patient with glucose-6-phosphatase deficiency.

judicious treatment. Cerebral function is usually normal so long as hypoglycemic damage is prevented. Left untreated, associated hyperuricemia frequently causes gout.

Because of effective therapy preventing fatal hypoglycemia, the life expectancy of these individuals has greatly improved, and consequently some late-onset complications have emerged. Rarely, hepatic adenomas become malignant, hyperuricemia and gout are now rare, but progressive focal glomerular sclerosis is a serious risk and can lead to renal failure. Anemia and osteopenia are also late-onset problems.

#### Metabolic derangements

Failure to dephosphorylate glucose-6-phosphate means that glucose production from both glycogenolysis and gluconeogenesis is blocked. However, the Embden–Meyerhof glycolytic pathway (see Fig. 26.11) is intact and during fasting is intensified under hormonal stimulation. This increases lactate production that can serve as a fuel to the brain. However, chronic lactic acidemia is usual and probably contributes to the retarded growth and osteoporosis. Excess acetyl-CoA is also produced and is converted into fatty acids and cholesterol; this probably underlies the hypertriglyceridemia, hypercholesterolemia and hyperprebeta-lipoproteinemia seen in most of these patients. Some of the excess glucose-6-phosphate is channeled via the pentose monophosphate shunt to urate, thus explaining the hyperuricemia, which can be severe.

#### Diagnosis

In the past, oral glucose tolerance tests were employed as a diagnostic aid. During this test, in GSD I patients, the blood lactate *decreases* from an initially high level to (near) normal. This is the opposite from the normal response. Oral glucose tolerance tests, fasting and other stress tests, however, can be hazardous. Assay of glucose-6-phosphatase activity in liver confirms the diagnosis and delineates the different forms of this syndrome (see below). In the liver, fat accumulation often exceeds that of glycogen; this does not contradict the biochemical diagnosis. DNA mutational analysis is becoming increasingly available. Antenatal diagnosis can only be done on fetal liver tissue or by DNA studies.

#### Treatment

Acute hypoglycemia should be treated with glucose 0.25 g/kg in 50–100 ml water orally or by intravenous bolus infusion; importantly, this should be followed immediately by an intravenous drip providing twice the normal glucose requirement (see below). Lactic acidosis usually resolves without the need for sodium bicarbonate since glucose administration suppresses lactate overproduction. Oral nutrition is reintroduced as soon as possible.

For maintenance, a high carbohydrate diet with 60–65% of the total energy as carbohydrates, 10% as protein and 20–25% as fat is used. Both lactose and sucrose intake should probably be restricted since neither galactose nor fructose can be converted to glucose because of the enzyme defect. Low-lactose, sucrose-free formulae are preferable if breast milk is not available. Maltose or dextrins can be added to give a total 65% of energy as carbohydrate. Feedings should be administered at 2–3 h intervals around the clock before the age of 3 months, followed by a wider spacing from 3–6 months onwards. Gastric drip feeding at night is introduced as early as possible using carbohydrate derived from glucose, maltose or glucose polymers to provide a constant supply of carbohydrate at 7–9 mg/kg/min for infants, 5–6 mg/kg/min for 1–6-year-olds and 4 mg/kg/min for older children. This treatment improves the clinical condition, decreases the liver size, suppresses the bleeding tendency and promotes growth. Since disconnection of the tubing or pump malfunction in the GSD I patient receiving enteral feedings can be fatal, good equipment and alarm systems are crucial.

Most older patients prefer to use uncooked cornstarch as a slow-release form of carbohydrate which becomes the mainstay of therapy. Because of its thick consistency, even mixed in water, it cannot easily be given via a gastric or nasogastric tube but can be given orally, between or together with meals, and normalizes the blood sugar for several hours (Fig. 26.16); with close supervision, care and good parents, it can also

Fig. 26.16 Blood glucose curves of a patient with glucose-6-phosphatase deficiency after the ingestion of glucose or various uncooked starches, 2g/kg body weight each.

be used in infants, although prior to about 1 year of age infants may not produce sufficient amylase to metabolize the cornstarch effectively. Early introduction of cornstarch may, however, induce earlier production of amylase. Even optimum treatment may not correct the hypoglycemia, lactic acidosis and hyperlipidemia completely and some patients continue to grow poorly. Captopril is being evaluated for treating the renal disease; osteoporosis requires a generous calcium and vitamin D intake and periodic assessment of bone density. Hyperuricemia is treated with allopurinol. Liver transplantation has been successful.

### Glucose-6-phosphate translocase deficiencies (GSD types IB and IC)

These are defects of translocases located on the luminal wall of the endoplasmic reticulum that normally allow entry of glucose-6-phosphate (GSD type IB) and exit of phosphate (GSD type IC). Both defects render glucose-6-phosphatase functionally inactive. A defect of glucose translocase has not yet been described.

The clinical and metabolic symptoms and treatment of GSD IB are not discernibly different from GSD IA except for a grave propensity to immunological abnormalities. There is neutropenia and defective neutrophil and monocyte function; bacterial infections are frequent and may be fatal. Inflammatory bowel disease akin to Crohn disease and myelogenous leukemia are added potential complications. The prognosis of translocase deficiency traditionally was worse than that of type IA because of the increased risk of metabolic derangements due to the frequent infections, but the introduction of granulocyte macrophage-stimulating factor (GM-CSF) as a treatment has improved the prognosis tremendously (see Ch. 27).

Translocase 1 defect (GSD type IB) accounts for 12–15% of the total cases of glucose-6-phosphatase deficiency; type IC is extremely rare.

### Debranching enzyme deficiency (GSD type III, 'limit dextrinosis')

During glycogenolysis, this enzyme normally prunes the alpha-1,6 linkage branch points as the straight, alpha-1,4 links are being broken down by phosphorylase. When this does not happen, glycogen degradation stops at the branch points, leaving 'limit dextrin'. This abnormal glycogen may behave as a foreign body and elicit high transaminase levels, recurrent jaundice, fibrosis and even cirrhosis. Gluconeogenesis, however, is unimpeded and this drains glucogenic amino acids from muscle protein, presumably contributing to poor growth and muscle wasting. This also explains the observation that GSD III patients are not as prone to severe hypoglycemia as GSD I patients.

#### Clinical features

Two forms exist; one is confined to liver but the more common one involves the muscles as well. In younger children the liver symptoms predominate and are very similar to GSD type IA with hypoglycemia

in the neonatal period or later or during decreased food intake or metabolic stress. The liver is markedly enlarged and extremely high transaminases are common; the spleen and kidneys are not affected. Hypotonia, truncal obesity and a doll face develop and the patient may show retarded growth which gradually catches up later. Motor development is slow but mental development is usually normal. The liver has a normal consistency, but rarely cirrhosis may develop. Surprisingly, for unknown reasons, the liver size often returns to normal at or before puberty.

In the myopathic form, which has probably been underdiagnosed in the past, there is increasing muscle weakness and a slowly progressive distal muscle wasting, starting in childhood or later. It may be accompanied by cardiomyopathy with left ventricular hypertrophy and electrocardiogram (ECG) abnormalities. These developments warrant close supervision of muscle function and regular ECG in all patients.

#### Diagnosis

Conspicuous findings during fasting are ketosis (not lactic acidosis), hyperlipidemia (mainly hypercholesterolemia) and hypoglycemia. An oral galactose tolerance test elicits a normal increase of blood glucose and an abnormal increase of blood lactate. A fasting glucagon test is characterized by an abnormally flat glucose response but such stress tests can be dangerous in GSD.

The liver pathology shows an increase of reticulin fibers between hepatocytes and of fibrous tissue in portal tracts. In the myopathic form, the muscles show myofibrillary destruction and degeneration of the neuromuscular junctions. Enzyme assay in liver or muscle is required to confirm the diagnosis.

#### Treatment and prognosis

Treatment of the hepatic form is similar to that of GSD I except that restriction of galactose and fructose is not necessary as both can be converted normally into glucose. Although gastric drip-feeding is not a prerequisite for glucose homeostasis at a later age, this treatment and extra protein may be useful in delaying or improving the myopathy. Thus, the diet for both forms of the disease should contain approximately 55–60% energy as carbohydrates, particularly starch, 15–20% energy as protein and 20–25% energy as fat, predominantly polyunsaturated; uncooked cornstarch is also often used. The late development of myopathy and cardiomyopathy remains a concern.

### Liver phosphorylase and liver phosphorylase b kinase deficiencies (GSD type VI)

Phosphorylase b kinase is required to convert phosphorylase b (inactive) to the activated form and the kinase itself is regulated by another (cyclic AMP-dependent) kinase, the whole system being stimulated by hormones, particularly glucagon. The clinical heterogeneity of phosphorylase b kinase deficiency is due to the fact that it consists of four different subunits at least one of which is coded on the X chromosome. These two defects are discussed together because their clinical features and metabolic derangements are similar.

#### Clinical features

In early childhood, pronounced hepatomegaly, without splenomegaly, and a protuberant abdomen due to muscle hypotonia are the most striking features; the liver enlargement resolves slowly and usually disappears by puberty. Equally, the muscle hypotonia and weakness, which initially cause slow motor development, also tend to improve. Growth and puberty are often delayed. Mental development is normal. There are exceptions to this usually mild course, particularly in phosphorylase b kinase deficiency, of which many variants exist. Rare cases have had combinations of hepatic symptoms and myopathy, fatal cardiomyopathy and even myopathy without hepatic symptoms. The X-linked form of phosphorylase b kinase deficiency is the most common and mildest form, and can present with isolated hepatomegaly in children.

### Diagnosis

A tentative diagnosis is based on the pronounced hepatomegaly in contrast to the mild clinical and metabolic findings. Mild fasting hypoglycemia may develop; elevated serum transaminases, hypercholesterolemia and a marked tendency to fasting ketosis are evident at a young age, but normalize completely by puberty.

An oral galactose test is abnormal as blood lactate increases excessively. Contrary to expectation, glucagon tests are not of much help as the increase of blood glucose is variable. Fasting or stress tests may be dangerous. Kinase defects can theoretically be detected in blood cells but assay of liver or muscle or DNA studies may be required in some cases.

### Treatment

Treatment of this self-limiting disease is not necessary except for prevention of hypoglycemia, which may require uncooked cornstarch. Use of polyunsaturated fat suppresses hypercholesterolemia. Severe forms of phosphorylase b kinase deficiency may be refractory to dietary treatment, and liver transplantation may be indicated for severe cases with liver failure.

### Muscle phosphorylase deficiency (GSD type V, McArdle syndrome)

#### Clinical features

This disorder is characterized by increasing intolerance for strenuous exercise. During early childhood no symptoms occur except easy fatigability. In adults, strenuous muscle activity is accompanied by severe cramps and may be followed by rhabdomyolysis, which can precipitate anuria and renal failure. In middle life, the fatigue increases and muscle wasting and weakness predominate. The serum CPK may be permanently or intermittently elevated.

### Diagnosis

In myophosphorylase deficiency, ischemic exercise testing shows that lactic acid production is blocked and release of ammonia and the purine nucleotide cycle compounds is exaggerated. The ensuing myogenic hyperuricemia is one of the characteristic features of defects of muscle glycogenolysis. The normal increase in lactate is also absent in other glycolytic defects in muscle, such as phosphofructokinase deficiency.

Phosphorylase activity must be assayed in muscle; liver phosphorylase is presumably normal, as is glucose homeostasis. DNA mutation analysis can be useful as there are several common mutations.

### Treatment

Treatment is symptomatic and consists of the avoidance of strenuous exercise. 'Carbo loading' and a high protein diet are of some help and glucose should always be taken during exercise. Strenuous exercise is always a risk. Carefully monitored exercise training has been shown to improve muscle function.<sup>63</sup>

### Muscle phosphofructokinase deficiency (GSD type VII)

#### Clinical features

The three clinical and metabolic characteristics of this rare disorder are myopathy, increased hemolysis and gout. The myopathy is similar to GSD type V and manifests itself in childhood by weakness, limitation of vigorous activity and exercise-induced cramps, accompanied by myoglobinuria and raised CPK. As in muscle phosphorylase deficiency, there is no rise of venous lactate after exercise and ammonia, inosine, hypoxanthine and urate are produced in excess. Continued myogenic hyperuricemia explains the gout. The block in glycolysis may be partly compensated by increased fatty acid oxidation. Different isoenzymes of phosphofructokinase exist in various tissues. The absence of the M-subunit in erythrocytes results in hemolytic anemia (see Ch. 23, p. 967).

### Treatment

Provision of extra glucose does not bypass the enzyme defect and is therefore of no help. This is different from muscle phosphorylase defi-

ciency in which glucose enters the glycolytic pathway 'downstream' from the enzyme defect. A high protein diet and prevention of excessive activity are the only measures.

### Lysosomal alpha-1,4-glucosidase deficiency (GSD type II, Pompe disease)

Deficiency of this enzyme, also called acid maltase deficiency, leads to a generalized GSD. However, this defect is not in the regular cascade of glycogenolysis and is not associated with defects of circulating fuels (see p. 1112).

## DISORDERS OF PYRUVATE METABOLISM AND THE KREBS CYCLE, AND LACTIC ACIDEMIA

Glycolytic (see p. 1072), gluconeogenic, ketone and fatty acid (see p. 1067) pathways all feed into the Krebs cycle (Fig. 26.17) for aerobic metabolism. Pyruvate, derived from glycolysis or glucogenic amino acids, is converted to acetyl-CoA via the unidirectional pyruvate dehydrogenase complex (PDHC). Pyruvate is in equilibrium with lactate and the normal lactate:pyruvate ratio is about 20:1, being dependent upon the NAD:NADH ratio and the availability of oxygen for aerobic metabolism. If pyruvate oxidation is compromised, lactate accumulates, resulting in lactic acidosis. When this central furnace is disrupted, other precursor fuels such as organic acids also accumulate and can be detected in body fluids.

All the disorders of pyruvate metabolism are associated with neurological damage, usually of a severe onset any time after birth. Developmental and motor delay, seizures, pyramidal and/or basal ganglion signs are usually severe and present major problems.

### Pyruvate dehydrogenase complex

Defects in this three-enzyme complex are the most common of the pyruvate disorders. The first component, E1, is the thiamine-dependent *dehydrogenase*. It has two subunits one of which is coded for on the X-chromosome. Female carriers of this defect may be almost as severely affected as males. Severe cases may show mild mid-facial hypoplasia,

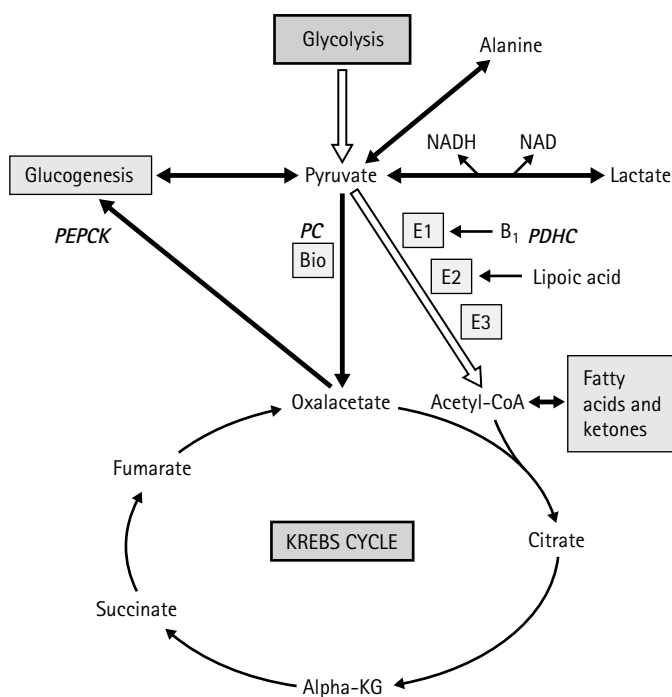

Fig. 26.17 Metabolic pathways involving lactate and pyruvate. PEPCCK: phosphoenolpyruvate carboxykinase; PDHC: pyruvate dehydrogenase complex; PC: pyruvate carboxylase; Bio: biotin; B1: thiamine; E1,E2,E3: Separate complexes of PDHC; Alpha-KG: Alpha-ketoglutarate.

evidence of prenatal effects of the block. Apart from the severe neonatal forms, milder mutations can present with later onset of cerebellar signs with ataxia being prominent and proportionally less developmental delay. These signs are exacerbated by carbohydrate ingestion that can induce coma.

The other two components are *dihydrolipoamide acyltransferase* and *dihydrolipoamide dehydrogenase* (E2 and E3). These two involve lipoic acid and are common to other dehydrogenases, including branched chain amino acid dehydrogenase and, if defective, involve additional metabolic systems. Deficiency usually causes very serious neurological damage.

### Pyruvate carboxylase and phosphoenolpyruvate carboxykinase

These enzymes are both involved in recycling pyruvate to gluconeogenesis and defects can provoke hypoglycemia. Both can present with severe neonatal crises or with a more indolent course. Pyruvate carboxylase (PC) requires biotin and is thus involved in multiple carboxylase deficiency (p. 1066).

Diagnosis can be done on fibroblasts. Treatment is supportive with avoidance of hypoglycemia.

### DEFECTS OF THE KREBS CYCLE

These include *alpha-keto acid dehydrogenase*, *fumarase* and *succinic dehydrogenase* (complex II of the respiratory chain, see below) deficiencies. All are associated with severe neurological disease and poor prognosis.

### LACTIC ACIDEMIA

#### Diagnosis and treatment

Transient and acquired lactic acidemia is not an infrequent finding in any seriously ill child and may be caused by a number of conditions (Table 26.8). A struggling child, use of tourniquets during blood draw, poor tissue perfusion secondary to sepsis, cardiac or pulmonary disease, severe anemia, seizures, liver failure, toxins and IEM can all lead to an abnormal accumulation of L-lactate. Ischemia of tissues including brain and various brain defects, including cerebral atrophy, agenesis of the corpus callosum and brainstem, and deep gray matter abnormalities can also cause persistent lactic acidosis.

When acquired causes are not evident, primary (hereditary) lactic acidemia must be sought. However, it is often difficult to determine whether it is primary or secondary to conditions in a very sick child who does not have an IEM; indeed, these two possibilities are not mutually exclusive. Lactic acidosis may be fulminating or minimal. There may be facile ketosis and abnormal organic aciduria.

Initial laboratory investigations include serial measurements of blood (if feasible, arterial), lactate and, if possible, pyruvate. In general, a blood lactate:pyruvate ratio > 20 suggests a respiratory chain disorder; below that, a block proximal to the respiratory chain (e.g. pyruvate

dehydrogenase deficiency) is more likely. While the lactate:pyruvate ratio reflects the redox state in the cytoplasm, the plasma beta-hydroxybutyrate:acetoacetate ratio reflects the intramitochondrial redox state; a ratio > 1 suggests mitochondrial dysfunction. However, in most centers, quantitative assays for pyruvate, and the ketone bodies are unavailable or notoriously unreliable. Plasma alanine, which is transaminated pyruvate, is normally maintained in narrow limits and when elevated, often reflects an elevated pyruvate or a distorted redox state. Elevated CSF lactate may be present in some patients with normal blood lactate.

In general, acquired lactic acidemia corrects relatively quickly after the underlying cause is treated but primary causes tend to persist. This is a generalization because even in proven primary disorders the lactic acidemia may be transient. Every effort should be made to find the cause of the lactic acidosis, including echocardiography, brain MRI (preferably with spectroscopy as MRS can quantitate brain lactate) and appropriate metabolic investigations (Table 26.9). Confirmation of a suspected abnormality may be provided by measuring lactate and pyruvate levels in cultured fibroblasts. Precise diagnosis requires assays of leukocytes or fibroblasts and is only available in a few centers. Prenatal diagnosis is very tricky.

In most cases, the primary cause of the acidosis is not clear at the outset; thus it is necessary to make some empiric decisions. The acidosis may require large doses of bicarbonate for an extended period. PDHC may respond to a strict ketogenic diet; however, PC and phosphoenolpyruvate carboxykinase (PEPCK) deficiencies can become dramatically worse with it. Most other causes do not respond to such diets. In EI cases, thiamine up to 750 mg/d for an adult can be beneficial. Dichloroacetate is used to maintain the E1 in active form and it has had some limited success.<sup>70</sup>

### D-Lactic acidemia

D-Lactate is not made by humans. D-Lactic acidemia is caused by intestinal bacterial overgrowth, usually associated with short bowel and blind loop syndromes, and may cause intermittent neurological symptoms, including dizziness, ataxia and disorientation. D-lactic acidemia is one

Other studies	Chest X-ray, ECG, echocardiography, EEG, head imaging
Laboratory tests	Routine – complete blood count with differential, glucose, electrolytes, liver enzymes, blood urea nitrogen, creatinine, blood gases, serial lactate/pyruvate measurements, blood cultures (urine and CSF cultures if indicated), toxicology screen
Special tests	Metabolic studies – quantitative plasma amino acids, ammonia level, acylcarnitine profile, urine organic acids Assay of enzyme activities in WBC or fibroblasts Muscle exercise testing Muscle biopsy for histochemistry, electron microscopic, immunological and biochemical studies 31P NMR spectroscopy DNA studies on muscle, WBC, fibroblasts, liver, etc

\*Decreased cardiac function (e.g. secondary to cardiomyopathy) may be present in patients with apparently normal perfusion, blood pressure and cardiac examination.

cause of unexplained acidosis because the D dimer is not detected by standard lactate assays but is seen on organic acid analysis; it requires a specific method. It is easily treated by a course of oral antibiotics.

## MITOCHONDRIAL DISEASE

Mitochondria contain a special DNA (mtDNA) that replicates continuously and is highly pleomorphic with differences between individuals and even greater differences between populations. This makes it useful for forensic and anthropological studies. mtDNA is double-stranded and circular, being 16 569 base pairs long. It encodes 13 subunits of the respiratory chain, 22 transfer RNAs (tRNAs) and two ribosomal RNAs (rRNAs) (Fig. 26.18). Mitochondria contain ~1000 structural proteins and enzymes, including the tricarboxylic acid and fatty acid oxidation cycles, part of the urea cycle and numerous others, all of which are encoded by nuclear genes, being imported into the mitochondrial matrix after initial cytoplasmic synthesis.

The term mitochondrial disease is limited to disorders of the respiratory (electron transport ETC) chain with resultant decreased production of adenosine triphosphate (ATP). Disorders of other intra-mitochondrial enzymes are not classified as mitochondrial diseases.

Each mitochondrion contains between 2 and 10 copies of mtDNA, and each cell contains a few to 1000 mitochondria, depending on its energy requirements. With rare exceptions, mtDNA is inherited entirely from the ovum and mitochondria are distributed randomly to daughter cells during embryogenesis. If an mtDNA mutation arises in a cell, both mutant and normal mtDNA molecules will coexist in that cell, a condition known as *heteroplasmy*. At all subsequent cell divisions, a mix of mutant and normal mtDNAs are then transmitted randomly to daughter cells, so that the proportion of normal to mutant DNA in each cell is determined stochastically. Even without functional or environmental pressure, with repeated cellular division, the proportions of the two tend to drift towards either completely normal or completely mutant in a given cell line (*replicative segregation*).

The term *threshold effect* refers to the expression of an abnormal phenotype only when the percentage of mitochondria harboring mutant mtDNA exceeds the proportion of normal mitochondria needed for the energy demands of the tissue. In general, there is a greater likelihood of tissue dysfunction if a high percentage of abnormal mitochondria is present.<sup>71</sup> In most maternally inherited disorders, heteroplasmy is common although *homoplasmic* disorders also exist. The clinical phenotype and potential disease expression ultimately depends on the severity of the mutation, the percentage of affected mitochondria and the energy requirements of the involved tissues (Table 26.10).

Mitochondrial disorders have an overall incidence of approximately 1 in 8500 children and are therefore more common than phenylketonuria or myotonic dystrophy.<sup>72</sup> They may occur sporadically or be inherited in a Mendelian (autosomal recessive, autosomal dominant, X-linked) fashion. Defects of mtDNA are inherited by maternal inheritance (see below). Mitochondrial disorders have been recently reviewed.<sup>73</sup>

## THE RESPIRATORY CHAIN

The mitochondrial respiratory (electron transport) chain (Fig. 26.19) produces the majority of energy through the process of oxidative phosphorylation (OXPHOS), in which the reduction of oxygen to water is coupled to the production of the high energy compound ATP. Because of the critical role mitochondria play in generating cellular energy, mitochondrial disorders can cause dysfunction of any organ system, although the high energy needs of the neuromuscular system make it the most vulnerable.

The respiratory chain consists of four inner mitochondrial membrane multi-subunit protein complexes (complexes I–IV) that transport electrons down an electrochemical gradient using a variety of electron carriers, including iron–sulfur clusters, cytochromes and coenzyme  $Q_{10}$ , and an ATPase (complex V). Electron transport between the complexes is coupled to the extrusion of protons across the inner mitochondrial membrane by proton pump components of the respiratory chain.

**Fig. 26.18** Mitochondrial genome. Human mtDNA is a double-stranded, circular genome of 16 569 base pairs that encodes 13 OXPHOS subunits, 22 tRNAs, and two rRNAs. The locations of common pathogenic mutations are shown, with the base pair positions given in parentheses. Different disease phenotypes may occur with the same mutation. For example, mutations at position 3243 have been reported in MELAS, PEO, cardiomyopathy and MIDD and 8344 mutations are associated with MERRF, deafness and cardiomyopathy, and PEO with myoclonus. On the other hand, different mutations may cause a similar clinical presentation (e.g. LHON). The common deletion is associated with KSS, PEO and PS. ATPase 8/6, complex V subunits; COIII, complex IV subunits; Cyt b, cytochrome b (complex III subunit); K, lysine tRNA; KSS, Kearns–Sayre syndrome; L, leucine tRNA; LHON, Leber hereditary optic neuropathy; MELAS, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; MERRF, myoclonic epilepsy with ragged-red fibers; MIDAS, maternally inherited deafness with aminoglycoside sensitivity; MIDD, maternally inherited diabetes and deafness; NARP, neurogenic weakness, ataxia and retinitis pigmentosa; ND1–6, complex I subunits (7); PEO, progressive external ophthalmoplegia; PS, Pearson marrow–pancreas syndrome. White bars indicate position of mitochondrial tRNAs.

ATP is synthesized by complex V from adenosine diphosphate (ADP) and inorganic phosphate using energy from the flow of protons back into the mitochondrial matrix from the intermembrane space (Fig. 26.19). This process converts physicochemical energy into a biomedical source of energy.

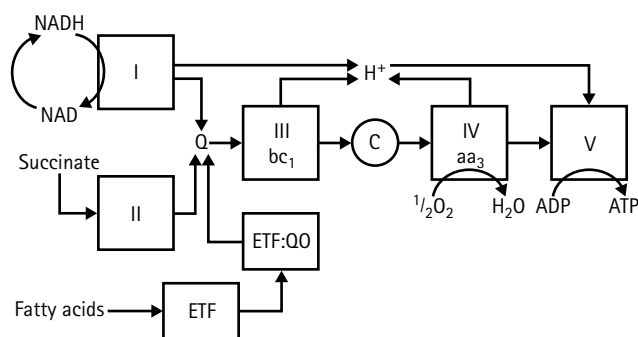

Fig. 26.19 The respiratory chain is embedded in the inner mitochondrial membrane and consists of five multisubunit enzymes (complexes I–V). Complex I, (NADH Co Q oxidoreductase); complex II, succinate Co Q oxidoreductase; complex III, ubiquinol cytochrome c reductase; complex IV, cytochrome c oxidase; complex V, ATP synthase; Q, coenzyme Q; C, cytochrome c; ETF, electron transfer flavoprotein; ETF:QO, electron transfer flavoprotein oxidoreductase. Electrons generated by complexes I, III and IV create the proton gradient that drives ATP synthesis. Their transport (using transition metal compounds, flavins and coenzyme Q<sub>10</sub>) is coupled to proton extrusion across the inner mitochondrial membrane by complexes I, III and IV. Protons then re-enter the mitochondrial matrix through complex V and ATP is synthesized from ADP and inorganic phosphate. NADH (via complex I) and FADH<sub>2</sub> (via complex II or coenzyme Q<sub>10</sub>) donate electrons to the respiratory chain.

Dysfunction of the ETC causes decreased ATP production, as well as increased production of reactive oxygen and free radicals that can further impair respiratory chain function and exacerbate the already diminished energy production. These changes subsequently activate the mitochondrial membrane permeability transition pore, resulting in egress of apoptotic factors and cell death. All these factors play a role in the pathogenesis of these disorders.<sup>74</sup> They are also postulated to explain the progressive emergence of mutant mtDNA in several adult-onset diseases.

mtDNA codes for 7 of the 43 subunits in complex I, 0 of 4 in complex II, 1 of 11 in complex III, 3 of 13 in complex IV and 2 of 14 in complex V. Nuclear DNA encodes the remaining subunits as well as all the other proteins responsible for the assembly and maintenance of the respiratory chain, ribosomal proteins and enzymes responsible for mtDNA replication. The respiratory chain is thus formed and maintained by the coordinated interaction of two genomes.

## CLINICAL FEATURES

Mitochondrial diseases are typically multisystem disorders that affect virtually any tissue or organ system and they may present with a broad array of symptoms and signs; myopathy, neurological symptoms and cardiomyopathy being the most common. With the capricious nature of mtDNA distribution during meiosis and cell replication, it should not surprise clinicians to find unusual combinations of tissue involvement in these cases. Once a family is recognized, it is usual to find members with apparently unrelated diseases (see below) and others who possess the mutant mtDNA but who are totally normal. Progressive dysfunction of seemingly unrelated organ systems may indeed provide the first clue to the presence of underlying mitochondrial disease.<sup>75</sup> While several classic clinical syndromes have been described (Table 26.11),<sup>76,77</sup> there is considerable overlap in their presentations. Mitochondrial disease can

present at any age, prenatal to adulthood.<sup>75</sup> The disorders are listed in Table 26.12.

### Leigh syndrome and Alpers syndrome

The terms Leigh syndrome (subacute necrotizing encephalomyelopathy) and Alpers syndrome are clinical descriptions that do not imply a specific biochemical cause. Leigh syndrome is a severe neurological disorder characterized by pyramidal and extrapyramidal symptoms, brainstem dysfunction and a progressive course that typically presents in children aged 1–5 years. Onset is usually gradual hypotonia, weakness, ataxia, tremor, optic atrophy, ophthalmoplegia, retinitis pigmentosa and respiratory abnormalities. Bilateral basal ganglia lesions are a common neuroradiological finding. Symmetric necrotic lesions in the thalami, brainstem and posterior columns of the spinal cord are pathological features. Patients usually do not have ragged-red fibers on histochemistry of muscle. Leigh syndrome is heterogeneous and may be caused by mtDNA, autosomal recessive and X-linked disorders. The most common are in nuclear genes coding for various subunits of complex I and II and in SURF I and II, proteins that are required for assembly of complex IV. The usual mtDNA mutations are mtATP6 (complex V; maternally inherited Leigh syndrome [MILS], see Table 26.9) and in several mitochondrial tRNAs. Leigh syndrome can also be seen in pyruvate dehydrogenase deficiency, an X-linked disorder (see p. 1079).

Alpers syndrome (progressive infantile poliodystrophy) is a comparable neurodegenerative disorder with onset in infancy and death in early childhood in which liver disease is characteristic. Patients have lactic acidemia and a variety of symptoms, including myoclonic epilepsy, ataxia, hypo- or hyper-tonia and abnormal respirations. Alpers syndrome primarily affects the cerebral cortex and cerebellum, with lesser

involvement of the basal ganglia and brainstem. Both respiratory chain and tricarboxylic acid cycle defects have been found in this disorder. Alpers syndrome is primarily caused by mutations in the gene coding for mtDNA polymerase (POLG), an enzyme essential for mtDNA replication and repair.<sup>78</sup> A mutation in mtDNA-encoded cytochrome c oxidase II gene may cause a similar clinical picture.<sup>79</sup>

### Mitochondrial myopathy

Stable or progressive hypotonia, muscle weakness and poor exercise tolerance with dyspnea are common features in mitochondrial disorders of muscle; myalgia and myoglobinuria are much less frequent. The severity ranges from fatal infantile myopathy to milder presentation in later childhood or adulthood. Although severe lactic acidosis and multiorgan system failure may accompany severe infantile forms of mitochondrial myopathy, there is one form in which complete, spontaneous remission occurs during the first years of life.<sup>80</sup>

Histologically, there are usually subsarcolemmal aggregates of mitochondria that, on staining with Gomori trichrome, give what is termed a ragged-red fiber picture (RRF). On electron microscopy, the mitochondria are large and misshapen with inclusions. Numerous mtDNA (especially involving mitochondrial tRNAs) and nuclear DNA (nDNA) mutations (e.g. mtDNA depletion syndrome) have been associated with myopathy.

### Cardiomyopathy

Respiratory chain dysfunction is also a cause of cardiomyopathy from birth through adult life. This is usually concentric and hypertrophic but dilated forms are not uncommon. Heart pathology usually shows fibroelastosis, interstitial fibrosis and abnormal mitochondria. Cardiac

Table 26.12 Classification of mitochondrial respiratory chain disorders

<i>Defects of mitochondrial DNA (maternal inheritance)</i>	
Point mutations	MELAS, MERRF, LHON, NARP, MIDAS
Single deletions	KSS, CPEO, PS
Duplications or duplications/deletions	KSS
<i>Defects of nuclear DNA (Mendelian inheritance)</i>	
Respiratory chain subunit disorders	
Complex I deficiency: NDUV1, NDUFS1, NDUFS2, NDUFS4, NDUFS7, NDUFS8 mutations	
Complex II deficiency: Fp subunit of succinate dehydrogenase	
Disorders of intergenomic communication	
Respiratory chain subunit stability/assembly: SURF-1, SCO1, SCO2, COX10 mutations	
mtDNA replication: mtDNA depletion syndrome, multiple mtDNA deletions (autosomal dominant and recessive types), thymidine phosphorylase deficiency (MNGIE)	
Defective oxidative phosphorylation coupling	
Luft disease	
Mitochondrial substrate pores/translocase defects	
ANT deficiency	
VDAC deficiency	
Malate/aspartate shuttle deficiency	
Defects of mitochondrial protein importation	
Chaperonins: hsp60, paraplegin (SPG7 mutations), Mohr-Tranebjaerg syndrome (DPP1 mutations)	
Defects of intramitochondrial metal homeostasis	
Freidreich ataxia (frataxin mutations)	
X-linked sideroblastic anemia and ataxia (ABC7 mutations)	
Wilson disease (ATP7B mutations)	
Other nuclear genome defects	
Barth syndrome (G4.5/taffazin mutations)	
Cartilage-hair hypoplasia (RNase MRP mutations)	
Other neurodegenerative disorders	
Alzheimer disease	
Parkinson disease	
Huntington disease	
Amyotrophic lateral sclerosis	

ANT, adenine nucleotide translocator; CPEO, chronic progressive external ophthalmoplegia; KSS, Kearns-Sayre syndrome; LHON, Leber hereditary optic neuropathy; MELAS, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; MERRF, myoclonic epilepsy and ragged-red fibers; MIDAS, maternally inherited deafness with aminoglycoside sensitivity; MNGIE, myoneurogastrointestinal disorder and encephalopathy; NARP, neurogenic weakness, ataxia, and retinitis pigmentosa; PS, Pearson marrow-pancreas syndrome; VDAC, voltage-dependent anion channel.

conduction defects are relatively common. The cardiomyopathy may be isolated or associated with other organ involvement.

A number of respiratory chain defects (especially complex I and complex IV deficiencies), mtDNA point mutations and deletions have been associated with cardiomyopathy.<sup>81,82</sup> Mutations of nDNA that affect the function of the respiratory chain may cause cardiomyopathy in addition to causing neurological impairment (e.g. mutations in the SCO2 or frataxin genes). The X-linked Barth syndrome is an important cause of dilated cardiomyopathy in boys (see p. 1098).

### Hepatic disease

Severe early-onset liver failure is associated with a mitochondrial depletion syndrome caused by a defect in *deoxyguanosine kinase*. Both infantile and more indolent hepatic disease also have been associated with various defects of the respiratory chain, often affecting multiple complexes. Other organs can also be involved. Histopathology is nonspecific, often showing steatosis, fibrosis and cholestasis. General

depletion of mtDNA and mtDNA rearrangements have been found in some of these patients.

### Renal disease

Renal tubules depend on oxidative metabolism, so it is not surprising that kidney involvement is relatively common in mitochondrial disease. Proximal renal tubular dysfunction, manifesting as the *renal Fanconi syndrome*, is most frequently encountered, but the nephrotic syndrome, focal segmental glomerulonephrosis and chronic interstitial nephropathy have also been reported (see Ch. 18). The Fanconi syndrome (see also p. 550) may be extreme or partial with only mild aminoaciduria or renal tubular acidosis. It can present at any age. Kidney involvement is often associated with disease in other organ systems.

### Endocrine disease

Diabetes mellitus, hypoparathyroidism, growth failure secondary to IgF1 deficiency, hypothyroidism, hypothalamic dysfunction and adrenocorticotrophic hormone (ACTH) deficiency may occur in children with mitochondrial disease, particularly in Kearns-Sayre syndrome (KSS). These are often associated with other features including sensorineural hearing loss, cardiomyopathy, myopathy, renal tubular defects and neuropsychiatric disease (e.g. Maternally inherited diabetes and deafness MIDD). Various mtDNA point mutations, including the A3243G tRNA mutation associated with MELAS syndrome, and mtDNA rearrangements have been associated with diabetes. Patients may present as neonates with ketosis, prominent hyperglycemia and lactic acidosis or in later childhood or adulthood.

*Pearson marrow-pancreas syndrome* is characterized by exocrine, and sometimes endocrine, pancreatic dysfunction and refractory sideroblastic anemia with variable neutropenia and thrombocytopenia, and is caused by a large mtDNA deletion.

*Wolfram syndrome* is characterized by diabetes insipidus, diabetes mellitus, optic atrophy and deafness (DIDMOAD) (see also p. 112). Wolfram syndrome in many cases is an autosomal recessive condition caused by mutations in the WFS1 gene which codes for a protein that localizes to the endoplasmic reticulum and is likely involved in membrane trafficking, protein processing and/or calcium homeostasis, but has also been described in patients with mtDNA point mutations and deletions.<sup>83</sup>

### Mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS)

Mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS) classically presents with stroke-like episodes and focal neurological deficits (which may be transient), headache, emesis, lactic acidosis, myopathy with abnormal muscle morphology; symptoms occur by age 15 years in 80%. Short stature, seizures, developmental regression, pigmentary retinopathy, deafness, diabetes mellitus and cardiomyopathy are variably present. A heteroplasmic A3243G tRNA<sup>Leu</sup>(UUR) mtDNA mutation is the most common cause. This same mutation has been associated with mitochondrial epilepsy and ragged red fibers (MERRF), progressive external ophthalmoplegia (PEO), MIDD and autistic spectrum disorders.<sup>84</sup> Multiple white matter lesions and basal ganglia calcification are common.

Muscle histochemistry shows cytochrome c oxidase (COX)-positive RRF and strong succinate dehydrogenase reactivity in blood vessels most of the time. Although biochemical studies may be normal, complex I deficiency or partial combined deficiencies of complexes I, II and IV have been described.

### Mitochondrial epilepsy and ragged-red fibers (MERRF)

Mitochondrial epilepsy and ragged-red fibers (MERRF) is characterized by myoclonic epilepsy, myopathy and progressive cerebellar ataxia. Deafness is common, and optic atrophy, peripheral neuropathy and heart block may occur. Symptoms usually emerge in the second or third decade.

Mild to moderate elevations of lactate and creatine kinase may be present. On histochemistry, the muscle shows prominent COX-negative RRF and, most often, complex I and IV deficiencies. The most common mutation is A8344G in the mtDNA tRNA<sup>Lys</sup> gene, although other mtDNA point mutations may result in a similar phenotype.

### Leber hereditary optic neuropathy

Leber hereditary optic neuropathy (LHON) is one of the most common causes of blindness in young men (1 in 10 000–50 000). Although most patients show only sudden or subacute vision loss due to degeneration of the optic nerve, non-ophthalmological features also occur and can include encephalomyopathy, deafness, ataxia, a multiple sclerosis-like illness and cardiac conduction defects. The male:female ratio is about 3:1 but the reason for this is not understood. A G11778A mutation in the ND1 subunit of complex I causes >60% of cases, but ~20 different mutations in mtDNA are known. These mutations are usually homoplasmic, in contrast to the heteroplasmy in most mitochondrial disorders. It should be recognized that homoplasmy can also be found in *unaffected* members of a known pedigree. This disorder should not be confused with Leber hereditary amaurosis.

### Neurogenic weakness ataxia and retinitis pigmentosa (NARP)

The disorder NARP is characterized by proximal neurogenic weakness, pigmentary retinopathy, seizures, ataxia, sensory neuropathy and developmental delay. Mutations in mtDNA (T8993G and T8993C) cause dysfunction of the ATPase 6 subunit of complex V. Leigh syndrome is often present when the mutant mtDNA load is particularly high (>90%). Imaging may show cerebral or cerebellar atrophy, in addition to features of Leigh syndrome. Biochemical findings on muscle biopsy may be normal and RRF or COX-negative fibers are usually absent.

### Kearns–Sayre syndrome, chronic progressive external ophthalmoplegia and Pearson syndrome

Large single deletions or duplications of mtDNA are most often sporadic, with patients having only a single type of abnormal mtDNA, theoretically arising from clonal expansion of a chance rearrangement event in oogenesis or early embryogenesis. Human oocytes contain approximately 100 000 mtDNA molecules, but only about 1000 are passed on to the fetus. If a defective mtDNA molecule passes through this 'bottle-neck', transmission to the fetus may result in mitochondrial disease.<sup>85</sup> Kearns–Sayre syndrome (KSS), chronic progressive external ophthalmoplegia (CPEO) and Pearson syndrome can be associated with sporadic mtDNA duplications/deletions.

Patients with KSS present in childhood with variable combinations of CPEO, pigmentary retinopathy, endocrinopathy, ataxia, proximal myopathy, areflexia, sensorineural deafness, stroke-like episodes, bulbar symptoms, heart block, CSF protein >1 g/L (100 mg/dl) and lactic acidosis. Up to 60% of muscle fibers are COX negative, with RRF in 5–20%. Nearly all patients have a large mtDNA deletion; one that encompasses 4.9 kb from nucleotide 8482 to 13 459 is present in ~40% of cases. This 'common deletion' is also associated with isolated PEO or Pearson syndrome.

PEO consists of ptosis, external ophthalmoplegia and proximal weakness; the autonomic innervation of the eye is not affected. Life span may be normal. The muscle pathological features are similar to KSS.

Pearson syndrome presents in early infancy with a refractory sideroblastic anemia, variable neutropenia and thrombocytopenia, and exocrine pancreatic dysfunction. Diabetes mellitus, liver dysfunction and renal tubular dysfunction may also occur. The 'common deletion' is present in 90% of total blood or bone marrow mtDNA, but may be quite low in muscle or fibroblasts. Muscle histology and biochemistry are often normal. The initial refractory anemia resolves in patients surviving infancy, but these children may progress to KSS, with subsequent accumulation of deleted mtDNA species in muscle and lessening of the mutant mtDNA in blood.<sup>86</sup>

### Mitochondrial DNA depletion syndromes

This term encompasses a number of autosomal recessive conditions in which the concentration of mtDNA is decreased or nearly absent.<sup>87</sup> Deficiency of mitochondrial DNA polymerase gamma, encoded by POLG1, causes Alpers syndrome, epilepsy and fulminant hepatic failure associated with mtDNA depletion.<sup>88</sup> Mitochondria do not contain enzymes for de novo deoxyribonucleoside-5'-triphosphate (dNTP) synthesis and thus rely on salvage pathways, including thymidine kinase and deoxyguanosine kinase for mtDNA replication.

Profound mtDNA depletion may occur in patients with a severe myopathy, lactic acidemia and elevated creatine kinase levels (900–4000 IU/L) who had reduced activity of *mitochondrial thymidine kinase*.<sup>89</sup> Marked elevation of creatine kinase is otherwise rare in mitochondrial disorders and, therefore, serves as a diagnostic clue.

A significant depletion of mtDNA occurs in children with early progressive liver failure and neurological abnormalities secondary to a single nucleotide deletion in the mitochondrial *deoxyguanosine kinase (dGK)* gene.<sup>90</sup> Severe infantile liver disease associated with mtDNA depletion may also be caused by mutations in MPV17, which codes for a mitochondrial inner membrane protein.<sup>91</sup> Mutations in MPV17 also cause *Navajo neurohepatopathy*, a condition characterized by hepatopathy, peripheral neuropathy, corneal anesthesia, failure to thrive and leukoencephalopathy.<sup>92</sup>

Mutations in SUCLA2, a gene that encodes *succinyl-CoA synthetase*, cause early infantile-onset encephalomyopathy and mtDNA depletion.<sup>93</sup> Autosomal recessive POLG1 mutations also cause mtDNA depletion and variable clinical phenotypes, including Alpers syndrome.

Although the majority of cases of mtDNA depletion have autosomal recessive inheritance, the X-linked *mental retardation, epileptic seizures, hypogonadism and hypogenitalism, microcephaly, obesity (MEHMO) syndrome* has been associated with a decreased amount of mtDNA.<sup>94</sup>

Mutations in OPA1, a gene that encodes a dynamin-related protein with GTPase activity that is targeted at mitochondria, cause a common form of autosomal dominant optic atrophy characterized by progressive loss of visual acuity in childhood and mtDNA depletion.<sup>95–97</sup> Some HIV patients treated with nucleoside reverse transcriptase inhibitors have mtDNA depletion and subsequent organ toxicity, possibly secondary to inhibition of DNA polymerase gamma by this class of drug.<sup>98</sup>

### Myoneurogastrointestinal disorder and encephalopathy (MNGIE)

This disorder is characterized by a chronic intestinal pseudo-obstruction, ophthalmoplegia, peripheral neuropathy with 'stocking/glove' sensory loss and myopathy. Deafness is common and developmental regression with white matter disease may be present. Histologically, RRF, a partial COX deficiency and neurogenic changes are seen on muscle histology.<sup>99</sup>

MNGIE is most often caused by mutations in the nuclear gene ECGF1, which encodes thymidine phosphorylase, and is inherited in an autosomal recessive fashion; however, in some cases, mtDNA depletion, multiple mtDNA deletions and a single base pair deletion in the mitochondrial tRNA<sup>Thr</sup> gene have been reported.

### Luft hypermetabolic syndrome

This rare disorder is associated with defective OXPHOS coupling. Patients develop symptoms in childhood consisting of myopathy and euthyroid hypermetabolism, with increased body temperature, sweating, respiratory rate and heart rate. Skeletal muscle OXPHOS is uncoupled with dissipation of the electrochemical gradient generated by the respiratory chain and decreased ATP production.<sup>100</sup>

### Coenzyme Q<sub>10</sub> deficiency

Coenzyme Q<sub>10</sub> is essential to the function of the electron transport chain. Defective synthesis results in loss of coupling and a wide range of typical mitochondrial symptoms in differing combinations. Activities of the individual complexes are normal but when linked together in the assay, are shown to be defective.

Treatment with coenzyme Q<sub>10</sub> in doses up to 300 mg/d are helpful especially in this disorder but also often in other forms of mitochondrial disease

### Other clinical features

Additional manifestations of mitochondrial disease are prenatal effects, including intrauterine growth retardation, hydranencephaly, polyhydramnios, microcephaly, facial dysmorphism and abnormalities of fetal tone and movement.<sup>101,102</sup> In addition, gastrointestinal illness (cyclic vomiting, chronic diarrhea, exocrine pancreatic dysfunction, intestinal pseudo-obstruction, failure to thrive), as well as dermatological findings (mottled pigmentation) can occur.<sup>81,103</sup>

### CLASSIFICATION (Table 26.12)

Because the components of the respiratory chain are coded by both the nuclear and mitochondrial genomes, familial cases of mitochondrial disorders may show either maternal or Mendelian inheritance. Sporadic cases also occur as a result of new mutations, presumably in the oocyte or early after fertilization.

### Defects of the mitochondrial genome

#### Point mutations

Many benign mtDNA polymorphisms are known; they are used in anthropologic studies. Over 100 pathogenic mtDNA point mutations have been described. MELAS, MERRF, LHON and NARP have each been associated with several specific point mutations.<sup>77</sup> Conversely, the same mtDNA mutations can lead to different findings in different patients. *Maternally inherited deafness with aminoglycoside sensitivity (MIDAS)* is caused by an A to G transition at base pair 1555 in the mitochondrial 12S ribosomal subunit gene.

#### Multiple deletions, duplications or duplications/deletions

Other major rearrangements of mtDNA include duplications, most commonly present in the context of duplications/deletions, and multiple deletions. While *single* mtDNA deletions may exhibit maternal inheritance and can be associated with various phenotypes, including KSS, *multiple* deletions of mtDNA exhibit Mendelian inheritance and are caused by defective signaling between the nuclear and mitochondrial genomes, with resultant defective mtDNA replication (see below).

### Nuclear genome defects

Defects of nDNA that result in abnormal mitochondrial respiratory chain function are inherited in a Mendelian fashion and may be responsible for the majority of cases of mitochondrial disease. They can cause dysfunction of specific respiratory chain subunits; intergenomic communication between nuclear and mitochondrial genomes, oxidation/phosphorylation coupling; substrate pores or translocases; mitochondrial protein importation; or intramitochondrial metal homeostasis.<sup>76,77</sup>

#### Defects in nuclear genes of respiratory chain subunits

Defects in respiratory chain subunits encoded by nDNA are inherited in an autosomal recessive manner. The first reported defect was a mutation in the flavoprotein (Fp) subunit gene of succinate dehydrogenase (complex II) in Leigh syndrome.<sup>104</sup> Succinate dehydrogenase mutations have been associated with familial pheochromocytoma and paraganglioma, highlighting an interesting link between mitochondrial dysfunction and hereditary cancer.<sup>105,106</sup>

Mutations in 10 nuclear genes coding for complex I have been described; these cause brain and brainstem pathology, especially Leigh syndrome or leukoencephalopathy. Mutations in complex I subunit genes NDUF2 and NDUFB2 cause hypertrophic cardiomyopathy and encephalomyopathy.<sup>82,107</sup>

### Defects in intergenomic communication

Certain nDNA mutations result in either aberrant subunit biogenesis/maintenance or mtDNA replicative errors. Mutations in NDUF6 cause defective assembly or stability of complex I, resulting in a lethal neonatal encephalomyopathy.<sup>108</sup> Mutations in BSCIL, an assembly gene for complex III, result in encephalopathy, renal tubulopathy and liver disease.<sup>109</sup> Similarly, nuclear mutations have been detected in a number of genes coding for assembly factors for COX (complex IV). Patients with COX deficiency secondary to mutations of SURF-1, which is important in the assembly of stability of complex IV, develop Leigh syndrome.<sup>110,111</sup> Impaired mitochondrial copper metabolism, and subsequent defective COX activity, occurs in mutations affecting the SCO1 and SCO2 genes, with patients having early-onset encephalopathy and either liver disease or hypertrophic cardiomyopathy, respectively.<sup>112,113</sup> COX10 codes for heme A:farnesyltransferase, an inner mitochondrial membrane protein important in the biogenesis of COX; deficiency has been reported in siblings who have died with progressive neurological deterioration and proximal renal tubulopathy.<sup>114</sup> Nuclear defects involved in the biosynthesis of complex V have also been reported. Clinical features include severe neonatal disease with lactic acidosis, hypotonia or hypertonia, seizures, contractures, cardiomegaly and hepatomegaly.<sup>115,116</sup>

Because nDNA codes for enzymes involved in mtDNA transcription, translation and replication, defects in intergenomic communication may cause qualitative or quantitative alterations of mtDNA. Although all the genes responsible have not yet been identified, multiple mtDNA deletions (cf. single sporadic deletions) and depletion in the amount of mtDNA are inherited in a Mendelian fashion.<sup>87</sup> Autosomal recessive and autosomal dominant forms of PEO are associated with multiple deletions of mtDNA. POLG1 encodes mitochondrial DNA polymerase gamma; mutations in this gene are a relatively common cause of autosomal dominant and autosomal recessive PEO.<sup>117</sup> POLG1 mutations are also associated with a wide array of overlapping clinical features, including severe encephalomyopathy, ataxia, myalgia and liver failure.<sup>118</sup> PEO may also be caused by mutations in POLG2, the gene encoding the p55 accessory subunit of polymerase gamma.<sup>119</sup> Mutations in ANT1 (encodes the heart and muscle-specific isoform of the mitochondrial adenine nucleotide transporter) and C10orf0002 (encodes Twinkle, a mtDNA helicase) are less common causes of autosomal dominant PEO.<sup>121,122</sup>

#### Defects in mitochondrial substrate pores or translocases

All the molecules required for OXPHOS reactions, including ATP, ADP, phosphate and other ions, must cross the inner and outer mitochondrial membranes through protein channels. Dysfunction of the *adenine nucleotide* translocator (ANT) by voltage-dependent anion channel (VDAC), or the *malate-aspartate shuttle* may cause classic symptoms and signs of mitochondrial disease.

The ANT transports ADP and ATP across the inner mitochondrial membrane; a defect of this system has been reported in a patient with myopathy and lactic acidosis.<sup>122</sup> (Mutations in ANT1 have also been associated with autosomal dominant PEO.) VDAC (also called porin) is an outer mitochondrial membrane transporter that opens differentially for anions, cations and certain uncharged molecules at different transmembrane voltages. VDAC deficiency was documented in a dysmorphic infant with hypothalamic hypothyroidism and psychomotor retardation.<sup>123</sup> Investigation of a young adult with exercise-induced myalgia documented a defect in the inner mitochondrial membrane malate-aspartate shuttle.<sup>124</sup>

#### Defects in importation of mitochondrial proteins

Proteins that are destined for import into mitochondria contain a leader sequence that acts as a targeting signal. They are then translocated into the mitochondrial matrix by import machinery consisting of chaperonins and translocases of the outer and inner mitochondrial membranes (*Tom* and *Tim* complexes). The mitochondrial matrix chaperonin heat shock protein 60 (hsp60) ensures proper folding of the imported proteins.

*Defective hsp60* synthesis was associated with decreased activities of multiple mitochondrial enzymes in a patient who died aged 2 d, after presenting with dysmorphic features, hypotonia and severe lactic acidosis.<sup>125</sup> A defect in *paraplegin*, a ubiquitous inner mitochondrial membrane protein with proteolytic and chaperonin activities, was found in patients with hereditary spastic paraplegia (HSP) in which progressive weakness and spasticity of the lower limbs occur; other features, including developmental delay, optic atrophy, retinitis pigmentosa, deafness, ataxia and ichthyosis, may be present. Muscle biopsies from two patients with HSP showed RRF, a finding consistent with impaired OXPHOS.<sup>126</sup>

Finally, the X-linked neurodegenerative disorder *Mohr-Tranebjaerg syndrome* (DFN-1/MTS) is caused by mutations in the gene coding for the deafness/dystonia peptide (DDP), a protein which bears strong resemblance to the Tim subclass of mitochondrial transmembrane carrier proteins.<sup>127</sup> Mutations in the DDP1 gene cause decreased levels of the inner mitochondrial membrane Tim23 complex, which is required for mitochondrial import of proteins responsible for the translocation, assembly and integrity of the OXPHOS system. Patients with MTS have dystonia, spasticity, developmental delay and progressive sensorineural hearing loss.

### Defects in intramitochondrial metal homeostasis

The neurodegenerative disorders Friedreich ataxia, X-linked sideroblastic anemia and ataxia (XLSA/A), and Wilson disease are associated with aberrant intramitochondrial metal homeostasis, which may secondarily cause dysfunction of the respiratory chain.<sup>128</sup> Friedreich ataxia (see Ch. 29) is caused by an expansion of a GAA triplet repeat in the gene frataxin that codes for a mitochondrial protein involved in iron homeostasis. The result is an intramitochondrial accumulation of free iron, which impairs oxidative metabolism, possibly by interfering with the normal production of heme and iron-sulfur clusters.<sup>129</sup>

Iron homeostasis is also altered in XLSA/A, a disorder characterized by nonprogressive cerebellar ataxia and mild anemia starting in infancy or early childhood. The mitochondrial inner membrane iron transporter ABC7 is defective in XLSA/A.<sup>130</sup>

In Wilson disease (see p. 1125) a modified, cleaved, form of the mutant protein is found in mitochondria.<sup>131</sup> The mutation results in intramitochondrial copper overload, mtDNA deletions and abnormal respiratory chain function. Mutations in SCO1 and SCO2, nuclear genes that play a role in mitochondrial copper delivery, have been found in patients with COX deficiency.

### Other nuclear genome defects

*Barth syndrome* (3-methylglutaconic aciduria type II) is discussed on p. 1098.

### Other neurodegenerative disorders

Diminishing respiratory chain function and increasing clones of mutant mtDNA occur as we age and are thought to play a role in the development of several neurodegenerative disorders with onset in adulthood, including Alzheimer disease, Parkinson disease, Huntington disease and amyotrophic lateral sclerosis.<sup>132-134</sup> In this context, the roles of aging, damage from free radicals, external toxins and genetics are still not understood.

## GENETIC COUNSELING (see also Ch. 14)

A meticulous pedigree is essential to evaluating any patient with suspected mitochondrial disease; it may reveal Mendelian (dominant, recessive or occasionally X-linked) or maternal inheritance [matrilineal] with family members having variable phenotypes). A family history of hearing loss, vision problems, muscle weakness, behavior abnormalities, migraines, diabetes mellitus and other endocrine disease, or short stature, transmitted only by females, should always be sought.

Single mutations in mtDNA are transmitted matrilineally. Both single and large deletions in mtDNA are usually sporadic with little or no

risk of recurrence, but more complex deletion/duplications of mtDNA may be inherited (possibly ~5% transmission to offspring, but little data exist to support this figure). Multiple mtDNA mutations may be inherited in an autosomal dominant or autosomal recessive manner. Genetic counseling is more straightforward in cases of nDNA mutations; affected relatives tend to have similar features and classic Mendelian inheritance can be more readily understood by the family.

Most children with mitochondrial disease are diagnosed clinically or by the finding of decreased activity in one or more of the respiratory chain complexes and do not have a specific mutation identified. In these cases, it is difficult to provide accurate recurrence risk estimates, unless a particular mode of inheritance is suggested by the pedigree. Because of the inherent characteristics of mitochondrial biology (heteroplasmy, replicative segregation, threshold effect), genetic counseling is particularly challenging. Moreover, even if maternal inheritance seems likely on the basis of family history, it may not be possible to predict the expression of disease in current or future children. In a given family with mtDNA disease, future offspring may be more, similarly or less affected than the proband. Empiric recurrence risks have been estimated for some of the more common mtDNA disorders based on maternal blood mutation loads.<sup>71</sup> The blood percentage of abnormal mtDNA in MELAS and MERRF does *not* correlate well with expression of clinical features, but there appears to be relatively good correlation with mutant load and outcome in NARP. Nevertheless, while counseling is relatively straightforward in NARP with either a very high or very low percentage of mutant mtDNA, difficulty is encountered in less clear-cut patients with intermediate mutant loads.<sup>135</sup>

Prenatal diagnosis of mtDNA disorders has been attempted by mutation analysis on amniocytes or chorionic villi. However, the mutant load in these tissues does not necessarily predict the distribution or percentage of mutant mtDNA in other tissues after birth. It has been suggested that mutant loads < 30% or > 90% may predict a low or high probability, respectively, of having a child with clinical disease, although this information must still be treated with caution.<sup>71</sup>

Molecular prenatal genetic diagnosis of oocytes, oocyte cytoplasmic transfer to dilute mutant mtDNA and transfer of an unfertilized oocyte nucleus into an enucleated donor oocyte (followed by in vitro fertilization and reimplantation) are experimental techniques that may offer female carriers of an mtDNA mutation reproductive options in the near future.

## CLINICAL EVALUATION OF SUSPECTED MITOCHONDRIAL DISEASE

Lactic acidosis is discussed on p. 1080 and the organic acidurias on p. 1066. Urine organic acid analysis may be normal, or show variable elevations of lactate, pyruvate, ketone bodies, tricarboxylic acid cycle intermediates or other organic acids, including ethylmalonic, malic, fumaric, 3-methylglutaconic, 2-ethylhydracrylic, 2-methylsuccinic and glutaric acids.<sup>136</sup> Orotic acid, from the urea cycle, and dicarboxylic acids, from compromised fatty acid oxidation, may also be present. All these reflect distorted intramitochondrial homeostasis secondary to primary respiratory chain dysfunction.<sup>137</sup> Generalized aminoaciduria is present in the renal Fanconi syndrome (see Ch. 18, p. 550).

Because elevations of specific acylcarnitines are characteristic of fatty acid oxidation disorders, a plasma acylcarnitine profile may help to differentiate a fatty acid oxidation disorder from a defect in the respiratory chain (see Appendix 1). Plasma carnitine can be low due to increased excretion of conjugates or to poor nutrition. Highly elevated creatine kinase levels are unusual, but have been reported in the mtDNA depletion syndrome.

Periodic screening tests to monitor ophthalmological, hearing, cardiac, liver and renal function are an essential part of the evaluation of these patients. In patients with neurological symptoms, brain MRI is routinely performed and EEG may be indicated. Positron emission tomography (PET), single photon emission computed tomography

(SPECT) and proton MRS have also been used to study blood flow, lactate, oxygen and glucose metabolism in brain and muscle. Deep gray matter signal abnormalities on MRI and abnormal lactate elevation on proton MRS are relatively common.<sup>138</sup>

### Muscle biopsy

Muscle tissue for histology, histochemical staining, ultrastructural morphology and biochemical analysis may be needed to diagnose a respiratory chain disorder.<sup>76</sup> It is essential that processing of the tissues be discussed with the referral laboratories *before* any biopsy is done since samples are processed differently depending on what tests might be required; this is especially true for biochemical testing.

Histologically, the modified Gomori trichrome stain detects abnormal red-staining subsarcolemmal collections of mitochondria that give rise to the term RRF and are considered to be a classic feature of mitochondrial disease. However, these are often not present in children and therefore, their absence does *not* exclude the consideration of mitochondrial disease. Conversely, RRF and ultrastructurally abnormal mitochondria, reflecting oxidative stress, may be present in other conditions, including overtraining, inflammatory myopathies, myotonic dystrophy and Duchenne muscular dystrophy.<sup>76</sup> Histochemical staining for succinate dehydrogenase (SDH) and COX activities is also routine. SDH staining is a sensitive indicator of mitochondrial proliferation. COX staining is particularly useful in distinguishing mtDNA defects, which show a differential mosaic staining pattern with some fibers staining COX positive and others COX negative. In nuclear defects that affect COX activity, fibers are uniformly COX negative.<sup>76</sup> In addition, COX-positive RRF are seen in MELAS. Other nonspecific histopathological findings of respiratory chain disorders include accumulation of glycogen and/or lipid, fiber-type variation, or neurogenic changes.<sup>139</sup> In some cases, muscle histology may appear entirely normal. Abnormal mitochondria, often with paracrystalline inclusions or alteration in shape and size, or an increased number of mitochondria may be apparent by electron microscopy, but such changes are nonspecific.

Muscle is the best surrogate tissue for quantitation of respiratory chain function using spectrophotometric or polarographic techniques, because of its higher oxidative enzyme activities. However, some defects are only expressed in an affected tissue, in which case that tissue must be tested to find the biochemical defect.<sup>75</sup> Biochemical analyses may reveal isolated respiratory chain deficiencies, indicating a new somatic mutation in a specific mtDNA respiratory chain subunit gene or a nuclear defect, or combined partial complex deficiencies suggestive of a mtDNA tRNA mutation. The absence of a biochemical defect does not exclude a diagnosis of mitochondrial disease, and may be seen, for example, in some cases of mtDNA mutations affecting mitochondrial tRNAs. Some laboratories use monoclonal antibodies that recognize different respiratory chain subunits to perform immunohistochemical and/or Western blotting analyses on skin fibroblasts or biopsy specimens.<sup>140,141</sup>

When mitochondrial disease is suspected, some experts prefer to start by searching for mutations in blood since tests for several common point mutations and deletions of mtDNA are available. However, these are limited and if none is found, a mitochondrial disorder is not excluded. Furthermore, the mutation may simply not be present in a high enough concentration to be detected in the assayed tissue. While many mtDNA point mutations and some deletions or duplications can be detected in blood, multiple mtDNA deletions or complex rearrangements may require analysis of a muscle specimen. Overall, mtDNA deletions have been found in approximately 12% (11% single, 1% multiple) of patients with documented respiratory chain dysfunction and mitochondrial tRNA mutations in 16%, while the remainder are undiagnosed at the molecular level (possibly reflecting the presence of rare mtDNA or nDNA mutations that are not usually screened for).<sup>142</sup> In cases where a nuclear gene is suspected, further investigations may be available in specialized laboratories. On the Internet, Genetests (<http://www.genetests.org>) is a reliable search tool.

### THERAPY

There is no proven specific therapy for most respiratory chain disorders although some successes have been reported. Almost all approaches attempt to capitalize upon compounds that are known to facilitate or to interdigitate with the respiratory chain. These include various combinations of L-carnitine, ascorbate, tocopherol, succinate, riboflavin, menadione, nicotinamide, thiamine, creatine, idebenone and coenzyme Q<sub>10</sub> (Table 26.13).<sup>72</sup> However, it is difficult to assess the efficacy of any therapy given the genetic heterogeneity and broad clinical spectra of these diseases. Riboflavin may stabilize or improve features in some cases of complex I deficiency<sup>143</sup> and rarely, menadione can act as an electron acceptor. In some patients, especially those with a primary deficiency of coenzyme Q<sub>10</sub> in muscle,<sup>144-146</sup> coenzyme Q<sub>10</sub> decreases blood lactate levels and may improve oxygen utilization and clinical symptoms. Vitamin E and coenzyme Q<sub>10</sub> have improved cardiac and skeletal muscle bioenergetics in Friedreich ataxia.<sup>147</sup> Succinate, if given

Table 26.13 Vitamin, cofactor and drug therapy of mitochondrial disease

Medication	Mechanism	Dose
Ubiquinone (coenzyme Q <sub>10</sub> )	Bypass of complex I Antioxidant	5 mg/kg/d 30–250 mg/d in adults
Idebenone	Bypass of complex I Antioxidant	90–270 mg/d in adults
Carnitine	Corrects secondary Deficiency	50–100 mg/kg/d Up to 3 g/d in adults
Dichloroacetate	Stimulates PDH activity	15–200 mg/kg/d
Succinate	Directly donates electrons to complex II	1–6 g/d
Thiamin (vitamin B <sub>1</sub> )	PDH cofactor Stimulates NADH production	15–30 mg/kg/d 500–1000 mg/d in adults
Riboflavin (vitamin B <sub>2</sub> )	Cofactor for complex I and II and ETF after conversion to FAD	10–15 mg/kg/d 500–1000 mg/d in adults
Nicotinamide	Increase NAD, NADH pool	20 mg/kg/d 100–1000 mg/d in adults
Ascorbic acid (vitamin C)	Antioxidant Bypass complex III when given with K <sub>1</sub> or K <sub>3</sub>	25–100 mg/kg/d Up to 6 g/d in adults
Menadione (vitamin K <sub>3</sub> )	Antioxidant Bypass complex III when given with ascorbate	40–80 mg/d
Creatine	Increases muscle phosphocreatine	Up to 10 g/d in adults
Pantothenic acid	Increases CoA synthesis	15 mg/kg/d
A-Tocopherol (vitamin E)	Antioxidant	15 mg/kg/d (22 IU/kg/d)
Lipoic acid	Antioxidant	15 mg/kg/d

These vitamins and cofactors are typically given together in various combinations. For example, coenzyme Q<sub>10</sub>, vitamin C, vitamin E and lipoic acid are often used simultaneously for antioxidant action, because together their cooperative action is more effective in free radical defense than if given singly. Vitamin K<sub>3</sub> should not be given unless there is conclusive evidence of a complex III deficiency. K<sub>3</sub> shunts electrons from complex I to complex IV in the presence of vitamin C, effectively bypassing complex III. This has the potential to decrease ATP production in patients without complex III deficiency. ETF, electron transfer flavoprotein; FAD, flavin adenine dinucleotide; FMP, flavin monophosphate; NAD, nicotine adenine dinucleotide (oxidized); NADH, nicotine adenine dinucleotide (reduced); PDH, pyruvate dehydrogenase complex.

in quantities as a potential fuel, may be beneficial in patients with complex I deficiency, because of its ability to donate electrons directly to complex II.

Dichloroacetate (DCA) stimulates pyruvate dehydrogenase (p.1080) activity and causes a decrease in blood lactate, improved brain oxidative metabolism on MRS, and amelioration of clinical symptoms in some patients with mitochondrial disease.<sup>148,149</sup> However, a controlled clinical trial using DCA to treat a variety of causes of lactic acidemia, including mitochondrial disorders, showed that the medication was well tolerated and blunted the postprandial increase in circulating lactate, but did not improve neurological or other measures of clinical outcome.<sup>70</sup> A trial of DCA in MELAS patients was terminated early because it was found to cause peripheral neuropathy.<sup>150</sup> On the other hand, L-arginine (a precursor of creatine) appears to improve endothelial function and has potential for treatment in MELAS.<sup>151</sup> Patients with mitochondrial disease may have uridine deficiency and supplementation with triacetyluridine has resulted in improved strength, growth and renal tubular function in some patients.

OXPHOS disorders may cause hyperglycemia due to difficulty in oxidative metabolism of a large glucose load; in which case, a diabetic diet may be of value. In patients with secondary impairment of beta-oxidation of fatty acids, a low fat diet should be tried.

When mtDNA mutations in muscle are heteroplasmic, a novel therapeutic approach has been proposed by which exercise-induced muscle damage could result in altering the proportions of normal and mutant mtDNA as the tissue repairs. This is called *gene shifting*.<sup>152</sup> Resistance exercise training that induces muscle damage has the potential to stimulate dormant myoblast satellite cells to fuse with regenerating myofibers. In theory, myoblasts with normal mtDNA (and energy production) would be at a selective advantage and more likely to undergo such fusion as has been shown in a patient undergoing such exercise training. Spontaneous improvement, with a decrease in the proportion of mutant mtDNA in muscle, has been observed in a patient with a mtDNA point mutation, giving further support to the theoretical possibility of this approach.<sup>153</sup> Aerobic exercise appears to increase oxidative capacity in patients with mtDNA mutations, possibly by inducing mitochondrial proliferation. It is not clear, however, why production of the normal mtDNA might exceed that of the mutant and the long term outcome of such training is unknown.<sup>154</sup>

Experiments in gene therapy for respiratory chain disorders include complementation by cytosolic synthesis of mitochondrial proteins containing an appropriate targeting sequence, with subsequent translocation into mitochondria; direct mitochondrial transfection with an entire normal mitochondrial genome or polymerase chain reaction (PCR)-generated fragments of complementing DNA;<sup>155</sup> and sequence specific oligonucleotide or peptide–nucleotide conjugate targeting of mutant mtDNA.<sup>156</sup>

## DISORDERS OF LIPID, LIPOPROTEIN AND BILE ACID METABOLISM

Disorders of lipid and lipoprotein metabolism are important and common in pediatrics, frequently with a genetic basis. Detection of dyslipidemia or early onset of cardiovascular disease in a closely related adult is an indication for young relatives also to be tested. Treatment of affected children with lipid-lowering medication may be warranted in some situations. Although atherosclerotic vascular disease is almost non-existent in children, homozygous familial hypercholesterolemia may cause myocardial infarction (MI) and death before age 20 years, and other forms of severe hyperlipidemia may cause MI in the third or fourth decade. Severe hypertriglyceridemia is also associated with increased risk of pancreatitis, a potentially life threatening complication. In addition to familial disorders, hyperlipidemia is an important complication of other metabolic disorders such as diabetes, obesity and the use of some medications. Finally, identification of secondary hyperlipidemia may indicate an underlying condition, such as hypothyroidism.

## Basic biochemistry

The primary lipids in plasma are triglycerides, cholesterol and phospholipids. Other lipids that occur in small amounts in plasma include free fatty acids, mono- and di-glycerides, steroid hormones (e.g. testosterone, estradiol, cortisol), sterol-derived vitamins (e.g. vitamin D), terpenes (e.g. vitamins A, E and K) and sterols other than cholesterol (e.g. desmosterol, 7-dehydrocholesterol). Because of their innate insolubility in aqueous media, lipids are transported in plasma as a constituent of lipoproteins or bound to plasma carrier proteins.

## Triglycerides and fatty acids

Triglycerides, which are composed of three fatty acid molecules covalently bound to a glycerol molecule, are synthesized in the liver from acetate or fatty acids and in the intestinal mucosa from absorbed dietary fat. Triglycerides are secreted into plasma in lipoproteins via the endogenous and exogenous pathways (Fig. 26.20). Free fatty acids (non-esterified) are normally present in plasma in small amounts, primarily bound to albumin, and have a short half-life of 4–8 min, but the majority of fatty acids in plasma occur in the form of triglycerides and to a lesser extent in phospholipids and cholesteryl esters in lipoproteins. Release of free fatty acids and glycerol from adipose tissue triglyceride stores normally is increased during exercise, stress and fasting as a consequence of increased activity of hormone sensitive lipase. Increased release of free fatty acids in patients with uncontrolled diabetes occurs as a result of the loss of insulin-mediated inhibition of phosphorylative activation of hormone-sensitive lipase. A sustained increase in delivery of free fatty acids and/or glucose to the liver, as occurs in uncontrolled diabetes, greatly stimulates hepatic synthesis of triglycerides, leading to hypertriglyceridemia. Relative deficiency of lipoprotein lipase in uncontrolled diabetes contributes to hypertriglyceridemia by delaying triglyceride lipolysis. During hydrolysis of triglycerides, mono- and di-glycerides are generated as intermediate products.

Fatty acids are classified on the basis of chain length and degree of saturation. Short chain fatty acids contain 2–6 carbon atoms, medium chain fatty acids contain 8–10 carbon atoms and long chain fatty acids contain > 12 carbon atoms. Very long chain fatty acids normally are a minor component of the fatty acid pool, but these molecules accumulate in patients with peroxisomal disorders (see p. 1113). Saturated fatty acids (e.g. stearic acid, C18:0) contain no double bonds, whereas mono-unsaturated fatty acids (e.g. oleic acid, C18:1 $\omega$ 9) contain a single double bond and polyunsaturated fatty acids (e.g. linoleic acid, C18:3 $\omega$ 6) contain two or more double bonds. Unsaturated fatty acids are further subclassified into four classes,  $\omega$ 3 (e.g. linolenic acid),  $\omega$ 6 (e.g. linoleic acid),  $\omega$ 7 (e.g. palmitoleic acid) and  $\omega$ 9 (e.g. oleic acid), on the basis of

Fig. 26.20 Exogenous and endogenous sources of plasma triglycerides. TG, triglyceride; VLDL, very low density lipoprotein.

the position of the first double bond from the methylene end of the molecule. The  $\omega 3$  fatty acids found in marine oils and fish, such as eicosapentaenoic acid (EPA, C20:5 $\omega 3$ ) and docosahexaenoic acid (DHA, C22:6 $\omega 3$ ), have potent triglyceride-lowering effects when given in sufficient doses, may modulate immunity and platelet function, may have additional cardioprotective effects, and also may have a role in pre- and post-natal development of the brain and retina.

### Cholesterol

Cholesterol is synthesized from acetate by the liver and intestinal mucosa and released into plasma in lipoproteins. Other cell types also have the capacity to synthesize cholesterol in response to local cellular requirements, but most of this does not appear in plasma. All cholesterol in the brain is synthesized within the CNS. Current evidence suggests that a large proportion of cholesterol in high-density lipoprotein (HDL) particles may be derived by receptor-mediated efflux from peripheral tissues. Although the majority of cholesterol in the body is synthesized endogenously, dietary cholesterol nonetheless influences the plasma cholesterol concentration by modulating hepatic secretion and uptake of cholesterol via transcriptional regulation of key enzymes and receptors. Delivery of dietary cholesterol to the liver inhibits proteolytic activation of sterol regulatory element binding protein-2 (SREBP-2), which is an agonist for the SRE in the regulatory sequence of the low density lipoprotein (LDL) receptor gene and other genes. Hence, increased intake of dietary cholesterol decreases hepatic expression of the LDL receptor, thereby contributing to hypercholesterolemia. Under normal conditions, about 40–50% of dietary cholesterol is absorbed. Cholesterol biosynthesis is regulated in the liver by the rate-limiting enzyme, 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase), which is the inhibitory target of 'statin' cholesterol lowering medications. A large amount of cholesterol and cholesterol derived bile acids circulate in the enterohepatic circulation, a pathway that consists of hepatic secretion of bile acids and cholesterol into the intestinal lumen via the bile duct followed by reabsorption of a portion of bile acids and cholesterol distally. The majority of cholesterol in plasma and tissues is esterified with a single fatty acid molecule to form cholesteryl esters.

### Phospholipids

The plasma phospholipids are primarily derived from hepatic and intestinal synthesis, but can be synthesized by many body tissues. Phospholipids are acylglycerols that contain phosphoric acid esterified to the C<sub>3</sub>-hydroxyl group. The four major classes of phospholipids are phosphatidyl choline (lecithin), phosphatidyl serine, phosphatidyl ethanolamine and phosphatidyl inositol. As a consequence of their polar

structure, three of the four phospholipid classes form bilayers in aqueous media and are a critical component of cell membranes and the surface coat of lipoproteins. Phosphatidyl ethanolamine also is incorporated into cell membranes, but in isolation it has a tendency to form hexagonal complexes. As a consequence of the localization of phospholipids in the surface coat of lipoproteins, the phospholipid content of lipoprotein particles (expressed as a percentage of total weight) tends to be inversely proportional to particle size.

### Lipoproteins

The three main lipids, triglycerides, phospholipids and cholesterol, are transported in plasma as constituents of various lipoproteins that can be characterized on the basis of lipid composition, protein composition, particle size and density, nuclear magnetic resonance (NMR) spectroscopy and electrophoretic mobility. The various lipoprotein particles also differ in their origin and metabolic fate. The characteristics of the six major lipoprotein classes are shown in Table 26.14. The lipoprotein classes are sometimes subfractionated on the basis of density (e.g. HDL2a, HDL2b, HDL3; LDL1, LDL2, LDL3) or size (e.g. LDL pattern A [large] and B [small]), but subfractionation is unnecessary for most clinical situations. The protein moieties of lipoproteins, which are referred to as apoproteins (Table 26.15), contribute to the structure and metabolic fate of various lipoprotein particles. HDL particles also can be subfractionated into particles containing apo A-I without A-II [HDL(A-I)] and particles containing apo A-I and A-II [HDL(A-I/A-II)]. HDL(A-I) particles may be more cardioprotective than HDL(A-I/A-II) particles.

## LIPOPROTEIN METABOLISM

### Chylomicrons

Chylomicrons are synthesized by enterocytes in the small intestine and secreted into the thoracic duct in response to absorption of dietary fat. Dietary lipids undergo hydrolysis in the intestinal lumen, allowing absorption of the resulting fatty acids and glycerol by enterocytes. Fatty acids with a chain length of <10–12 carbon atoms tend to be absorbed into the portal circulation, whereas other fatty acids are utilized by the intestinal mucosal cells for synthesis of chylomicrons. Enterocytes use hydrolyzed lipid products as substrates for synthesis of triglycerides, cholesteryl esters and phospholipids, which are combined with a single apo B-48 molecule, apoproteins A-I, A-II, A-IV and some apo C-II and E to form chylomicrons. Chylomicrons are slowly released into the circulation via the thoracic duct, normally resulting in a peak plasma triglyceride concentration 4–6 h after fat ingestion and return to baseline after 8–10 h. After release into the plasma, chylomicrons are

Table 26.14 Characteristics of plasma lipoproteins

Lipoprotein	Electrophoretic mobility	Density (g/ml)	Size (Å)	Lipid composition (% of total weight)*	Major apoproteins	Origin
Chylomicrons	Alpha <sub>2</sub>	0.95	800–5000	2% P, 7% PL, 2% FC, 5% CE, 84% TG	B-48, C-I, C-II, C-III, E	Intestine
VLDL	Pre-beta	0.95–1.006	300–800	8% P, 19% PL, 7% FC, 13% CE, 53% TG	B-100, C-I, C-II, C-III, E	Liver
IDL	Low pre-beta (broad beta)	1.006–1.019	250–350	19% P, 19% PL, 9% FC, 29% CE, 23% TG	B-100, E	VLDL, chylomicrons
LDL	Beta	1.019–1.063	200–250	21% P, 22% PL, 8% FC, 37% CE, 11% TG	B-100	VLDL, liver
Lipoprotein(a)	Sinking pre-beta	1.06–1.08	200–300	33% P, 22% PL, 9% FC, 33% CE, 3% TG	B-100, apo(a)	Liver
HDL	Alpha <sub>1</sub>	1.063–1.21	75–100	50% P, 23% PL, 4% FC, 18% CE, 4% TG	A-I (70–75% of protein) A-II, (A-IV, D, CI-III, E)	Liver, peripheral tissues, intestine

\*Dominant lipid in each protein is in italics.

CE, cholesteryl ester; FC, free cholesterol; HDL, high density lipoprotein; IDL, intermediate density lipoprotein; LDL, low density lipoprotein; P, protein; PL, phospholipid; TG, triglyceride; VLDL, very low density lipoprotein.

Table 26.15 Major plasma apoproteins

Apoprotein	Origin	Molecular weight	Metabolic function
A-I (apolipoprotein I)	Liver, intestine	28 000	Activates LCAT; ligand for ABC-A1 receptor, ABCG1, SR-B1, cubulin/megalin
A-II	Liver, intestine	17 500	May facilitate activation of hepatic lipase, may inhibit LCAT
A-IV	Intestine, liver	44 500	May facilitate LPL activation; activates LCAT, affects HDL assembly and metabolism
A-V	Liver		May be important determinant of plasma triglyceride concentrations
Apo(a)	Liver	Variable: 400–800 000	Covalently bound to apo B-100 in Lp(a) via sulfhydryl linkage; may adversely influence fibrinolysis and lipid deposition at sites of arterial injury
B-48	Intestine	264 000	Structural protein in chylomicrons. Truncated version of apo B-100
B-100	Liver	550 000	Structural protein in LDL and VLDL, binds to LDL receptor; essential for synthesis and secretion of VLDL
C-I	Liver, adrenal	7000	Cofactor for LCAT, inhibits CETP
C-II	Liver, (intestine)	9000	Cofactor for LPL
C-III	Liver	9000	Inhibits LPL activation, cofactor for sphingomyelinase, may activate LCAT
C-IV	Liver	16 000	Associated mostly with VLDL, some in HDL. Probably involved in triglyceride metabolism
D	Adrenal, kidney, pancreas, placenta, brain, intestine, spleen, testes	29 000	May facilitate interlipoprotein and intercell lipid transfer, involved in brain lipid metabolism, activates LCAT. Carried in HDL
E (E2, E3, E4)	Liver, (intestine), CNS, peripheral tissues, macrophages	34 000	Binds to LDL and apo E receptors, facilitates hepatic uptake of VLDL and chylomicron remnants. Dominant apoprotein in brain
F	Liver	33 000	Lipid transfer inhibitor protein (LTIP), inhibits CETP, associated with LDL
H ( $\beta$ 2-glycoprotein I)	Liver	43 000	Component of HDL and chylomicrons, may facilitate LPL activation
J (clusterin)	Liver, other?	70 000	Binds to megalin (LRP2); found in amyloid, may be involved in neurodegenerative disorders, found in all human fluids including CSF
M (protein G3a)	Liver, kidney	26 000	Member of lipocalin protein superfamily. Associates with HDL, but also VLDL and LDL. Binds to megalin (LRP2).
Transfer proteins	Liver	Variable	Transfer of lipids between lipoproteins

CETP, cholesteryl ester transfer protein; HDL, high density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low density lipoprotein; LPL, lipoprotein lipase; SR-B1, scavenger receptor-B1; VLDL, very low density lipoprotein.

rapidly remodeled and catabolized with a half-life < 15 min. Transfer of apo C and E from HDL to chylomicrons facilitates the hydrolysis of chylomicron triglycerides by lipoprotein lipase (LPL) and subsequent hepatic uptake of triglyceride-depleted chylomicron remnants via the LDL receptor-related protein (LRP), apo E receptor and proteoglycan-mediated uptake pathways. During chylomicron degradation, fatty acids released by LPL in peripheral tissues can be utilized for energy or storage as triglycerides in adipose tissue. Apoproteins A-I and A-II and phospholipids are transferred to HDL during chylomicron catabolism.

### Very low density lipoprotein

Very low density lipoprotein (VLDL) particles are primarily secreted by the liver, although there is evidence for intestinal secretion of VLDL. The rate of synthesis of VLDL is dependent on hormonal factors (such as insulin), time of day, diet, amount of adiposity (particularly visceral fat mass), and availability of substrate for triglyceride synthesis. Apo B-100 synthesis is essential for VLDL synthesis and secretion. During the initial steps of VLDL synthesis, apo B-100 is required on the endoplasmic reticulum to facilitate the aggregation of triglyceride and other lipids

to form VLDL particles. Thus, lack of apo B-100, or the presence of truncation mutations in apo B-100, can suppress VLDL secretion. The metabolic pathways for VLDL particles in plasma are similar to those of chylomicrons, but VLDL particles also are remodeled by hepatic lipase and typically have a much longer half-life in plasma of 6–12 h. In addition, VLDL particles are sequentially metabolized to become intermediate density lipoprotein (IDL) particles and subsequently LDL particles. VLDL remnants can be taken up by hepatic LDL, apo E and LRP receptors. The important role of apo E in hepatic clearance of VLDL from plasma is illustrated by the marked accumulation of VLDL and chylomicron remnants in patients with type III hyperlipidemia resulting from increased VLDL secretion in the context of homozygosity for apo E2, a defective ligand for the apo E receptor and LRP.

### Low density lipoprotein

The majority of LDL particles in plasma derives from intravascular catabolism and remodeling of VLDL particles. To a lesser extent, de novo synthesis of LDL does occur in the liver. Unlike chylomicrons and VLDL particles that can sequentially deliver fatty acids and other lipids to

various tissues during catabolism, LDL particles primarily deliver cholesterol, which occurs via whole particle uptake by the LDL receptor or alternative pathways. Modified LDL particles may be taken up by scavenger receptors or oxidized LDL receptors. Transfer of cholesteryl esters from HDL to LDL is mediated in part by cholesteryl ester transfer protein (CETP) in the process of reverse cholesterol transport. Modification of LDL by LPL and hepatic lipase (HL) influences the size and density of LDL particles, as well as their atherogenicity. Small dense LDL (pattern B) is more atherogenic than buoyant LDL (pattern A). The normal half-life of LDL particles in plasma is 3–4 d. Although peripheral tissues can catabolize LDL particles, and steroidogenic endocrine tissues (e.g. adrenal) take up proportionately large amounts of LDL per amount of tissue, the liver is the major site of LDL removal from plasma. Decreased numbers of functional LDL receptors in the liver resulting from genetic defects (e.g. familial hypercholesterolemia), hypothyroidism or aging, lead to hypercholesterolemia due to accumulation of LDL particles in plasma. The liver is a key regulator of plasma LDL cholesterol concentrations.

### High density lipoprotein and reverse cholesterol transport

HDL particles are believed to be the primary mediators of reverse cholesterol transport, the process whereby cholesterol is removed from peripheral tissues and delivered to the liver for disposal. Studies of Tangier disease (see below) have greatly advanced our understanding of the genesis and metabolism of HDL particles. In Tangier disease, the absence of functional ABCA1 receptors results in dramatic reductions in the formation of HDL particles and a very low plasma HDL cholesterol concentration. This observation suggests that the acquisition of free cholesterol from peripheral tissues by apo A-I via the ABCA1 transporter is a major source of HDL cholesterol in plasma. Apo E-rich HDL is the dominant lipoprotein in the brain.

Most free cholesterol in nascent HDL particles is normally esterified in plasma by lecithin-cholesterol acyltransferase (LCAT) to form cholesteryl esters. Sequestration of additional cholesterol by HDL via SRB1 and ABCG1, and further remodeling in plasma, results in larger mature HDL particles, typically in the HDL2 subfraction. CETP mediates the transfer of cholesteryl ester from HDL to VLDL and LDL for subsequent delivery to the liver via the LDL, apo E and LRP receptors. HDL also can selectively deliver cholesterol directly to the liver via the scavenger receptor class B, type 1 (SR-B1), without uptake of the whole HDL particle. Cubulin is an additional HDL receptor that may mediate uptake of free apo A-I in the renal tubule. Megalin, a member of the LDL receptor family, also binds apo A-I and may mediate catabolism of HDL. After delivery of cholesterol to the liver at the terminus of the reverse cholesterol transport pathway, a portion of the cholesterol is utilized for bile acid synthesis by the rate-limiting enzyme CYP7A1 under the regulatory control of heterodimers of the nuclear retinoid X receptor (RXR) and farnesoid X (bile acid) receptor (FXR). Cholesterol and bile acids are secreted into the bile for subsequent excretion of a portion of the enterohepatic circulatory pool of cholesterol and bile acids in the feces. Additional cardioprotective effects of HDL may be related to antioxidant (related in part to paraoxonase) and anti-inflammatory properties.

Exercise, weight loss, alcohol intake, estrogen and phenytoin can increase plasma HDL cholesterol concentrations, but not all mechanisms for HDL cholesterol elevation are beneficial. Among lipid-lowering medications, niacin and fibrates have the greatest HDL cholesterol-raising efficacy. Torcetrapib, an experimental CETP inhibitor, substantially increases the plasma HDL cholesterol concentration, but this drug has been withdrawn due to excess mortality. Puberty in males (testosterone), weight gain, type 2 diabetes, hypertriglyceridemia, cigarette smoking and a low fat diet can be associated with decreases in plasma HDL cholesterol. It is important to realize that the cardioprotective benefits from HDL are probably more dependent on the flux of cholesterol from peripheral tissues to the liver for disposal than on the absolute HDL cholesterol concentration. For example, increased removal of HDL cholesterol from plasma by overexpression of hepatic SR-B1 receptors in experimental animals lowers the plasma HDL cholesterol concentration, but reduces the risk of atherosclerosis. Conversely, deficiency of

CETP in humans increases the plasma HDL cholesterol concentration to 3.8–5.1 mmol/L (150–200 mg/dl) by blocking transfer of cholesteryl esters from HDL to VLDL and LDL, but this condition can be associated with increased risk for atherosclerosis if the LDL cholesterol concentration also is high. Thus, the relationship between risk for atherosclerosis and increases or decreases in plasma HDL cholesterol needs to be interpreted with an understanding of the potential effects of such changes on reverse cholesterol transport.

### Lipoprotein(a)

Lipoprotein(a) [Lp(a)] probably is formed in plasma as a consequence of the covalent cysteine-cysteine disulfide linkage of circulating apo(a) to the C-terminal region of apo B-100 in LDL particles. More than 95% of apo(a) in plasma is found in Lp(a). The liver is the predominant site of apo(a) synthesis. Plasma concentrations of Lp(a) vary 100-fold in the general population, largely due to genetic factors resulting in >70–80% heritability of plasma Lp(a) concentrations. Genetically mediated apo(a) size polymorphisms are an important determinant of the Lp(a) concentration, as reflected by the inverse association between the apo(a) size and the plasma Lp(a) concentration. Additional factors that can increase plasma Lp(a) concentrations are renal insufficiency, menopause and dietary intake of trans fatty acids. Factors that may decrease plasma Lp(a) concentrations are postmenopausal estrogen replacement, treatment with niacin, anabolic steroids and LDL apheresis (a process that removes apo B-containing particles from plasma). High plasma concentrations of Lp(a) are associated with increased risk for cardiovascular disease, but the atherogenicity of Lp(a) may require the presence of elevated plasma concentrations of LDL cholesterol. Reducing the LDL cholesterol concentration below ~2.0 mmol/L (80 mg/dl) may abrogate the atherogenicity of elevated Lp(a). The normal physiological function of Lp(a) is unclear, but it may be involved in the delivery of cholesterol and other lipids to sites of vascular injury. A deficiency syndrome is unknown, even among individuals with very low concentrations of Lp(a). The presence in apo(a) of multiple kringle-4 repeats with homology to plasminogen may contribute to alterations in fibrinolysis.

### Enzymes and transfer proteins involved in lipoprotein metabolism

A variety of enzymes and transfer proteins serve important roles in lipoprotein metabolism (Table 26.16). Beginning in the small bowel, pancreatic lipase hydrolyzes dietary fats to release glycerol and triglycerides that are absorbed by enterocytes. Within the enterocyte, microsomal triglyceride transfer protein (MTP) is involved in the formation of chylomicrons. MTP also is involved in formation of VLDL particles in the liver. Three additional enzymes are involved in intravascular metabolism of lipoproteins.

LPL and HL are bound by heparan sulfate to the vascular endothelium, where they are involved in hydrolysis of triglycerides (and phospholipids by hepatic lipase) in triglyceride-rich lipoproteins, remodeling of lipoproteins (LDL, remnants and HDL), and hepatic uptake of remnant lipoproteins. Heterozygous deficiency of LPL may be a subgroup of the familial disorder, familial combined hyperlipidemia, which is discussed below. Endothelial lipase is primarily a phospholipase that may be involved in HDL metabolism, placental lipid metabolism and release of fatty acids from phospholipids for energy utilization.

Cholesterol ester transport protein (CETP) and phospholipid transfer protein (PLTP) are involved in the bidirectional transfer of lipids between lipoproteins. CETP is secreted by the liver and circulates in plasma mainly bound to HDL. It plays an important role in reverse cholesterol transport by facilitating the transfer of cholesteryl esters from cholesterol replete HDL particles to VLDL and LDL for subsequent delivery to the liver for disposal. CETP deficiency results in very high plasma HDL cholesterol concentrations, but may increase risk for atherosclerosis due to the block in reverse cholesterol transport. PLTP is involved in the transfer of surface phospholipids from shrinking triglyceride-rich lipoprotein particles during their catabolism.

**Table 26.16** Enzymes and transfer proteins involved in lipoprotein metabolism

Enzyme	Function
Pancreatic lipase	Hydrolysis of dietary fat in intestinal lumen
Hormone-sensitive lipase	Hydrolysis of triglycerides in adipose cells to release free fatty acids
Lipoprotein lipase	Hydrolysis of triglycerides in circulating VLDL and chylomicrons to release free fatty acids to peripheral tissues; uptake of triglyceride-rich lipoproteins
Hepatic lipase	Hydrolysis of triglycerides and phospholipids in VLDL and VLDL remnants, uptake of remnant lipoproteins, facilitation of SR-B1-mediated uptake of HDL cholesteryl esters by liver
Endothelial lipase	Hydrolysis of lipoprotein phospholipids, involved in HDL metabolism
Lecithin cholesterol acyltransferase (LCAT)	Catalyzes transfer of position 2 fatty acids from phosphatidyl choline to cholesterol in HDL to form cholesteryl esters
Acyl cholesterol acyltransferase (ACAT)	Catalyzes esterification of cholesterol to form cholesteryl esters in intracellular pools
<i>Transfer proteins</i>	
Cholesteryl ester transfer protein (CETP)	Facilitates transfer of cholesteryl esters from HDL to VLDL and LDL
Phospholipid transfer protein (PLTP)	Facilitates transfer of phospholipids from triglyceride-rich lipoproteins to HDL, may facilitate recycling of HDL back to discoidal particles

HDL, high density lipoprotein; LDL, low density lipoprotein; SR-B1, scavenger receptor-B1; VLDL, very low density lipoprotein.

### Lipoprotein receptors

The number of recognized lipoprotein receptors has been expanding rapidly during recent years. These receptors are important for the metabolism and uptake of lipoproteins by various tissues (Table 26.17). The classic genetic disorder caused by defective lipoprotein receptors is familial hypercholesterolemia, which most commonly is a consequence of a variety of types of mutations in the LDL receptor. It is anticipated that a myriad of genetic disorders related to mutations in lipoprotein receptors, lipolytic enzymes and transfer proteins have yet to be identified.

### HYPERLIPIDEMIA

The hyperlipidemias have traditionally been classified descriptively as Fredrickson types I–V on the basis of the type of lipoprotein particle that is increased in plasma (Table 26.18). Although the classification of hyperlipidemia as types I–V is still occasionally used, it rarely adds information that is not already apparent from the fasting lipid profile. In addition, problems arise because multiple disorders can result in the same lipoprotein phenotype. For example, both the genetic disorder familial hypercholesterolemia and hypothyroidism can be associated with type IIa hyperlipidemia. Moreover, a single disorder may cause several patterns of hyperlipidemia in different individuals, and in a single individual over time. The Fredrickson classification does not accommodate important disorders such as hypoalphalipoproteinemia (low HDL cholesterol), elevated Lp(a) or qualitative changes in lipoprotein particles such as small dense LDL. The one exception to these limitations is the diagnosis of type III hyperlipidemia, which refers to a specific genetically mediated metabolic disorder that is described in more detail below.

The hyperlipidemias can be subdivided into primary (hereditary) hyperlipidemias (Table 26.19), and secondary hyperlipidemias resulting

from acquired (often reversible) metabolic conditions (Table 26.20). The best ‘classification scheme’ involves identifying the precise genetic and/or metabolic defect in an individual patient, although currently this is often not possible.

### PRIMARY HYPERLIPIDEMIAS

#### Familial hypercholesterolemia

Familial hypercholesterolemia (FH) occurs in ~1 in 500 people and is classically an autosomal dominant disorder of the LDL receptor, resulting in an absent or functionally defective receptor protein; hundreds of mutations are known. Defects have been identified in transcription, post-translation modification, translocation to the plasma membrane, LDL binding, localization to clathrin coated pits, internalization and degradation. Individuals heterozygous for such LDL receptor defects typically have about half-normal levels of LDL-receptor expression in the liver and twice-normal plasma LDL-cholesterol concentrations. Other dominant causes of FH include defects in apo B that diminish LDL receptor binding (familial defective apo B) and heterozygous gain of function defects in PCSK9, a gene that encodes NARC1, an LDL receptor ligand that promotes degradation of the LDL receptor after internalization from the plasma membrane. Autosomal recessive familial hypercholesterolemia (ARH) is caused by homozygous defects in ARH-1, an adapter-like protein that modulates internalization of LDL–LDL receptor complexes from clathrin coated pits.

Severe hypercholesterolemia in FH greatly increases the risk for atherosclerotic vascular disease, with about 50% of untreated males and females developing myocardial infarction by the ages of 50 and 60 years, respectively. The lifetime risk for myocardial infarction is > 85% in untreated patients. In accordance with the concept that atherosclerosis is a generalized process that can affect multiple arterial trees, the risk for stroke and peripheral vascular disease also is increased in patients with this disorder, although myocardial infarction is the most common. In some families, other atherogenic factors, such as increased Lp(a), may accentuate the risk for vascular disease, resulting in earlier clinical expression of cardiovascular disease as early as the third decade. Homozygous familial hypercholesterolemia is associated with LDL cholesterol levels > 12.8–18 mmol/L (500–700 mg/dl) and myocardial infarction and death in childhood without very aggressive treatment.

#### Clinical findings and treatment

The primary physical manifestations of heterozygous FH are early corneal arcus and tendon xanthomas, which are not always present and may not develop until the fifth or sixth decade. Children with homozygous FH commonly develop tendon and tuberous xanthomas in early childhood. Treatment for homozygous FH requires aggressive pharmacological therapy, often in combination with LDL apheresis, which should be provided in collaboration with a lipid disorders clinic. Liver transplantation has been used successfully in some patients to alleviate the severe hypercholesterolemia, but this aggressive intervention is itself associated with complications. It is possible that targeted gene therapy for delivery of normal LDL receptors to the liver may become feasible at some point in the future.

Treatment is discussed on p. 1100.

#### Familial defective apo B

This autosomal dominant disorder is a subtype of FH in which a defect in apo B-100 prevents binding of LDL to normal LDL receptors. The most common mutation is a glutamine to arginine point mutation at amino acid 3500, but other mutations have been described.

#### Polygenic hypercholesterolemia

This is a heterogeneous group of prevalent disorders that clearly have a familial component, presumably resulting from interactions between two or more genes. Polygenic hypercholesterolemia is probably the most common primary hyperlipidemia. The genetic basis for such disorders is unknown, but is an area of intense interest.

Table 26.17 Lipoprotein receptors

Receptor (R)	Family	Ligand(s)	Function(s)
LDL-R	LDL-receptor	Apo B-100, E	Uptake of LDL, IDL and VLDL remnants
VLDL-R	LDL-receptor	Apo B-100, E, reelin	VLDL uptake
Apo E-R2	LDL-receptor	Apo E, reelin	Uptake of apo E-containing lipoproteins
MEGF7	LDL-receptor		
LDL-R related protein (LRP orLRP-1)	LDL-receptor	Apo E, LPL, PAI-1, tPA, lactoferrin, others	Uptake of VLDL and chylomicron remnants. Multiple LRP subtypes exist; some are not involved in lipoprotein metabolism
LRP1B	LDL-receptor	Comparable to LRP	Comparable to LRP
Megalin (LRP-2)	LDL-receptor	Apo E, HDL	Endocytic uptake of retinoids and steroids
Scavenger receptor, class A, types I and II (SRA-I, SRA-II)	Scavenger receptor, class A	Acetylated LDL, oxidized LDL, polyanionic molecules, others	Uptake of modified lipoproteins, and apoptotic and senescent cells by macrophages
CD36	Scavenger receptor, class B	Oxidized LDL, acetylated LDL, others	Uptake of oxidized LDL
SR-BI	Scavenger receptor, class B	LDL, HDL, acetylated LDL, oxidized LDL	Uptake of modified lipoproteins, selective uptake of HDL cholesteryl ester by liver, transfer of cholesterol from peripheral cells to HDL and other lipoproteins
SR-BII	Scavenger receptor, class B	Modified lipoproteins	SR-BI splice variant
Lectin-like oxidized LDL receptor-1 (LOX-1)	C-type lectin-like protein super family	Oxidized LDL	Uptake of oxidized LDL
ATP binding cassette subfamily A, member 1 (ABCA1)	ABC transporter	Apo A-I	Peripheral HDL receptor, mediates formation of nascent HDL from tissue derived cholesterol and apo A-I, modulates uptake of sterols in small intestine
ATP binding cassette subfamily G, member 1 (ABCG1)	ABC transporter		Facilitates transfer of cholesterol from peripheral cells to HDL and other lipoproteins
Cubulin		Apo A-I, intrinsic factor-vitamin B <sub>12</sub> complexes	Uptake of apo A-I in renal tubule complexes

HDL, high density lipoprotein, IDL, intermediate density lipoprotein; LPL, lipoprotein lipase; LRP, LDL receptor-related protein; PAI, Plasminogen activator inhibitor; SR, scavenger receptor; tPA, tissue plasminogen activator; VLDL, very low density lipoprotein.

Table 26.18 Descriptive classification of hyperlipidemia on the basis of lipoprotein accumulation

Type	Lipoprotein abnormality	Possible etiologies	Lipid values
I	↑Chylomicrons	LPL deficiency, apo C-II deficiency	↑↑TG. Total cholesterol is 4–7% of TG level
Ila	↑LDL	Familial hypercholesterolemia, hypothyroidism	↑Total cholesterol and LDL-cholesterol
Ilb	↑LDL and VLDL	Familial combined hyperlipidemia, type 2 diabetes	↑Total cholesterol, LDL- and VLDL-cholesterol and TG
III	↑Remnants (IDL)	Homozygosity for mutant apo E2 + disorder of lipoprotein overproduction	↑↑IDL and remnants, ↑total cholesterol ( TG
IV	↑VLDL	Type 2 diabetes, familial combined hyperlipidemia, ethanol	↑TG (< 1000 mg/dl), 11.2 mmol/L ↑Total and VLDL cholesterol
V	↑VLDL and chylomicrons	Type 2 diabetes, ethanol, high fat diet	↑↑TG (> 1000 mg/dl), 11.2 mmol/L total cholesterol. 7–10% of TG level

IDL, intermediate density lipoprotein; LDL, low density lipoprotein; LPL, lipoprotein lipase; TG, triglyceride; VLDL, very low density lipoprotein.

Table 26.19 Primary hyperlipidemias and lipoprotein deficiencies

Disorder	Prevalence	Inheritance	Lipoprotein pattern	Genetic cause
<i>Hyperlipidemias</i>				
LPL deficiency	1 in 10 <sup>6</sup>	Recessive	Type I	LPL mutation resulting in absent or defective protein
Apo C-II deficiency	Rare	Recessive	Type I	Apo C-II deficiency
Familial hypercholesterolemia (heterozygous)	1 in 500	Dominant	Ia/IIb	Defective LDL receptor; hundreds of mutations. Homozygotes occur in 1:10 <sup>6</sup>
Familial defective apo B	1 in 700–1000	Dominant	Ia/IIb	Glutamine < arginine 3500 in apo B-100 causes defective binding to LDL receptor. Phenotype similar to familial hypercholesterolemia
PCSK9 polymorphisms	Variable	Dominant	↑ or ↓ LDL cholesterol	PCSK9 gene encodes a protein that promotes degradation of the LDL receptor. Gain of function or loss of function mutations modulate hepatic LDL receptor activity
Polygenic hypercholesterolemia	1 in 100?	Polygenic	Ia/IIb	Unknown
Familial combined hyperlipidemia	1 in 100–200	Dominant	Ia/IIb, IV, V	Associated with increased apo B secretion. Single defects in a variety of genes may cause a common phenotype. Polymorphisms in upstream transcription factor-1 (USF1) may be a key underlying defect.
Familial hypertriglyceridemia	1 in 200–500	Dominant	IV/V	Unknown
Type III hyperlipidemia (Broad-beta disease, dysbetalipoproteinemia)	1 in 5000–10 000	Usually recessive	III	Homozygosity for mutant apo E2 is permissive, but not sufficient Requires concurrent disorder of increased lipoprotein secretion Prevalence of E2/E2 homozygotes is about 1 in 100; most do not have hyperlipidemia. Rare dominant mutations occur
Sitosterolemia	≈40–60 cases reported	Recessive	Ia	Mutations in ABCG5 and G8 sterol transporters
Cerebrotendinous xanthomatosis (CTX)	≈150 cases reported	Recessive	Ia/IIb	Defect in 27-hydroxylase blocks bile acid synthesis
<i>Lipoprotein deficiencies</i>				
Tangier disease	< 100 cases reported	Recessive	Very low HDL-C	Defect in ABCA1 (HDL receptor)
Abetalipoproteinemia	Rare	Recessive	Cholesterol 20–30 mg/dl 0.5–0.75 mmol/L	Absence of apo B-100 with decreased or absent apo B-48; MTP mutations
Hypobetalipoproteinemia	1 in 1000–2000	Dominant	LDL-C 20–40 mg/dl 0.5–1.0 mmol/L	Apo B truncations
Chylomicron retention disease	Rare	Recessive	Low cholesterol, TG	Inability to synthesize or secrete chylomicrons
Familial hypoalphalipoproteinemia	> 1 in 100–200	Dominant	HDL-C 30 mg/dl 0.75 mmol/L	Apo A-I mutations, heterozygous ABCA1 mutations
Fish eye disease	Rare	Recessive	–	Defect in LCAT activity
LCAT deficiency	Rare	Recessive	–	Absence of LCAT activity

HDL, high density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low density lipoprotein; LPL, lipoprotein lipase; MTP, microsomal triglyceride transfer protein; TG, triglyceride.

### Familial combined hyperlipidemia

Familial combined hyperlipidemia is genetically heterogeneous with a common phenotype characterized by hepatic overproduction of apo B-100 and accumulation in plasma of apo B-100-containing lipoproteins (VLDL, IDL and LDL). This disorder has a prevalence of 1–2% and may account for up to 20% of premature coronary heart disease.

The resulting hyperlipidemia is variable among affected family members and can vary over time in a given individual. The lipoprotein abnormalities often consist of increased plasma apo B in association with increased plasma concentrations of triglycerides (in VLDL) or LDL-cholesterol, or both. The plasma HDL cholesterol concentration often is reduced and the LDL particles often are characterized as small

Table 26.20 Secondary dyslipidemias

Category	Condition	Lipoprotein abnormality
Dietary	Excess saturated fat/ cholesterol	↑cholesterol, ↑LDL-C, ↑TG from fat intake in susceptible patients
	Very low fat	↓LDL-C, ↓HDL-C, possible ↑ TG
	Excess calories	↑TG, ↓HDL-C
Endocrine	Diabetes	↑TG if uncontrolled; abnormal lipoprotein composition in type 2
	Insulin resistance	↑TG
	Hypothyroidism	↑total cholesterol, ↑LDL-C, ↑TG
	Obesity	TG overproduction
	Cushing syndrome	↑TG, possible ↑LDL-C
	Lipodystrophy	↑TG
Drugs	Acromegaly	↑TG
	Alcohol	↑TG
	Thiazide diuretics	↑LDL-C, ↑TG
	Beta-adrenergic blockers	↑TG, ↓HDL-C
	Glucocorticoids	↑TG, possible ↑LDL-C
	Oral estrogen/tamoxifen	↑TG
	Retinoic acid derivatives	↑TG
	Ciclosporin	↑Total cholesterol, ↑LDL-C
	Protease inhibitors	↑TG (↑total cholesterol, ↑ LDL-C)
	Renal failure/nephrotic syndrome	↑Total cholesterol, ↑LDL-C, ↑ TG, ↑lipoprotein(a)
	Cholestatic liver disease	↑↑Total cholesterol, ↑lipoprotein X
Other	Lupus, myeloma, autoimmune disease	↑TG
	Some glycogen storage diseases	↑TG, ↑LDL-C

HDL, high density lipoprotein; LDL, low density lipoprotein; TG, triglyceride.

and dense (e.g. pattern B), which are more atherogenic than buoyant larger LDL particles. Patients with this disorder develop premature myocardial infarction, stroke and peripheral vascular disease in mid-adulthood. It has been suggested that the hyperlipidemia phenotype of familial combined hyperlipidemia may not be fully expressed until young adulthood, but hyperlipidemia may emerge in childhood. Heterozygous LPL deficiency appears to be one subtype of this disorder. The genetic basis for familial combined hyperlipidemia may be related to upstream transcription factor-1 (USF1), a ubiquitous basic-helix-loop-helix leucine zipper transcription factor that modulates expression of at least 13 genes involved in lipid and glucose metabolism. The results of recent studies suggest that polymorphisms in USF1 may be the key defect that confers susceptibility to familial combined hyperlipidemia.

### Familial hypertriglyceridemia

This disorder may be a subtype of familial combined hyperlipidemia, although the phenotype is one of hypertriglyceridemia with triglyceride concentrations usually < 11.2 mmol/L (1000 mg/dl). Older studies suggested this condition may be benign, other than the increased risk for pancreatitis during exacerbation of hypertriglyceridemia (triglycerides > 16.8–22.4 mmol/L [1500–2000 mg/dl]). The absence of coronary artery disease in a family with an autosomal dominant pattern of inheritance of hypertriglyceridemia suggests the diagnosis, but the possibility of increased risk for coronary artery disease should not be excluded. The genetic basis for this disorder is uncertain.

### Type III hyperlipidemia

Type III hyperlipidemia, also known as broad beta disease or familial dysbetalipoproteinemia, is associated with homozygosity for the abnormal apoprotein E2 that is a poor ligand for triglyceride-rich lipoprotein receptors in the liver. Rare autosomal dominant forms of this disorder have been identified. Surprisingly, apo E2/E2 homozygosity is seen in about 1% of the general population, but the prevalence of type III hyperlipidemia is only 1 in 5000–10 000. Thus, only 1–2% of individuals with the homozygous genetic abnormality in apo E develop type III hyperlipidemia. Under normal conditions, the apo E2/E2 mutation alone is insufficient to cause hyperlipidemia, since alternative pathways exist for clearance of small amounts of triglyceride-rich lipoprotein remnants. However, in the setting of overproduction of triglyceride-rich lipoproteins, which occurs in hypothyroidism, obesity, high fat diet consumption, menopause, uncontrolled diabetes, familial combined hyperlipidemia, and other conditions, the clearance pathways become saturated, thereby resulting in the accumulation of atherogenic VLDL and chylomicron remnants.

### Clinical findings

Palmar xanthomas (yellowish deposits in palmar creases) are said to be pathognomonic, but often are not present. Tuberoeruptive xanthomas also occur, but resolve over months during effective lipid lowering therapy. Patients with this disorder are susceptible to diffuse premature atherosclerosis.

### Treatment

Treatment is directed to alleviation of factors causing lipoprotein overproduction. A low fat diet, regular exercise, and avoidance of obesity are key lifestyle interventions. Alcohol exacerbates the dyslipidemia. Fibrates are the first line drug therapy, but statins, niacin and fish oil also are helpful.

### Lipoprotein lipase and apo C-II deficiency

LPL deficiency is a rare condition detectable at birth that is thought to occur with a frequency of about 1 in 10<sup>6</sup>. Causes of LPL deficiency can include homozygous deficiency of functional enzyme, absence of the cofactor apo C-II and dominant inheritance of a lipase inhibitor.

### Clinical findings

The clinical manifestations of recurrent pancreatitis and eruptive xanthomas may not be recognized until late infancy or childhood, but the severity of hypertriglyceridemia and its complications are related to dietary fat intake. Other symptoms may include abdominal pain in the absence of pancreatitis, dyspnea and mild cognitive dysfunction. Plasma triglyceride concentrations may be > 33.7–112 mmol/L (3000–10 000 mg/dl; lower in young children) in association with moderately increased plasma cholesterol concentrations. Lipemia retinalis often is visible when the triglyceride concentration is > 44.9–56 mmol/L (4000–5000 mg/dl), but it is much easier to examine the blood ex vivo after separation of plasma or serum from blood cells by centrifugation or standing. The plasma typically appears turbid when the triglyceride concentration exceeds 5.6–6.7 mmol/L (500–600 mg/dl). Plasma with a triglyceride concentration of 11.2 mmol/L (1000 mg/dl) has the appearance of skimmed milk. Plasma with a triglyceride concentration > 22.4–33.7 mmol/L (2000–3000 mg/dl) (2–3% fat) appears creamy, whereas levels > 33.7–67.4 mmol/L (5000–6000 mg/dl) (5–6% fat) will have the appearance of whipping cream.

### Treatment

Initial treatment for severe hypertriglyceridemia requires a very low fat diet containing no more than a few grams of dietary fat daily. Children with overt pancreatitis require hospitalization for intravenous hydration and cessation of oral intake. In stable children, the fat intake may be increased to 5–10 g/d or higher as tolerated. Medium chain triglycerides, which are absorbed into the portal circulation and do not contribute to chylomicron formation, may be used to improve the palatability of

the low-fat diet. Older children may succumb to the high fat dietary habits of their peers, but the development of abdominal pain helps to attenuate such behavior. Pharmacological therapy is generally unhelpful.

### Wolman disease and cholesterol-ester storage disease (lysosomal acid lipase deficiency)

This lysosomal enzyme hydrolyses esterified cholesterol back to the free form. This step is required for feedback inhibition of new cholesterol synthesis. Its absence results in excess cholesterol production.

Wolman disease is most severe with xanthomatous deposits in many tissues resulting in hepatosplenomegaly, steatorrhea, failure to thrive and death in infancy. In cholesterol-ester storage disease (CESD) xanthomas are much less evident but this is one cause of hypercholesterolemia and should be aggressively treated. The disorders are allelic.

### Phytosterolemia/sitosterolemia

This is a rare autosomal recessive disorder that is associated with tendon xanthomas, premature atherosclerosis and occasionally hemolytic anemia. It can present as 'pseudohomozygous familial hypercholesterolemia' with LDL-C > 12.8 mmol/L (500 mg/dl) in childhood, and xanthomas occasionally on the buttocks. Affected patients typically are very sensitive to diet-induced hypercholesterolemia due to enhanced intestinal absorption of cholesterol, as well as plant sterols. Sitosterol and other plant sterols, which are normally present in minimal amounts in plasma, accumulate in plasma of affected individuals. The disease is caused by defects in ABC-G5 or ABC-G8, two sterol transporters that normally export nonspecifically absorbed sitosterol and other plant sterols from the intestinal mucosa back into the intestinal lumen.

The diagnosis can be established by identifying increased levels of plasma sitosterol, or possibly by genetic testing. A low cholesterol diet in combination with bile acid-binding agents is helpful. Avoidance of dietary plant sterols is difficult, but affected individuals should avoid using over-the-counter cholesterol-lowering margarines containing sitosterol or sitostanol esters (Benecol and Take Control margarines in the USA). A selective inhibitor of cholesterol absorption, ezetimibe, is efficacious in these patients and can also lower LDL-C in conditions other than sitosterolemia.

## OTHER GENETIC AND METABOLIC DISORDERS AFFECTING LIPID METABOLISM

### Generalized lipodystrophy

There are several distinct genetic forms; some may be evident at birth (Berardinelli-Seip congenital lipodystrophy), others develop in childhood or adult life (Lawrence syndrome). Patients with generalized lipodystrophy have minimal amounts of body fat (subcutaneous and visceral). The congenital form of this disorder is often familial whereas the acquired form is commonly sporadic. Familial generalized lipodystrophy is primarily caused by mutations in the seipin gene (type 2 lipodystrophy) and AGPAT 2 (1-acylglycerol-3-phosphate O-acyltransferase 2 [lysophosphatidic acid acyltransferase, beta]) (type 1 lipodystrophy). Children with generalized lipodystrophy tend to be tall, have advanced bone age, and have the appearance of increased muscle bulk. Insulin resistance and subsequent development of type 2 diabetes and hypertriglyceridemia are common. Treatment consists primarily of correction of the metabolic abnormalities, but leptin may be efficacious for hyperglycemia and hypertriglyceridemia in some subtypes of lipodystrophy.

### Partial lipodystrophy

Partial lipodystrophy consists of several overlapping phenotypes. Some may be due to recessive mutations in zinc metalloproteinase Ste-24 homolog (ZMPSTE-24) (type B lipodystrophy), recessive mutations in lamin A/C (type A lipodystrophy), dominant mutations in lamin A/C (Dunnigan type) or lamin A alone, lamin B2 (acquired) or defects in PPAR-gamma, but many cases seem to be sporadic. Typically there is progressive symmetrical loss of subcutaneous body fat, most commonly from the face, with progressive involvement of the arms, trunk and hips.

Other variations can involve loss of fat in the extremities (Kobberling type), preservation of subcutaneous fat in the face or patchy lipodystrophy. The age of onset varies from 5 to young adult life. Girls are affected much more frequently than boys. Insulin resistance is common and can be severe, resulting in very high insulin requirements and possibly increased responsiveness to insulin-sensitizing thiazolidinediones in those who develop type 2 diabetes. Hypertriglyceridemia can be a consequence of insulin resistance and/or hyperglycemia.

The use of highly active antiretroviral therapy (HAART) for human immunodeficiency virus (HIV) infections (see Ch. 27) is commonly associated with lipodystrophy, insulin resistance and dyslipidemia, all of which contribute to increased risk for atherosclerosis in patients with HIV. Abnormal fat distribution is seen in some of the carbohydrate deficiency syndromes.

### Tangier disease

Tangier disease, a rare autosomal recessive disorder, is characterized by the near absence of plasma HDL cholesterol, very low plasma concentrations of apo A-I, and pathognomonic orange-yellow tonsillar enlargement, lymphadenopathy and splenomegaly. The physical findings are a consequence of the accumulation of cholesteryl esters in the reticuloendothelial system. Premature atherosclerosis may occur in individuals with sufficient amounts of LDL cholesterol in plasma. The genetic basis was once thought to be due to primary deficiency of HDL, but defects in the ABCA1 transporter protein are now known to be the cause. In Tangier disease, apo A-I is unable to sequester cholesterol from peripheral cells due to impaired interaction with the defective or absent ABCA1 protein, resulting in a dramatic reduction in formation of HDL particles and increased degradation of apo A-I. Typically, the LDL cholesterol concentration is low, which diminishes the risk of cardiovascular disease, but premature atherosclerosis occurs in individuals with the highest LDL cholesterol concentrations.

### Familial hypoalphalipoproteinemia

Familial hypoalphalipoproteinemia is typically a consequence of heterozygous defects in ABCA1 (resulting in decreased formation of HDL and increased degradation of apo A-I) or apo A-I. Affected subjects have low concentrations of plasma HDL cholesterol (<0.9 mmol [1135 mg/dl]) and increased risk of atherosclerosis. Uncommon forms of low HDL cholesterol may result from accelerated reverse cholesterol transport, which may lower the plasma HDL cholesterol without increasing the risk of atherosclerosis.

### Abetalipoproteinemia

Abetalipoproteinemia is characterized by nearly complete absence of LDL in plasma. It is caused by autosomal recessive defects in microsomal triglyceride transfer protein (MTP) or homozygous truncation defects in apo B.

The net result of the defect is deficient assembly of chylomicrons, resulting in failure to absorb fat and fat-soluble nutrients from the gut, and inability to form VLDL in the liver, resulting in defective transport of vitamin E to peripheral tissues. Fat malabsorption causes steatorrhea and consequent growth failure with deficiency of several nutrients. The malabsorption can be so marked that night blindness (vitamin A deficiency), rickets (vitamin D deficiency) and neurological disease (ataxia, peripheral neuropathy; vitamin E deficiency) may occur in childhood. Pigmentary degeneration of the retina also occurs. Abnormal red cell membranes lead to acanthocytosis and anemia.

### Diagnosis and treatment

The plasma cholesterol concentration is usually below 1.2 mmol/L (45 mg/dl). It may be possible to confirm the defect by DNA studies.

Treatment involves the monitored use of a low fat diet that is supplemented with high doses of essential fatty acids and fat-soluble vitamins, especially high-dose vitamin E to prevent neurological disease. Many of the complications are related to vitamin E deficiency. Heterozygotes may have normal or low plasma lipids.

### Hypobetalipoproteinemia

Hypobetalipoproteinemia is an uncommon disorder characterized by a low plasma concentration of LDL cholesterol  $< 1.3$  mmol/L (50 mg/dl). It typically is a consequence of heterozygous truncation mutations in apo B, resulting in the absence of apo B-100, or heterozygous defects in MTP. Apo B-100 is required for formation of VLDL particles, which are subsequently metabolized to become LDL particles. The disorder is associated with protection against atherosclerosis.

### Lecithin:cholesterol transferase deficiency and fish eye disease

Familial lecithin:cholesterol transferase (LCAT) deficiency (complete) and fish eye disease (partial LCAT deficiency) are caused by autosomal recessive mutations in LCAT. Normally, 95% of LCAT in plasma is associated with HDL particles (alpha-LCAT) and the rest is associated with VLDL and LDL (beta-LCAT). LCAT is required for synthesis of esterified cholesterol and lysolecithin. In 'classical' deficiency, LCAT activity on HDL and VLDL/LDL is nearly absent, which results in corneal opacities and progressive renal disease. If the deficiency is less severe, sometimes associated with deficiency of LCAT only in HDL particles, the eye findings are present (fish eyes) but there is no renal disease. Most cases are diagnosed in adulthood.

The diagnosis is made by finding low levels of HDL-C, severely reduced LCAT activity in plasma or by DNA studies. The ratio of free: total cholesterol in plasma may be elevated. Treatment is with a low fat diet and statins.

### Cerebrotendinous xanthomatosis

The primary abnormality in this disease is the accumulation in plasma of cholestanol resulting from homozygous deficiency of the mitochondrial enzyme sterol 27-hydroxylase, a key enzyme involved in hepatic bile acid synthesis and cholesterol oxidation (see Table 26.19). It is a rare disorder characterized by development of xanthomas in tendons, the lungs and brain in the setting of low or normal plasma cholesterol concentrations. Affected patients may also develop progressive cerebellar ataxia, dementia, spinal cord paresis, diminished intelligence and cataracts. Diarrhea may be frequent in infants and young children. Dementia, ataxia, tendon xanthoma and cataracts may become apparent between the ages of 10 and 18 years, but milder cases may not be identified until later in adulthood.

Treatment with chenodeoxycholic acid has beneficial effects on plasma cholestanol levels, but it may take years to diminish levels of cholestanol in the brain. Sometimes statins are added, but must be used with caution. Early initiation of treatment is advised.

### Barth syndrome

Barth syndrome is an X-linked disorder associated with cardiomyopathy, biventricular hypertrophy, systemic myopathy, neutropenia and growth failure associated with increased tissue lipid deposition. Plasma cholesterol and carnitine are reduced and levels of urinary 3-methylglutaconic and 3-methylglutaric acids are increased. Barth syndrome is caused by mutations in the tafazzin gene (TAZ1, G4.5). Mutation analysis can be diagnostic. Urine organic acids should be evaluated in all children with cardiomyopathy. Treatment with carnitine and possibly additional cholesterol have been proposed. Advanced cases may require cardiac transplantation.

## DISORDERS OF CHOLESTEROL SYNTHESIS

### Mevalonate kinase deficiency

Mevalonate is the product of HMG-CoA reductase, the rate-limiting enzyme for cholesterol and isoprenoid synthesis. Deficiency of mevalonate kinase, a peroxisomal enzyme, may be associated with developmental delay, dysmorphic features, cataracts, cerebellar atrophy, hepatosplenomegaly, lymphadenopathy, anemia, diarrhea, malabsorption and early death. Recurrent crises with fever, lymphadenopathy, arthralgia, edema and a morbilliform rash are reported. A milder vari-

ant causes the autoinflammatory hyper IgD/periodic fever syndrome without other manifestations.

Mevalonic acid is massively increased in blood and urine. Plasma cholesterol is normal. No specific treatment is known, but gene therapy is a theoretical possibility.

### Smith–Lemli–Opitz syndrome

This condition is the most prevalent genetic disorder of cholesterol synthesis; it occurs in ~1 in 30 000 births. The genetic basis for this syndrome is homozygous deficiency of 7-dehydrocholesterol- $\Delta^7$ -reductase, an enzyme that catalyzes the final step in cholesterol synthesis.

#### Clinical findings

It is characterized by dysmorphic features with characteristic facies, micrognathia, microcephaly, high forehead, a short anteverted nose, low-set ears, cleft palate, syn- and/or poly-dactyly (particularly second and third toes), mental retardation and growth failure (Fig. 26.21). Male infants have hypospadias or more severe feminization of the external genitalia. Frequent additional features are cleft palate, hepatocellular

(a)

(b)

Fig 26.21 Smith–Lemli–Opitz syndrome. (a) Face showing typical features; note the microcephaly, arched eyebrows, upturned nares, 'cod fish' mouth, micrognathia and cleft palate (not infrequent). These features with hypotonia, developmental delay and ambiguous genitalia are very suggestive. (b) Syndactyly of second and third toes.

damage, heart malformations, renal and cerebellar hypoplasia. Severely affected individuals may die at birth or in infancy, but survival into later adulthood is common in milder cases.

### Diagnosis and treatment

Plasma cholesterol concentrations are usually low, but an elevated 7-dehydrocholesterol concentration establishes the diagnosis. Brain development is presumably impaired due the lack of availability of cholesterol, but toxicity of cholesterol precursors cannot be excluded. Increased dietary intake of cholesterol in egg yolk, sometimes with bile acid supplementation to enhance intestinal cholesterol absorption, increases plasma cholesterol and decreases the 7-dehydrocholesterol concentration, but does not improve outcomes. Plasma cholesterol does not cross the blood–brain barrier, so exogenous cholesterol cannot ameliorate cholesterol deficiency in the brain. Strategies to diminish prenatal complications will require initiation of treatment early in gestation and methods of delivering cholesterol to the brain.

### Other defects in cholesterol synthesis

A number of other genetic disorders associated with enzymatic defects in cholesterol synthesis have been identified. Most are characterized by severe developmental anomalies, including brain malformation and mental retardation. They include X-linked dominant chondrodysplasia punctata (CDPX2 or 'Conradi–Hunermann syndrome') caused by 3-beta-hydroxysteroid delta<sup>8</sup>,delta<sup>9</sup>-isomerase deficiency and X-linked dominant CHILD syndrome (congenital hemidysplasia with ichthyosiform erythroderma and limb defects) caused by mutation of a gene coding for 3-beta-hydroxysteroid dehydrogenase. A defect of 4-alpha-methylsterol-4-demylase is also associated with developmental delay, cataracts and severe, generalized psoriasis-like dermatitis. Desmosterolosis and lathosterolosis are caused, respectively, by 3-beta-hydroxysteroid delta<sup>24</sup>-reductase and 3-beta-hydroxysteroid-delta<sup>5</sup>-desaturase (sterol C5-desaturase) deficiency. They are identified by analysis of plasma sterols.

### DEFECTS IN BILE ACID METABOLISM

The bile acids, cholic and chenodeoxycholic acids, are synthesized in a complicated process that involves peroxisomes, mitochondria, the endoplasmic reticulum and the cytosol. They are essential for normal absorption of fats from the gut and undergo considerable recycling and reuse. At least 10 inherited synthetic diseases have been identified; they fall into two main categories:

1. disorders affecting specific enzymes of the bile acid synthetic pathway (Table 26.21);
2. disorders in which bile acid metabolism is secondarily altered as a consequence of abnormal peroxisomal function. Enzymatic defects usually result in accumulation of synthetic intermediates.

These disorders all cause progressive familial intrahepatic cholestasis presumably the consequence of bile acid intermediate accumulation. In some cases this leads to cirrhosis and liver failure.

These defects cannot be readily differentiated clinically from other causes of aggressive liver disease with biliary obstruction, except by sophisticated mass spectrometry analysis of urine and/or serum bile acids.

Early treatment with chenodeoxycholic or cholic acid may be very effective and can be continued for years. Liver transplantation is required in advanced cases.

### Progressive familial intrahepatic cholestasis (PFIC)

This term comprises a heterogeneous group of autosomal recessive disorders caused by defects in the transport of bile acids and associated with early-onset cholestasis and the development of hepatic fibrosis, cirrhosis and end-stage liver disease before adulthood. Progressive familial intrahepatic cholestasis type 1 PFIC1 is severe and usually lethal in the first decade of life. Symptoms include early onset of loose, foul-smelling stools, jaundice, hepatosplenomegaly and impaired growth. Extreme pruritus without jaundice has been described in the last trimester of pregnancies carrying affected infants. PFIC1 was

Table 26.21 Inherited disorders of bile acid synthesis: Enzyme defects and phenotype

Enzyme defect	Gene	Biochemical phenotype	Clinical symptoms
<i>Affecting the sterol ring</i>			
7-Dehydrocholesterol reductase	DHCR7	↓Cholesterol ↓PBA	↓Growth, mental retardation, rare neonatal cholestasis
Cholesterol 7β-hydroxylase	CYP7A1	↑LDL- and liver cholesterol ↓↓PBA	No liver disease, hyperlipidemia, premature vascular disease, gallstone disease
Oxysterol 7β-hydroxylase	CYP7B1	↑Oxysterols ↓PBA, ↑BIA	Neonatal liver failure, cholestasis, cirrhosis (-)
3β-hydroxy-β5-C27-steroid oxidoreductase (C27 3βHSD)	HSD3B7	↓PBA, ↑BIA	Neonatal liver failure, fat-soluble vitamin deficiency, steatorrhea (+)
β4-3-Oxosteroid 5β-reductase (5βRD)	AKR1D1	↑BIA	Neonatal liver failure, cholestasis, jaundice (+)
<i>Affecting the side chain</i>			
Sterol 27-hydroxylase	CYP27A1	↓PBA ↑Bile alcohols ↑Cholesterol	Cerebrotendinous xanthomatosis (CTX), CNS neuropathy (slow progression)
2-Methylacyl-CoA racemase	AMACR	↑(R) BIA ↑Pristanic acid	Adult-onset sensory motor neuropathy, neonatal hepatitis, fat-soluble vitamin deficiency (+)
α-Bifunctional protein	EHHAD17	↑BIA ↑Pristanic acid ↓PBA	Neurological deficiencies, minimal liver failure
25-Hydroxylase pathway*	?	↑Bile alcohols	Neonatal (giant cell) hepatitis, cirrhosis
Bile acid CoA:amino acid N-acyltransferase (BAAT)	?	↓Conjugated PBA	Minimal/transient liver disease, fat-soluble vitamin deficiency

\*Enzyme defect has not been identified.

BAI, bile acid synthetic intermediates; LDL, low density lipoprotein; PBA, primary bile acids (cholic and chenodeoxycholic acids); (R), bile acid R enantiomers; + or -, response to bile acid treatment.

first described in the old order Amish, and is also known as Byler disease. It results from mutations in the ATP8B1 gene.<sup>157</sup> Mutations in the same gene are also found in benign recurrent intrahepatic cholestasis (BRIC1), which is characterized by recurrent episodes of cholestatic jaundice with elevation of serum bile acids that spontaneously resolves after a period of weeks to months. Mutations of ABCB11, which encodes a liver-specific ATP-binding cassette transporter gene, can also result in similar severe (PFIC2) and benign (BRIC2) forms of intrahepatic cholestasis. A further form (PFIC3) results from mutations in ABCB4, which encodes a multidrug resistant P-glycoprotein (MDR3); it is unique among the three types of PFIC, showing high serum gamma-glutamyltransferase levels, portal inflammation and ductular proliferation in an early stage.

## SECONDARY HYPERLIPIDEMIA

Secondary hyperlipidemia is the most common form of hyperlipidemia and can exacerbate primary hyperlipidemias. Excess intake of dietary saturated fat and cholesterol is the most common cause of secondary hyperlipidemia which is prevalent in Western populations; diabetes and hypothyroidism also are common causes. Additional types of secondary hyperlipidemia are described in Table 26.20.

## TREATMENT OF HYPERLIPIDEMIA

The cornerstone of treatment for all forms of hyperlipidemia is lifestyle modification consisting of regular physical activity, healthy diet and avoidance of excess body weight and smoking. A healthy diet typically is based on complex carbohydrates with increased amounts of fruits and vegetables, increased dietary fiber and reduced intake of saturated and total fat and cholesterol. Although controversy still prevails regarding the optimal dietary composition, such a diet helps to minimize body weight, is replete with essential vitamins and phytochemicals, and helps to minimize most forms of hyperlipidemia. A low fat, low cholesterol diet, such as the American Heart Association Step 1 diet, is generally safe in children, but more restrictive diets in children should not be prescribed without supervision of a dietitian and/or pediatric health care provider.

Drug therapy for treatment of hyperlipidemia is usually reserved for young adults unless there are compelling reasons for initiation of treatment in childhood. Concerns about possible unforeseen toxicity of lipid-lowering medications in growing children, the typically long delay in the onset of clinically significant vascular disease, and the imperfect association of hyperlipidemia in childhood with hyperlipidemia in adulthood, support the avoidance of drug therapy in children. Important exceptions need to be considered, however.

Untreated homozygous familial hypercholesterolemia usually results in death from myocardial infarction in childhood. Thus, aggressive drug and nondrug therapy (often including LDL apheresis) is essential in affected children. Among children with heterozygous familial hypercholesterolemia (or other severe conditions) associated with a very early onset of cardiovascular events in relatives (e.g. before age 30), it often is advisable to initiate some form of drug treatment during childhood to prevent the accumulation of a heavy burden of atherosclerosis prior to adulthood.

Bile acid-binding agents are believed to have the lowest risk for toxicity because they are not absorbed systemically, and they are approved for use in children, but such agents alone may lack efficacy. Several studies of children with heterozygous familial hypercholesterolemia showed no evidence of toxicity after 1–2 years of treatment with several statins. Additional studies have demonstrated normalization of accelerated progression of carotid intima-media thickening by long term treatment with statins in children with heterozygous familial hypercholesterolemia. The results of such studies have suggested that it may be appropriate to initiate lipid lowering drug therapy at the age of 8–10 years in affected children. It may be acceptable to treat with a low or moderate dose of a 'statin' in combination with a bile acid-binding agent and a healthy lifestyle, but the long term safety and benefit of such an intervention remain unproven. Ezetimibe, an inhibitor of cholesterol absorption, can reduce the plasma LDL cholesterol concentration by 16–20% and may be useful in treatment of children, but experience in children is limited. Drugs available for treatment of hyperlipidemia are outlined in Table 26.22. In the USA, the FDA has approved lovastatin, fluvastatin, simvastatin, pravastatin and atorvastatin for use in boys and postpubertal girls  $\geq 10$  years (8 years

Table 26.22 Drugs for treatment of hyperlipidemia\*

Indication	Possible drugs
Elevated LDL cholesterol	'Statins' (lovastatin, simvastatin, pravastatin, fluvastatin, atorvastatin, fosuvastatin) Niacin Lovastatin + niacin (Advicor) Bile acid sequestrants (colestyramine, colestipol, colesevelam) Cholesterol absorption inhibitors (ezetimibe)
Hypertriglyceridemia (not type I)	Fibrates (gemfibrozil, clofibrate, fenofibrate) Niacin Fish oil (>6g/d in adults). Omacor (3–4g/d) is distilled fish oil (>80% EPA + DHA)
Type I hypertriglyceridemia (chylomicronemia)	Drugs not helpful. Treatment is very low fat diet
Combined hyperlipidemia (LDL cholesterol and triglycerides)	'Statins' Niacin Fibrates Lovastatin + niacin (Advicor)
Type III hyperlipidemia	Fibrates Statins Niacin Fish oil Oral estrogen in estrogen-deficient women may help (raises triglycerides in other conditions)
Low HDL cholesterol	Niacin (most efficacious agent) Fibrates 'Statins' (less efficacious than niacin and fibrates) CETP inhibitors (experimental); torcetrapib (withdrawn in late 2006) – caused increased mortality
Elevated lipoprotein(a)	Niacin (clinical benefit unproven)

CETP, cholesteryl ester transferase protein; DHA, docosahexanoic acid; EPA, eicosapentanoic acid; HDL, high density lipoprotein; LDL, low density lipoprotein;

\*Most of these interventions have not been tested adequately for safety and efficacy in children.

for pravastatin) with heterozygous familial hypercholesterolemia. All of these statins and rosuvastatin are approved for treatment of homozygous familial hypercholesterolemia.

## LYSOSOMAL STORAGE DISEASES

### GENERAL CONSIDERATIONS

Lysosomes are cytoplasmic organelles containing hydrolytic enzymes that digest a wide range of macromolecules, thus acting as waste disposal units. The majority of lysosomal storage diseases (LSDs) arise from defects in sugar hydrolases in the acidic intralysosomal environment. In common with all other intraorganelle proteins, lysosomal hydrolases are synthesized on ribosomes and then glycosylated in the Golgi, receiving specific mannose side chains that function as recognition sites for targeting and uptake into lysosomes. Deficiency of a lysosomal enzyme leads to intralysosomal accumulation of the undegraded substrates, in the tissues where they are normally metabolized. As the stored materials accumulate within the affected cells, they lead to increasingly impaired function of the involved organs. Table 26.23 summarizes these disorders.

There are over 40 recognized LSDs.<sup>1</sup> Classification can be confusing. Eponyms as well as numbering systems and alphabetical designations have accumulated haphazardly as new conditions have emerged. The LSDs include glycolipidoses, mucopolysaccharidoses, glycogenoses, oligosaccharide and glycoprotein disorders, defects of entry of enzymes or egress of products into or out of lysosomes, and the neuronal ceroid lipofuscinoses. Apart from cystinosis, accumulated substrates have a common structure—carbohydrate attached to a protein or a lipid. Figure 26.22 illustrates the biochemical pathways implicated in many of these disorders.

### Incidence and genetics

Individually, LSDs are rare with incidences ranging from about 1 in 50 000 to just a few known cases. Some affect up to 10 000 patients worldwide; the overall incidence for LSDs is estimated at 1 in 7000 to 1 in 10 000 births.<sup>158,159</sup> Some, particularly Tay–Sachs and Gaucher disease, are much more frequent in specific populations (these two being frequent in Ashkenazim). All, with the exceptions of Hunter syndrome, Fabry disease and sialuria, are inherited as autosomal recessive traits. Most of the disorders present in childhood but almost all have late-onset variants that may not emerge until adult life. With few exceptions, genotype–phenotype correlations are not well understood and should rarely be used for counseling.

### Clinical features

Storage diseases characteristically have three clinical phases. In the first, which may last from weeks to decades, clinical findings are absent or occult. This is followed by emerging evidence of tissue involvement that can be relatively acute or evolve over years. Finally, the involved tissues begin to lose function.

LSDs should be considered in: developmental delay, especially with loss of milestones or loss of fine motor control; coarsening of facial features; hepatosplenomegaly; leukodystrophy; ophthalmological abnormalities especially corneal clouding; characteristic radiological skeletal changes; angiokeratomas; and hydrops fetalis.

### Diagnosis

Diagnostic evaluation of LSDs can be complex, and assistance of a specialist in clinical biochemical genetics is critical since testing involves a progressive cascade of biochemical and genetic testing. Mucopolysaccharides (MPS, now known as glycosaminoglycans [GAGs]) and oligosaccharides can be screened, identified and quantitated in urine. Specific enzyme assays for almost all the disorders are available but often only in special centers. Some enzymes can be measured in serum, while others require leukocytes or cultured skin fibroblasts. Occasionally, high enzyme activities erroneously appear to rule out disease and falsely low activities can be due to vagaries of testing

and enzyme behavior (e.g. Tay–Sachs variants and pseudodeficiencies in metachromatic leukodystrophy and others). Carrier testing is usually feasible but overlap between carrier and normal values can be confusing; mutation analysis, if available, is preferable.

When considering the possible diagnosis of an LSD, it may be appropriate to start with simple urine screening tests for GAGs and/or oligosaccharides. If a specific disorder is suspected, then appropriate enzyme assay is indicated. If the diagnosis remains obscure, electron microscopic study of fibroblasts from skin, conjunctival or rectal biopsy, or even leukocytes may reveal lysosomal inclusions that then lead to further analyses. Virtually all of these disorders are amenable to prenatal diagnosis using chorionic villus samples or cultured amniocytes.

### Treatment

There is currently no cure for any of these disorders. Where specific therapies are in use or under trial, these are discussed under the individual disorders. Genetic counseling and family support are always required.

Great care must be taken when considering surgery or anesthesia in patients with LSDs since uncontrolled neck movements can pose a grave risk of atlanto-occipital dislocation. Airway narrowing from tissue infiltration, possible cardiopulmonary disease, and the need to position and stabilize the neck during induction make anesthesia high risk in many LSDs.

## SPHINGOLIPIDOSES

In sphingolipids, sphingosine is linked through its amino group to a variety of fatty acids containing 16–26 carbon atoms. Ceramide is a C-18 sphingosine linked to a fatty acid and therefore, is a long chain amino-alcohol base attached to carboxylic acid (Fig. 26.23). Esterification through the hydroxyl group on the first carbon of ceramide is the basis for synthesis of many lipid compounds. Ceramide with sialyl-oligosaccharides yields gangliosides, with phosphorylcholine it yields sphingomyelins, and with monosaccharides or oligosaccharides it yields neutral glycolipids. The degradative pathway for higher gangliosides to sphingosine is depicted in Figure 26.22.

Although the sphingolipidoses are closely related chemically, their phenotype varies considerably depending on the role of the individual metabolites or their precursors in different tissues. For example, glucocerebrosidase, which accumulates in Gaucher disease, derives from peripheral cells which are particularly rich in membrane glycolipids. Gangliosides, on the other hand, are concentrated in neuronal membranes, thereby involving the gray matter of the brain.

### Tay–Sachs and Sandhoff diseases: the GM<sub>2</sub>-gangliosidoses

Both disorders result in a progressive neurodegenerative disorder caused by deficiency of N-acetyl glucosaminidase (beta-hexosaminidase) and accumulation of ganglioside GM<sub>2</sub>. Hexosaminidase exists in two forms; hex a is a heterodimer and has two alpha and beta subunits; hex b has four beta subunits; both isozymes cleave terminal sugars from GM<sub>2</sub>. Defects in the alpha subunit cause hex a deficiency (Tay–Sachs disease [TSD]); defects in the beta subunit cause hex a and b deficiency (Sandhoff disease). Gangliosides are glycosphingolipids consisting of ceramide and an oligosaccharide side chain with sialic acid residues.

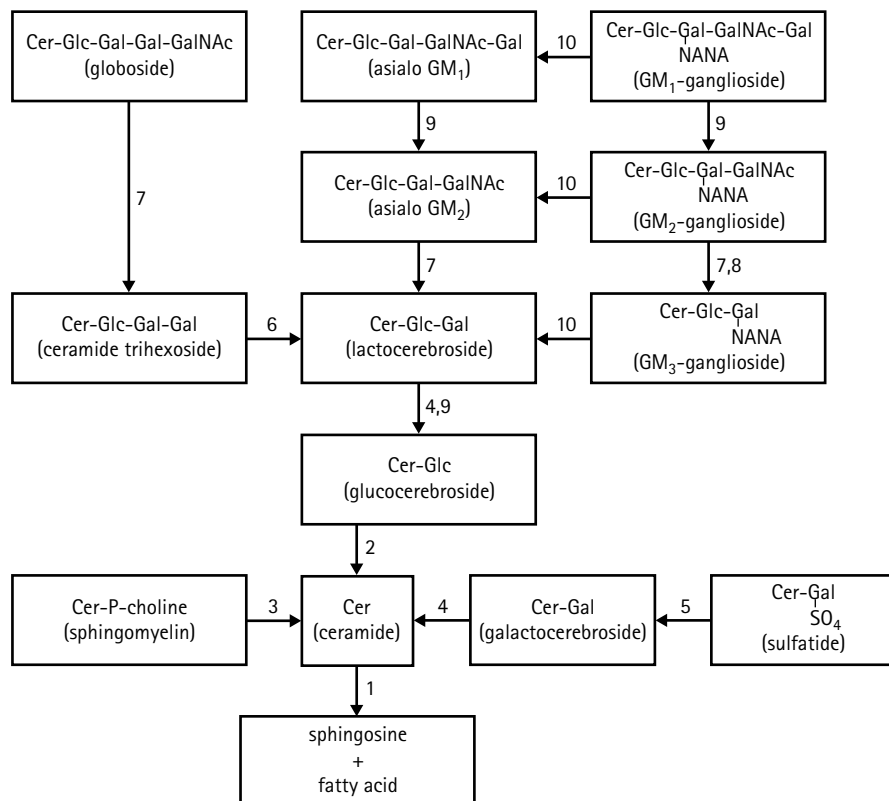

An activator protein facilitates the binding of GM<sub>2</sub>-ganglioside to hex a; deficiency of the activator can also cause TSD.

### Clinical features

Classic infantile TSD is characterized by the gradual onset of progressive weakness, hypotonia, poor head control, decreasing attentiveness followed by paralysis, dementia, blindness and seizures in early infancy. Although some motor skills may be achieved, most affected children never sit alone or crawl. An exaggerated startle response is characteristic, indicating brainstem involvement. By 6–10 months, upper and

**Fig. 26.22** Schematic representation of ganglioside and sphingolipid degradation, showing enzyme steps and metabolic blocks. 1, Ceramidase (Farber); 2,  $\alpha$ -glucosidase (Gaucher); 3, sphingomyelinase (Niemann-Pick); 4, galactocerebrosidase (Krabbe); 5, arylsulfatase A (metachromatic leukodystrophy); 6,  $\alpha$ -galactosidase (Fabry); 7, total hexosaminidase (Sandhoff); 8, hexosaminidase A (Tay-Sachs); 9,  $\beta$ -galactosidase (GM<sub>1</sub>-gangliosidosis); 10,  $\alpha$ -neuraminidase (sialidosis).

**Fig. 26.23** Structure of a typical ceramide.

lower neurone involvement is obvious and seizures and macrocephaly become evident. Ophthalmological examination reveals 'cherry red spots' at the maculae – a gray-white halo of lipid-laden cells that creates the appearance of a central red spot (Fig. 26.24). They were once considered diagnostic of TSD, but can be found in other GM<sub>2</sub>-gangliosidoses and variably in GM<sub>1</sub>-gangliosidosis, Niemann-Pick disease, Farber disease and sialidosis. Continued deterioration leads to complete unresponsiveness, blindness, deafness and spasticity with decerebrate posture and death by 3–5 years.

Variants of TSD include juvenile, adult and b<sub>1</sub> (normal activity with artificial substrate) variants and activator protein defect. Late-onset juvenile hex a deficiency usually presents between 2 and 10 years with ataxia, progressive spasticity, dementia and increasing seizures. Most patients die as teenagers. Adult forms present somewhat later and are often misdiagnosed as multiple sclerosis.

Infantile Sandhoff disease is similar to infantile TSD but with the combined hex a and b deficiency, there is more extraneural involvement with mild visceromegaly and occasional foamy histiocytes in bone marrow or vacuolated lymphocytes in blood. Minor bony changes may also be present. There is no ethnic predilection. Juvenile and adult forms are similar to their counterparts of TSD with delayed onset, slower progress and longer survival.

Activator protein deficiency is clinically and histologically identical to TSD except that hexosaminidase activities are normal when measured by conventional methods.

**Fig. 26.24** Tay-Sachs disease. A cherry-red spot is seen at the posterior pole due to the presence of ganglioside in the ganglion cells of the macula. There are no ganglion cells at the fovea which presents as a red spot but the surrounding area appears white or milky in color.

### Diagnosis

Enzyme assays using artificial substrates are done in serum, leukocytes or tissues. In TSD, hex a is reduced but hex b activity is normal; Sandhoff disease shows both hex a and b deficiency. Serum assays can give erroneous results especially in pregnancy, with liver disease and with certain medications including oral contraceptives; in these circumstances,

the assay must be done in leukocytes. Sophisticated assays are needed to identify unusual variants. Urine oligosaccharides are normal in TSD but in Sandhoff, oligosacchariduria can be seen.

Enzymatic prenatal diagnosis for TSD is available but molecular testing is optimal, although > 70 mutations for TSD are described.

**Population screening for Tay–Sachs disease.** Prior to population screening, TSD incidence was about 1 in 3500 Ashkenazim but only about 1 in 300 000 non-Ashkenazim; it was also common in French Canadians. There are common mutations in Ashkenazi Jews, so that mutational analysis is sometimes used for screening. Since about 1 in 27 Ashkenazim is a heterozygote (~1 in 160 in non-Jews), widespread screening for heterozygotes is now common practice in selected populations. In the international TSD prevention program, > 1 million people have been tested, resulting in a dramatic decrease in TSD in Jewish infants. Since 1970, screening has reduced the incidence from approximately 60/year to 3–5/year in Jews in the USA.

### Treatment

Supportive care is the only treatment option at present. Platt et al evaluated a potential strategy for treatment based on N-butyldeoxynojirimycin (formerly OGT-918, now miglustat), an inhibitor of glycosphingolipid biosynthesis. TSD mice treated with this agent had no accumulation of GM<sub>2</sub> in the brain.<sup>160</sup> Clinical trials with miglustat in later-onset forms are in progress. Animal studies of bone marrow transplant showed some encouraging preliminary results,<sup>161</sup> but this was ineffective in a child also treated with miglustat.<sup>162</sup>

## Gaucher disease

### Clinical features

Gaucher disease is the most prevalent of the LSDs. Three types have been described (Table 26.24). Type 1 is by far the most frequent. Common signs include splenomegaly (typically 4–70 times normal) often with hypersplenism and bone marrow crowding leading to thrombocytopenia and/or anemia with easy bruising or bleeding, especially menorrhagia and nosebleeds. Less extreme hepatomegaly (1.5–10 times normal) is usual; bony infiltration leads to avascular necrosis of the hip and disseminated damage elsewhere, and bone pain can lead to a misdiagnosis of trauma or infection and, with the bleeding tendency, to consideration of malignancy. Growth retardation and delayed puberty are common in children. There are no neurological problems in type 1. Rarely, pulmonary hypertension, infiltrative lung disease, portal hypertension, and renal involvement are seen.

Type 2 presents in infancy with opisthotonus, visceromegaly, strabismus, severe neurological dysfunction with spasticity, failure to thrive and cachexia leading to early death (Fig. 26.25). Type 3 is characterized by visceral enlargement which may be massive, and slowly progressive neurological dysfunction. Age at presentation for type 3

is later than type 2, and progression is slower. The presentation, however, is variable, and some patients with type 3 do not have massive organomegaly.

Gaucher disease is panethnic with an incidence of about 1 in 1000 in Ashkenazim in whom it is much more common than in the general population.

### Diagnosis

Often typical 'Gaucher cells' are the initial finding in bone marrow or liver. Diagnosis is confirmed by enzyme activity in leukocytes or by mutation analysis. There are well-established genotype–phenotype correlations, so mutation analysis can be used, with some caution, to predict prognosis. High levels of acid phosphatase, chitotriosidase, and angiotensin converting enzyme in blood and/or increased levels of glucocerebroside in tissues are also found but are not considered diagnostic.

### Treatment

In the past, supportive care was limited to blood transfusions, splenectomy and androgen therapy. Treatment for skeletal complications included pain management for bone crises and orthopedic management of bone lesions. Bone marrow transplantation is now superceded.<sup>163</sup>

Enzyme replacement therapy (ERT) has become the treatment of choice.<sup>164</sup> Response to therapy is shown in Figure 26.26. It partially or completely reverses the hepatomegaly and the bone marrow abnormalities, and can probably prevent bone crises and avascular necrosis of the hips if begun early enough. However, established skeletal changes may require 2–3 years to improve.

Virtually all children with symptomatic Gaucher disease, even those with isolated splenomegaly, should be considered for treatment with ERT since presentation in childhood indicates moderate to severe disease. Asymptomatic adults are sometimes not treated with ERT because treatment requires intravenous infusions every 2 weeks, and is extremely expensive.<sup>21,165</sup> Substrate reduction therapy with miglustat, as discussed above for TSD, may also prove helpful<sup>166</sup> and is now approved in several countries.

## Fabry disease

Fabry disease is caused by decreased alpha-galactosidase activity, with intralysosomal accumulation of globotriaosylceramide (GB-3) (also known as CTH, ceramide trihexosamide or GL-3). The frequency is estimated at 1 in 40 000–117 000 births with no apparent ethnic predisposition. Most families have a unique mutation. Although Fabry disease is inherited as an X-linked trait, most female heterozygotes, though not often symptomatic in childhood, eventually develop signs, symptoms and complications of the disease, though this often occurs more slowly and later than in men.

**Table 26.24** Clinical types of Gaucher disease

Clinical features	Type 1	Type 2	Type 3
Age at onset of signs/symptoms	Any	Infancy	Childhood
Splenomegaly	Mild to extreme	Moderate	Mild to extreme
Hepatomegaly	Mild to extreme	Moderate	Mild to extreme
Skeletal disease/bony crises	Absent to severe	Absent	Moderate to severe
Primary central nervous system disease	Absent	Significant	Mild to significant, increasing with age
Life span	Normal with enzyme replacement therapy	~2 years	2–60 years
Ethnicity	Panethnic	Panethnic	Panethnic
Demographic group	Ashkenazi Jewish		Norrbottnian
Frequency	~1 in 60 000–200 000 (~1 in 500–1000 Ashkenazim)	< 1 in 100 000	< 1 in 50 000

Fig 26.25 Severe opisthotonus in a 3-month-old infant with type II Gaucher disease.

### Clinical features

Males typically present in childhood with peripheral neuropathy, the most striking feature being attacks of acroparesthesia characterized by intense pain in the hands and feet; over time the neuropathy worsens causing impaired temperature and vibratory perception. Suspicion of psychiatric disease often delays the diagnosis for years. Renal damage, evidenced by increasing proteinuria, occurs typically in adulthood, fol-

lowed years later by renal dysfunction and renal failure. Without treatment, renal failure is usually fatal in males typically in their fourth or fifth decade.

Other major sites of involvement are the skin, heart and nervous system. Angiokeratomas are clusters of dark, nonblanching, petechioid punctate lesions that are usually present in the 'bathing trunk' area, and especially the umbilicus or scrotum. Hypertrophic cardiomyopathy is the most common cardiac manifestation. Autonomic nervous system involvement is characterized by dysautonomia, decreased vessel compliance and hypo/anhydrosis. Abdominal pain is not uncommon and gastrointestinal dysfunction can result in pain, diarrhea and mesenteric infarction. CNS involvement may cause transient ischemic attacks and stroke, especially in older men. The cornea have whorl-like opacities and tortuous retinal vessels which can occlude. Constitutional difficulties may include fatigue, depression and an impaired quality of life. Cases due to milder mutations can present with cardiomyopathy in adulthood but few, if any, other problems.

### Diagnosis

Decreased activity of alpha-galactosidase a in serum, leukocytes or other tissue is diagnostic. In urine, crystalline glycosphingolipids show birefringence under polarization microscopy (so called 'maltese crosses'). Histologically, lysosomal inclusions are present in almost all cell types, including the skin and glomeruli.

The corneal changes are virtually pathognomic, can be seen by slit lamp examination, and may be a useful adjunctive test for females who, even when affected, often have normal enzyme activity levels. DNA mutation analysis is the definitive diagnostic test in females.

### Treatment

Analgesics are usually required, and phenytoin, neurontin, carbamazepine or narcotics were often used for pain before ERT was developed. Renal dialysis or transplant are used for renal failure but the disorder progresses in other tissues. ERT given by intravenous infusion has revolutionized the treatment of this disorder.<sup>167,168,169</sup>

## Niemann–Pick disease types a and b

### Clinical features

The common feature of these disorders is accumulation of sphingomyelin due to a defect of sphingomyelinase. Typically, type a patients present in infancy with marked hepatosplenomegaly, failure to thrive and relentlessly progressive psychomotor regression; about 50% have Jewish ancestry. Lymphadenopathy is also often present. Neurological regression leads to hypotonia and weakness with feeding difficulties. A macular cherry red spot is seen in about 50% of cases, and corneal clouding and retinal abnormalities can be seen. Xanthomas and a yellow–brown discoloration of the skin may be observed. Hypersplenism can be aggressive with widespread infiltration of foam cells. Most patients die before 2 years.

Type b is a chronic non-neuronopathic disorder with variable onset from early childhood to adult life. All patients have marked hepatosplenomegaly usually with hypersplenism. Patients may suffer general malaise and there may be a delay in sexual development. Lung infiltration may become prominent and lead to respiratory difficulties and cardiopulmonary failure. There is generally no bone or neurological involvement and cherry red spots are rarely found. Most affected children survive into adulthood.

### Diagnosis and treatment

Deficient enzyme activity in leukocytes or cultured fibroblasts is diagnostic, the values being very low in type a but there is up to 15% residual activity in type b. Characteristic foam cells (or 'sea-blue histiocytes') can be seen in bone marrow, liver and spleen, but they are not diagnostic.

Only supportive care is currently available. Liver transplantation has been used in the severe non-neuropathic cases. ERT is in early clinical trials for type b but is unlikely to be effective for type a.

## Niemann–Pick type c

Niemann–Pick type c (NPC) is entirely different from types a and b and is caused by one of two non-allelic defects: NPC1 codes for a large endosomal glycoprotein and NPC2 codes for a lysosomal cholesterol binding protein. It is known by several other names including juvenile dystonic lipidosis, neurovisceral storage disease with vertical supranuclear ophthalmoplegia and sea-blue histiocytosis. NPC is characterized by defective cholesterol esterification.

### Clinical features

Onset may vary from infancy to late adult life; findings include intellectual impairment and impaired fine motor movements and behavioral problems, progressive ataxia, dementia, dysarthria, dystonia and tremors, seizures, cataplexy and mild hepatosplenomegaly. Supranuclear ophthalmoplegia with impairment of upward gaze is almost invariable. A history of neonatal hepatitis, sometimes with cholestasis, is often reported and rare cases develop liver failure. With time, the disease progresses to bulbar palsy and encephalopathy but patients seem to maintain a cheerful demeanor though they gradually lose contact with the environment. There is generally no cherry red spot. Death typically occurs after one to three decades of deterioration, though early-onset cases often die in early childhood.

### Diagnosis

Many cases are misdiagnosed for years as multiple sclerosis, Parkinson disease, Leigh syndrome or other neurological conditions, although the vertical ophthalmoplegia is highly suggestive. Foamy histiocytes that stain an unusual sea-blue color are usually found in many tissues. These are similar to those seen in Niemann–Pick types a and b, Wolman

disease and cholesterol ester storage disease. Skin, nerve and conjunctival biopsies usually show a variety of inclusions. Unesterified cholesterol and secondarily, sphingomyelin, phospholipids and glycolipids are stored in excess in the liver, spleen and other organs. Sphingomyelinase activity may be low, but this is not the primary defect. Cultured fibroblasts show a disorder of cholesterol processing and accumulation of unesterified cholesterol in lysosomes. There is a characteristic pattern of filipin-cholesterol staining in cultured fibroblasts (filipin stains unesterified cholesterol). These approaches are used for the definitive diagnosis, though mutational analysis is becoming more widely available. Prenatal diagnostic testing is offered in a few centers.

### Treatment

Substrate reduction therapy with miglustat is in clinical trials, but results are not yet available. Allopregnanolone may soon be tested in clinical trials. For now, treatment remains supportive.

## Metachromatic leukodystrophy

Three arylsulfatases are designated as a, b and c. Metachromatic leukodystrophy is caused by deficiency of arylsulfatase a; the b enzyme is deficient in Maroteaux–Lamy syndrome (MPS VI) and arylsulfatase c in steroid sulfatase deficiency. All three, as well as iduronate sulfatase, heparan N-sulfatase and N-acetyl-galactosamine-6-sulfatase, are involved in multiple sulfatase deficiency.

Deficiency of arylsulphatase a leads to accumulation of lipid in neurones. Since sulfatide is a major constituent of myelin, progressive demyelination occurs, leading to a characteristic leukodystrophy. The most common forms are late infantile and juvenile.

### Clinical features

In the late infantile type, onset is usually between 1 and 2 years of age with learning difficulties and incoordination, and gradually increasing signs of deteriorating psychomotor function with signs of cortical, cerebellar and peripheral nerve involvement. Increasing speech difficulties with dysarthria, ataxia and optic atrophy accompany marked mental and motor regression and within a few years the children are decerebrate, rarely surviving beyond 8 years.

The juvenile form usually presents before 6 years, but may be delayed past puberty. Subtle behavioral difficulties and declining school performance accompany or precede increasing signs of cortical and cerebellar dysfunction. Clumsiness progresses to ataxia, spasticity and increasingly obvious deterioration. The course is variable but most patients die by about 20 years of age.

An adult-onset form is rare but may emerge at any age, starting with behavioral or personality changes that may include paranoia, dementia or psychosis. Neurodegenerative signs and peripheral neuropathy become progressively more obvious. Most succumb after a prolonged course.

A defect of the enzyme activator, saposin b, results in a disease that is clinically indistinguishable from the usual cases except that the activity of arylsulfatase a is totally normal when initially assayed.

### Diagnosis

Symmetrical attenuation of white matter, most prominent in the parietal and occipital regions, is seen on brain MRI. Peripheral neuropathy causes decreased nerve conduction velocity and raised protein levels in CSF. Peripheral nerve biopsy shows segmental demyelination with metachromatic material within Schwann cells and histiocytes.

Diagnosis requires enzyme assay in leukocytes or cultured fibroblasts. Diagnosis of the activator protein deficiency form requires special assays in cultured fibroblasts. Urine sulfatide excretion measurement may occasionally be helpful in diagnosing atypical cases.

The standard enzyme assay uses artificial substrates: values < 10% of control occur in all types of metachromatic leukodystrophy; however, 2.5% of healthy individuals have 'pseudodeficiency' due to a mutant enzyme with in vitro activity as little as ~20% of normal; these cases require mutational analysis. Because disease-causing and

pseudodeficient genes can coexist, prenatal diagnosis should always test the parents as well as the proband. Special care is required if using chorionic villus tissue due to the presence of high steroid sulfatase activity.

### Treatment

Treatment is supportive; bone marrow transplantation has its detractors and advocates since there is some evidence of slowing or halting of the neurodegenerative process in select cases.<sup>170</sup>

### Other sulfatase deficiencies

*Multiple sulfatase* deficiency affects several sulfatases (see above) and thus exhibits similarities with other LSDs, particularly the mucopolysaccharidoses. Thus, coarse features, stiff joints, hepatosplenomegaly and short stature are standard findings, along with the findings of metachromatic leukodystrophy.

*Arylsulfatase c (steroid sulfatase)* deficiency causes X-linked ichthyosis and reduced activity in the placenta that often results in delayed onset of labor. The gene is located on the Xp22.3-pter region and escapes X-inactivation.

### Krabbe disease

#### Clinical features

Krabbe disease is caused by deficiency of galactocerebrosidase (galactocerebroside beta-galactosidase or galactosylceramidase). It is a rapidly progressive, invariably fatal disease. Most patients present between 3 and 6 months with pronounced irritability and increased sensitivity to stimulation. An exaggerated startle response may be seen, similar to TSD. Progressive psychomotor retardation soon becomes obvious with increasing hyperactivity often accompanied by tonic spasms and spasticity but with clear evidence also of peripheral neuropathy. There is usually no retinal degeneration nor cherry red spot; however, optic atrophy leads to blindness. Seizures become more frequent and patients rapidly deteriorate, most dying by 2 years of age. There is no visceromegaly and microcephaly is usual but not invariable.

Rare late infantile, juvenile and adult forms occur. They are similar to the infantile form but with a more protracted course. The earlier the onset, the more aggressive is the neurological deterioration; later variants may present with loss of vision and hemiparesis.

#### Diagnosis and treatment

This requires specific enzyme assay in leukocytes or cultured fibroblasts. Leukodystrophy is apparent on brain MRI and most patients have delayed nerve conduction velocity. CSF protein levels are usually raised in infants but may be normal in older patients.

Supportive treatment is often all that is available. Bone marrow or umbilical cord blood transplantation in patients with only minimal neurological involvement has shown some efficacy.<sup>171,172</sup>

### Farber disease

This disorder, caused by ceramidase deficiency, leads to lipogranulomatosis deposits in various tissues. It presents in infancy with painful subcutaneous swellings around joints and bony prominences. Lymphadenopathy and heart and lung involvement are usual and the brain is also variously involved; cherry-red spots may be present. Laryngeal involvement leads to a characteristic hoarse cry with both breathing and feeding difficulties that usually cause death in the first 2 years. Some variants have little tissue involvement and no brain damage. The differential diagnosis includes juvenile rheumatoid arthritis, histiocytosis and hyperphosphatemic tumoral calcinosis. Enzyme assay is available; no treatment is known.

### MUCOPOLYSACCHARIDOSES

Mucopolysaccharides (MPS), now usually called glycosaminoglycans (GAGs), are complex sugar/protein compounds that require at least 10 enzymes for their degradation. Deficiency of any of these enzymes leads

to accumulation of GAGs in tissues and their excretion in the urine. The GAGs include dermatan sulfate, heparan sulfate, keratan sulfate and chondroitin sulfate, and characteristic excretion patterns help to differentiate these disorders. Because lysosomal hydrolases are linkage specific,  $\alpha$ -L-iduronidase cleaves terminal  $\alpha$ -L-iduronic acid from both dermatan sulfate and heparan sulfate, resulting in accumulation of both compounds in Hurler syndrome (Fig. 26.27). These disorders are classified by the enzyme deficiency and type of GAG excreted. They are numbered I to IX but some numbers have been dropped as allelic disorders have been recognized, e.g. the designations MPS V and VIII are no longer used.

As in most LSDs, there is an initial period of normalcy followed by a chronic and progressive course, generally characterized by coarse facial features, hepatosplenomegaly, corneal clouding, skeletal abnormalities, cardiac valvular disease, stiff joints and later, cardiomyopathy. The Sanfilippo syndromes primarily exhibit developmental regression with little or no dysmorphism.

The radiographic features of these disorders are referred to as 'dysostosis multiplex'. The earliest findings are in the spine where defective ossification distorts the vertebral bodies giving rise to 'beaking' starting in T12 and L1; this extends to other vertebrae, resulting in a worsening gibbus (Fig. 26.28). There are obvious changes in the long bones, hands, ribs and clavicle (Fig. 26.29); the basilar portions of the ilia are hypoplastic with flaring of the iliac wings. Coxa valga and dysplasia of the capital femoral epiphyses can vary from minimal to severe. Macrocephaly is usual with thickening of the calvarium most apparent over the occiput. The sella becomes J- or shoe-shaped and the optic foramina are enlarged. In addition, cardiomegaly is progressive and increased pulmonary markings are frequent.

Several forms of MPS have prominent CNS involvement and developmental regression. Hydrocephalus, blindness, hearing loss, carpal tunnel syndrome, obstructive airway disease, persistent rhinorrhea, recurrent upper respiratory infections and otitis media, inguinal and umbilical hernias, hirsutism and thick hair, and spinal cord compression are variably present, all being due to accumulation of GAGs in the affected tissues.

### Diagnosis

There are several simple urine screening tests; however, they are relatively insensitive and nonspecific so that GAG quantitation and identification is preferred. Definitive diagnosis requires enzyme analysis either in leukocytes or cultured skin fibroblasts. Thus far, mutational analysis has not proven very useful in diagnosis nor in providing genotype-phenotype correlations. Hunter syndrome is an X-linked recessive trait

Fig. 26.27 Portions of polysaccharide chains of dermatan and heparan sulfate and nature of the defects in the various mucopolysaccharidoses.

Fig. 26.28 (a) Lateral view of the spine showing early changes in a 3-year-old child with Hurler syndrome and (b) late changes in the spine of a patient with Morquio syndrome.

Fig. 26.29 Dysostosis multiplex: (a,b) Hand X-rays of two 3-year-old children with mild and more severe bony changes; (c) the claw hands of Hurler syndrome.

but all the others are autosomal recessive traits. Prenatal diagnosis is available for most MPS but is not always easily available. Carrier testing is possible, but is not always conclusive.

### Treatment

Surgery poses great risk for these patients since airway narrowing from tissue infiltration, possible cardiopulmonary disease, and manipulation of the neck, which may be unstable in MPS disorders, during induction make anesthesia high risk.<sup>173–177</sup>

ERT is now available for MPS I, MPS II and MPS VI. Unfortunately, ERT does not address the neurological complications, so it may not prevent death in severe cases. Bone marrow or cord blood stem cell transplantation has shown some efficacy, especially for MPS I.<sup>174,176</sup> Other than this, supportive care is all that is available.

### MPS I – Hurler, Hurler–Scheie (I/V) and Scheie (V) syndromes

These conditions, earlier thought to be different disorders, are allelic and caused by different mutations of the gene encoding alpha-L-iduronidase, leading to severe and milder forms of the same disease. The accumulating GAGs are heparan and dermatan sulfates.

#### Clinical features

The frequency of MPS I – Hurler syndrome is around 1 in 100 000. These patients are usually diagnosed at 1–2 years of age, and typically have a life expectancy of 6–10 years. Major clinical manifestations include cardiomyopathy, hepatosplenomegaly, skeletal deformity, developmental regression, corneal clouding, hearing loss, rhinorrhea and dysostosis multiplex.

The frequency of MPS I – Hurler–Scheie syndrome is around 1 in 115 000. The clinical findings are similar to Hurler syndrome with the exception that there is no CNS involvement. Patients are often diagnosed at age 2–5 years, with death occurring in the late 20s without treatment.

The least severe form is Scheie syndrome which occurs in about 1 in 500 000. It is characterized by joint stiffness with tendon compression syndromes, glaucoma and variable aortic valve disease. There is normal growth and no CNS involvement, and life expectancy can be normal. The differential diagnosis includes acquired polyarthropathies and the multiple epiphyseal dysplasias.

### Hunter MPS II

Hunter syndrome is caused by a deficiency of iduronate sulfatase, with storage of dermatan and heparan sulfate. The presentation is very similar to MPS I except that the corneae never become cloudy and a pebbly skin lesion, usually most apparent over the scapulae ('peau d'orange'), is common. Severely affected children usually die in the second decade. Mild cases can have normal intelligence, short stature and survival into the sixth decade.

#### Diagnosis and treatment

Increased levels of the GAGs dermatan and heparan sulfate in urine are suggestive. Measurement of iduronate sulfatase in leukocytes or cultured fibroblasts is diagnostic.

Neither bone marrow nor cord blood stem cell transplant has been successful but ERT is beneficial.

### Sanfilippo syndrome MPS III A, B, C and D

Symptoms in all forms include the subtle onset of developmental regression, extreme hyperactivity and behavioral difficulties including aggressive behavior, mild hepatosplenomegaly and, frequently, very mild dysostosis. Coarsening of facial features in these disorders may be minimal or absent, making clinical recognition difficult. Life span is into the second to third decade. Sanfilippo A is a result of heparan N-sulfatase deficiency; MPS III B is caused by a deficiency of alpha-N-acetylglucosaminidase. MPS III C is a result of deficient acetyl-CoA: alpha-glucosaminide acetyltransferase and MPS III D is caused by N-acetylglucosamine 6-sulfatase deficiency.

### Diagnosis and treatment

The absence of dysmorphic features, subtle onset and psychiatric problems often delay the diagnosis for years. All forms are characterized by increased excretion of heparan sulfate but this may not be marked, so a normal urine screen does *not* rule out the diagnosis. Enzyme analysis in leukocytes or cultured fibroblasts is necessary.

Neither bone marrow nor cord blood stem cell transplant has been successful.

### Morquio syndrome A and B (MPS IV)

Morquio A is caused by deficiency of N-acetyl-galactosaminase-6-sulfatase. Morquio B by deficient beta-galactosidase – the same enzyme deficiency that causes GM<sub>1</sub>-gangliosidosis. Morquio A and B are clinically identical; both have less severe forms; atlantoaxial subluxation can occur.

Presentation is usually at 18–24 months with gait problems from genu valgum, coxa valga, kyphosis and growth failure. The trunk and neck are short and the facies are broad, but without the coarseness of MPS I. In the upper limbs, especially the hands, there is joint laxity rather than contractures. By 6 years, the corneae are typically cloudy, and there is progressive spinal and chest deformity with lumbar lordosis and dorsal kyphosis (see Fig. 26.28b). Contractures of the knees and hips produce a jockey-like stance and the fingers are short and hypermobile with ulnar deviation. Cardiac valvular lesions may occur. Intelligence is usually normal. An enamel dysplasia occurs that is not seen in other LSDs. Survival well into adulthood is usual, females seeming to fare better than males. A common and critical problem is odontoid hypoplasia with subluxation of C1 on C2. Myelopathy may occur acutely or insidiously, being precipitated by even minor trauma including flexion of the neck as during anesthesia. Mechanically induced pulmonary insufficiency and valvular heart disease are eventually fatal.

#### Diagnosis and treatment

The diagnosis is made with specific enzyme assays. The accumulated GAGs are keratan sulfate and chondroitin 6-sulfate. In early childhood MPS IV is similar to other MPSs, and a number of skeletal dysplasias with platyspondyly are easily confused, but, in them, corneal clouding and keratansulfaturia are absent.

Myelopathy may benefit from early treatment by surgical fusion of the spine or other orthopedic procedures, but the decision on whether to operate should be carefully considered by experts. Bracing alone is rarely satisfactory.

### Maroteaux–Lamy syndrome (MPS VI)

Maroteaux–Lamy syndrome results from deficiency of N-acetylgalactosamine-4-sulfatase (arylsulfatase B). Dermatan sulfate is excreted in excess. Mild and severe forms of the disorder are seen. MPS VI is usually diagnosed between 6 and 24 months. Signs include short stature, dysostosis multiplex, stiff joints, corneal clouding and normal intelligence. Eventually, cardiac valvular disease occurs and myelopathy is common. In the severe forms, life expectancy without treatment is into the second decade.

#### Diagnosis and treatment

Diagnosis is by assay of arylsulfatase B in leukocytes or cultured fibroblasts. Increased urinary dermatan sulfate is suggestive.

Bone marrow or cord blood stem cell transplant were formerly used but clinical trials have now confirmed efficacy of ERT.<sup>177,178</sup>

### Other mucopolysaccharide disorders (MPS VII and IX)

*Sly syndrome (MPS VII)* is rare and caused by beta-glucuronidase deficiency, with resultant excretion of dermatan sulfate, heparan sulfate and chondroitin 6-sulfate. Severe cases may have hydrops fetalis. Major clinical manifestations include dysostosis multiplex and hepatosplenomegaly with a wide variation in severity. Diagnosis is by enzyme analysis in serum, leukocytes or cultured fibroblasts. No specific therapy is available.

*Hyaluronidase deficiency (MPS IX)* with transient bilateral nodular soft tissue masses and painful generalized edema has been reported. The patient had mildly dysmorphic features, acquired short stature, normal joint movement and intelligence. Pelvic radiographs revealed multiple intra-articular soft tissue masses and acetabular erosions.

### MUCOLIPIDOSES [I-CELL DISEASE (ML II) AND PSEUDO-HURLER POLYDYSTROPHY (ML III)]

These two conditions are allelic and caused by a defect of N-acetylglucosamine-1-phosphotransferase which normally attaches phosphate to a polymannose side chain on the precursor proenzymes in the Golgi. This destroys the uptake-recognition site on the enzymes and results in several of them showing elevated levels in serum, having altered electrophoretic patterns and multiple intralysosomal enzyme deficiencies. This accounts for a heterogeneous accumulation of intralysosomal storage material. The gross cytoplasmic inclusions seen in cultured fibroblasts gave rise to the name 'inclusion (I) cell disease'.

ML II and ML III are similar to severe and mild Hurler syndrome, respectively, except that corneal clouding never develops. In ML II, the features may even be detectable at birth. ML III is milder and is often diagnosed as polyarticular arthropathy for years before the true cause is recognized. Clinical and radiological appearances are shown in Figures 26.30.

#### Diagnosis and treatment

Diagnosis is suspected based on the clinical findings associated with elevated levels of several lysosomal enzymes in serum. Assay of the specific enzyme defect is available in a few centers. Mutation analysis should become available soon. No specific therapy is available.

### OLIGOSACCHARIDOSES AND GLYCOPROTEINOSES

The glycoproteinoses are rare disorders in which different enzyme deficiencies result in accumulation of oligosaccharides that are excreted

in urine; some have ethnic predilections. The clinical presentations are often similar to a mild MPS but with no increased excretion of GAGs. Two typical oligosaccharide chains are shown in Figure 26.31. As with all untreated LSDs, once the conditions manifest, they follow a steady downhill course. No specific treatment is available.

### GM<sub>1</sub>-gangliosidosis (beta-galactosidase deficiency)

Early-, severe- and later-onset forms are described; they involve the same enzyme as MPS IV B and galactosialidosis (combined with neuraminidase deficiency).

#### Clinical features

Infantile GM<sub>1</sub>-gangliosidosis (type I) is the commonest form. It presents in infancy and mimics a severe Hurler phenotype with increasing psychomotor retardation and failure to thrive. Dysostosis and hepatosplenomegaly are prominent and cardiomyopathy may develop. About 50% have a macular cherry red spot and by 1 year, blindness and seizures are usual. Continued deterioration results in death by 2 years of age.

In juvenile GM<sub>1</sub>-gangliosidosis, development starts to slow around 1 year, progressing to seizures, abnormal movements and progressive decline, leading to death between 3 and 10 years of age. Skeletal changes, hepatomegaly and cherry red spots are usually absent. Adult GM<sub>1</sub>-gangliosidosis presents in the second or third decade; it is the rarest form but is more frequent in Japan. Symptoms include slowly progressive dystonia, spinocerebellar degeneration and increasing cognitive deficits. Dysmorphic features, visceromegaly, cherry red spots and seizures are absent.

#### Diagnosis and treatment

Beta-galactosidase is deficient in all tissues and may be assayed in leukocytes. Lymphocytes often show a characteristic vacuolation. Low levels of keratan sulfate may be excreted; more often there is a characteristic oligosacchariduria that includes a specific octasaccharide. At autopsy, many tissues contain large histiocytes ballooned with GM<sub>1</sub>-ganglioside.

No specific therapy is available.

### Aspartylglucosaminuria

#### Clinical features

Most cases have originated from Finland, where a consistent phenotype, reminiscent of the MPSs, is found. They present between 1 and 5 years of age with coarse features and loose, sagging skin, often with prominent acne. Angiokeratomas are common and connective tissue involvement leads to joint laxity. Growth is usually poor, often with mild dysostosis. There is generally no significant hepatosplenomegaly but recurrent respiratory infections, urinary tract infections, hernia, clubfoot or planovalgus deformity, corneal opacities and strabismus are frequent. Mental deterioration and bizarre behavior become evident between 6 and 15 years with death 20–30 years later from pulmonary disease.

#### Diagnosis and treatment

Deficient aspartylglucosaminidase activity can be demonstrated in leukocytes or fibroblasts. Most patients have vacuolated lymphocytes, lymphopenia and increased urinary levels of glycoasparagines that may be detected on amino acid analysis.

No specific treatment is available.

### Fucosidosis

A severe form with onset between 3 and 18 months and a milder form are described; both are rare. Both are similar to the MPS phenotype with skeletal abnormalities, coarse facial features, growth retardation, hepatosplenomegaly, cardiomegaly and mental retardation. Early-onset cases are severely delayed and never achieve normal milestones. Milder patients have angiokeratomas identical to Fabry disease.

Deficient enzyme activity in leukocytes is diagnostic. Vacuolated lymphocytes are found. Oligosaccharide analysis of urine is helpful. No specific treatment is available.

Fig. 26.30 Mucopolipidosis II (I-cell disease) in an 18-month-old girl. (a) Facies and habitus, (b) gum hypertrophy.

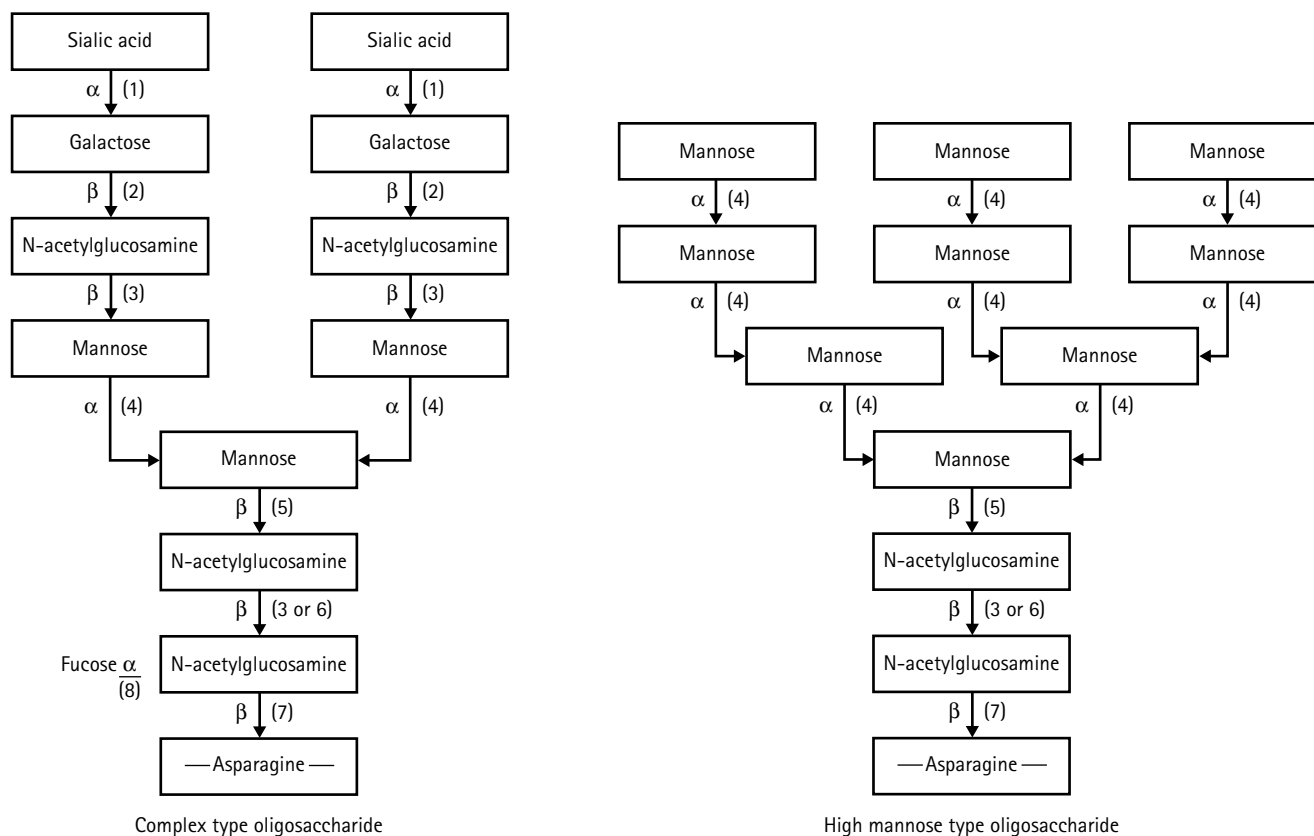

Fig. 26.31 Structures of two typical oligosaccharide chains as found on glycoproteins. Alpha and beta linkages are indicated and the specific degradative enzyme steps are numbered as follows: 1,  $\alpha$ -neuraminidase; 2,  $\beta$ -galactosidase; 3,  $\beta$ -hexosaminidase; 4,  $\alpha$ -mannosidase; 5,  $\beta$ -mannosidase; 6, endo- $\beta$ -hexosaminidase; 7, asparylglucosaminidase; 8,  $\alpha$ -fucosidase.

### Alpha-mannosidosis

Two phenotypes are described; both are rare. Type I presents in infancy and type II between 1 and 4 years of age. The clinical features are very similar and include mildly coarse MPS-like facies, marked mental retardation, recurrent infections, impaired speech, hearing loss, corneal clouding, hepatosplenomegaly and dysostosis. There may also be marked hyperplasia of the gingiva.

Vacuolated lymphocytes are generally present in peripheral blood and bone marrow. Several mannose-rich oligosaccharides are found in urine. The enzyme is measurable in leukocytes. No specific treatment is available.

### Beta-mannosidosis

The few reported severe cases have had seizures, quadriplegia and rapid decline to death. Symptoms have included mental retardation, angiokeratoma, feeding difficulties, recurrent infections, speech difficulties and hearing loss. The enzyme can be measured in leukocytes. Vacuolated lymphocytes are not present and the major storage substance is an oligosaccharide. No specific therapy is available.

### Schindler disease

This rare disorder is due to deficiency of alpha-N-acetylgalactosaminidase. Type I is an infantile-onset neuroaxonal dystrophy with rapid deterioration starting about 1 year and leading to pancerebral damage, blindness and myoclonic seizures. There is no visceromegaly or any peripheral storage cells. Type II develops later, even in midlife. Angiokeratoma corporis diffusum, lymphedema and mild, progressive cerebral involvement are reported; inclusions may be seen in leukocytes and dystrophic axons in rectal biopsies. Urinary oligosaccharides are abnormal. The enzyme assay can be performed in leukocytes.

### SIALIDOSES

The sialic acids are a family of compounds derived from neuraminic acid. Neuraminidase deficiency occurs in several forms.

#### Clinical features

In type I (cherry red spot–myoclonus syndrome), debilitating myoclonic seizures and movement disorders develop, usually in the second decade and are accompanied by progressive visual loss associated with macular cherry red spots. Nystagmus, ataxia and seizures may occur. Intelligence is usually preserved until late, and visceromegaly and dysostosis are mild or absent.

The phenotype of type II (previously called mucopolipidosis type I) is of a severe MPS disorder presenting in infancy or even as fetal hydrops. The phenotype is with dysostosis, hepatosplenomegaly and developmental delay. Survival depends upon the severity of the symptoms.

Galactosialidosis is very similar to type II sialidosis. An early infantile form is characterized by coarse facies, macrocephaly, growth disturbance, hepatosplenomegaly, fetal hydrops, ascites, kidney and heart involvement, angiokeratomata, telangiectasia, seizures, myoclonus, ataxia, pyramidal tract signs, progressive neurological deterioration, cherry red spots, corneal and lens opacity, hearing loss and dysostosis multiplex. Late infantile cases are less severe with slower progression. A late juvenile form, most common in Japan; develops more insidiously with survival into adult life.

#### Diagnosis and treatment

In types I and II, deficient alpha-neuraminidase activity can be shown in cultured fibroblasts. In galactosialidosis, combined deficiency of neuraminidase and beta-galactosidase is caused by the primary defect of an intralysosomal protein that protects these enzymes from degradation. In all three disorders, foam cells may be seen in bone marrow.

Vacuolation is rare in lymphocytes in type I but present in type II and can be prominent in other cells. The urine contains several sialylated oligosaccharides.

No specific therapy is available.

### Mucopolipidosis IV

This is a rare disorder that typically presents in infancy or early childhood, with psychomotor retardation that becomes evident by 2–3 years of age. There is corneal clouding and retinal degeneration but no facial dysmorphism, visceromegaly or skeletal changes. Survival is usually well into the third decade. Later-onset, milder cases are known. More than 80% of patients have been Ashkenazi Jews in whom the carrier frequency is ~1 in 100 (giving a frequency of ~1 in 40 000). There is no cellular metachromasia or mucopolysacchariduria, although gangliosides, MPS, lamellar membrane structures and amorphous, periodic-acid Schiff (PAS)-positive cytoplasmic inclusions can be seen in many tissues, including conjunctiva, and even in conjunctival swabs. The defect is in a protein (mucolipin) the function of which is unknown. Plasma gastrin levels are elevated for unknown reasons. Two mutations account for 95% of disease alleles in Ashkenazim so that molecular testing can be diagnostic. No specific therapy is available.

### Infantile sialic acid storage disease, Salla disease and sialuria

#### *Clinical features*

Four clinical entities present with intracellular accumulation and urinary excretion of sialic acid; all are rare.

1. Infantile sialic acid storage disease (ISSD) and Salla disease are probably allelic, caused by mutations in a lysosomal membrane transport protein.
2. Sialuria is an error of impaired feedback inhibition in the synthesis of sialic acid.
3. Sialidosis is due to deficiency of lysosomal neuraminidase leading to storage of sialyloligosaccharides, or bound sialic acid.
4. Galactosialidosis is due to deficiency of a 32 kDa protective protein; affected patients also excrete sialyloligosaccharides in urine.

ISSD presents with a severe 'Hurler' phenotype. Growth retardation is common but there may only be mild dysostosis. Some patients have had punctate calcification of the epiphyses similar to Zellweger syndrome. There is also marked hypopigmentation with pale wispy hair. Corneae are usually clear but optic atrophy is common. Failure to thrive leads to death in the first years of life.

In Salla disease, symptoms emerge in the first year or two of life and include ataxia, athetosis and pyramidal signs. Many patients are exotropic and later, most develop mild 'storage' facies. There is usually no corneal clouding and the fundi are normal. Most patients have a very low IQ. Growth retardation is usual, but apart from a somewhat thickened calvarium, the radiological picture is usually normal. Most patients live for decades.

Sialuria presents with developmental delay, visceromegaly and coarse facies. There is massive excretion of free sialic acid in urine but no lysosomal storage. It is caused by overproduction of sialic acid due to a failure in negative feedback control on uridine diphosphate N-acetyl-glucosamine-2-epimerase.

Galactosialidosis and sialidosis are described above.

#### *Diagnosis and treatment*

In ISSD and Salla disease there are prominent lysosomal vacuoles in lymphocytes and free sialic acid levels are markedly increased in urine, leukocytes and fibroblasts. Urinary oligosaccharides are abnormal. In sialuria, the cells contain sialic acid in the cytosol. Prenatal diagnosis is possible for all conditions; sialic acid is markedly raised in amniotic fluid in ISSD but not in Salla disease. Chorionic villus cells are vacuolated. No specific therapy is available.

### OTHER LYOSOMAL DISEASES

#### Lysosomal alpha-1,4-glucosidase deficiency (GSD type II, Pompe disease)

This condition is caused by lysosomal alpha-1,4-glucosidase (acid maltase) deficiency, with an incidence of 1 in 40 000–100 000. Acid maltase catalyzes the cleavage of alpha-1,6 and alpha-1,4 linkages in glycogen and therefore completely hydrolyzes glycogen. It is present in all tissues. Infantile, juvenile and adult forms are known. The clinical presentation of infantile Pompe disease is a result of massive glycogen deposition in the heart and skeletal muscle. Previously it has been classified as a glycogen storage disorder (see p. 1076).

#### *Clinical features*

Infantile Pompe disease is characterized by the rapid onset in the first months of life of profound muscle hypotonia, weakness, hyporeflexia, macroglossia, massive cardiomyopathy and variable hepatomegaly. The infant is usually alert and the cognitive development is normal. The clinical course is downhill and, without treatment, cardiopulmonary failure or pneumonia lead to death by around 1 year.

Childhood or adult forms are less severe and progress more slowly. The heart is not usually affected in late-onset Pompe disease but motor milestones are delayed and weakness of limb girdle and truncal muscles mimics chronic myopathies, especially the limb girdle muscular dystrophies. Involvement of respiratory muscles ultimately causes ventilatory insufficiency with death often between the second and fourth decade.

#### *Diagnosis*

The diagnosis can be suspected from the characteristic ECG that shows huge QRS complexes, left or biventricular hypertrophy and shortened PR interval. Muscle biopsy reveals glycogen freely dispersed in the cytoplasm and vacuoles that stain for glycogen (PAS positive) and acid phosphatase. Increased glycogen content is usually found, and electron micrographs showing intralysosomal accumulation of glycogen are also highly suggestive, though not diagnostic.

The enzyme can theoretically be assayed in leukocytes but that assay is fraught with difficulties and assay in muscle and/or fibroblasts is often preferred. A new and reliable assay in blood has been developed but should only be done in experienced laboratories. In the infantile form, glycogen-laden lysosomes are present in all organs except the kidneys and the cerebral cortex, being particularly abundant in anterior horn cells and motor nuclei of the brainstem. In the adult disorder, glycogen storage may be absent in heart, brain and liver, and varies greatly in different muscles (note this can cause difficulties with diagnostic testing). A second enzyme, neutral maltase, is produced by the kidneys and is also present in the leukocytes and must be differentiated during enzyme analysis. Antenatal diagnosis is possible.

#### *Treatment*

Recent trials of intravenous recombinant alpha-glucosidase infusions have been promising,<sup>179–185</sup> particularly for the myopathic forms, and ERT is now approved for use both in the USA and Europe.<sup>184</sup> Extensive supportive care is required.<sup>185</sup>

#### *Cystinosis*

Cystinosis (see also Ch. 18, p. 550) Cystinosis occurs in approximately 1 in 60 000 births. It is a disorder in which there is intralysosomal storage of cystine in many tissues, secondary to deficient egress from the lysosomes. It is the most common cause of a chronic renal Fanconi syndrome in childhood (see p. 550).

#### *Clinical features*

Infantile cystinosis presents in infancy with tremendous water and salt craving (ketchup and pickle juice!), food refusal and failure to thrive, vomiting, lethargy, polyuria, irritability, anorexia and signs of progressive renal tubular and glomerular damage that can lead to death in the first decade. Growth failure is usually severe and rickets may be

prominent. The skin is pale and the hair becomes blonde due to inhibition of melanin formation; photophobia is common due to a crystal keratopathy and a characteristic retinopathy. Later, progressive damage of the thyroid gland causes hypothyroidism, proximal myopathy, and sometimes, cerebral lesions.

Milder variants present in childhood or adolescence with slower progression of retinopathy and renal disease; there is also an adult form in which there is no renal damage, although cystine crystals are still present in the cornea.

### Diagnosis

The symptoms, blonde hair and blood values are so striking that the diagnosis should suggest itself. The biochemical features of the severe form are those of the renal Fanconi syndrome with renal tubular acidosis, hyponatremia, hypokalemia, hypouricemia, hypophosphatemia, hypocalcemia and raised alkaline phosphatase. In the urine polyuria, glycosuria, proteinuria and aminoaciduria are prominent. Plasma amino acids, including cystine, are normal or low. The diagnosis can be confirmed by the demonstration of refractile corneal crystals seen on slit lamp examination (they can also be seen in other tissues) and by measurement of intracellular cystine levels in leukocytes or cultured skin fibroblasts (up to 100 times normal); levels in heterozygotes are typically 5–10 times normal. Histological examination shows severe damage of the proximal renal tubules. Cystinotic cells take up 35S-cysteine at about twice the normal rate but accumulate the disulfide, cystine, in greatly increased amounts.

### Treatment

There is no cure. Therapy is directed towards correction of the fluid and electrolyte imbalances, acidosis, rickets and hypothyroidism. Dietary restriction of cystine and methionine, and also penicillamine, are ineffective. Cysteamine or phosphocysteamine are the drugs of choice since they deplete intracellular cystine; they must be given every 6 h and the dose monitored by regular assay of leukocyte cystine. They are used as eye drops to control cystine levels in the cornea and thus to mitigate the photophobia. These drugs delay or prevent renal failure and other systemic consequences. Transplanted kidneys do not express the cystinotic defect and have the same prognosis as any renal transplant. The biochemical defect, however, continues in other tissues and long term complications, including myopathy and CNS damage, are now recognized.

## Neuronal ceroid lipofuscinosis

### Genetics

Lipofuscin is an autofluorescent complex of lipid and protein that can be detected in lysosomes by electron microscopy. The neuronal ceroid lipofuscinoses (NCLs) are a group of disorders that collectively are probably the most common causes of progressive neurodegeneration in childhood. Infantile (Santavuori–Haltia), late infantile (Jansky–Bielschowsky), juvenile (Batten, Spielmeyer–Vogt), and adult (Kufs)-onset forms represent the ‘classic’ clinical presentations but as many as 20% of cases are ‘atypical’, and a Finnish variant, Gypsy/Indian early-juvenile variant, Turkish variant and Northern epilepsy are additional well defined variants described in specific populations. Seven different gene loci are currently known. It is important to recognize that identical clinical variants can be caused by different protein/enzyme/gene defects (Table 26.25).

### Clinical features

All forms of NCL develop signs of neurological impairment that may be rapid or slow, followed by seizures, often myoclonic, and overt deterioration, involving all brain functions, and that leads inevitably to death. Retinal degeneration is prominent in virtually all forms of NCL; the younger the onset, the more rapid the progression. Infants may die within a year or two, but juvenile cases may survive for 10–20 years. In the juvenile form, the first symptom is either rapid loss of vision over a few months or the sudden onset of seizures. Cerebral atrophy is often apparent by brain MRI even before the onset of symptoms. In adults, initial symptoms include psychiatric disorders, myoclonic seizures and signs of pyramidal involvement. In most NCLs, there is a characteristic pigmentary retinopathy; it is notably absent in at least one form of late infantile NCL reported from Finland. There is no dysmorphism or visceromegaly.

### Diagnosis

The history of rapid loss of sight and neurodegeneration, especially when brain imaging reveals only atrophy, is highly suggestive. Early changes can be seen in visual evoked responses, ERG and MRI of the brain. Diagnosis formerly was based on detection of characteristic ‘curvilinear’ and fingerprint inclusions by electron microscopic examination of lysosomes of conjunctiva, rectum, leukocytes or skin. Experts differ, depending upon their experience, as to which tissue is optimal for finding the inclusions. In the juvenile form, leukocytes often show inclusions; however, in some NCLs, the inclusions are sparse or absent in leukocytes. The deposits are distinctive but with subtle differences in each subtype; rare cases show a granular appearance. In the late infantile and juvenile forms, the lipofuscin contains large amounts of subunit c of ATP synthase; in the infantile form this is absent but the deposits are rich in sphingolipid activator protein. The reason for the incorporation of these products is unknown. Activity of the enzymes defective in several forms of NCL can now be measured in blood. In addition, mutation analysis for many of the types of NCL is available. Prenatal diagnosis can often be achieved through a combination of microscopic and/or biochemical and genetic studies.

### Treatment

There is no proven treatment for any of the NCLs although cysteamine is under investigation as a potential treatment in the infantile forms. A gene therapy trial for late infantile NCL and a trial of purified human fetal neural stem cells are underway for infantile and late infantile NCL.

## PEROXISOMAL DISORDERS

### GENERAL CONSIDERATIONS

Peroxisomes are single membrane-bound organelles found in most eukaryotic cells. They are responsible for a variety of metabolic functions. Biosynthetic activities include synthesis of plasmalogens, which are important components of cell membranes and myelin, cholesterol, bile acids, glyoxylate and docosahexanoic acid (DHA). Additionally, two aminotransferases involved in gluconeogenesis are located in liver peroxisomes. Catabolic functions include H<sub>2</sub>O<sub>2</sub>-based cellular respiration, glutaryl-CoA, purine and pipercolic acid catabolism, alpha-oxidation of branched chain fatty acids (phytanic acid) and beta-oxidation of very long chain fatty acids (VLCFAs) which have more than a 22-carbon chain.<sup>186,187</sup>

Table 26.25 Types and features of neuronal ceroid lipofuscinosis

Clinical types	Frequency (% of total)	Age of onset (years)	Usual gene defect	Other reported genes
Infantile	~16	0–3	CLN1	
Late infantile	~50	2–8	CLN2	CLN 1,3,5,6,7
Juvenile	~30	4–10	CLN3	CLN1,2 (5–8?)
Adult	~2	11–55	CLN4	

From Zhong, 2000. Genereviews.

Peroxisomal disorders can be classified into two categories: disorders of biogenesis (PBDs), which are associated with a general loss of peroxisomal function, and disorders associated with single enzyme deficiencies.

## DISORDERS OF PEROXISOME BIOGENESIS

### Zellweger syndrome, neonatal adrenoleukodystrophy and infantile Refsum disease

There are at least 12 different complementation groups that account for three distinct but overlapping diseases. All three disorders show dysmorphic features and all share some common clinical and biochemical abnormalities.

#### Clinical features

These three conditions all result from defects in peroxisome assembly.<sup>186</sup> Their overall incidence is approximately 1 in 50 000. They share clinical and biochemical features and represent a spectrum of disease severity. Microscopically, the peroxisomes may be absent or in the form of 'peroxisome ghosts', remnant membrane structures that lack normal matrix enzymes. Rhizomelic chondrodysplasia punctata (RCDP) is considered a partial PBD and is considered separately below.

Zellweger syndrome (cerebrohepato-renal syndrome) is the most severe phenotype and is characterized by marked neonatal hypotonia, seizures, psychomotor retardation, feeding difficulties, hepatomegaly, renal cysts, sensorineural deafness and developmental brain abnormalities, such as polymicrogyria, heterotopias and agenesis of the corpus callosum. Ocular abnormalities include corneal clouding, cataracts, glaucoma, nystagmus and pigmentary retinopathy. There is characteristic craniofacial dysmorphism that includes a high forehead, large fontanelles, midface hypoplasia, shallow orbital ridges, hypertelorism with upslanting palpebral fissures and epicanthal folds, posteriorly rotated ears with abnormal helices, anteverted nares, and micrognathia (Fig. 26.32). There is often radiographic stippling of epiphyses, most prominent in the knee and hip. Prolonged neonatal jaundice and

Fig 26.32 Facies of Zellweger syndrome with a high forehead, anteverted nares, micrognathia and hypertelorism.

liver disease are frequent. Death usually occurs within the first year.<sup>187-189</sup> Individuals with prolonged survival (> 1 year) are at increased risk for hyperoxaluria, nephrocalcinosis and subsequent nephropathy.<sup>190</sup> Histologically peroxisomes are absent from the liver and kidneys.

Infants with neonatal adrenoleukodystrophy (NALD) and infantile Refsum disease (IRD) show milder phenotypes. In NALD, there are similar but less pronounced dysmorphic features than seen in Zellweger syndrome and renal cysts, cataracts and epiphyseal stippling are absent. Patients with NALD may initially show relatively normal development, but this is followed by regression. While survival may extend into the teen years, such children typically exhibit severe neurodevelopmental delay, with sensorineural hearing loss and blindness due to pigmentary retinopathy.<sup>186,189</sup> In the brain, demyelination is frequent as are neuronal migration abnormalities. NALD is also characterized by adrenal dysfunction, as well as liver disease. Of note, NALD is a completely separate entity from X-linked adrenoleukodystrophy (see below).

Dysmorphic features in IRD are more subtle but include fairly marked mid-facial hypoplasia (Fig. 26.33). The main features of IRD include severe sensorineural deafness, pigmentary retinopathy, failure to thrive, hypotonia, absent limb reflexes and psychomotor retardation. Neuronal migration abnormalities are present but there is no overt demyelination, as seen in NALD. Occasionally infants with IRD present with bleeding due to a vitamin K-responsive coagulopathy. Non-infantile Refsum disease is discussed below.

### Rhizomelic chondrodysplasia punctata

Three different genetic defects are known to cause this disorder. It has a distinct clinical presentation and is associated with defects in only two peroxisomal metabolic functions: plasmalogen biosynthesis and branched chain fatty acid oxidation.<sup>186</sup> The most striking difference between rhizomelic chondrodysplasia punctata (RCDP) and the Zellweger spectrum disorders is the presence of major skeletal abnormalities which include rhizomelia (shortening of the proximal limbs), short stature, coronal clefts of vertebrae, metaphyseal splaying, kyphoscoliosis and joint contractures; calcific stippling is present but disappears within the first year of life. As with the other PBDs, there is also characteristic facial dysmorphism, cataracts, sensorineural deafness, psychomotor retardation and feeding difficulty with severe failure to thrive (Fig. 26.34). The majority of children with RCDP die before 2 years of age. However, milder cases are now recognized, characterized by congenital cataracts and chondrodysplasia, with or without rhizomelia.<sup>191</sup>

Type I RCDP is associated with a peroxisomal receptor defect (PTS2) and deficiency of at least three peroxisomal enzymes. Types 2 and 3 are each associated with single enzyme defects, dihydroxyacetone phosphate acyltransferase (DHAPAT) and alkyl-DHAP synthase, respectively.

Fig 26.33 Side view of two children with infantile Refsum disease, showing the marked similarity and mid-facial hypoplasia.

Fig 26.34 Rhizomelic chondrystrophia punctata in a 4-year-old.

### Biochemical features

In varying degrees, all three disorders of peroxisome biogenesis share the same biochemical abnormalities: elevations of plasma VLCFAs, phytanic acid and pipecolic acids, and decreased plasmalogen and DHA (Table 26.26). In RCDP, the findings are similar except the VLCFAs are normal.

### Molecular genetics

To date, pathogenic mutations are known in 12 PEX genes that encode peroxisomal membrane proteins, targeting signals and receptors required for peroxisome assembly and protein importation.<sup>192</sup> Approximately 65% of these patients have mutations in PEX1. A complete lack of PEX1 protein is associated with the Zellweger phenotype, while residual amounts are found in patients with NALD and IRD.<sup>193</sup> Correlations between clinical and biochemical phenotype and genotype are gradually emerging.<sup>188,194</sup> RCDP type 1 is associated with mutations in PEX7.<sup>191</sup>

### Diagnosis

These disorders should always be considered in infants with both nerve deafness and visual deficit, particularly when associated with hypotonia and psychomotor retardation and/or characteristic dysmorphic features.

The best screening test is measurement of plasma VLCFAs, which are increased in all three disorders but not in RCDP. Additional assays of plasma phytanic acid, pipecolic acid, plasmalogen, bile acid intermediates and essential fatty acids may also be useful in characterizing the diagnosis, but abnormalities of phytanic acid and plasmalogen may be age dependent.<sup>186</sup> Definitive diagnosis may require enzymatic studies in cultured fibroblasts, particularly to differentiate a generalized PBD from a single enzyme defect, or in the characterization of RCDP. Molecular genetic testing is currently available for PEX1, PXMP3 (PEX2), PEX3, PEX5, PEX6, PEX7, PEX10 and PEX12.<sup>189,191,193</sup>

### Therapy

The underlying etiology of clinical features of the PBDs is not known and their treatment remains largely supportive and symptomatic. Coagulation abnormalities may require treatment with vitamin K; adrenal insufficiency may require steroid treatment; liver dysfunction may improve with oral bile acid treatment;<sup>195</sup> and hyperoxaluria may require increased fluid intake and oral citrate to prevent nephrolithiasis.<sup>188,190</sup>

As individuals with milder phenotypes are surviving longer, there is active research into possible primary treatment. Because patients with PBDs have low levels of DHA, an important component of brain and retina, oral administration of its ethyl ester has been studied. While controlled trials are lacking, an open label study of 20 patients with PBDs receiving DHA ethyl ester 100–500 mg/d reported normalization of DHA levels in plasma and erythrocytes, decrease in plasma VLCFAs, improvement in liver function, improved vision in 50%, and MRI findings suggesting improvement in myelination.<sup>196</sup> Sodium 4-phenylbutyrate has been shown to increase peroxisome numbers and functions in normal fibroblasts but no trials are yet reported.<sup>197</sup>

## DISORDERS ASSOCIATED WITH ISOLATED ENZYME DEFICIENCIES

Numerous enzymatic reactions are localized to peroxisomes and pathogenic disorders involving five metabolic pathways are currently recognized: fatty acid beta-oxidation, phytanic acid alpha-oxidation, etherphospholipid synthesis, glyoxylate detoxification, and possibly isoprenoid synthesis. Table 26.27 summarizes the clinical and screening biochemical abnormalities associated with the best characterized disorders in this group. The two most common disorders, X-linked adrenoleukodystrophy (X-ALD) and Refsum disease, are discussed below.

### X-linked adrenoleukodystrophy

X-ALD is caused by a defect in the gene ABCD1 that codes for ALDP, a peroxisomal membrane adenosine triphosphate (ATP)-binding cassette transporter, and is associated with increased levels of VLCFAs in blood and tissues.

Table 26.26 Biochemical abnormalities in selected peroxisomal disorders

	Plasma VLCFA	Plasma phytanic acid	RBC plasmalogens
Peroxisome biogenesis disorders: Zellweger syndrome, adrenomyeloneuropathy, infantile Refsum disease, neonatal adrenoleukodystrophy	Increased	Increased	Increased
Rhizomelic chondrodysplasia punctata	Normal	Increased (type I) Normal (types 2 and 3)	Decreased
X-linked adrenoleukodystrophy/adrenomyeloneuropathy	Increased	Normal	Normal
Refsum disease (classical)	Normal	Increased	Normal

RBC, red blood cell; VLCFA, very long chain fatty acids.

Table 26.27 Peroxisomal disorders due to single enzyme deficiencies

Metabolic pathway	Disorder	Clinical phenotype	Best screening test
Fatty acid beta-oxidation	X-ALD/AMN	Progressive neurodegeneration, adrenal insufficiency, myeloneuropathy	Increased VLCFA
	Acyl-CoA oxidase deficiency	NALD-like	Increased VLCFA
	Thiolase deficiency		
	Bifunctional protein deficiency		
	2-Methylacyl-CoA racemase deficiency	Late-onset neuropathy	
Phytanic acid oxidation	Refsum disease	Retinitis pigmentosa, cerebellar ataxia, polyneuropathy	Increased phytanic acid
Etherphospholipid synthesis	DHAPAT synthase deficiency	RCDP	Decreased RBC plasmalogen
	Alkyl DHAP synthase deficiency		
Isoprenoid synthesis	Mevalonate kinase deficiency	Dysmorphic features, hepatosplenomegaly, hypotonia, cerebral atrophy, failure to thrive	Increased urinary mevalonic acid
Glyoxylate detoxification	Hyperoxaluria type 1	Recurrent nephrolithiasis and nephrocalcinosis	Increased urinary oxalic, glyoxylic and glycolic acids

AMN, adrenomyeloneuropathy; DHAP, dihydroxyacetone phosphate; DHAPAT, DHAP acyltransferase; NALD, neonatal adrenoleukodystrophy; RCDP, rhizomelic chondrodysplasia punctata; VLCFA, very long chain fatty acids; X-ALD, X-linked adrenoleukodystrophy.

### Clinical features

This disease (once known as Schilder disease) occurs in 1 in 20 000–50 000 males. There are several distinct phenotypes, all of which can be seen within the same family. In childhood-onset cerebral X-ALD, which accounts for approximately 35% of cases, development is entirely normal prior to the onset, typically between 4 and 8 years. School difficulty, behavioral disturbances and vision impairment are the most frequent initial symptoms.<sup>198</sup> These are followed by progressive neurological deterioration with seizures, nystagmus, vision and hearing impairments, behavior and memory problems. As the disease progresses, dementia, blindness and quadriplegia develop, and death ensues. Adrenal insufficiency is present in at least 90%.<sup>198</sup> This rapidly progressive cerebral form is associated with an inflammatory, demyelinating leukodystrophy.

The second phenotype, adrenomyeloneuropathy (AMN), accounts for 35–40% of cases and presents either with Addison disease or with signs of myelopathy with progressive polyneuropathy and bladder dysfunction in the second or third decade of life. Less common phenotypes include adults with adrenal insufficiency but without neurological abnormalities, and adults who develop cerebral symptoms without evidence of myelopathy. Neurological abnormalities occur in approximately 15% of heterozygous females and are commonly misdiagnosed as multiple sclerosis. It should be noted that some patients never develop neurological abnormalities.

### Diagnosis

The diagnosis of X-ALD in males can be made by the detection of elevated plasma VLCFAs. Plasma VLCFA should be measured in all males who develop Addison disease. Plasma VLCFA is normal in 15% of heterozygous females, therefore DNA analysis is required for reliable diagnosis and carrier testing.<sup>199</sup> Approximately 85% of patients with the childhood form have characteristic abnormalities on brain MRI consisting of symmetrical areas of increased signal in the parieto-occipital region on T2-weighted imaging.<sup>198</sup>

Over 400 different mutations have been identified; DNA mutation analysis is available.<sup>199</sup> There appears to be no genotype–phenotype correlation associated with mutations within the X-ALD gene and the basis of the unpredictable intrafamilial phenotypic variability is unknown.

### Therapy

Stem cell (bone marrow or cord blood) transplantation, if performed at the very earliest sign of CNS symptoms, has been shown to stabilize the progression of cerebral X-ALD. In a recent 5–10 year follow-up study of 12 patients with childhood-onset cerebral X-ALD who had undergone bone marrow transplantation early in the course of the disease, there was MRI evidence for stabilization or even reversal of demyelination.<sup>200</sup> Eight of the 12 children were functioning normally in school with no additional support. At this time, transplantation prior to the onset of any neurological signs or symptoms is not recommended since a fair proportion of affected males do not develop neurological symptoms, even without treatment.

Diet therapy with 'Lorenzo's oil' (a 4:1 mixture of glyceryl trioleate and glyceryl trierucate) has been shown to normalize plasma concentrations of VLCFA in patients with X-ALD, but lack of well-controlled clinical studies has limited conclusions regarding clinical efficacy.<sup>199</sup> Single-arm clinical trials have shown little effect of Lorenzo's oil in changing the course of cerebral or myelopathic X-ALD among symptomatic individuals.<sup>201</sup> However, in a recent single-arm study in 89 asymptomatic boys with normal baseline brain MRI findings, Moser et al reported that 74% remained free of neurological symptoms with normal MRI results over the mean study period of 6.9 years.<sup>202</sup> This compares with the authors' estimation that at least 35% of untreated X-ALD patients become symptomatic by age 10 years. Adverse effects include thrombocytopenia and elevated liver enzymes.

New therapeutic approaches are based on the observations of an improved ability of cultured fibroblasts to metabolize VLCFAs in the presence of lovastatin and 4-phenylbutyrate. Two small studies on the efficacy of lovastatin/simvastatin have failed to show clinical or biochemical benefit.<sup>203,204</sup> There are currently no published randomized controlled trials.

### Refsum disease

#### Clinical features

Refsum disease is an autosomal recessive disorder with cardinal manifestations that include retinitis pigmentosa, cerebellar ataxia and polyneuropathy.<sup>205</sup> The age of onset is very variable; 40% of patients develop symptoms prior to 10 years of age and up to 75% by age 20.<sup>205</sup> The onset is usually insidious and often begins with night blindness. Sensory–motor

polyneuropathy typically begins in the distal lower extremities and, if untreated, progresses to involve the upper extremities and trunk. Ataxia and cerebellar dysfunction usually become evident later than the retinal degeneration and polyneuropathy. Additional clinical features can include sensorineural hearing loss, anosmia, ichthyosis and skeletal manifestations (epiphyseal dysplasia, shortening or elongation of the third or fourth metatarsals, hammer toes). Cardiac conduction abnormalities and cardiomyopathy are a frequent cause of sudden death in untreated patients.

Refsum disease is caused by a deficiency of phytanoyl-coenzyme A (CoA) hydroxylase, an enzyme in alpha-oxidation that catalyzes an essential step in phytanic acid degradation. Deficiency of this enzyme results in the accumulation of phytanic acid, with plasma levels usually  $>200\ \mu\text{mol/L}$ .<sup>206</sup> Mutations in PHYH account for over 90% of cases; mutations in PEX7, which encodes the PTS2 receptor, account for fewer than 10% of cases. Molecular testing is available for confirmatory testing, prenatal diagnosis and carrier testing.<sup>206</sup>

### Therapy

Phytanic acid enters the food chain from plants so therapy focuses on diets low in phytanic acid. Aggressive dietary intervention results in stabilization or improvement in the peripheral neuropathy, auditory and visual deficits.<sup>205</sup> Fasting and rapid weight loss, which result in the release of phytanic acid-containing lipids, should be avoided. Plasmapheresis or lipid apheresis can be used to reduce plasma phytanic acid rapidly in the management of acute arrhythmias or severe weakness, and may have a role in maintenance therapy.<sup>206</sup>

## OTHER GENETIC DISORDERS OF PEROXISOMES

Other peroxisomal disorders include mevalonate kinase deficiency (see p. 1098), oxalosis type I (see p. 1061), at least four other disorders of fatty acid oxidation, two defects in etherphospholipid synthesis and an ill-defined defect of hyperpipecolic acidemia.

## CONGENITAL DISORDERS OF GLYCOSYLATION

### GENERAL CONSIDERATIONS

Glycosylation of proteins and lipids is a multienzyme process that adds carbohydrate side chains, known as glycans, which confer special characteristics to lipids and to proteins or classes of proteins. For protein glycoconjugates, this attachment is either through asparagine residues (N-glycosylation) or serine/threonine residues (O-glycosylation).<sup>207</sup> In spite of the fact that over 25 enzyme defects are now known, two broad clinical categories of congenital disorders of glycosylation (CDG) are recognized although the clinical spectrum of these disorders is still emerging. In type I CDGs, defects of N-glycosylation result from malfunction

of cytosolic or endoplasmic reticulum enzymes involved in oligosaccharide assembly or the attachment of oligosaccharides to proteins.<sup>208,209</sup> In type II CDGs the abnormalities involve the endoplasmic reticulum and Golgi.<sup>210,211</sup>

To date, at least 12 different CDG I and six CDG II disorders have been reported (Tables 26.28 and 26.29; Fig. 26.35).

### CONGENITAL DISORDERS OF GLYCOSYLATION TYPE I CDG type Ia

The first CDG to be described was type Ia, which is panethnic and the most common entity. The defect is in phosphomannomutase which blocks conversion of mannose-6-phosphate to mannose-1-phosphate.<sup>208,212</sup> It is a multisystem disease affecting the central and peripheral nervous system, as well as the gastrointestinal tract, liver, fat, muscles, skeleton, heart, kidney, gonads and hematological system.<sup>213–218</sup> Not all forms of CDG are dysmorphic and some are being found with hypoglycemia or thromboembolic disease as a presenting feature.

Once observed, it can be seen that the facies are remarkably similar and mildly dysmorphic (Figs 26.36 and 26.37). Cardinal manifestations include psychomotor retardation, micro- or macrocephaly, strabismus, roving eye movements, pigmentary retinopathy, hypotonia, hyporeflexia, ataxia, muscular dystrophy and epilepsy. In some cases, stroke-like episodes are often associated with febrile illness, transient lethargy, coma, hemiparesis, hemiplegia and vision loss, without neuroradiological evidence for thrombosis or hemorrhage. The neurological symptoms are stable; cerebellar hypoplasia is almost invariable and approximately 20% of cases die in the first year. Cardiomyopathy or pericarditis is not uncommon. Inverted nipples may be present, and in the early months, unusual fat pads may be seen, especially supra-iliac/pubically (see Fig. 26.36c) but also on the trunk and extremities.<sup>208</sup> Females never enter puberty.

The defect in glycosylation involves transferrin and many other proteins, including most hormone and lipid-binding proteins (thyroid, sex hormones, apo B and cholesterol binding); other findings are increased arylsulfatase activity and Factor XI. Phosphomannomutase activity may be determined in leukocytes and fibroblasts (although occasionally affected patients manifest intermediate activities) and mutation analysis is available. There is no specific treatment.<sup>217,219–221</sup>

### CDG type Ib

In CDG type Ib phosphomannose isomerase deficiency blocks conversion of fructose-6-phosphate to mannose-6-phosphate. It is characterized by gastrointestinal illness (recurrent diarrhea, vomiting, liver dysfunction, coagulopathy and hypoglycemia) without prominent neurological symptoms.<sup>223–225</sup> The diagnosis is critical since this disorder responds to oral mannose supplementation ( $4 \times 150\ \text{mg/kg/d}$ ) with correction of clinical and biochemical abnormalities.<sup>222</sup>

Table 26.28 Clinical features of congenital disorders of glycosylation

Neurological	Hypotonia, developmental delay, hypo/areflexia, ataxia, seizures, stroke-like episodes, peripheral neuropathy, microcephaly, cerebellar hypoplasia, demyelination, epilepsy, demyelinating polyneuropathy
Ophthalmological	Strabismus, abnormal eye movements, optic atrophy, nystagmus, retinitis pigmentosa, iris or retinal colobomata, cortical blindness, corneal dystrophy
Gastrointestinal	Protein-losing enteropathy, failure to thrive, cyclic vomiting, hepatic dysfunction, liver fibrosis, intestinal villus atrophy, hypoalbuminemia, low protein C, protein S, antithrombin III, increased aspartate aminotransferase
Hematological	Coagulopathy, thrombosis, thrombocytopenia, thrombocytosis, decreased Factor XI
Cardiac	Pericardial effusion, cardiomyopathy
Endocrinological	Hyperinsulinemic hypoglycemia, hypothyroidism, hypogonadism, hypoplastic genitalia
Renal	Nephrotic syndrome, renal tubular defects, hyperechogenic kidneys
Immunological	Recurrent infections, hypogammaglobulinemia
Orthopedic	Scoliosis, contractures, osteopenia, thoracic scoliosis
Other	Cholinesterase and pseudocholinesterase deficiency Craniofacial dysmorphism, inverted nipples, unusual fat distribution

Table 26.29 Congenital disorders of glycosylation types I and II

Disorder	Enzymatic or protein defect	Gene
CDG Ia	Phosphomannomutase	PMM2
CDG Ib	Phosphomannose isomerase	PMI
CDG Ic	Dolichol-P-Man:Man5GlcNAc-PP-dolicholmannosyltransferase	ALG6
CDG Id	Dolichol-P-Man:Man5GlcNAc-PP-dolicholmannosyltransferase	ALG3
CDG Ie	Dolichol-P-mannose synthase	DPM1
CDG If	LEC35 protein	LEC25MPDU1
CDG Ig	Dolichol-P-Man:Man7GlcNAc-PP-dolicholmannosyltransferase	ALG12
CDG Ih	Dolichol-P-glucose:Glc-1-Man-9-GlcNAc-PP-dolichyl-alpha-3-glucosyl transferase	ALG8
CDG Ii	GDP-Man:Man1GlcNAc <sub>2</sub> -PP-dolichol mannosyltransferase	ALG2
CDG Ij	UDP-GlcNAc:dolichyl-phosphate-N-acetylglucosamine phosphotransferase	DPAGT1
CDG Ik	Beta-1,4-mannosyltransferase	ALG1
CDG IL	Alpha-1,2-mannosyltransferase	ALG9
CDG IIa	N-acetylglucosaminyltransferase II	MGAT2
CDG IIb	Glucosidase I	GSI
CDG IIc	GDP-fucostransporter-1	FUCT1
CDG IId	Beta-1,4-galactosyltransferase	B4GALT1
CDG IIe	Oligomeric Golgi complex-7	COG7
CDG IIIf	Cytidinemonophosphate (CMP)-sialic acid transporter	SLC35A1

CDG, congenital disorders of glycosylation; Glc, glucose; GlcNAc, N-acetylglucosamine; Man, mannose; P, phosphate; PP, pyrophosphate; GDP, guanosine diphosphate; UDP, uridine diphosphate.

### Other forms of CDG type I

Severe neurological impairment is the most striking finding in most other forms of CDG type I (Table 26.28).<sup>226</sup> Although such patients (CDG types Ib–II) have different biochemical defects (Table 26.29), the transferrin isoelectric focusing (IEF) pattern is similar to that of CDG type Ia.<sup>209,212,223</sup> Clinically, CDG type Ic (glucosyltransferase I deficiency) is similar to type Ia in terms of axial hypotonia and seizures, but with milder psychomotor retardation, strabismus and absence of cerebellar hypoplasia or retinitis pigmentosa.<sup>227</sup> Patients with type Id (mannosyltransferase VI deficiency)

present with profound psychomotor retardation, hypoplasia of the corpus callosum, epilepsy, microcephaly, optic atrophy and colobomas.<sup>228</sup> CDG type Ie (dolichol-phosphate mannose synthase deficiency) manifests profound psychomotor retardation, epilepsy, hypotonia, failure to thrive, mild dysmorphic features and a mildly increased serum creatine kinase activity.<sup>229</sup> In CDG type If (lec 35 deficiency) the phenotype is of severe psychomotor retardation, epilepsy, poor vision and ichthyosiform skin anomalies, variably associated with dwarfism, hypotonia, contractures and feeding difficulties.<sup>209,230</sup> CDG Ig (mannosyltransferase

Fig 26.35 Metabolic scheme of a typical N-linked carbohydrate side chain built upon asparagine (ASN). This represents one form of a mature side chain. The linkages between the sugars vary and other sugars including N-acetylgalactosamine, galactose and sialic acid are commonly present. The side chain is built step by step and additional sugars are added and then later pruned. GlcNAc, N-acetylglucosamine; Man, mannose.

Fig. 26.36 Congenital disorder of glycosylation (CDG) syndrome. (a) Facies at 15 months. (b) Facies at 16 years. (c) Pelvic area at 18 months showing the fat pads.

Fig 26.37 Two siblings aged 15 and 17 years with congenital disorder of glycosylation (CDG) type Ia.

VIII deficiency) manifests a clinical phenotype of generalized hypotonia, facial dysmorphism, severe psychomotor retardation, feeding difficulties and progressive microcephaly.<sup>231</sup> CDG 1h mimics the non-neural phenotype of the 1b disorder with protein-losing enteropathy, moderate hepatomegaly and severe hypoalbuminemia.<sup>232</sup>

The phenotype of CDG type 1i includes psychomotor retardation, hyperreflexia, retarded myelination, infantile spasms and bilateral iris coloboma associated with unilateral cataract.<sup>233</sup> CDG type 1j is a disorder associated with infantile spasms, esotropia, severe hypotonia, microcephaly, micrognathia and psychomotor retardation.<sup>234</sup> CDG 1k presents with intractable seizures, generalized hypotonia, blindness and liver dysfunction,<sup>235</sup> whereas the type 1L disorder features severe microcephaly, axial hypotonia, seizures, hepatomegaly and psychomotor retardation.<sup>236</sup>

## CONGENITAL DISORDERS OF GLYCOSYLATION TYPE II

Type 1Ia CDG (N-acetylglucosaminyl-transferase II deficiency) presents with developmental retardation, stereotypical behavior, craniofacial dysmorphism, epilepsy and mild liver damage with increased serum transaminases.<sup>237-239</sup> CDG type 1Ib (glucosidase I deficiency) manifests dysmorphic features, severe hypotonia and epilepsy, and is associated with an unusual urine tetrasaccharide.<sup>240,241</sup> The phenotype of CDG 1Ic (GDP-fucose transporter deficiency) includes a severe neurological syndrome, retarded growth, craniofacial dysmorphism and recurrent infections (e.g. leukocyte adhesion deficiency syndrome II).<sup>210,211,242</sup> CDG type 1Id (beta-1,4-galactosyltransferase deficiency) manifests psychomotor retardation associated with a Dandy-Walker malformation and myopathic features.<sup>243,244</sup> CDG type 1Ie manifests multiple defects associated with a defect in COG 7 (conserved oligomeric Golgi complex, subunit 7), involved in shuttling various glycoproteins from the ER to the Golgi.<sup>210,211,245</sup> The defect results in both N- and O-linked glycosylation defects. The findings included dysmorphic features, neurological findings and cholestatic liver disease. CDG 1If is a disorder of CMP sialic acid transport across the Golgi membrane, and manifests primarily hematological findings (microthrombocytopenia with hemorrhage, and neutropenia leading to opportunistic infections).<sup>210,211,246</sup>

## DIAGNOSIS OF THE CONGENITAL DISORDERS OF GLYCOSYLATION SYNDROMES

These disorders are multifaceted and not well recognized by most clinicians. The primary screening tool is assessment of the glycosylation pattern of serum transferrin using IEF or other methods.<sup>225,247,248</sup> Typically, increased asialo- and disialo-transferrin and decreased tetrasialo- and pentasialo-transferrin suggests a type I, whereas elevated tri- and disialotransferrin patterns with decreased tetrasialotransferrin species suggest a type II disorder. Although transferrin is the surrogate protein for these analyses, many other transport proteins are also affected. Rare cases of both types I and II have been identified with normal transferrin patterns.

Transferrin IEF should be used freely as an initial diagnostic tool in evaluating patients with dysmorphism, developmental delay and evidence of multisystem involvement. Enzymatic confirmation is available in special centers.

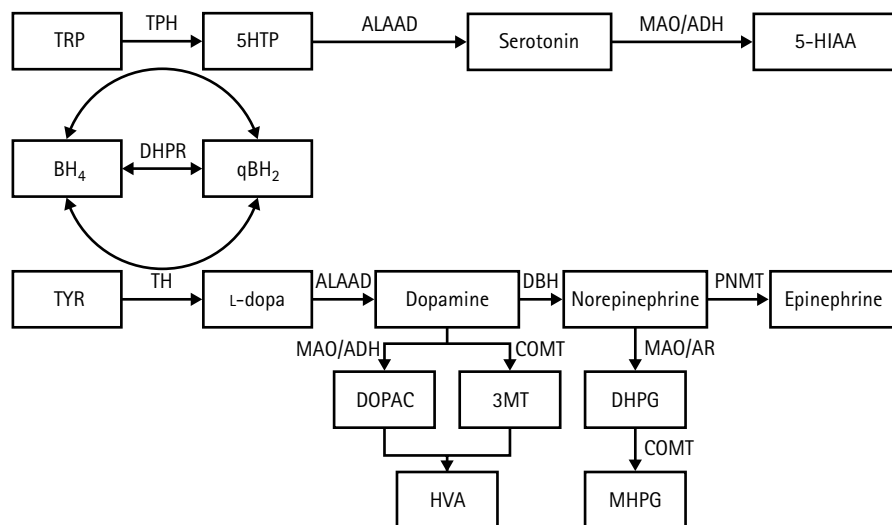

## CONGENITAL DISORDERS OF LIPID GLYCOSYLATION

A disorder of ganglioside synthesis, GM<sub>3</sub> synthase deficiency (lactosylceramide alpha-2,3-sialyltransferase deficiency) represents the first defect in lipid glycosylation.<sup>249</sup> Clinical features in the single old order Amish pedigree included early onset of irritability and poor feeding, seizures, profound developmental regression and diffuse brain atrophy. The plasma contained decreased quantities of GM<sub>3</sub>, ganglioside and increased lactosylceramide associated with deficient GM<sub>3</sub> synthase activity.

## DISORDERS OF NEUROTRANSMITTER METABOLISM

### BACKGROUND – METABOLISM AND FUNCTION OF BIOGENIC AMINES

Biogenic amines include the catecholamines (dopamine, epinephrine [adrenaline] and norepinephrine [noradrenaline]) and serotonin, which are derived from hydroxylation of tyrosine and tryptophan by their respective hydroxylases (Figs 26.38 and 26.39).<sup>250,251</sup> Both enzymes

**Fig. 26.38** Schematic diagram of catecholamine and serotonin metabolism. Not all steps are shown. TRP, tryptophan; TPH, tryptophan hydroxylase; 5HTP, 5-hydroxytryptophan; ALAAD, aromatic L-amino acid decarboxylase; MAO, monoamine oxidase; ADH, aldehyde dehydrogenase; 5-HIAA, 5-hydroxyindoleacetic acid; BH<sub>4</sub>, tetrahydrobiopterin; qBH<sub>2</sub>, quinoid dihydrobiopterin; DHPR, dihydropteridine reductase; TYR, tyrosine; TH, tyrosine hydroxylase; L-dopa, L-3,4-dihydroxyphenylalanine; COMT, catechol-O-methyltransferase; DOPAC, dihydroxyphenylacetic acid; 3MT, 3-methoxytyramine; HVA, homovanillic acid; DBH, dopamine beta-hydroxylase; AR, aldehyde reductase; DHPG, dihydroxyphenylglycol; MHPG, 3-methoxy-4-hydroxyphenylglycol; PNMT, phenylethanolamine-N-methyltransferase.

utilize tetrahydrobiopterin (BH<sub>4</sub>; see p. 1054), a product of guanosine 5-triphosphate (GTP) metabolism, as a cofactor. The products of the hydroxylation reactions, 3,4-dihydroxy-L-phenylalanine (L-dopa) and 5-hydroxytryptophan, are further metabolized to active neurotransmitters (dopamine and serotonin) via decarboxylation catalyzed by aromatic L-amino acid decarboxylase (AADC), a pyridoxine-dependent reaction. Dopamine is further metabolized to norepinephrine (noradrenaline) in noradrenergic neurons in a reaction catalyzed by dopamine beta-hydroxylase. Serotonin is converted to melatonin in the pineal gland.

Catechol O-methyltransferase (COMT) and monoamine oxidase (MAO) catalyze the breakdown of dopamine, serotonin and norepinephrine (noradrenaline) to homovanillic acid (HVA), 5-hydroxyindoleacetic acid (5-HIAA) and 3-methoxy-4-hydroxyphenylglycol (MHPG), respectively (Fig. 26.38). The latter are the primary metabolites quantitated in human CSF on the presumption that CSF correctly reflects

brain neurotransmitter metabolism. The biogenic amines control a host of critical processes, including (but not limited to) psychomotor function, memory, appetite, mood, sleep, vascular tone and body temperature.<sup>250-252</sup> Thus, defects in the metabolism of neurotransmitters are expected to have severe, multisystem manifestations.

Recent studies have shown abnormal numbers of 5-hydroxytryptophan neurons and receptors in the brainstems of sudden infant death syndrome (SIDS) victims; the significance is not yet clear.<sup>253</sup>

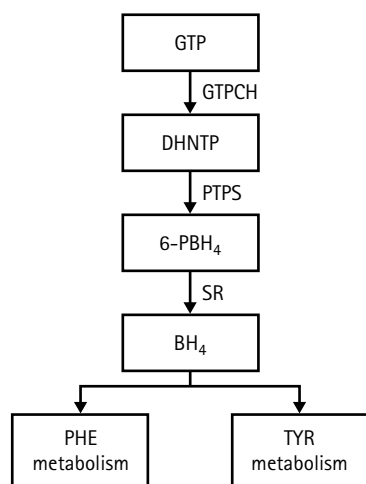

## DEFECTS OF BIOGENIC AMINE SYNTHESIS

Defects of biogenic amine synthesis include deficiencies of tyrosine hydroxylase (TH) and aromatic amino acid decarboxylase (ALAAD) (Fig. 26.38). Because BH<sub>4</sub> is a critical cofactor for tryptophan hydroxylase and TH (as well as phenylalanine hydroxylase, see p. 1054), defects of enzymes in its synthetic pathway can also cause pathologically low levels of biogenic amines (Fig. 26.39). These include guanine triphosphate cyclohydrolase I (GTPCH), 6-pyruvoyl tetrahydrobiopterin synthase (PTPS), sepiapterin reductase (SR), pterin carbinolamine reductase (PCD) and dihydropterin reductase (DHPR). While most of these disorders are also inherited in an autosomal recessive manner, autosomal dominant GTPCH deficiency (also called Segawa disease, dystonia with diurnal fluctuation, or dopa-responsive dystonia) is the most common disorder of biogenic amine metabolism.

### Clinical features

Deficiency of *tyrosine hydroxylase* causes impaired synthesis of dopamine, which in turn leads to deficiencies in the other catecholamines. It manifests with parkinsonism, oculogyric crises, ptosis, miosis, postural hypotension, truncal hypotonia and irritability.<sup>254,255</sup> CNS catecholamine levels (dopamine, norepinephrine [noradrenaline] and epinephrine [adrenaline], as well as HVA and MHPG) are decreased, while serotonin metabolism (5-HIAA) remains unaffected. BH<sub>4</sub> and neopterin levels are normal, enabling distinction between TH deficiency and the disorders of BH<sub>4</sub> synthesis described below.<sup>256</sup>

Deficiency of *aromatic amino acid decarboxylase* causes symptoms similar to TH deficiency.<sup>257</sup> A neonatal presentation has been reported with early feeding difficulties, hypotonia and autonomic dysfunction.<sup>258</sup> Other clinical features are limb and orofacial dystonia, athetosis and an overall paucity of voluntary movement. Dysautonomic features include diaphoresis, temperature instability, nasal congestion, ptosis, pupillary changes, hypotension and bradyarrhythmias.<sup>259</sup> Dysautonomia related to impaired catecholamine synthesis may underlie paroxysmal events in these patients, including apneic spells and sudden cardiorespiratory arrest.

**Fig. 26.39** Generation of tetrahydrobiopterin from guanosine triphosphate. Not all steps are shown. GTP, guanosine triphosphate; DHNTP, dihydroneopterin triphosphate; PTPS, 6-pyruvoyltetrahydrobiopterin synthase; 6-PBH<sub>4</sub>, 6-pyruvoyltetrahydrobiopterin; SR, sepiapterin reductase; PHE, phenylalanine; TYR, tyrosine. Tetrahydrobiopterin serves as bound cofactor in phenylalanine and tyrosine hydroxylase reactions, the first committed steps in the metabolism of both amino acids. Regeneration of tetrahydrobiopterin from quinoid dihydrobiopterin requires the action of pterin-4a-carbinolamine dehydratase (PCD), which is not shown.

Metabolically, ALAAD deficiency results in central and peripheral deficiency of catecholamines, serotonin, HVA, MHPG and 5-HIAA. In addition, the CSF profile shows high L-dopa, 5-OH-tryptophan and 3-OH-methyl-dopa, OMD (an L-dopa metabolite), and normal pterin levels.<sup>250</sup> Neither TH or ALAAD deficiency demonstrates hyperphenylalaninemia.

*Segawa syndrome* is due to autosomal dominant guanosine triphosphate cyclohydrolase deficiency (GTPCH). It presents with dystonia and parkinsonism, with resting tremor, spasticity, postural instability and oculogyric crises with normal cognition. There tends to be a diurnal fluctuation of symptoms, with worsening in the evenings and improvement following sleep.<sup>250</sup> Both the dystonia and tremor may have a prominent postural component. Isolated toe gait, female predominance and presentation with only prominent postural tremor in adulthood have all been described.<sup>260</sup> Adults have a striking incidence of major depression and obsessive-compulsive disorder, as well as sleep disorders including insomnia, excessive daytime somnolence and frequent parasomnias characterized as nightmares.<sup>261</sup> Thus, an expanded phenotype with psychopathology appears to be present in this disorder.

The defects in BH<sub>4</sub> metabolism are important since they are detectable by newborn screening, can cause the 'malignant PKU' syndrome and are treated differently from PKU (see p. 1054). They include autosomal recessive synthetic steps of *GTPCH*, *6-pyruvoyltetrahydropterin synthase (PTPS)*, and *sepiapterin reductase (SR)* and the recycling enzyme *dihydropteridine reductase (DHPR)*. Untreated, they all present with progressive psychomotor retardation, dystonia, seizures, choreoathetosis, temperature instability, hypersalivation, microcephaly and irritability. Patients with SR deficiency also manifest dystonic posturing with diurnal variation, oculogyric crises, tremor, hypersomnolence, oculomotor apraxia and weakness.<sup>250,262</sup>

An early defect in this pathway, pterin-4a-carbinolamine dehydratase, may not manifest significant clinical abnormalities, other than transient alterations in tone.

## DEFECTS OF MONOAMINE DEGRADATION

### *Clinical features*

Orthostatic hypotension is the hallmark of *dopamine beta-hydroxylase (DBH)* deficiency, which results in decreased norepinephrine (noradrenaline) production from dopamine.<sup>263</sup> The disease has generally been diagnosed in adults, with retrospective case histories suggesting a neonatal period associated with ptosis, hypothermia, hypoglycemia and hypotension.<sup>250</sup> A normal variant of undetectable DBH levels associated with normal norepinephrine and epinephrine (adrenaline) concentrations has been identified in 4% of the population.<sup>264</sup>

Catabolism of serotonin and catecholamines requires the actions of *monoamine oxidase A or B (MAO-A and MAO-B)*.<sup>265</sup> A point mutation in the MAO-A gene on the X chromosome has been associated with borderline mental deficits and aggressive behavior.<sup>250</sup> Conversely, several males with X chromosome deletions, including the MAO-A and MAO-B genes, manifested severe retardation, while males with an unusual deletion involving a portion of the MAO-B gene (but with an intact MAO-A gene) had normal mental capacity. To date, no specific isolated abnormality of the MAO-B gene has been reported.

### *Diagnosis*

In general, CSF is required for measurement of biogenic amines and metabolites but is available in only a few specialty laboratories. Collection of CSF requires special considerations, including a rostro-caudal gradient of metabolite levels, and oxidation of BH<sub>4</sub> and neurotransmitter metabolites that occurs without immediate freezing or via contamination with blood.<sup>266</sup> Thus, a specific protocol with orderly collection of predefined volumes and rapid handling on dry ice is essential so that the values can be compared to reference ranges established with the same collection criteria.

TH deficiency results in low levels of catecholamines and related metabolites; ALAAD deficiency results in similar decreases accompanied by low CSF serotonin concentrations. Neurotransmitter

precursors (5-hydroxytryptophan, levodopa and OMD) also accumulate in ALAAD deficiency. Urine organic acid testing may show elevation of vanillic acid, representing a potential clue during metabolic screening.<sup>267</sup>

The disorders PTPS, DHPR, PCD and recessive GTPCH deficiencies are usually detected by newborn screening since BH<sub>4</sub> is required for phenylalanine hydroxylase activity. Blood phenylalanine levels are normal in autosomal dominant GTPCH deficiency (*Segawa disease*) and SR deficiency, as well as TH and ALAAD deficiencies. Further evaluation for these disorders requires accurate quantification of CSF pterins, HVA and 5-HIAA. In many cases, loading with phenylalanine and tetrahydrobiopterin followed by measurement of phenylalanine and tyrosine can provide important diagnostic information (see also p. 1054).<sup>250,268</sup> Prenatal diagnosis of TH deficiency by mutation analysis has been reported.<sup>257</sup>

Measurement of urinary biopterin further helps to distinguish these disorders, with decreased biopterin in PTPS deficiency and elevated in DHPR deficiency (versus normal in PKU); it is mandatory in any infant detected by newborn screening to have an elevated phenylalanine.

In DBH deficiency, CSF shows low levels of MHPG with accumulation of HVA, while patients with MAO-A deficiency manifest increased biogenic amine and *O*-methylated metabolites. The most sensitive index of MAO-A activity is MHPG, the major norepinephrine (noradrenaline) metabolite.<sup>269</sup>

### *Treatment*

Treatment for the monoamine synthesis disorders and MAO/COMT include substitution with neurotransmitter precursors (dopa, 5-HTP) and BH<sub>4</sub>. Autosomal recessively inherited GTPCH-1 deficiency and PTPS deficiency should be treated with BH<sub>4</sub>. Dietary phenylalanine restriction is beneficial in DHPR and PCD deficiencies, but may also require tyrosine supplementation.<sup>270,271</sup> Folinic acid supplementation in DHPR deficiency restores methyltetrahydrofolate and prevents progressive calcification of the basal ganglia and subcortical white matter.<sup>250,269</sup> Dietary supplementation of long chain polyunsaturated fatty acids may have therapeutic relevance in those disorders with hyperphenylalaninemia.<sup>272</sup> Patients with BH<sub>4</sub> synthesis disorders may deteriorate if given folate antagonists such as methotrexate, which interfere with a salvage pathway through which BH<sub>2</sub> is converted into BH<sub>4</sub> via dihydrofolate reductase. Use of dihydroxyphenylserine (which may be decarboxylated to norepinephrine [noradrenaline]) is aimed at correction of norepinephrine (noradrenaline) deficiency in DBH deficiency.<sup>250</sup>

Patients with *Segawa disease* and SR, ALAAD and TH deficiency all show improvement often with L-dopa combined with carbidopa; the latter is a peripheral dopa-decarboxylase inhibitor.<sup>269,273</sup> A diagnostic trial of L-dopa for dystonia can be clinically helpful and, if positive, should be followed by more definitive testing.<sup>274</sup>

*Segawa disease* is the most amenable to treatment.<sup>258,275</sup> It should be initiated with levodopa 1 mg/kg/d, with gradual titration usually to 4–5 mg/kg/d based on efficacy or adverse effects.<sup>274</sup> Some authorities recommend up to 20 mg/kg/d, but this is isolated L-dopa without carbidopa.<sup>260</sup> The diagnoses should be considered in atypical presentations, such as spastic diplegia, asymmetric limb dystonia or even writer's cramp. The genetic penetrance is incomplete and phenotypic variation can be highly variable even within the same family.<sup>276</sup> Contraindications to L-dopa therapy include psychosis, narrow-angle glaucoma and melanoma.<sup>275</sup> L-Dopa should be used with caution in hypotension and asthma, and with antihypertensive agents. Reduced benefit may occur if combined with dopamine receptor blockers, e.g. neuroleptics. Adverse effects are frequent and dyskinesias are reported in 20% of patients with *Segawa disease*, although they respond to reduction in dose.<sup>277</sup> Trihexyphenidyl may also be tried. Tetrahydrobiopterin may be helpful but is rarely used. The dopamine synthesis line appears far more involved than the serotonergic line; hence, serotonin reuptake inhibitors are not standard therapy.

Results of treatment of ALAAD deficiency are variable. Several agents have been tried in a small number of patients. As described above, standard initial treatment is L-dopa 1 mg/kg/d with doses tailored to results.<sup>269</sup> TH deficiency is a progressive and often lethal disorder, which

can be improved by L-dopa. A combination of low-dose L-dopa (3 mg/kg/d divided in six doses) with selegiline (5 mg/d in a single dose) has been reported as beneficial; hypersensitivity to L-dopa has been described.<sup>273,278</sup> As with all cases of parkinsonism and basal ganglion dysfunction, treatment must be individually tailored, making use of emerging medications and adapting to changing presentations.

### Succinic semialdehyde dehydrogenase deficiency

Succinic semialdehyde dehydrogenase (SSADH) deficiency is a disorder in the catabolism of the neurotransmitter GABA. GABA is transaminated to form succinic semialdehyde, which is then reduced by SSADH to succinate. In the presence of a block at this step, succinic semialdehyde is reduced to gamma-hydroxybutyric acid that accumulates in the urine, serum and CSF.

Patients with this disease have variable degrees of ataxia and hypotonia, convulsions and mild psychomotor retardation. Gamma-hydroxybutyric aciduria is an interesting model disorder of metabolism because the basic defect leads to the accumulation of a compound of known neuropharmacological activity. Gamma-hydroxybutyric acid was originally developed as an analogue of GABA that could readily cross the blood–brain barrier and be used as an intravenous anesthetic. It is currently employed for treatment of cataplexy associated with narcolepsy.

The gene is known and many mutations have been found. Prenatal diagnosis is available. Treatment is supportive and employs standard anticonvulsant drugs. Recent work with a murine model of SSADH deficiency suggests that treatment with taurine and/or antagonists of the GABA-B receptor may be of benefit.<sup>279</sup>

### GABA-transaminase deficiency

Deficiency of GABA transaminase has been reported associated with progressive neurological deterioration, leukodystrophy and hypotonia resulting in eventual death. CSF levels of GABA and homocarnosine were highly elevated.

### Riley–Day syndrome, familial dysautonomia

This disease, long thought to be due to a defect of neurotransmitter metabolism, is actually one of the hereditary sensory and autonomic neuropathies (type 3 HSN3). It occurs mostly in Ashkenazim and is associated with varying signs of autonomic dysfunction, alacrima, vasomotor instability, cardiac dysfunction and variable peripheral neuropathy; abnormal tongue papillae were once thought to be pathognomonic.

## DISORDERS OF PURINE METABOLISM

For clinicians, the best known purine is uric acid which, however, is only the end product of a complex synthetic and catabolic pathway in which at least 14 metabolic disorders are known (Fig. 26.40). In these disorders, the most common symptoms are those of gout or nephrolithiasis; however, since purines are bases for DNA and RNA synthesis and other compounds, some disorders present with hematological, neurological, musculoskeletal or immunological problems.<sup>280</sup>

### HYPERURICEMIA

#### Hypoxanthine-guanine phosphoribosyl transferase deficiency

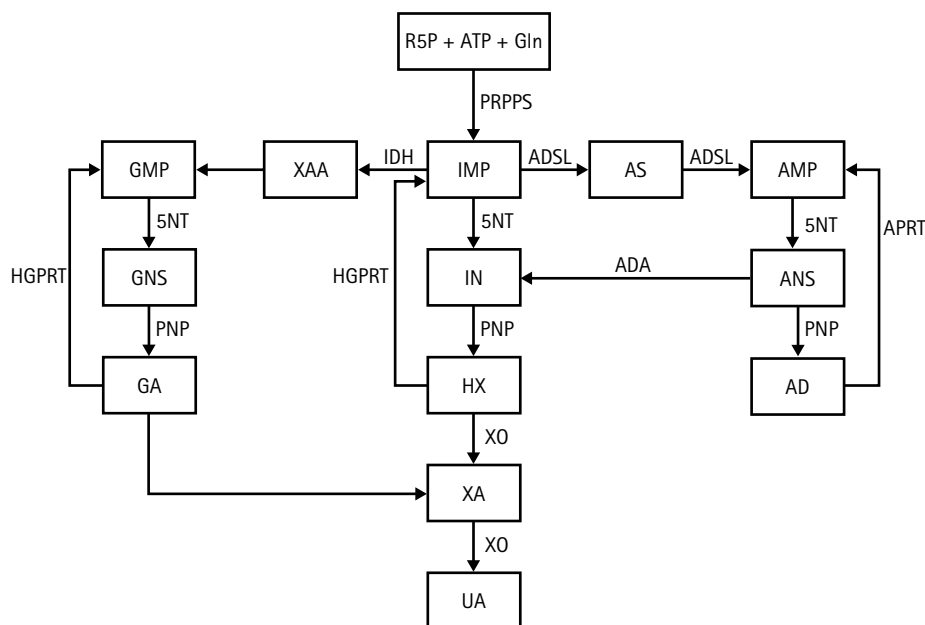

This enzyme is coded on the X chromosome. Mild deficiency is extremely common and results in hyperuricemia that frequently leads to gout. Gout is caused by precipitation of uric acid in and around joints, very often the big toe, which leads to extremely painful arthritis (podagra). Renal involvement can lead to uric acid nephrolithiasis and progressive renal damage. Hyperuricemia can be asymptomatic for many years.

Hyperuricemia can be caused by several mechanisms including dehydration, a high meat diet, increased absorption and reduced renal excretion. In the kidney, uric acid is filtered and then reabsorbed in the proximal tubules before being re-excreted. Re-excretion occurs in a system that also transports other organic acids; thus, in ketoacidosis, hyperuricemia is frequent as a result of competitive inhibition at that site. Increased production, due to faulty feedback inhibition, occurs in several of the inherited disorders discussed in this section and also in glycogen storage disease type I (see p. 1077). It is also commonly seen during the early stages of chemotherapy for malignancy.

### Lesch–Nyhan syndrome

#### Clinical features

This condition is caused by severe deficiency of hypoxanthine-guanine phosphoribosyl transferase (HGPRT).<sup>281,282</sup> The first sign may be a pink discoloration of the diapers (nappies) due to large amounts of urate crystals that presage nephrolithiasis. The condition is characterized by severe choreoathetosis that emerges in the first months of life; it is so severe that most patients never walk. Dysarthria is extreme and this, together with the neurological picture, leads many to believe that these patients are mentally retarded which is not necessarily the case. The most distressing aspect is an extraordinary degree of self-mutila-

**Fig. 26.40** Schematic overview of purine metabolism (not all steps are shown). R5P, ribose-5-phosphate; Gln, glutamine; PRPPS, phosphoribosylpyrophosphate synthetase; IMP, inosine monophosphate; 5NT, 5-nucleotidase; IN, inosine; HX, hypoxanthine; XO, xanthine oxidase; XA, xanthine; UA, uric acid; ADSL, adenylosuccinate lyase; AS, adenylosuccinate; AMP, adenosine monophosphate; ANS, adenosine; PNP, purine nucleoside phosphorylase; AD, adenine; APRT, adenine phosphoribosyl transferase; ADA, adenosine deaminase; IDH, IMP dehydrogenase; XAA, xanthyllic acid; GMP, guanosine monophosphate; GNS, guanosine; GA, guanine; HGPRT, hypoxanthine guanine phosphoribosyl transferase.

tion that manifests with biting, hitting, kicking or head banging that the patients are unable to control. It is so bad that most patients beg to be restrained in their wheelchairs or beds. Dental prostheses or even total edentulation may be required to prevent damage of oral tissues and other sites. The basis of the neurological damage is not known.

### Diagnosis

The clinical diagnosis is often delayed but is based upon the classical presentation associated with hyperuricemia that, however, may only be marginally abnormal. DNA diagnosis is possible but most families exhibit private mutations of the gene.<sup>283-287</sup>

### Treatment

Allopurinol must be used to control the uric acid levels but results in accumulation of xanthine that is also lithogenic so metabolite levels should be monitored. It does nothing for the neurological problems that can only be marginally helped by the standard drugs used for movement disorders. Education is very challenging but often rewarding. It is important to recognize the emotional state of the patients (and their families), especially during adolescence. Antidepressants, anxiolytics and extensive counseling are required for this condition.

## OTHER DISORDERS OF PURINES

For the remaining disorders of purine metabolism, the phenotype is predominantly neurological with renal abnormalities, but may also involve the musculoskeletal system.

*Adenine phosphoribosyl transferase (APRT)* deficiency causes marked urolithiasis with all of its complications due to the insolubility of 2,8-dihydroxyadenine.<sup>288,289</sup> In *phosphoribosyl pyrophosphate (PRPP) synthetase superactivity*, hearing loss, developmental delay, ataxia, dysmorphism, gout and uric acid lithiasis are variable.<sup>289</sup> *Adenylosuccinate lyase (ADSL)* deficiency presents with psychomotor retardation, hypotonia, epilepsy, autism and occasionally cerebellar hypoplasia.<sup>290-293</sup> ADSL-deficient patients accumulate succinylaminoimidazole carboximide riboside (SAICAR) which may be identified colorimetrically using a spot test of urine.<sup>293</sup>

*Xanthine oxidase/dehydrogenase, combined xanthine oxidase/sulfite oxidase, xanthine dehydrogenase/aldehyde oxidase and molybdenum cofactor deficiencies* (see pp. 1056 and 1126) variably manifest psychomotor retardation, intractable seizures, features of hypoxic ischemic encephalopathy, lens dissociation and xanthine lithiasis, often leading to renal failure.<sup>294-299</sup>

Hypouricaemia is characteristic of all these conditions. Increased hypoxanthine may serve as a benzodiazepine agonist at the GABA<sub>A</sub> receptor complex, perhaps contributing to neurological sequelae.<sup>300</sup> Hypouricaemia is also seen in starvation and from renal loss in the renal Fanconi syndrome, such as cystinosis.

*Adenosine deaminase (ADA)* deficiency presents with severe combined immunodeficiency (see Ch. 27, p. 1150) and lymphopenia,<sup>301-304</sup> potentially related to lymphocyte toxicity induced by accumulated ADA substrates, adenosine and 2'-deoxyadenosine.<sup>305</sup> Recent studies have revealed that the ADA gene is responsive to tumor suppressor elements linked to the p53 family.<sup>306</sup> *Purine nucleoside phosphorylase (PNP)* deficiency manifests isolated T-cell deficiency, developmental delays, lymphopenia and dysplastic marrow morphology.<sup>307-309</sup> Patients with both disorders are subject to unrelenting infection.

The remaining defects of purine metabolism are heterogeneous. *Myoadenylate deaminase deficiency (MDA)* is discussed on p. 1072.<sup>310-312</sup> Deficiency of *thiopurine methyltransferase (TPMT)*, which converts thioinosine monophosphate (IMP) to methylthio-IMP, does not manifest as 'disease' until intervention with thiopurine which may be used in chemotherapy, thus making TPMT deficiency a 'pharmacogenetic' disorder.<sup>313-315</sup>

### Diagnosis and treatment

For most of these disorders, the initial suspicion comes from the clinical presentation backed up by plasma uric acid levels. Measurement

of uric acid:creatinine ratio in urine may be helpful, but is very variable. Adequate, age related control ranges for uric acid are needed, and dietary intake of purines varies considerably between populations; purine analogues are found in many foods including all flesh, chocolate and caffeine. Disorders featuring accumulation of insoluble purine bases (e.g. xanthine, 2,8-dihydroxyadenine) should be included in the differential of urolithiasis.

In all forms of hyperuricemia, treatment with allopurinol controls the blood levels but does not address the underlying causes. Colchicine, or rarely aspirin, is also used during acute podagra crises.<sup>280</sup>

Severe combined immune deficiency in ADA deficiency makes it one of the prototypic disorders amenable to bone marrow transplantation, enzyme replacement therapy employing polyethylene glycol (PEG)-associated ADA or erythrocyte-encapsulated ADA, in addition to gene therapy.<sup>302,316</sup> Limited reports have suggested clinical efficacy of ribose intervention for ADSL deficiency.

## DISORDERS OF PYRIMIDINE METABOLISM

### Clinical features

Pyrimidines, like purines, are essential for DNA and RNA synthesis. Disorders of pyrimidine metabolism (Fig. 26.41) manifest significant

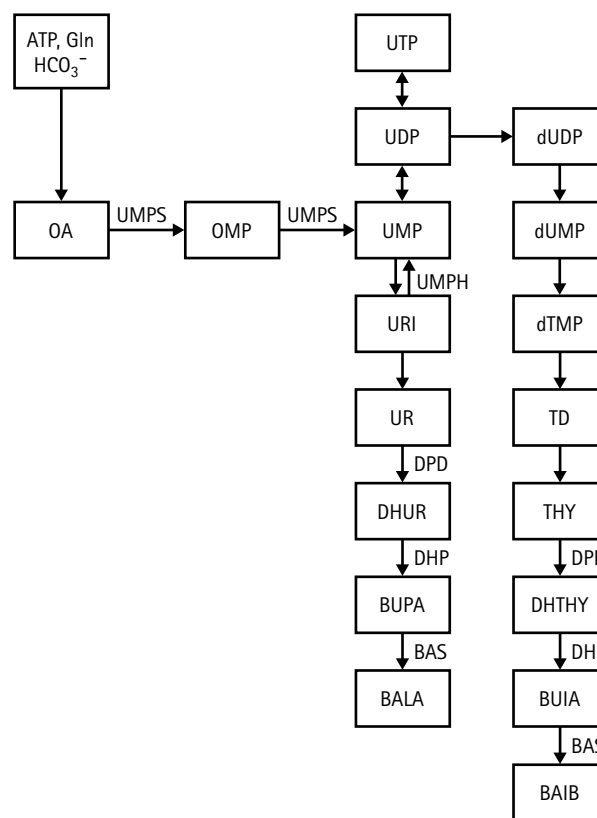

Fig. 26.41 Schematic diagram of pyrimidine catabolism (not all steps are shown). Gln, glutamine; OA, orotic acid; UMPS, uridine monophosphate synthetase; OMP, orotidine monophosphate; UMP, uridine monophosphate; UDP, uridine diphosphate; UTP, uridine triphosphate; dUDP, deoxyuridine diphosphate; dUMP, deoxyuridine monophosphate; UMPH, uridine monophosphate hydrolase; URI, uridine; dTMP, deoxythymidine monophosphate; UR, uracil; TD, thymidine; DPD, dihydropyrimidine dehydrogenase; THY, thymine; DHUR, dihydrouracil; DHP, dihydropyrimidinase (dihydropyrimidine amidohydrolase); DHTHY, dihydrothymine; BUPA, beta-ureidopropionic acid; BUIA, beta-ureidoisobutyric acid; BAS, beta-alanine synthase; BALA, beta-alanine; BAIB, beta-aminoisobutyric acid.

phenotypic/genotypic heterogeneity. Three disorders affect metabolism of uridine monophosphate (UMP), including *UMP synthetase (UMPS)* deficiency, *UMP hydrolase 1 (UMPH 1)* deficiency and *UMP hydrolase (UMPH) superactivity*.<sup>280,289,301</sup>

UMPS deficiency, sometimes known as hereditary *orotic aciduria*, causes megaloblastic anemia and T-cell immunodeficiency, failure to thrive, orotic acid crystalluria associated with renal orotic acid accumulation and intractable diarrhea. UMPH 1-deficient patients display a characteristic nonspherocytic hemolytic anemia with basophilic stippling, while those with UMPH superactivity manifest developmental delays, seizures, hyperactivity and recurrent infection.

In *dihydropyrimidine dehydrogenase (DPD)* deficiency<sup>317</sup> there is a variable phenotype including psychomotor retardation, seizures, microcephaly, feeding difficulties, autistic features and hypertonia.<sup>318,319</sup> DPD deficiency is a 'pharmacogenetic' disease, since treatment with 5-fluorouracil (5-FU) in patients with DPD deficiency can lead to severe 5-FU toxicity.<sup>320,321</sup> Neurological dysfunction in *dihydropyrimidine amidohydrolase (DHP)* deficiency includes microcephaly, psychomotor retardation, spastic quadriplegia and seizures. Both DPD and DHP deficiencies have 'thymine/uraciluria', with accumulation of dihydrothymine and dihydrouracil in DHP deficiency.<sup>317,320</sup>

*Beta-ureidopropionase (beta-alanine synthase; BAS)* deficiency is a rare neurological disorder, manifesting optic atrophy, dystonia, convulsions and severe mental retardation associated with excretion of beta-ureidopropionate and beta-ureidoisobutyrate.<sup>322-325</sup> The latter may be detected by NMR analysis.

*Thymidine phosphorylase (TP)* deficiency is an autosomal recessive disorder that causes a mitochondrial syndrome known as MNGIE (mitochondrial neuropathy, gastrointestinal encephalomyopathy; see p. 1085), in which gastrointestinal symptoms are found along with demyelinating polyneuropathy and leukoencephalopathy.<sup>326-330</sup>

### Diagnosis and treatment

Several specialist laboratories now offer extended screening for purine and pyrimidine disorders employing HPLC, capillary electrophoretic and/or tandem mass spectrometric screening protocols.<sup>331-334</sup> For the disorders described above, DPD deficiency is detectable by employing a recently devised [2-<sup>13</sup>C] uracil breath test.<sup>335,336</sup>

Few of the above disorders are treatable beyond palliative measures. However, uridine treatment of UMPS deficiency reverses the biochemical and clinical abnormalities.

## DISORDERS OF METAL METABOLISM

(Calcium and magnesium metabolism and the nutritional aspects of trace metals are discussed in Chapter 16).

Metals function via association with proteins in a way similar to vitamins. They are required for a variety of functions, including electron transfer, oxygen binding and structural support. Inherited disorders that result in either deficiency or overload can have severe consequences.

### COPPER

An adult body contains approximately 100 mg of copper. Copper is capable of functioning in electron transfer reactions (a so called redox active metal) and is required for the activity of many critical enzymes in a wide variety of metabolic pathways (Table 26.30). Consequently, copper deficiency has numerous effects on metabolism. Copper excess also has significant clinical consequences, which result from the ability of copper to transfer electrons to oxygen and generate toxic oxygen free radicals.

In serum, over 90% of copper is bound to ceruloplasmin (see below). The circulating pool of available copper is believed to be bound to histidine and other amino acids. Copper homeostasis is maintained via a balance between copper absorption from the gut and loss via biliary excretion. The two most common inherited disorders of copper

Table 26.30 Copper-dependent enzymes and their function

Enzyme	Function
Cytochrome c oxidase	Electron transport
Tyrosinase	Melanin biosynthesis
Peptidylglycine α-amidating Monooxygenase	Activation of neuropeptides (gastrin, vasoactive intestinal peptide, melanocyte stimulating hormone, thyrotrophin releasing hormone, cholecystokinin, vasopressin, corticotrophin releasing hormone and calcitonin)
Dopamine β-hydroxylase	Catecholamine biosynthesis
Lysyl oxidase	Collagen cross-linking
Cu-Zn superoxide dismutase	Protection from oxidative stress
Ceruloplasmin	Iron metabolism

metabolism affect either the absorptive (Menkes disease) or excretory (Wilson disease) phases of copper homeostasis.<sup>337</sup>

### Menkes disease

Menkes disease (~1 in 250 000) is an X-linked disorder resulting from mutations in a gene (ATP7A) that encodes an ATP-dependent copper transporter that is expressed in nearly all tissues except the liver. The Menkes protein is required for the absorption of copper from the gut and the placenta. Lack of this protein results in accumulation of high levels of copper in enterocytes and the placenta due to an inability to release copper absorbed from the gut or maternal blood, respectively, resulting in profound systemic copper deficiency. ATP7A also functions in the transport of copper across the blood-brain barrier.

### Clinical features

Menkes disease results in severe developmental delay and failure to thrive. Drowsiness, lethargy, hypotonia, hypothermia and feeding difficulties are often evident within a few days of birth, and low birth weight is common.<sup>338</sup> The skin is pale, soft and doughy. The most characteristic feature is the hair, which is sparse and depigmented, with a corkscrew-like microscopic appearance (pili torti) and a texture reminiscent of steel wool, leading to the term 'Menkes kinky hair syndrome' (Fig. 26.42). Seizures are common. Death occurs commonly in the first decade.

The clinical features are caused by the loss of function of copper-dependent enzymes (Table 26.30). Tyrosinase deficiency results in hypopigmentation of the skin and hair. Peptidylglycine alpha-amidating monooxygenase (PAM) deficiency leads to a broad spectrum of neuroendocrine derangements. Abnormalities of collagen cross-linking due to lysyl oxidase deficiency cause osteoporosis, flared metaphyses and fractures, which may suggest battering; Wormian bones are also common. Arteries are often tortuous and may rupture, which can lead to subdural hematomas. The ureters and the bladder wall are weakened and dilated. Deficiency of cytochrome oxidase and dopamine beta-hydroxylase results in CNS degeneration, characterized by abnormalities of myelin, and cerebral and cerebellar atrophy.

Heterozygous females have normal levels of copper, ceruloplasmin and catecholamines. Patches of pili torti are present in approximately 50% of obligate carriers; their absence does not exclude carrier status.

A well characterized variant of Menkes disease, associated with milder mutations in the ATP7A gene, is the *occipital horn syndrome*, also known as X-linked cutis laxa (see Ch. 29, p. 1397). This is a disorder of connective tissues characterized by lax skin and joints, bladder diverticula, inguinal hernias and arterial tortuosity. Ossification within the tendons that attach the trapezius and sternocleidomastoid muscles to the skull give rise to the pathognomonic occipital horns, which can be felt by palpation and demonstrated radiographically. As in Menkes, these abnormalities are caused by deficient activity of lysyl oxidase. Dopamine beta-hydroxylase activity is also sometimes affected, leading to symptoms of autonomic dysfunction, such as orthostatic hypotension.

Fig. 26.42 (a) Features and (b,c) typical hair of Menkes syndrome.

### Diagnosis

The clinical picture is so striking that a presumptive diagnosis should be easy. Usually, the serum copper and ceruloplasmin are low, but these can be low even in healthy infants. Abnormalities of catecholamine levels in serum, CSF and urine, secondary to dopamine beta-hydroxylase deficiency, are more consistent; in neonates, plasma levels of these neurotransmitters are the preferred diagnostic tool.<sup>339</sup> Radioactive copper uptake by cultured fibroblasts is increased and can also be used for diagnosis. Because of the large number of mutations that have been identified in the gene, molecular diagnosis is not readily available.

### Treatment

Since copper absorption from the gut is defective, oral copper supplementation is ineffective. In contrast, parenteral administration of copper–histidine can rapidly normalize serum levels of copper and ceruloplasmin. However, most of the enzymes that require copper are intracellular, and it is difficult to evaluate the adequacy of treatment effectively, particularly in the brain. When begun prior to the onset of severe neurological symptoms, copper–histidine may improve neurological outcome and decrease seizure activity, but since significant connective tissue problems persist, this therapy should be considered experimental.<sup>340</sup> A single unsuccessful attempt at in utero copper treatment has also been reported.<sup>341</sup>

### Wilson disease

Wilson disease is an autosomal recessive disorder caused by mutations in the *ATP7B* gene, which codes for a different copper transporting ATPase that is homologous to *ATP7A*. Lack of either results in a defect of intracellular copper transport. The differences between Menkes and Wilson diseases are a result of the different tissue distributions of the two proteins; Wilson primarily affecting the liver, whereas the Menkes gene is expressed in nonhepatic tissues. The Wilson protein is required for the export of copper from hepatocytes into the bile and also for transport of copper into the Golgi apparatus for ceruloplasmin synthesis.

### Clinical features

Wilson disease, also known as hepatolenticular degeneration, primarily affects the liver and the nervous system, particularly the basal ganglia. Patients may present at any time from early childhood to the fifth decade. Children most commonly present with liver disease, which usually becomes evident in the first or second decade. Hepatosplenomegaly, jaundice and symptoms of hepatitis are the most common findings; acute hepatic failure can occur. Hemolytic anemia is not uncommon.

After adolescence, the disease more commonly presents with neurological symptoms. The first signs of CNS involvement, which can occur even in the absence of hepatic damage, include deterioration of school performance and changes in mood and behavior. Concomitantly or subsequently, findings of basal ganglia damage develop. Progressive extrapyramidal signs, including rigidity, dysarthria, dysphagia, drooling and intellectual deterioration may mimic Parkinson disease. Psychiatric symptoms ranging from mania to depression, paranoia or anxiety can also be encountered. Occasionally, flapping tremor, schizophrenic behavior or the renal Fanconi syndrome may be the presenting feature. A brown or green ring around the corneal limbus in the eye – the Kayser–Fleischer ring – is caused by copper deposited in Descemet's membrane but may not be present in the first decade.

### Diagnosis

Wilson disease should be considered in any child with unexplained liver disease, neurological dysfunction or hemolytic anemia. Plasma copper and ceruloplasmin are usually, but not invariably, low, but this is not specific for Wilson disease, being seen in other liver diseases. The best diagnostic test is determination of 24 h urine copper excretion, which is elevated ( $>100$  mcg/24 h; normal = 20–50 mcg/24 h) in nearly all symptomatic patients. Presymptomatic patients and carriers can have intermediate levels of copper excretion (50–100 mcg/24 h), and may require a liver biopsy and direct measurement of copper content for definitive diagnosis. A Kayser–Fleischer ring is best identified by slit lamp examination and is nearly always present in patients with neurological and psychiatric symptoms. It is rarely present in children, particularly in the absence of neurological symptoms. Though singly not 100%

effective for diagnosis, the combination of 24 h urine copper excretion, ceruloplasmin level and a slit lamp examination is unlikely to miss a real case.<sup>342</sup> The large number of disease-causing mutations makes DNA diagnosis impractical at present.

### Treatment

D-Penicillamine was the drug of choice for many years; it is now superseded. In children with minimal liver dysfunction, zinc acetate, combined with a diet limited in high copper containing foods (shellfish, chocolate) is highly effective. Oral zinc induces metallothionein expression in enterocytes, which binds to copper and blocks its absorption. This affects the absorption of both dietary copper and that secreted into the gastrointestinal tract. Overtreatment can cause copper deficiency, which manifests with hypochromic, microcytic anemia. Significant liver disease should be treated with trientine (Syprine), a copper chelator, in addition to zinc.<sup>343</sup> For patients with neurological or psychiatric symptoms, a recently developed chelator, tetrathiomolybdate, is effective in halting and in many cases reversing symptoms.<sup>344</sup> Currently, this agent is available as an investigational new drug. Patients with significant liver and/or neurological disease should be referred to a center with extensive experience in the treatment of Wilson disease. Liver transplantation is indicated for progressive hepatic insufficiency and in fulminant hepatic failure. Liver transplant results in complete correction of copper homeostasis and reversal of most neurological dysfunction.

### Aceruloplasminemia

Aceruloplasminemia is a rare autosomal recessive disorder affecting the ceruloplasmin gene.<sup>345</sup> Ceruloplasmin is a copper-containing ferroxidase that is required for the mobilization of iron from reticuloendothelial cells. It is also expressed in astrocytes, where it functions in iron metabolism. Accumulation of iron in the pancreas, basal ganglia and retina are responsible for the primary symptoms, which usually develop in the fourth decade of life. Clinical features include an extrapyramidal movement disorder, diabetes mellitus and retinal degeneration. Excess iron is also seen in the liver. Plasma copper is low secondary to the ceruloplasmin deficiency. The abnormalities of iron metabolism result in a mild anemia and decreased serum iron level. No specific treatment is known.

## IRON

The nutritional aspects of iron metabolism are discussed in Chapter 16.

Maintenance of normal iron homeostasis depends of the ability to regulate the rate of iron absorption from the gut in response to total body iron stores. The major iron transport protein of the plasma is transferrin. After birth, transferrin is about 65% saturated with iron, this value falling to a norm of 20–30% as iron stores are used. Transferrin saturation decreases in iron deficiency, and increases in the presence of iron overload. Adult total body iron content is about 3–4 g, of which 40–60% is in hemoglobin, 10–20% is in myoglobin and tissue enzymes, and 10–40% is stored as ferritin. Newborn infants have total body iron levels of about 250–400 mg.

### Hereditary hemochromatosis

Hemochromatosis results when too much dietary iron is absorbed. It can be acquired, but hereditary hemochromatosis is one of the most common genetic disorders of Caucasians, with an incidence of 3–5 in 1000. However, the penetrance of clinical symptoms is low, with estimates ranging from 1% to 50%.<sup>346,347</sup> The most common form results from mutations in the HFE gene and it is inherited as an autosomal recessive condition. The total body iron levels are 5–10 times normal (15–40 g). Only a few milligrams of excess iron are absorbed each day, usually resulting in a delay of symptoms until adulthood. Rare forms can present during the second or third decade, and it may be identified in children serendipitously during routine lab testing of iron status. Clinical onset is delayed in females as a result of menstrual blood loss.

### Clinical features

The most common symptoms in adults are fatigue, arthralgia, loss of libido and impotency. Associated findings include hepatomegaly leading to cirrhosis and sometimes hepatocellular carcinoma, increased skin pigmentation, diabetes mellitus (an old name for this condition was 'bronzed diabetes'), abdominal pain and cardiomyopathy. The first symptoms in juvenile-onset forms are commonly hypogonadotropic hypogonadism and heart failure. All of the tissue damage is from excess accumulation of iron, which is believed to be due to iron-catalyzed generation of toxic oxygen radicals.

### Diagnosis

Biochemical measures of iron status must be used for diagnosis. A persistent elevation of the fasting transferrin saturation (>45% for one year) identifies 98% of affected patients.<sup>348</sup> The transferrin saturation is elevated even when the level of ferritin and total body iron stores are normal, allowing for diagnosis prior to the onset of symptoms.

### Treatment

Decisions regarding initiation of treatment should be based upon measures of total body iron load and symptoms. Most patients with an elevated transferrin saturation and normal ferritin do not require therapy, but should be re-evaluated yearly. When the ferritin is elevated ( $\geq 200$  mcg/L in pre-menopausal women,  $\geq 300$  mcg/L in men and post-menopausal women), or in the presence of liver disease, therapy should be started.

The iron can be readily mobilized, allowing for treatment via repeated phlebotomy (500 ml of blood contains 200–250 mg of iron). Therapy is monitored by monitoring the serum ferritin, which should be maintained in the low normal range. When treatment is begun before significant tissue damage occurs (cirrhosis, diabetes mellitus), the prognosis is excellent. However, much of the damage that occurs in hemochromatosis is irreversible, emphasizing the need for early diagnosis and treatment. Because of the high incidence and excellent response to early therapy, population screening for hereditary hemochromatosis has been considered.

### Neonatal hemochromatosis

Neonatal hemochromatosis is a rare cause of neonatal liver failure that results from the accumulation of excess iron in utero. The liver demonstrates cirrhosis, fatty infiltration and bile duct proliferation with hemosiderin deposits. The pancreas, adrenals, thyroid and myocardium may also be affected. The cause is uncertain, but maternal immunization against a fetal antigen has been proposed,<sup>349,350</sup> and is leading to attempts at immunotherapy. Elevated iron has also been seen in the liver of neonates with viral infections (cytomegalovirus, echovirus), neonatal lupus and inherited disorders of bile acid synthesis. There is no specific therapy, though liver transplant has been successfully employed.

## ZINC

Zinc is an essential element that plays both catalytic and structural roles in many proteins. Zinc deficiency is rare in the absence of generalized malnutrition (see Ch. 16), or malabsorption. *Acrodermatitis enteropathica* (see also Ch. 30, p. 1458) is an inherited disorder associated with severe zinc deficiency due to mutations of the SLC39A4 gene, which encodes an intestinal zinc transporter.<sup>351</sup> Typical symptoms include diarrhea, acrodermatitis, alopecia and failure to thrive. Infants present shortly after weaning from breast milk or in the first weeks of life in formula fed infants. The symptoms respond rapidly to oral zinc sulfate supplementation. Hereditary hyperzincemia is benign.

### MOLYBDENUM (see also p. 1057 and p. 1123)

Molybdenum is required for the function of three oxidases, xanthine, sulfite and aldehyde oxidase. The functional complex of molybdenum

is called the *molybdenum cofactor*, and consists of a single metal atom in complex with a pterin. Mutations in three genes (MOCS1 and 2, and GPHN) can cause molybdenum cofactor deficiency; all result in severe progressive neurological deterioration, seizures, dislocated lenses and early death. Serum uric acid is very low and the urine contains xanthine, hypoxanthine, sulfite and thiosulfate.

Diagnosis can be made on the basis of low serum uric acid, an abnormal urinary purine profile and an elevation of urine sulfite, which can be detected by special dipstick in fresh urine. A more stable marker is urine S-sulphocysteine, which is the preferred metabolite for diagnosis. No successful treatment has been reported. The genes for all three proteins are known and prenatal diagnosis is possible.

## PORPHYRIAS

The porphyrias are a heterogeneous group of disorders resulting from inherited or acquired abnormalities in heme biosynthesis.<sup>352</sup> Symptoms associated with these disorders result primarily from the accumulation of heme precursors, as opposed to heme deficiency. The tissues with the highest rates of heme biosynthesis are the liver and the erythroid bone marrow, leading to the frequent classification of porphyria as either hepatic or erythropoietic. An alternative classification is based upon the nature of the clinical symptoms. Acute porphyrias are characterized by symptom-free periods alternating with episodic attacks. Non-acute or cutaneous porphyrias are more chronic conditions.

Heme is biosynthesized in eight sequential steps, the first and last three occurring in mitochondria. The initial and rate-limiting enzyme is delta-aminolevulinic acid synthase (ALAS), which catalyzes the first committed step in the pathway. This enzyme is subject to feedback inhibition by heme. Deficiency at any subsequent step of the pathway results in decreased heme production, loss of the normal feedback inhibition and thus increased synthesis of the early, symptom-producing intermediates.

The cytochrome P450 enzymes involved in metabolite and drug metabolism in the liver require large amounts of heme. Drugs such as phenobarbital that induce P450 enzymes, lead to an increased rate of heme production by stimulating ALAS production (see Table 26.31). In the acute forms of porphyria, a rapid rise of heme precursors then precipitates symptoms. In contrast, the cutaneous porphyrias are primarily the result of the chronic accumulation of photosensitizing intermediates of heme biosynthesis in the skin. The specific symptoms in individual patients vary widely in all types of porphyria, depending on the nature of their specific mutation(s). Since an absolute block in heme biosynthesis would be lethal, all patients have some residual enzyme activity.

### ACUTE PORPHYRIAS

Acute intermittent porphyria (AIP) is the most common of the acute porphyrias in the UK (1 in 10 000–20 000); it results from a 50% reduction in hydroxymethylbilane synthase (formerly known as porphobilinogen deaminase) activity. It is an autosomal dominant disorder, as are the two other common forms of acute porphyria, variegate porphyria and hereditary coproporphyria, resulting from mutations in the *porphyrinogen oxidase* and *coproporphyrinogen oxidase* genes, respectively.

**Table 26.31** Drugs and toxins which may aggravate acute porphyrias (the list is not exhaustive)

Barbiturates	Oral contraceptives
Chloroquine	Pentazocine
Erythromycin	Phenytoin
Estrogens	Primidone
Ethanol	Sulfonamides
Griseofulvin	Theophylline
Ketamine	Trimethadione
Meprobamate	Valproic acid

Though rare in the general population, variegate porphyria has a prevalence of 1 in 3000 in Afrikaners. A very rare form of acute porphyria, *aminolevulinic acid dehydratase* deficiency porphyria, is an autosomal recessive condition. In spite of the genetic basis, a family history of acute porphyria is frequently negative. Only 10–20% of patients who inherit the gene for AIP ever develop symptoms, and symptoms almost never occur before the onset of puberty.

### Clinical features

The most common symptom of acute porphyria is attacks of severe abdominal pain, typically constant and poorly localized, and often associated with nausea, vomiting and constipation. Tachycardia is the second most common symptom. Dark urine, motor neuropathy and psychiatric symptoms, including depression, anxiety, hallucinations and paranoia, are also frequently observed. In severe cases, muscle weakness can lead to paralysis and respiratory compromise. Peripheral neuropathy may result in sensory changes and urinary retention. The symptoms of acute porphyrias are believed to result primarily from the effects of ALA and porphobilinogen (PBG) on the nervous system. Heme deficiency and free radical damage may also be involved. Significantly, the symptoms of acute porphyrias are not associated with an inflammatory response, thus fever, leukocytosis and raised erythrocyte sedimentation rate are not typical.

Both endogenous and exogenous agents can trigger the onset of symptoms, the common feature being their induction of liver cytochrome P450s and increased liver heme biosynthesis. Precipitating factors include prescription and illicit drugs, fasting, smoking, starvation, alcohol and stress. The cyclical hormonal changes associated with menstruation as well as oral contraceptives can also precipitate attacks, resulting in a higher incidence of symptoms in females. Drugs that have been associated with symptoms are listed in Table 26.31. (A more complete listing is available at <http://www.drugs-porphyria.com/>.)

Patients with variegate porphyria and hereditary coproporphyria have neurovisceral symptoms similar to, but generally milder than, those seen in AIP. In addition, variegate porphyria (and occasionally hereditary coproporphyria) can cause cutaneous photosensitivity and skin lesions similar to those seen in the non-acute porphyrias (see below). Aminolevulinic acid dehydratase deficiency porphyria is highly variable in regards to both age of onset and severity. This variability likely results from heterogeneity in regards to the amount of residual enzyme activity in individual patients. In general the symptoms resemble those of AIP.

### Diagnosis

Symptoms of acute porphyria before puberty are extremely rare; therefore, more common causes of acute abdominal symptoms must first be excluded. In adults, the symptoms are often attributed to psychosomatic disease or dysfunctional family dynamics. Any history of affected relatives must be carefully evaluated. Photosensitive skin lesions in addition to the neurovisceral symptoms are highly suggestive of variegate porphyria and may be seen in hereditary coproporphyria. With the exception of aminolevulinic acid dehydratase deficiency, all other acute porphyrias result in marked elevations of urine porphobilinogen (PBG) during an acute attack. Levels of urine ALA are also elevated to a lesser degree. Initial testing can be done on a single urine specimen, but requires special handling to avoid sample degradation and referral to an experienced laboratory. Normal levels of ALA and PBG on a spot urine sample taken during an acute episode effectively rule out the diagnosis of acute porphyria. In the presence of skin lesions total plasma porphyrins and fecal porphyrins should also be measured.

Between episodes of AIP, urinary levels of PBG are often normal but can remain elevated and can be quantitated in a 24 h urine sample. Specific enzyme testing is essential to confirm the diagnosis. DNA testing is available for most of the porphyrias, and can be used as an alternative to enzymatic testing in the evaluation of asymptomatic family members. Minor elevations of porphyrins can be seen in a variety of disorders, including constipation and lead poisoning, and care must be

taken to interpret the values correctly. Many patients with chronic pain syndromes are erroneously labeled as porphyrics and often develop narcotic dependency.

### Treatment

Measures to reduce the increased heme synthesis in the liver include elimination of any drugs that may have contributed, infusion of heme and i.v. fluids containing glucose. Infusion of a 10% glucose solution and correction of any electrolyte imbalances should begin immediately. Heme arginate (Normosang, Leiras) (3 mg/kg i.v. in a single daily dose) is given to inhibit the endogenous production of heme and decrease the production of ALA and PBG. Nausea and vomiting can be treated with chlorpromazine or other phenothiazines. Pain should be managed aggressively, using narcotics if required. Symptoms usually resolve in several days, so long term treatment with narcotics should not be necessary. Propranolol can be used for tachycardia and hypertension. Long term management includes the avoidance of precipitating drugs and a high carbohydrate diet (60–70% of total calories). Regular infusions of heme arginate may also be effective.

## CHRONIC (NON-ACUTE) PORPHYRIAS

The non-acute porphyrias usually present in childhood and symptoms are chronic rather than episodic. Their primary symptom is skin damage, which results from photosensitivity caused by the accumulation of porphyrins in the skin. In contrast to the acute porphyrias the cutaneous forms of porphyria are exacerbated by exposure to ultraviolet (UV) light.

### Congenital erythropoietic porphyria (HEP)

This is a rare autosomal recessive porphyria, associated with reduced uroporphyrinogen III synthase activity. The first sign is often red tinted discoloration of urine, which fluoresces in the diaper (nappy). Accumulation of porphyrins in red cell membranes results in hemolytic anemia, which can cause severe in utero anemia and hydrops fetalis. Chronic anemia and splenomegaly are characteristic features in older patients. Accumulation of porphyrins in the skin results in blistering and friability following exposure to UV light. Abnormalities of pigmentation, hypertrichosis and thickening of the skin occur with repeated damage. Recurrent skin infections can lead to loss of digits and scarring of the eyelids, nose and ears. Deposition of porphyrins in the teeth results in red discoloration (erythrodontia). The porphyrins that accumulate in congenital erythropoietic porphyria (CEP) are fluorescent, and can be seen by long wave illumination of the teeth, red blood cells and urine. The severe symptoms in this disorder often lead to premature death.

### Porphyria cutanea tarda

There are two forms of porphyria cutanea tarda (PCT); type I is acquired and accounts for 80%, type II is inherited. Combined, they are the most common form of porphyria. Both result from decreased activity of liver uroporphyrinogen decarboxylase (UROD). Type I is the result of the sensitivity of UROD to a variety of insults including alcohol, hepatitis C, HIV infection, estrogens and smoking. Iron overload in hemochromatosis is a common precipitant. Type II is due to a mutation in the UROD gene. Patients with type II disease have a 50% reduction in UROD activity; its inheritance is autosomal dominant. The primary manifestation of PCT is photosensitivity, which results in somewhat milder symptoms than those of CEP. Mild elevations of liver enzymes are also characteristic. Patients with a homozygous deficiency of UROD have a more severe form of PCT called hepatoerythropoietic porphyria (HEP), which is similar to CEP.

### Erythropoietic protoporphyria

This is the most common inherited form of cutaneous porphyria. Erythropoietic protoporphyria (EPP) results from a reduction in ferrochelatase activity, and is an autosomal dominant disorder. Ferrochelatase

catalyzes the final step of heme biosynthesis, the addition of Fe<sup>2+</sup> to protoporphyrin. The cutaneous manifestations of EPP include burning, itching, erythema and swelling. Chronic sun exposure and skin damage can lead to scarring, though this is usually less severe than in CEP and HEP. Occasional patients develop severe liver dysfunction secondary to porphyrin accumulation. A mild hypochromic anemia may be present, but hemolysis is uncommon.<sup>353</sup>

### Diagnosis

In contrast to the acute porphyrias, most of the porphyrins that accumulate in the non-acute porphyrias are not highly water-soluble and therefore are not primarily excreted in the urine. Initial screening of patients suspected of having a cutaneous porphyria can be done by analysis of total plasma porphyrins. Subsequent analysis of stool, urine and red blood cells may be required for specific disease identification.

### Treatment

Because of the role of sun and UV exposure in the pathophysiology, their avoidance is essential. Special protective clothing and high sun protection factor (SPF) sunscreen lotions should be routinely utilized. Oral beta-carotene and cysteine may result in improved sun tolerance, particularly in EPP.<sup>354</sup> As in the acute porphyrias, avoidance of drugs that induce heme synthesis is also important. In CEP repeated blood transfusion to suppress bone marrow heme production is effective but chelation therapy is then essential to avoid iron overload. Because of the sensitivity of UROD to iron, phlebotomy to lower liver iron levels is beneficial in all types of PCT. Low dose chloroquine treatment is also beneficial in PCT. The liver dysfunction in EPP may be improved by a combination of oral bile acid supplementation to facilitate porphyrin excretion and cholestyramine to inhibit their reabsorption.

Liver transplantation has been performed in EPP where it has been shown that porphyrins accumulate in the transplanted liver allograft, indicating that the erythroid bone marrow is the main source of porphyrins in this disorder.<sup>355</sup> Bone marrow transplantation in an animal model of EPP resulted in a marked drop in tissue porphyrin levels, indicating that this approach may be helpful in EPP patients. Successful gene therapy for the photosensitivity in EPP has also been reported in the mouse. Several patients with CEP have been treated successfully by bone marrow transplant.<sup>356,357</sup> Gene therapy for this disorder is currently being developed.<sup>358</sup>

## DISORDERS OF BILIRUBIN

The pathophysiology and differential diagnosis of jaundice are discussed elsewhere (see Ch. 19) and only genetic abnormalities of bilirubin and bile acid metabolism are considered here.

### UNCONJUGATED HYPERBILIRUBINEMIA

#### Crigler–Najjar syndrome

The severe form (type I) of Crigler–Najjar syndrome results from a lack of hepatocyte uridine diphosphate-bilirubin glucuronosyl transferase (bilirubin-UGT) activity. Patients present as neonates with severe unconjugated hyperbilirubinemia (360–850 μmol/L [21–50 mg/dl]). Kernicterus rapidly develops unless repeated exchange transfusions or plasmapheresis and continuous phototherapy are instituted. Affected patients are always at risk of kernicterus, even as adults, if therapy is interrupted. Heterozygotes have normal bilirubin levels but may have impaired glucuronidation of other substrates. Diagnosis is based on the exclusion of other causes of hyperbilirubinemia, normal liver histology, lack of bilirubin conjugates and absent enzyme activity.

Treatment with enzyme-inducing agents such as phenobarbital is ineffective; however, phototherapy and plasmapheresis can be used to lower unconjugated bilirubin levels. Liver transplantation is curative, and preliminary studies suggest that partial transplantation may also be effective.<sup>359</sup> Infusion of isolated hepatocytes and gene therapy approaches are also being investigated.<sup>360</sup>

The type II form is allelic, caused by less severe mutations in the UGT1A1 gene. Patients usually present with jaundice in infancy but this may be delayed until childhood or later. The serum bilirubin may be intermittently raised to 80–360  $\mu\text{mol/L}$  (5–21 mg/dl), but falls with phenobarbital and other bilirubin-UGT inducing agents. Kernicterus is rare. Relatives may give a history of a similar pattern of jaundice. Molecular testing is available for both types I and II.

### Gilbert syndrome

Gilbert syndrome (~1 in 1000) is characterized by a mild, chronic and variable unconjugated hyperbilirubinemia (~50  $\mu\text{mol/L}$  [3 mg/dl]) that may be exacerbated by intercurrent infection, fasting, exertion and excessive alcohol intake. Hepatic morphology is normal and kernicterus does not occur. Males are more commonly affected than females, which likely reflects differences in rates of bilirubin production.<sup>361</sup> The disorder is benign but if skin pigmentation is distressing, phenobarbital reduces the bilirubin level. It is usually inherited as an autosomal recessive condition caused by a sequence variation in the promoter region of the UGT1A1 gene but autosomal dominant inheritance is also described. Compound heterozygosity for a severe UGT1A1 mutation and the promoter mutation seen in Gilbert patients results in an intermediate phenotype. Molecular testing is available.

## PREDOMINANTLY CONJUGATED HYPERBILIRUBINEMIA

### Dubin–Johnson syndrome

This is an autosomal recessive condition caused by a defect in the transport of conjugated bilirubin and other low molecular weight organic anions from hepatocytes into bile. The disorder results from mutations in a gene that encodes a canalicular multispecific organic anion transporter (cMOAT, also known as MRP2). Patients usually present during adolescence with mild conjugated hyperbilirubinemia (30–80  $\mu\text{mol/L}$  [2–5 mg/dl]), though levels can reach 340  $\mu\text{mol/L}$  (20 mg/dl), particularly during intercurrent illness, pregnancy or with oral contraceptives. Prolonged cholestatic jaundice may occur during infancy, but this usually resolves until the teen years.<sup>362</sup> The bromsulphthalein secretion test gives a characteristic rebound picture. Stools may be acholic and the urine dark; patients may complain of generalized weakness, anorexia, nausea and vague upper abdominal pain. The liver may be enlarged and tender. Serum transaminases, alkaline phosphatase and bile salts are normal. Total urinary coproporphyrinogen is normal or slightly increased but the ratio of coproporphyrinogen I:coproporphyrinogen III is markedly elevated, and can be used to make the diagnosis. Histologically, the liver demonstrates accumulation of a black pigment in lysosomes, but is otherwise normal. Long term follow-up studies show no evidence for chronic liver damage and suggest a benign course.<sup>363</sup>

### Rotor disease

Rotor disease is characterized by cholestatic jaundice, but in contrast to Dubin–Johnson syndrome there is no hepatic pigmentation. Bromsulphthalein clearance from the plasma is prolonged, but without the rebound phenomenon seen in Dubin–Johnson syndrome. The two disorders can also be distinguished by urinary coproporphyrinogen levels, which are markedly increased in Rotor disease, but have a normal ratio of coproporphyrinogen I to coproporphyrinogen III. Inheritance is likely autosomal recessive, though the molecular basis is still unknown.

## HEREDITARY DISORDERS OF VITAMIN METABOLISM

No genetic disorders affecting vitamins A or C are known. *Familial hypercarotinemias* is usually benign but plasma vitamin A levels should be measured. Most disorders of vitamin metabolism are discussed elsewhere but are summarized here for consistency.

In *thiamine responsive megaloblastic anemia with deafness and diabetes mellitus (TRADD)* the anemia is marked; MCVs well over 100 are seen. The diabetes and profound nerve deafness develop in childhood.

Thiamine 10–20 mg/d is enough to restore normal red cells but does not reverse the diabetes or deafness; these latter may be preventable by presymptomatic thiamine therapy.

*Pyridoxine dependent seizures* are discussed on p. 863 and *biotinidase deficiency* on p. 1066.

*Lipoic acid* is sometimes used in treating pyruvate dehydrogenase deficiency (see p. 1079).

There are five known defects of *folate* metabolism. Methylene-H4 folate reductase and methyl-H4 folate homocysteine methyltransferase are both in the recycling pathway to methionine (see p. 1056). Another defect is in the histidine pathway (see p. 1067) and hereditary malabsorption, which causes megaloblastic anemia, is also known. Several others defects have been proposed but are not proven.

*Folinic acid responsive seizures* are part of a severe nondysmorphic neurodevelopmental condition. The CSF contains an unknown compound that is characteristic of the condition.<sup>364</sup> The dose is between 10 and 40 mg/d; folic acid is ineffective.

For *vitamin B<sub>12</sub>*, hereditary lack of intrinsic factor, of ileal absorption and the plasma transport proteins transcobalamin I and II are just the early aspects of a cascade of defects (Fig. 26.43). Vitamin B<sub>12</sub> is known to be involved with only two pathways, namely in homocysteine (see p. 1056) and methylmalonic acid metabolism (see p. 1065). At least nine defects are known (Cbl A–I). Those that interfere with methyl B<sub>12</sub> functions affect homocysteine metabolism, cause serious brain damage and are usually associated with megaloblastic anemia. Those that affect mutase activity all cause methylmalonic aciduria. Thus some cause a combined defect of both pathways. It should be noted that plasma B<sub>12</sub> levels are low in the absorptive defects but normal in the remainder. Plasma methylmalonic acid is a sensitive indicator of B<sub>12</sub> deficiency and is usually abnormal in newborn infants whose mothers are B<sub>12</sub> deficient.

Disorders of *vitamin D* metabolism include defects of both the 1- $\alpha$ -hydroxylase and 25-hydroxylases (D-dependent rickets type I). Both are associated with severe rickets that responds to therapy with 1,25-dihydroxyvitamin D3. A defect of the vitamin D receptor (D-dependent rickets type II) is far more serious; the rickets resists almost all therapy and most patients have total alopecia, those who do not have hair loss exhibit a different D-binding protein defect. Vitamin D resistant rickets is discussed in Chapter 15, p. 478–527.

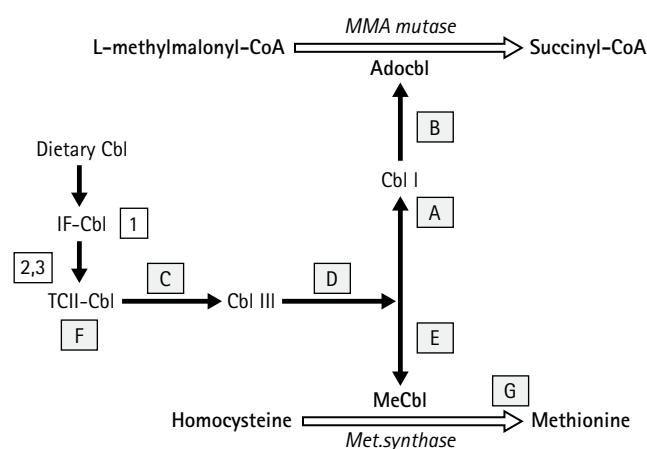

Fig 26.43 Vitamin B<sub>12</sub> metabolism. 1, denotes intrinsic factor deficiency; 2, defective absorption (in the distal ileum); 3, transcobalamin I and II deficiencies. Defect A results from failure of reduction of the cobalt from 2<sup>+</sup> to 1<sup>+</sup> in mitochondria. B results from failure of adenosyltransferase to synthesize adenosyl-B<sub>12</sub>. C and D are due to failures in the reduction of the central cobalt from 3<sup>+</sup> to 2<sup>+</sup> after efflux from the lysosomes. E is due to a defect in a reductase required to keep Cbl in a functional state. F is due to a failure to transport Cbl across the lysosomal membrane. G is due to a defect in methionine synthase.

A disorder of *vitamin E* metabolism is associated with progressive cerebellar dysfunction (similar to that seen in abetalipoproteinemia); it responds to increased doses of the vitamin.

## MISCELLANEOUS INBORN ERRORS OF METABOLISM

### Cerebral glucose transporter (GLUT 1) deficiency

There are several distinct glucose transporters. GLUT 1 is required for the transport of glucose into the CNS. Deficiency manifests as an autosomal dominant; it results in low CNS and CSF glucose *in the presence of normal blood glucose levels*. The result is severe and early onset of seizures and progressive brain damage. A high ketone diet, given to encourage brain metabolism of ketones, is beneficial. Well over 100 proteins have been identified in plasma. Many exhibit considerable genetic variation that is usually without functional significance. Selected disorders are discussed below.

### Alkaline phosphatase

Alkaline phosphatase comprises a family of at least four gene products that are normally bound to plasma membranes and accept a number of substrates such as phosphoethanolamine, pyrophosphate and pyridoxal-5'-phosphate. One isoenzyme is isolated to the intestine, a second to placenta, a third to germ cells. The fourth, which is present in most tissues and is called tissue nonspecific alkaline phosphatase (TNSALP), undergoes post-translational modification in almost all tissues producing liver, kidney, bone, leukocyte, etc isoenzymes that can be recognized electrophoretically. Alkaline phosphatase in plasma probably has no metabolic role; normally, in children, it derives largely from osteoblastic activity in bone, particularly during growth spurts. It can also reflect tissue damage in various organs, particularly the bile duct epithelium.

### Hypophosphatasia

This condition is due to absence or defective function of tissue nonspecific alkaline phosphatase (TNSALP). As with most disorders, there are severe and mild variants and both autosomal recessive and dominant inheritance are encountered. The principal presentations are of bone and/or dental abnormalities that may occur together or independently.

### Clinical features

The most severely affected cases can be detected prenatally by X-ray and these infants usually die prenatally or soon after birth. The skull and skeleton may be so unmineralized as to be almost invisible on X-ray. Shortening, bowing and rachitic changes of the bones are usual and undermineralization may seem reminiscent of osteogenesis imperfecta, although the radiological features are distinct. Thoracic dystrophy causes severe neonatal asphyxia; the differential diagnosis therefore includes Jeune asphyxiating thoracic dystrophy. This form is found in ~1 in 2500 Mennonite infants.

In less severely affected infants, failure to thrive, vomiting, hypotonia and constipation usually develop in the first year; they are related to hypercalcemia which is a usual feature of the condition and may be severe enough to cause nephrocalcinosis. The fontanelle is widely open and often tense. The skull may be misshapen and the face asymmetrical. In the skull, osteoporosis or copper-beaten skull is evident and may be associated with delayed bone growth. Bony deformities consist of shortening of long bones, bowing, thickening of the wrists, shortening of the digits, lordosis and a Harrison's sulcus; the metaphyses show characteristic translucencies in the growth plates. There may be premature loss of primary teeth, especially the incisors; there is no compensatory early eruption of permanent teeth.

In older children and in the dominant forms, the presentation can be more variable with little more than premature loss of primary teeth without periodontal disease, but with abnormal alveolar attrition and enlarged pulp chambers and root canals. Permanent teeth can also be involved. The condition may be first recognized in adults and presents with calcium nephrolithiasis. In such cases, osteoporosis and fractures are frequent,

pseudofractures can be seen on X-ray and some have the deformities of previous 'rickets'. Dental abnormalities may be the only finding.

Hypercalcemia is frequent in the infantile forms and can be life threatening when older patients are immobilized, as for orthopedic treatment. The hypercalcemia develops from failure of synthesis of apatite crystals in bone.

### Diagnosis and treatment

In the most severe cases, all TNSALP isozyme activities are virtually absent. In milder cases, the activity is present but diminished, a finding that becomes increasingly hard to evaluate in adults since normal values are lower than in childhood. In severe but not in mild cases, phosphoethanolamine is increased in the urine and pyridoxal-5'-phosphate is markedly increased in the blood. The latter test is less available but seems to be a better discriminant; both are most abnormal in the most severe cases. Prenatal diagnosis is tricky; ultrasound studies may help and analysis of TNSALP in an experienced laboratory is critical.

Pseudohypophosphatasia was reported in a family with the findings of hypophosphatasia but normal enzyme levels. Low values for TNSALP may occur in a number of conditions including malnutrition, hypothyroidism, zinc deficiency and glucocorticoid therapy.

There is no effective treatment; craniostenosis and limb deformity may require surgery.

### Hyperphosphatasia

The normal plasma alkaline phosphatase varies considerably throughout life and normal ranges are not clearly defined. Elevated values, derived from osteoblasts, occur in any condition with increased bone turnover, such as rickets, fractures, osteogenic sarcoma, osteolytic malignancies or juvenile Paget disease. The liver isozyme of ALP is increased whenever bile duct epithelium is damaged, as in obstructive jaundice.

Familial hyperphosphatasia, usually involving liver ALP, is usually benign, but may be associated with bone disease (e.g. juvenile Paget), and association with mental retardation, seizures and neurological damage is reported in several families.

*Transient hyperphosphatasemia* of infancy is not uncommon; it involves the bone and liver forms and can occur following a minor viral prodrome and is often detected during routine blood tests. The plasma level can easily reach well over 2000 IU/L but this only lasts for a few weeks; no other laboratory tests are abnormal. The etiology is unknown and no treatment is indicated.<sup>365</sup>

### Carbonic anhydrase II deficiency

This is a rare autosomal recessive trait that causes osteopetrosis, mixed proximal and distal renal tubular acidosis and developmental delay with cerebral calcifications; growth failure and dental malocclusion occur frequently. The osteopetrosis in this condition is usually less severe than in the classic disorder and patients may be asymptomatic for months or years after birth, but eventually fractures, failure to thrive or developmental delay bring the patient to attention.

Treatment for this disorder is symptomatic, whereas bone marrow transplantation is beneficial in 'classic' severe osteopetrosis. Prenatal diagnosis is not currently available.

### Transport proteins

In *congenital analbuminemia* plasma albumin is missing and the substances in plasma that are normally bound to it, such as calcium, are reduced. However, the unbound (active) fractions of these compounds in the plasma are normal and mild edema may be the only finding. The reason for the lack of gross edema is unclear. Heterozygotes have normal levels. Occasionally, electrophoretic variants of albumin are found in healthy people. Hypoalbuminemia due to malnutrition, hepatocellular disease and protein-losing enteropathy are discussed in 19.

Congenital deficiency of hormone-binding proteins are discussed in 15. Normal serum contains 0.3–2 g/L of haptoglobin, which binds to free hemoglobin in plasma. There are several common genetic variants and even total deficiency seems to be benign.

# Appendix 1

## Metabolic diseases and their associated abnormalities<sup>1-3</sup>

Results from expanded newborn screening using tandem mass spectrometry (MS/MS) to show the different metabolic diseases and the usual abnormal acyl-carnitines associated with them.

The designation 'C3, C5, etc' denotes the chain length of the metabolites detected. The amino acids are not listed since they are recognized by their own names.

Normal values and reference values vary in different programs and are therefore not provided here.

	Acylcarnitines by MS/MS
<i>Organic acid disorders</i>	
Propionic acidemia	C3
Methylmalonic acidemia	C3,
Malonic acidemia	C3DC
Isobutyryl-CoA dehydrogenase deficiency	C4
Isovaleric acidemia	C5
2-Methylbutyryl-CoA dehydrogenase deficiency	C5
3-Methylcrotonyl-CoA carboxylase deficiency	C5-OH
3-Methylglutaconic aciduria	C5-OH
3-Hydroxy-3-methylglutaric aciduria	C5-OH, C6DC
Holocarboxylase synthetase and biotinidase deficiencies	C5-OH and/or C3
2-Methyl-3-hydroxybutyric aciduria	C5-OH, C5:1
β-Ketothiolase deficiency	C5:1 and/or C5-OH
Glutaric acidemia type 1 (GAI)	C5DC
<i>Fatty acid oxidation disorders</i>	
Carnitine uptake defect/carnitine transport defect	CO (low free carnitine)
Short chain acyl-CoA dehydrogenase deficiency (SCAD)	C4
Medium/short chain L-3-hydroxyacyl-CoA dehydrogenase deficiency	C4-OH
Glutaric acidemia type II (multiple acyl-CoA dehydrogenase deficiency [MADD, GAI])	C4-C18 saturated and unsaturated species, C14:1
Medium chain ketoacyl-CoA thiolase deficiency (MCAT)	C8, C8-OH and C10-OH
Medium chain acyl-CoA dehydrogenase deficiency (MCADD)	C6-10, C10:1
2,4-Dienoyl-CoA reductase deficiency	C10:2
Very long chain acyl-CoA dehydrogenase deficiency (VLCAD)	C14, C14:1, C14:2, C16, C16:1, C14:1/C12:1
Carnitine palmitoyltransferase I deficiency (CPT IA)	CO/C16, CO/C18, CO/(C16+C18)
Carnitine palmitoyltransferase II deficiency (CPT II)	C16 (high), C18, C18:1, CO (low)
Carnitine acylcarnitine translocase deficiency (CACT)	C16, C18:1 (high)
Long chain L-3-hydroxyacyl-CoA dehydrogenase deficiency (LCHAD)	C16-OH and/or C18:1-OH, C16:1, C18-OH
Trifunctional protein deficiency (TFP)	C16-OH and/or C18:1-OH

## INTRODUCTION

'Immunity' describes the immune system response to a given antigenic challenge in a useful (protective) sense. The main role of the immune system is to repel invasion by microorganisms. Abnormalities in this system may increase susceptibility to infection as well as other non-infective problems such as allergy and autoimmunity. Our increased understanding of the immune mechanisms used in handling microbes has led to a better understanding of both primary and secondary immunodeficiency.<sup>1</sup> Conversely, much has been learned of the intricacies of immune function from studying patients with immunodeficiency.

## THE IMMUNE SYSTEM

The immune system protects the host from infectious or dangerous microbes in the environment and has evolved to contain or eliminate pathogens in a complex variety of ways. Key to this is the ability to distinguish between host and pathogen. Many of the mechanisms used, as with many of the defense processes, are found in a range of organisms including invertebrates and plants. The more complex parts of the immune system (such as T and B lymphocytes, the key players in adaptive immunity) have evolved to work in tandem with these aspects of recognition systems and innate immunity.

The initial host defense against infection involves innate factors. Physical and chemical barriers play an important role in pathogen exclusion by direct antimicrobial effects or prevention of microbial attachment. Physical barriers such as epithelial surfaces and mucous membranes provide the first line of defense, augmented by hair and cilia in conjunction with respiratory tract mucus secretions, stomach acids and other mucous membrane secretions. Commensal intestinal and skin flora produce locally acting antibiotics, excluding potential pathogens. The importance of such defenses is clearly demonstrated when they are significantly breached, e.g. bacterial sepsis following severe burns or repeated bacterial infection causing bronchiectasis in immobile bronchial cilia syndrome or cystic fibrosis (see Ch. 20). Although the role these barriers play in the initial defense is critical they will not be considered further in this chapter.

## COMPONENTS OF THE IMMUNE SYSTEM

The main organs of the immune system are the bone marrow, thymus, spleen and lymph nodes. The immune system is not predominantly organ based, and all parts of the body have a local immune system, for example Peyer's patches in the gut. The cells of the immune system are derived from pluripotent stem cells which originate in utero from fetal liver and bone marrow. Immune cells signal to each other and the rest of the body via cell surface molecules and soluble messengers. The latter are termed cytokines, chemokines or interleukins, depending on their exact function. The more important cytokines and their main effects are listed in [Table 27.1](#). Many of these proteins have multiple and overlapping effects and are important in the innate and adaptive immune systems. Cytokines interact with their ligands (or receptors) on the surface of target cells. Receptors are frequently composed of more than one protein chain, one of which is common to a group of receptors and one defines the exact specificity of the receptor. An example is the gamma chain of the interleukin (IL)-2 receptor which is shared with the receptors for IL-4, -7, -9, -15 and -21. Mutations in the gene for this chain result in X-linked severe combined immunodeficiency (SCID) (p. 1154).

Functional lymphocyte subsets are identified by their surface antigens. Particular antigens [defined by recognition by a specific monoclonal antibody and termed the cluster of differentiation (CD) number] are used to define cell type (e.g. T or B lymphocyte) or their state of differentiation or activation (e.g. naive or memory cell). The more important surface antigens recognized by different CD antibodies are listed in [Table 27.2](#). The functional roles of many of these surface antigens have been established.

## INNATE AND ADAPTIVE IMMUNITY

Pathogens that breach barrier defenses encounter two fundamentally different, but closely linked, types of response ([Fig. 27.1](#)): innate then adaptive components of the immune system. Innate immune responses employ a limited number of receptors specific for conserved microbial structures but are highly effective and include neutrophil and mononuclear phagocytes as well as humoral factors such as complement. This response is immediate but limited in scope.

The adaptive immune system is distinguished by the specificity of its response and ability to generate immunological memory. This results in an initial delay in immune response, when innate immune responses are critical, but leads to more rapid and enhanced responses upon subsequent antigen exposure.

Innate and adaptive mechanisms are interdependent and many adaptive immune mechanisms exert their effects using the innate elements. Innate function is often greatly potentiated by factors produced by the adaptive immune response.

## INNATE IMMUNE MECHANISMS

### Humoral innate immune mechanisms

#### *Complement*

One of the most important humoral defenses is the complement system, of which the central component ([Fig. 27.2](#)) is C3b, the active product of cleavage of the C3 molecule. Antigen bound C3b acts as a powerful opsonin by interacting with neutrophil and monocyte C3b receptors. C3 is cleaved by one of three pathways. The classical (antibody-dependent) pathway requires specific antibody – antigen interaction. In the alternative pathway, microbial products, such as polysaccharides and endotoxin, directly activate another cascade of reactions involving serum protein factors B and D to form an alternative C3 convertase which is stabilized by factor P (properdin). In the lectin pathway, mannose binding lectin binds to bacterial sugars and interacts with serine proteases MASP1 and 2 to cleave C4. The lectin pathway is of crucial importance early in an infection prior to the production of specific antibodies and in young children.<sup>2</sup>

The fixing of C3b to the surface of a microorganism becomes self-amplifying, since C3b itself forms a component of the enzyme responsible for C3 cleavage. This is strictly controlled by a number of soluble and cell surface regulatory proteins. The later complement components C5–C9 produce a membrane-attack complex which can lyse cell membranes, a mechanism particularly important in the handling of systemic neisserial infections.

As well as lysis and opsonization, the complement reactions generate pharmacologically and chemotactically active by-products, such as the cleavage products C3a and C5a, for which there are cell surface receptors.

Cell surface complement receptors bind complement components and any associated cells or organisms, resulting in activation of other parts of the immune system. Complement receptor 1 (CR1, CD35, [Table 27.2](#)) is found on neutrophils, monocytes, erythrocytes, B lymphocytes and glomerular epithelial cells. It recognizes C3b- and C4b-coated particles and facilitates phagocytosis. Erythrocyte CR1 helps clear circulating immune complexes. CR2 (CD21), found predominantly on B lymphocytes and recognizing C3d, the main C3b breakdown product, is believed to modulate activity of these cells. It is the receptor for Epstein–Barr virus (EBV). CR3 (CD11b/CD18) on phagocytic cells and on natural killer (NK) cells recognizes inactivated C3b (C3bi) and is important in phagocytosis. CR4 (CD11c/CD18) weakly binds C3bi. CR3 and CR4 are members of a family of adhesion molecules, the leukocyte integrins, also involved in intracellular adhesion.

#### *Other acute phase reactants*

Serum levels of this diverse group of proteins, including clotting factors, amyloid proteins and C-reactive protein (CRP), rise rapidly at the onset of acute inflammatory responses. Their precise biological role is poorly characterized. CRP has some immunomodulating effects and acts as a nonspecific opsonin for bacterial phagocytosis.

Table 27.1 Principal cytokines

Cytokine	Other (previous) names	Produced by	Main actions
IL-1		Monocytes	Proinflammatory; fever; T cell activation
IL-2	T cell growth factor	T cells	T (mainly T <sub>H</sub> 1), NK cell activation/proliferation
IL-3	Multicolony stimulating factor	T cells	Proliferation of bone marrow progenitor cells
IL-4	B cell stimulating factor	T cells (T <sub>H</sub> 2)	T <sub>H</sub> 2 cell growth factor; B cell isotype switching especially to IgE
IL-5		T cells	T <sub>H</sub> 2 cytokine; activation and proliferation of eosinophils (and B cells)
IL-6		T, B cells monocytes	General cell growth and differentiation factor
IL-7	Lymphopoietin I	Bone marrow and thymic stroma	General cell growth factor
IL-8		T cells, monocytes, PMN	PMN activation, chemotaxis and adhesion
IL-9		T cells	T cell, mast cell growth and differentiation
IL-10	Cytokine synthesis inhibitory factor	T cells (T <sub>H</sub> 2) monocytes, mast cells	Inhibits T <sub>H</sub> 1 cytokine production
IL-11		Stromal cells	Growth factor similar in actions to IL-6
IL-12	NK stimulating factor	B cells, monocytes	Increases T and NK cell cytotoxicity; T <sub>H</sub> 1 growth and differentiation factor
IL-13		T cells (T <sub>H</sub> 2)	B cell isotype switching similar to IL-4
IL-14	High mol wt B cell growth factor	T, B cells	B cell growth and differentiation
IL-15		Stromal cells, monocytes	Similar actions to IL-2 (utilizes same receptor)
IFN α and β		Leukocytes-α Fibroblasts-β	Antiviral, antiproliferative
IFN γ	Macrophage activating factor	T cells (T <sub>H</sub> 1) NK cells	Macrophage activation, increased MHC expression, T <sub>H</sub> 1 effects
TNF α	Cachectin	Monocytes	Proinflammatory
TNF β	Lymphotoxin	T cells	Proinflammatory
GM CSF		Leukocytes	Increased myelopoiesis, increased cytokine production by macrophages, proinflammatory
G CSF		Leukocytes	Increased granulopoiesis, activates PMN, reduces inflammatory cytokine production
M CSF		Monocytes, T, B cells	Increased monocyte growth and differentiation, increased cytokine production
TGF β		Platelets, monocytes	Suppresses inflammation and cell proliferation

IL, interleukin; IFN, interferon; TNF, tumor necrosis factor; CSF, colony stimulating factor; GM granulocyte macrophage; G, granulocyte; M, monocyte; TGF, transforming growth factor; PMN, polymorphonuclear cells; T<sub>H</sub>1/T<sub>H</sub>2, T helper cells.

**Interferon**

Alpha- and beta-interferons are proteins produced by virally infected cells. They render other cells immune to virus infection by producing an antiviral state. Interferons increase NK cell activity, increase human leukocyte antigen (HLA) class I antigen expression on cells, and decrease cell growth including that of tumor cells. Interferon (IFN) gamma, although it has some antiviral effect, is primarily a cytokine which upregulates immune responses, particularly by enhancing intracellular killing of microorganisms such as mycobacteria.

**Iron-binding proteins**

Many bacteria require iron for growth, and decreasing its availability is one mechanism of defense used by the host. An avid iron-binding protein, lactoferrin, present in human milk, reduces the growth of *Escherichia coli*. The reduction of serum iron which occurs during infections increases the bacteriostatic effect of serum.

**Cellular innate immune mechanisms**

**Adhesion molecules**

These molecules and ligands help cell-to-cell association, essential for normal immune and inflammatory responses. Found on all cells of the immune system and on vascular endothelium, their expression is tightly controlled during inflammatory responses by cytokines such as the interleukins, tumor necrosis factor (TNF) alpha and IFN-gamma. Two groups of adhesion molecules (the selectins and integrins) are crucial for the migration of immune cells out of the bloodstream to areas of inflammation.

Interaction between the selectins and their ligands results in the transient endothelial interactions of ‘rolling’ and margination which occur early in inflammatory reactions. Beta-2 integrins are subsequently upregulated, and their expression is responsible for the firm tethering of neutrophils to the endothelium and their subsequent egress from the circulation. Integrin expression is greatly upregulated by the proinflammatory cytokines such as TNF-alpha or IL-1 beta.

**Effector cells**

Phagocytic cells include neutrophils and monocyte/macrophages. Bacterial phagocytosis requires migration of neutrophils to the site of infection (chemotaxis). Products of the acute inflammatory response, including cleaved complement fragments (e.g. C5a), act as chemoattractants in this process. Chemotaxis is followed by adherence to the bacterium and ingestion (phagocytosis). This is aided by opsonization, particularly by immunoglobulin G (IgG) and complement (C3b), which bind to bacteria and also phagocyte cell surface receptors Fc gamma and CR1/3 respectively, but also C-reactive protein and soluble forms of fibronectin. Following phagocytosis, lysosomes rapidly fuse with the bacterium-containing phagosome exposing the bacterium to lysosomal enzymes (e.g. myeloperoxidase) which are involved in killing and digestion. The process is accompanied by the generation of hydrogen peroxide, superoxide and hydroxyl radicals which aid bacterial killing. Neutrophil numbers and function are enhanced by the inflammatory response.

Monocytes and macrophages ingest and kill extracellular bacteria in a similar fashion to neutrophils but more slowly and less efficiently.

Table 27.2 Leukocyte antigens

Designation	Main cellular expression	Properties/function
<b>T cells</b>		
CD1	Thymocytes. Langerhans' cells	Unknown
CD2	Mature T cells	Sheep erythrocyte (E Rosette) receptor; LFA-3 ligand
CD3	Pan T cell marker	Part of T cell receptor complex
CD4	Helper/inducer T cells	MHC class II receptor; HIV receptor
CD5	Mature T cells. B cell subset (B1)	Unknown
CD8	Cytotoxic/suppressor T cells	MHC class I receptor
CD25	Activated T cells	IL-2 $\alpha$ receptor
CD28	T cells	CD80 receptor; T cell activation
CD38	Thymocytes Activated cells	Unknown
CD71	Activated T cells Thymocytes	Transferrin receptor
<b>B cells</b>		
CD19	Pre B and B cells	Unknown
CD20	Pre B and B cells	Unknown
CD21	B cells	Complement receptor (CR) 2 EBV receptor
CD22	Pre B and B cells	Unknown
CD23	B cells	Low affinity IgE receptor
CD40	B cells	Ig isotype switching
Surface immunoglobulin	B cells	Antigen receptor
<b>Monocytes</b>		
CD14	Monocytes	Receptor for lipopolysaccharide
<b>NK cells</b>		
CD16	NK, monocytes	Fc $\gamma$ receptor III
CD56	PMN, NK and some T cells	Unknown
<b>General</b>		
CD11a	Leukocytes	Cell adhesion ICAM-I receptor
CD11b	NK cells, M $\Phi$ , PMN	CR3
CD11c	NK cells, M $\Phi$ , PMN	CR4
CD15	PMN	Lewis X antigen
CD18	Leukocytes	$\beta_2$ integrin associated with CD11 antigens
CD34	BM progenitor cells	L selectin ligand
CD35	Monocytes, PMN, B cells	CR1
CD43	All leukocytes	Sialophorin
CD45	All leukocytes	Tyrosine phosphatase. T cell activation. Variable isoforms – see text
CD58	All leukocytes	LFA-3; CD2 ligand
CD80	Activated B and T mono	CD28 receptor
HLA class I	All leukocytes	Antigen presentation
HLA class II	B, monocytes, activated T cells	Antigen presentation

CD, cluster of differentiation; LFA, lymphocyte function-related antigen; MHC, major histocompatibility complex; HIV, human immunodeficiency virus; IL = interleukin; EBV, Epstein-Barr virus; NK, natural killer cells; PMN = polymorphonuclear cells; ICAM, intercellular adhesion molecule; M $\Phi$  = macrophage; BM, bone marrow; HLA, human leukocyte antigen.

However, they are important in defenses against intracellular microorganisms, including bacteria such as *Mycobacterium tuberculosis* and *Listeria monocytogenes*. Such pathogens are recognized directly by the cell surface mannose/fucose receptor interacting with microbial carbohydrate moieties such as mannose, or are opsonized and bound to Fc gamma or CR1/3 receptors. Monocytes are also cytotoxic against infected host cells or malignant cells. Macrophage activity is greatly enhanced by cytokines, particularly IFN-gamma, produced by T lymphocytes as part of the specific cell-mediated immune response.

NK cells are part of the non-T, non-B cell lymphoid population and recognize and kill tumor and virus-infected cells. They have surface receptors for the Fc fragment of IgG and, when 'armed' with specific IgG against a target cell antigen, kill by a process called antibody-dependent cellular cytotoxicity (ADCC). They also have killer-activating and killer-inhibitory receptors. Killer-activating receptors recognize a number of different cell surface molecules and, when engaged, issue a 'kill'

message, normally over-ridden by the killer-inhibitory receptors engaging major histocompatibility complex (MHC) I molecules. Loss of MHC I expression due to viral cell infection or malignancy removes the inhibitory control, resulting in cytotoxic cell killing.

## ADAPTIVE IMMUNE MECHANISMS

Adaptive responses are orchestrated by T and B lymphocytes, whose receptors are highly specific for the antigens presented to them. Receptor diversity is generated during B and T lymphocyte development by random recombination of different genetic elements. Binding of antigen to receptor leads to the generation of antigen specific effector immune mechanisms, such as antibody production or the generation of cytotoxic T lymphocytes. This process converts a naive T or B lymphocyte to an effector T lymphocyte or plasma cell respectively. As part of this process, memory T and B lymphocytes are also generated.

Fig. 27.1 Functional compartments of the immune system illustrating some of the more important interactions (dotted arrows). Area 1 is mainly involved in handling pyogenic bacteria. Area 2 is mainly involved with intracellular pathogens.

Antigen presenting cells (APCs) (e.g. specialized cells of the macrophage lineage called dendritic cells and also B lymphocytes) present antigens to T lymphocytes. APCs take up antigens, degrade them to small peptide fragments and express them on the cell surface in association with the MHC molecules. The T lymphocyte receptor (T cell receptor, TCR) will only recognize the peptide in association with a self MHC molecule. Some MHC polymorphisms provoke better responses than others to specific antigens, explaining part of the genetic variability in immune responsiveness. CD4 positive helper T lymphocytes respond to antigen bound within the groove of class II MHC molecules (HLA DR) whilst

CD8 positive cytotoxic T lymphocytes respond to antigen bound to class I (HLA AB) molecules. Other receptor ligand interactions between the APC and T lymphocyte, including adhesion molecules, are important for maximizing T lymphocyte stimulation and are essential for the initial stimulation of naive cells.

When presented, antigen sits in a groove in the MHC molecule where it can interact with a complementary groove in the TCR (Fig. 27.3). Some antigens (superantigens) crosslink the presenting cell MHC molecule with other nonvariable parts of the TCR chains, resulting in stimulation of large numbers of T lymphocytes in an antigen nonspecific way. This causes immune mediated inflammatory diseases such as toxic shock syndrome. Superantigens are usually microbial products such as exotoxins.

There are two arms of the specific immune system – antibody mediated and cell mediated.

**Antibodies**

These are immunoglobulins produced by B lymphocytes and their effector cells, plasma cells, in response to exposure to specific antigens, e.g. during infection or after vaccination. Sometimes, specific antibodies may be present in the serum without prior exposure to the relevant

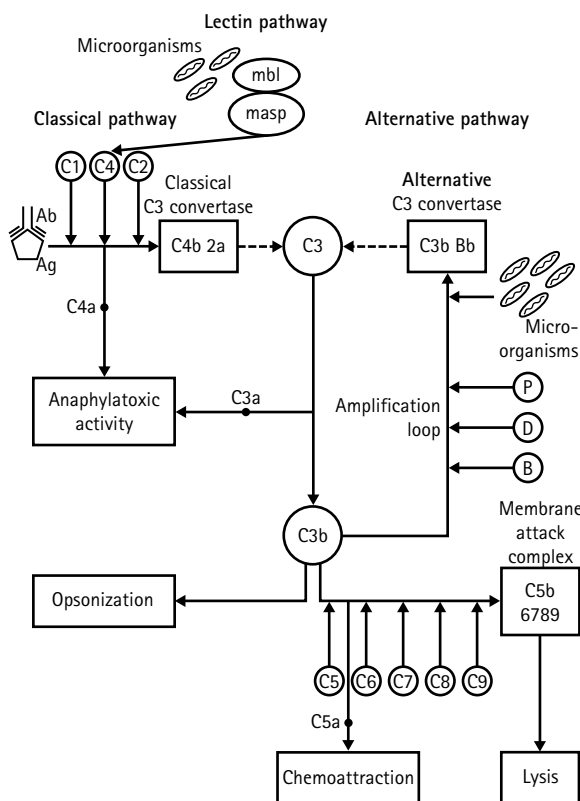

Fig. 27.2 The main features of the classical, alternative and lectin pathways of the complement system. Inactive cleavage and breakdown products are not shown.

Fig. 27.3 Antigen presentation.

Fig. 27.4 Basic structure of an antibody molecule. Heavy (H) and light (L) chains comprise variable regions ( $V_H$  and  $V_L$ ) – shown by solid bars – and constant regions ( $C_H$  and  $C_L$ ) open bars. Constant region domains ( $C_{H1}$ ,  $C_{H2}$  and  $C_{H3}$ ) are shown. Arrows indicate the site of pepsin-mediated cleavage to give Fc and Fab fragments.

antigen – so-called ‘natural’ antibodies, resulting from cross-reactivity between antigens, particularly nonprotein (polysaccharide) antigens.

The basic structure of the immunoglobulin molecule is shown in Figure 27.4. The variable region has a unique amino acid sequence, giving the antibody its unique specificity which ensures that there is an antibody complementary to every antigen that could be constructed. There are five main classes of immunoglobulin, each with its own structure and functions (Tables 27.3 and 27.4).

Immunoglobulin class or isotype is determined by the heavy chain. During B lymphocyte development, rearrangement of genes coding for the variable and constant parts of the immunoglobulin chain occurs (Fig. 27.5). One each of the V, D and J heavy chain genes is rearranged to lie adjacent to the relevant heavy chain constant region gene, so that transcription produces a single protein with a constant and a variable portion. Approximately  $10^{16}$  different receptors are generated. A similar process occurs during T cell development. Further rearrangement to bring a particular variable gene combination to lie adjacent to a different heavy chain constant region gene allows the B lymphocyte to switch to another antibody class (isotype) with the same antigen specificity. A mu chain is always produced first; class switching to other isotypes occurs later. Specific antibody diversity is created by the large number of possible combinations of variable region genes which can be selected and is increased further by a very high mutation rate in V genes and the effect of the enzyme deoxynucleotidyltransferase (TdT) during the

rearrangement process. A similar but slightly less complex process takes place with light chains, of which there are two types – kappa and lambda.

### IgM

This is the first antibody class produced in primary immune responses. For most antigens, there is a subsequent switching to other classes but for some, e.g. responses to the lipopolysaccharides of Gram negative bacilli, IgM remains the predominant class. Its large pentameric structure confines it to the intravascular space where it fixes complement.

### IgG

This is the main class of antibody produced in secondary immune responses. Functions include opsonization, complement fixation leading to C3 opsonization and complement mediated lysis, neutralization of toxins or viruses, and participation in antibody dependent cellular cytotoxicity. Though there is considerable overlap, the four subclasses of IgG tend to have different functions. In adults, antibodies to bacterial polysaccharides are predominantly of IgG2 subclass, but in children significant amounts are found in the IgG1 subclass. Responses to protein antigens are mainly in the IgG1 and IgG3 subclasses. The role of IgG4 is, as yet, unclear.

### IgA

This is the main antibody in secretions, where it forms a dimeric molecule consisting of two IgA subunits joined by a J chain and associated with a protective secretory piece synthesized by epithelial cells. In addition to protecting mucous membranes and the gastrointestinal tract from infection, IgA may have a role in limiting food antigen uptake from the gut. Serum IgA is mainly in monomeric form, though dimeric and trimeric forms are also found.

### IgD

This is mainly a surface molecule on the membrane of B lymphocytes which regulates B lymphocyte differentiation and maturation. Small amounts found free in plasma are not thought to have any biological role.

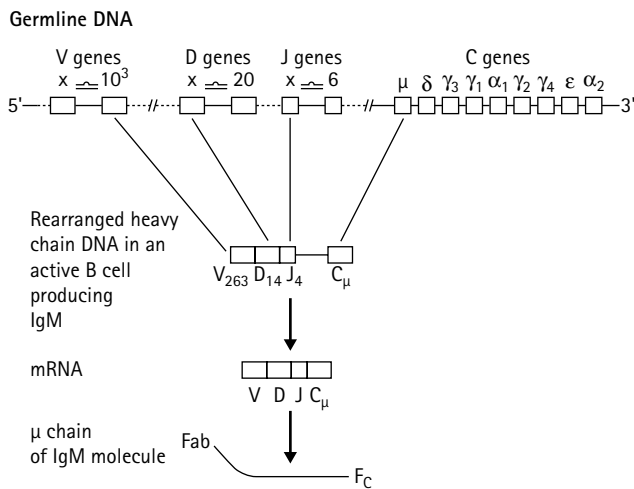

Table 27.4 Properties of IgG subclasses

	G1	G2	G3	G4
Mol wt ( $\times 10^{-3}$ )	150	150	165	150
% of total IgG (adults)	70	20	7	3
Biological half-life (days)	23	23	9	23
Complement-fixing ability	++	+	++	–
Fc receptor binding				
Monocytes	++	+/-	++	+/-
Neutrophils	++	+	+	+
Lymphocytes	+	+/-	+	+/-

Table 27.3 Properties of serum immunoglobulins

	IgG	IgM	IgA	IgD	IgE
Heavy chain	$\gamma$	$\mu$	$\alpha$	$\delta$	$\epsilon$
Light chain	$\kappa/\lambda$	$\kappa/\lambda$	$\kappa/\lambda$	$\kappa/\lambda$	$\kappa/\lambda$
Mol wt ( $\times 10^{-3}$ )	150	900	160–320	180	200
Polymeric status	Monomer	Pentamer	Monomer or dimer*	Monomer	Monomer
Sedimentation coefficient (Svedberg units)	6.7	19	7	7	8
Mean adult serum concentration (g/L)	12	1.5	3	0.03	0.001
Biological half-life (days)	23	5	7	2.8	2.3
Placental transfer	+	–	–	–	–

\* Trimeric IgA may also occur. Secretory IgA is in dimeric form.

**Fig. 27.5** Immunoglobulin heavy chain gene arrangements on chromosome 14 in germline configuration and showing an example of a rearrangement using V gene number 263,  $D_{14}$ , and  $J_4$  to produce a unique antigen binding site. In this example, the variable genes (V, D and J) have been combined with a  $\mu$  constant region heavy chain gene ( $C_\mu$ ) to produce a complete  $\mu$  chain of an IgM molecule.

### IgE

Mast cells and basophils have receptors for the Fc part of this molecule. Antigen binding may cause degranulation of the cells, triggering an immediate hypersensitivity response. Such reactions are often harmful rather than beneficial, but evolved as a mechanism for removing parasites.

### Antibody production

Antibodies are produced by B (bone marrow derived) lymphocytes. Naive B lymphocytes have membrane antibody which acts as a receptor for antigen. Initial stages of B cell development are antigen independent, but the final stages of B lymphocyte differentiation require stimulation with the appropriate antigen leading (after final class switching) to maturation into plasma cells. The full process requires the cooperation of antigen specific T helper (CD4 positive) lymphocytes. Isotype switching from IgM production to the other antibody classes is critically dependent on T/B lymphocyte interaction via the CD40 antigen on B lymphocytes and its ligand expressed on activated T lymphocytes (CD40L, CD154). The responses to some antigens, e.g. bacterial polysaccharides, can result in limited antibody production without T lymphocyte help. There is no immunological memory generated in such responses.

### Cell-mediated immunity

T (thymus-derived) lymphocytes predominate in immune responses to intracellular microbes and regulate immune responses by secreting cytokines and growth factors.

T lymphocytes are generated from bone marrow derived stem cells, but acquire functional capabilities during thymic maturation. Here the cells undergo a series of developmental stages including gene rearrangement to generate diversity in the variable domains of the TCR. They also become 'educated' with regard to self/nonself recognition so that self-reactive clones are deleted and only clones recognizing antigen in the context of self MHC are preserved.

The TCR, although not an immunoglobulin molecule, has a similar arrangement of constant and variable parts and the generation of diverse specificity is achieved along similar lines to the generation of antibody diversity in B lymphocytes. The TCR is a heterodimeric molecule with each chain having a constant and variable portion. The majority (>90%) of mature circulating T lymphocytes express alpha and beta

chains, the remainder are gamma and delta. Diversity is acquired in a method similar to that of the immunoglobulin molecule. A number of genes [artemis, recombinase activating genes 1 and 2 (RAG1, 2), DNA ligase 4, cernunnos-XLF] are critical for this gene rearrangement, and mutations in these genes lead to T-B- SCID (p. 1155).

During thymic maturation T lymphocytes also acquire important functional surface molecules. CD3 is constitutively expressed on T lymphocytes and is closely associated with the TCR (Fig. 27.3). Initially both CD4 and CD8 are expressed on the same cells, but only one of the molecules is retained. Most gamma delta T lymphocytes do not express CD4 or CD8. Their precise function is unclear, but they seem to play a role in mucosal defense and gut antigen clearance and tolerance.

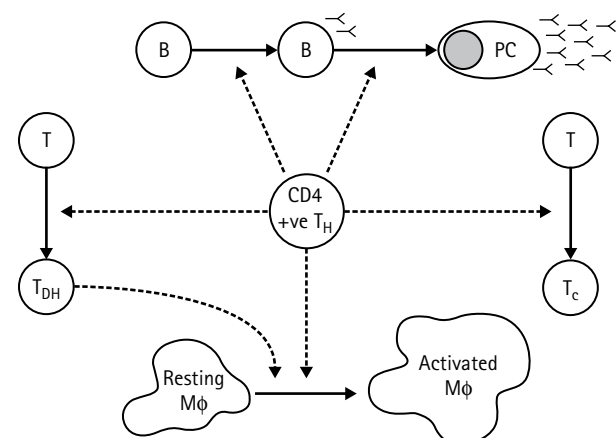

The primary effector cell in the adaptive response is the CD4+ T helper lymphocyte (Fig. 27.6). Once activated by antigen presentation these cells develop in one of two ways: the  $T_H1$  route with production of IL-2 and IFN-gamma whose main role is in stimulating macrophage function and cell-mediated immunity but also has effects on B lymphocytes including antibody class switching, particularly to IgG2.  $T_H2$  cells on the other hand produce predominantly IL-4 and IL-10 which promote antibody responses and class switching, particularly towards IgG1, IgG4 and IgE. Allergic responses and those against parasites are of  $T_H2$  type. Responses to an antigen may follow a  $T_H1$  or  $T_H2$  route depending on a complex set of circumstances. Once established these responses are self-amplifying in that production of IFN-gamma or IL-4 promotes  $T_H1$  and  $T_H2$  responses respectively and inhibits the other.

The functions of T lymphocytes can be summarized as:

1. help and regulation of antibody production by B lymphocytes;
2. cytokine production which stimulates and regulates other nonspecific immune effector cells;
3. secretion of growth and differentiation factors, e.g. colony-stimulating factors, B lymphocyte growth factors;
4. T lymphocyte-mediated specific cytotoxicity, e.g. against virus-infected cells or against foreign tissues.

### Signal transduction

Once T and B lymphocytes have engaged antigen via their specific receptors they must activate to generate the next step in the immune response. Cell surface receptors that have a signaling function are either transmembrane proteins or part of a complex of protein that contains intracellular signaling elements (Fig. 27.7). Both T and B lymphocyte receptor complexes have proteins with cytosolic tails containing immunoreceptor tyrosin-based activation motifs (ITAMs) that can be phosphorylated. After antigen binding, B and T lymphocyte receptors cluster on

**Fig. 27.6** Central role of CD4+ve T helper ( $T_H$ ) cell in immune responses.  $T_c$ , cytotoxic T cell;  $T_{DH}$ , delayed hypersensitivity T cell; Mφ, macrophage; B, B cell; PC, plasma cell.

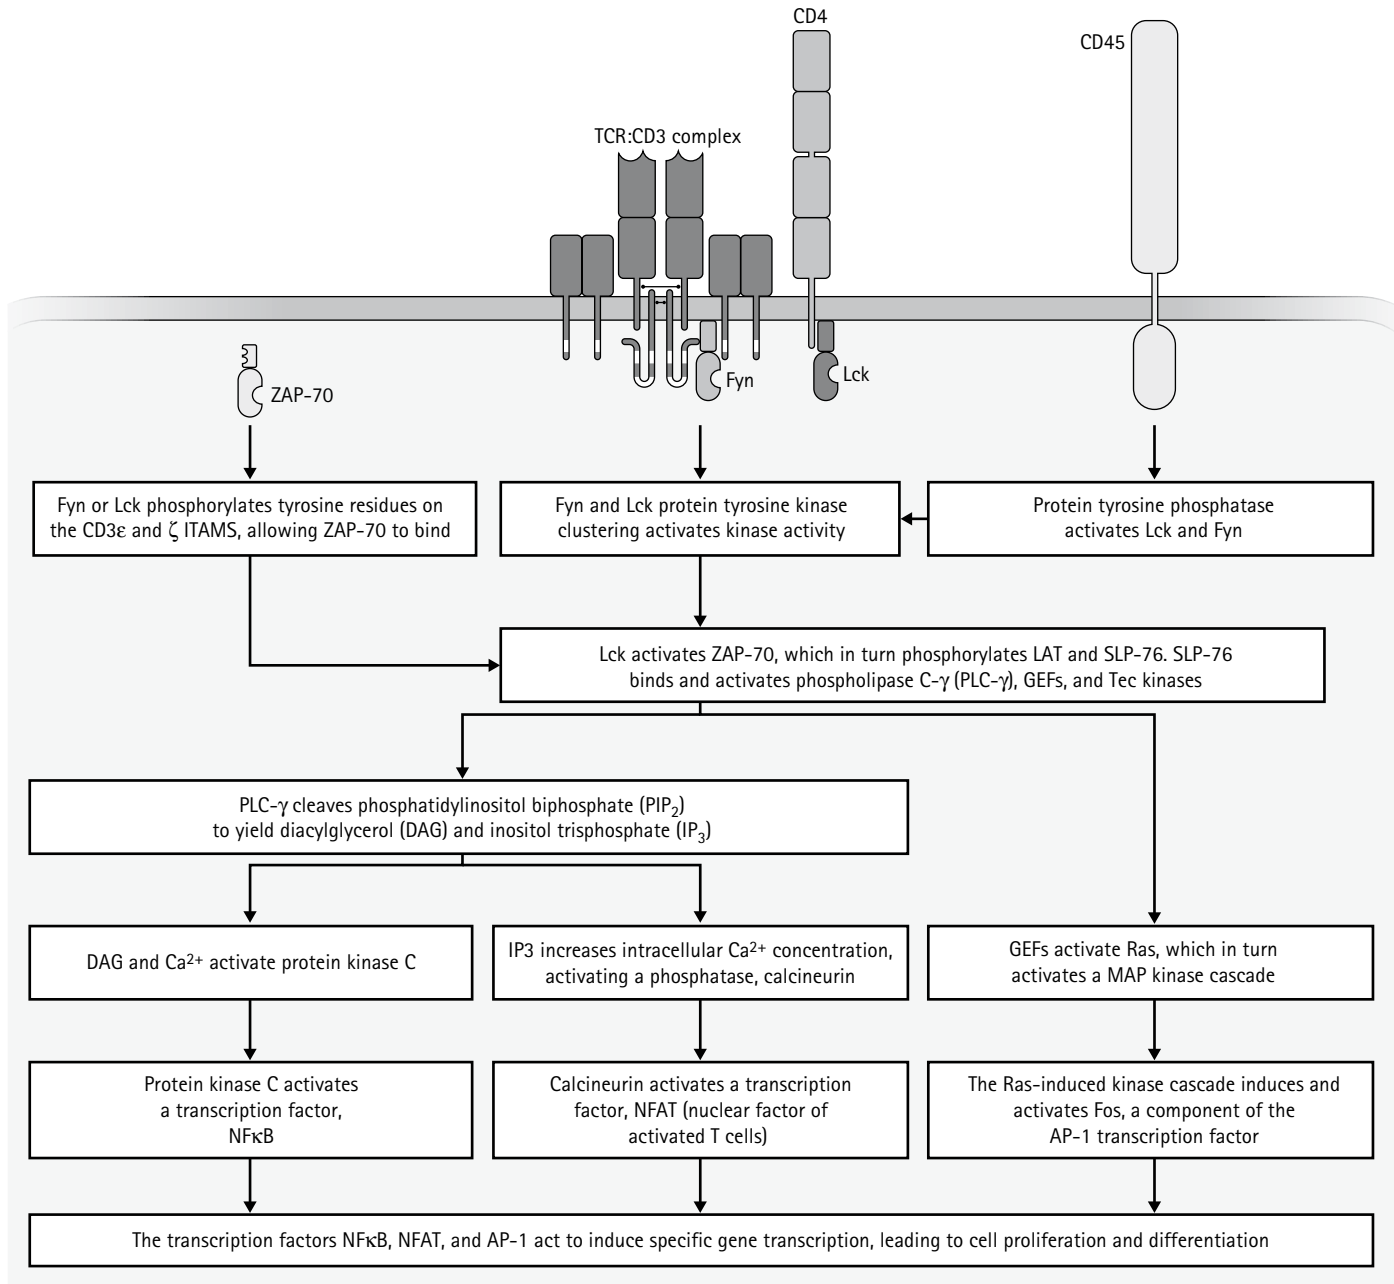

Fig. 27.7 Intracellular signaling pathways are induced following antigen-presenting cell/T cell receptor interaction. The T cell receptor (TCR) complex associates with Fyn, and the co-receptor (CD4/CD8) with Lck. Antigen/MHC binding to the TCR brings together the CD4 or CD8 co-receptor, TCR and CD45. The CD45 protein tyrosine phosphatase activates Fyn/Lck which in turn activate zeta chain associated protein (ZAP)-70. ZAP-70 activation signals through three separate pathways to activate three transcription factors, NFκB, NFAT and AP-1. These act on T cell genes in the nucleus to initiate gene transcription leading to T cell differentiation and proliferation. (Adapted from Janeway et al 2005<sup>4</sup> with permission.)

the surface of the lymphocyte which leads to the formation of a supramolecular adhesion complex (SMAC) in which the antigen receptors are co-localized with other cell surface signaling and adhesion molecules. This association between the APC and the T lymphocyte is termed the immunological synapse. Once clustered, the intracellular portions of antigen receptors associate with tyrosine kinases, in particular the Src family. This results in tyrosine phosphorylation of ITAMs in the receptor complex, and a cascade of intracellular proteins is activated. These include SH2 domain containing proteins, and small G proteins which transmit the signal to the nucleus after converting bound GTP to GDP. Antigen receptor signaling is enhanced by co-receptors that bind the same ligand; these include CD19, CD21 and CD81 for B lymphocytes.

## THE DEVELOPMENT OF THE IMMUNE SYSTEM

### PRENATAL DEVELOPMENT

T and B lymphocyte development commences very early in the gestation of the human fetus. Cells capable of responding in mixed lymphocyte culture or to the mitogen, phytohemagglutinin (PHA), and recognizable NK cells are present in the fetal liver from 6 weeks. T and B lymphocyte precursors are identifiable from 7–8 weeks and T lymphocyte precursors colonize the rudimentary thymus from the 9th week. By the second trimester, circulating lymphocytes with mature T lymphocyte surface markers including CD3, CD4 and CD8 are identifiable. Absence of these markers can be used for the antenatal diagnosis of SCID by fetal blood sampling (p. 1154). B lymphocyte precursors also originate in the fetal

liver, and mature in the bone marrow in mammals. Surface B lymphocyte markers, including surface immunoglobulin, can be detected by the second trimester, although at low levels.

Although the cellular elements of the specific immune system are present from early in gestation, their ability to respond to antigens, especially by making immunoglobulin, is limited until the time of birth.

The elements of the innate immune system also develop early in fetal life. Neutrophil precursors can be identified in the yolk sac. Mature neutrophils appear in the circulation in the second trimester but numbers are low until the onset of labor. C3 has been detected from 6 weeks of gestation. The serum levels of complement components, which are produced mainly by the fetal liver, rise slowly throughout fetal life.

## THE IMMUNE SYSTEM IN THE NEWBORN

The newborn immune system exhibits a physiological immunodeficiency<sup>5,6</sup> in full-term and preterm infants, but is more exaggerated in the premature and particularly marked in sick or stressed preterm infants. This accounts for the increased susceptibility to infection of the newborn, whether overwhelming group B streptococcal sepsis, or disseminated herpes simplex infection. Placentally transferred IgG partially offsets the deficiency. However, transfer of significant amounts of immunoglobulin (Fig. 27.8)<sup>7</sup> is a late event in gestation, and so preterm infants have significantly reduced levels; those at the limits of viability (23–24 weeks) have extremely low levels. The protective effect of maternal immunoglobulin depends on the mother having IgG antibody to the appropriate antigens and, in group B streptococcal sepsis, lack of maternal-type specific antibody to the relevant bacterial polysaccharides is a major risk factor. The newborn infant shows poor antibody responses, especially to T-independent antigens, poor ability to switch immunoglobulin isotypes and poor maturation of antibody affinity. These poor responses are a function of intrinsic B and T lymphocyte and APC immaturity. T lymphocyte responses are poor in neonates largely because of the high proportion of naive T lymphocytes which are more difficult to stimulate.

T lymphocyte surface marker expression differs between neonates and adults. There is a high CD4:CD8 ratio, a high expression of the thymocyte antigen CD38 and low numbers of cells expressing the gamma delta TCR. There is also a high proportion of B lymphocytes expressing the CD5 antigen (B1 cells). Expression of crucial signaling

molecules such as CD40L is also reduced. These differences resolve over the early months of life as a result of antigen exposure. Neonatal T lymphocytes have usually less than 10% of the CD45RO (memory) isoform and predominant expression of the CD45RA (virgin, naive) isoform. These proportions gradually reverse during childhood. Exposure to intrauterine infection may alter these neonatal patterns towards a more mature picture.

The overall balance of neonatal T lymphocyte responsiveness is tilted towards  $T_H2$  rather  $T_H1$  response. This may contribute to the susceptibility to intracellular bacterial pathogens, such as *Listeria monocytogenes* or *Salmonella* species, since defenses to these pathogens rely on a  $T_H1$  pattern response.

Nonspecific immune mechanisms are also immature at birth. Neutrophil bone marrow reserves are easily exhausted leading to neutropenia; chemotaxis and cell deformability may be reduced compared to values in adults or older children.<sup>8</sup> In contrast to the situation at other ages, neutrophil numbers and function have a tendency to deteriorate in the presence of infection or other stress.<sup>9</sup> Complement factor levels and function in a full-term infant are at approximately two thirds of the adult level, and often below one half in preterm babies. Alternative pathway factors are at relatively lower levels than classical pathway levels. The precise significance of these findings in predisposing to neonatal sepsis is not clear.

Low immunoglobulin and complement levels are directly proportional to gestational age. Depressed T lymphocyte function may occur in babies who have suffered severe intrauterine growth restriction. The latter has been demonstrated up to < 5 years of age, though the clinical significance of such findings is unclear.<sup>10</sup> The placental transfer of immunoglobulin in situations of severe intrauterine growth restriction is probably also compromised, though not all studies have confirmed this.<sup>11</sup>

## POSTNATAL DEVELOPMENT

Following birth the neonate is exposed to a wide variety of antigenic stimuli which trigger immunological maturation regardless of gestational age. Immunoglobulin production and specific antibody responses commence soon after birth. Initially, mostly IgM is produced, but gradually IgG responses develop and by 2 months of age infants are able to produce good IgG antibody responses to protein vaccines, such as tetanus toxoid. During this period, maternal IgG levels fall due to catabolism,

Fig. 27.8 Immunoglobulin levels in fetal life and in the first year postnatally. (From Miller & Steihm 1983<sup>7</sup> with permission.)

Fig. 27.9 Mean levels of IgG subclasses 1–3 in early life. Note the exaggerated fall and slow rise of IgG2 levels compared to IgG1 and IgG3. (Drawn from the data of Oxelius 1979<sup>12</sup>.)

and a physiological nadir in IgG level occurs at 3–6 months of age before the infant's production picks up (Fig. 27.8). Thereafter isotype levels rise at different rates: adult levels of IgM are achieved by 4–5 years, and IgG by 7–8 years, whilst serum IgA levels (and secretory IgA) rise only very slowly, not achieving adult values until teenage years.

The pattern of maturation of IgG subclass levels also varies. IgG2 shows a prolonged physiological trough compared to IgG1 and IgG3 (Fig. 27.9).<sup>12</sup> Though antibody responses to most protein antigens mature early, responses to many polysaccharide antigens do not. Most antipolysaccharide IgG antibody in adults is found in the G2 subclass, while in young children the G1 subclass contains these. There is a high degree of susceptibility to polysaccharide-encapsulated organisms such as pneumococcus in young children, and a lack of responsiveness of children under the age of 18–24 months to pure polysaccharide vaccines, such as the polysaccharide pneumococcal vaccine. Conjugation of the polysaccharide to a protein or peptide facilitates early responsiveness to both components as demonstrated by the high efficacy of *Haemophilus influenzae* type B (Hib) and the new pneumococcal conjugate vaccines.<sup>13</sup>

T lymphocyte immunity appears to mature rapidly in the early weeks of life following antigen exposure. T lymphocyte expression of CD40 ligand improves, as does cytokine production with the  $T_H2/T_H1$  balance shifting towards  $T_H1$ . However, the differences in T lymphocyte numbers and CD4:CD8 ratios between children and adults, and the unreliable responses of children to delayed hypersensitivity skin test antigens, such as *Candida* antigen, does suggest that maturation and development of the cell-mediated immune system continues through early childhood. Subtle immaturities in cell-mediated immunity probably account for the

increased susceptibility of young children to tuberculosis (TB), and of young infants to invasive salmonellosis and listeriosis.

## IMMUNODEFICIENCY DISORDERS: GENERAL PRINCIPLES

### CLASSIFICATION AND GENETICS

Immunodeficiency may be due to a primary (inherited) or secondary (acquired) defect. The WHO working party on immunodeficiency<sup>14</sup> has classified the primary disorders, and the main categories are listed in Tables 27.5A.B.<sup>14</sup> Figure 27.10<sup>1</sup> and Table 27.6 show the relative frequencies of the various disorders. The overall incidence of any significant immunodeficiency disorder (excluding selective IgA deficiency) has been estimated at 1 in 10 000.

Many of the primary disorders have a genetic basis.<sup>14</sup> Identification of the responsible gene(s) has been achieved in an increasing number of conditions. Chromosomal aberrations may be found in some immunodeficiency disorders. Deletions of heavy chain constant region genes have been described in a minority of patients with immunoglobulin class or subclass deficiencies, while deletions on chromosome 18 (in some cases of IgA deficiency) and on chromosome 22 (most cases of DiGeorge syndrome) have also been recorded. Immunodeficiency is often a feature of chromosomal breakage/repair disorders, such as ataxia telangiectasia.

The molecular basis of many of the primary immunodeficiency disorders has been elucidated. Usually several different mutations in the relevant gene have been described. Occasionally mutations at certain points are associated with partial forms of disease, presumably because of some residual function of the protein concerned. Recognition of the molecular pathways involved enhances understanding of the immune response, and identification and clarification of precise molecular mechanisms enable focused treatment of primary immune deficiencies, e.g. X-linked hyper-IgM used to be considered an antibody deficiency, although immunoglobulin replacement does not prevent liver disease secondary to *Cryptosporidium parvum* infection. Recognition of the primary T lymphocyte defect has led to curative hemopoietic stem cell transplant (HSCT) in selected patients. Identification of the genes involved enables genetic diagnosis (including antenatal diagnosis) and involves a number of techniques including restriction fragment length polymorphism (RFLP) and single strand conformational polymorphism (SSCP) analysis.

### DIAGNOSIS AND INVESTIGATION OF IMMUNODEFICIENCY

A careful history and examination will help determine which children should be investigated further and the nature and extent of investigations, and should precede any laboratory tests.

Table 27.5A Primary immunodeficiencies – predominantly antibody deficiency (Adapted from Notarangelo et al 2006<sup>14</sup>)

Immunodeficiency	Defect	Inheritance
X-linked agammaglobulinemia	Btk protein	XL
Autosomal recessive hyper-IgM syndromes	AID, CD40, UNG	AR
Common variable immunodeficiency	Unknown – some closely linked to C4 gene	Varied (occasionally AR or AD)
Ig heavy chain deletions	Deletion at Ig heavy chain locus (14q32)	AR
Ig kappa chain deletion	Mutation in Igκ chain locus (2p11)	AR
Selective IgA deficiency	Unknown – some closely linked to C4 gene	Varied (occasionally AR or AD)
IgG subclass deficiency (± IgA deficiency)	Unknown	Unknown
Antibody deficiency with normal immunoglobulin levels	Unknown	Unknown
Transient hypogammaglobulinemia of infancy	Unknown	Unknown

AD, autosomal dominant; AR, autosomal recessive; XL, X-linked.

**Table 27.5B** Combined immunodeficiencies (Adapted from Notarangelo et al 2006<sup>14</sup>)

Immunodeficiency	Defect	Inheritance
CD40 ligand deficiency (X-linked hyper-IgM syndrome)	CD40 ligand	XL
Wiskott-Aldrich syndrome (WAS)	WAS protein	XL
X-linked lymphoproliferative disease	SLAM-associated protein	XL
DiGeorge anomaly defect chromosomal deletion (usually 22q11.2)	Developmental field	Sporadic (some AD)
Cartilage-hair hypoplasia	RMRP gene	AR
Ataxia telangiectasia	ATM protein	AR
Nijmegen breakage syndrome	NBS1 (nibrin) gene	AR
Ataxia telangiectasia-like syndrome	Mre11	AR
DNA Ligase 4 deficiency	LIG4	AR

AD, autosomal dominant; AR, autosomal recessive; XL, X-linked.

**Table 27.5C** Defects of phagocytic function (Adapted from Notarangelo et al 2006<sup>14</sup>)

Immunodeficiency	Defect	Inheritance
XL chronic granulomatous disease	Killing defect gp91phox	XL
AR chronic granulomatous disease	Killing defect gp22phox, gp47phox, gp67phox	AR
Leukocyte adhesion deficiency type I	β integrin (CD18)	AR
Leukocyte adhesion deficiency type II	CD15	AR
Neutrophil G6PD deficiency	Neutrophil G6PD	XL
Myeloperoxidase deficiency	Myeloperoxidase	AR
AR severe congenital neutropenia	Elastase	AR
Chediak-Higashi syndrome	Lyst gene	AR
GrisCELLI syndrome	Rab27a gene	AR
Primary hemophagocytosis	Perforin	AR
	MUNC13-4	AR
	Syntaxin 11	AR
XL severe congenital neutropenia	WAS activating mutation	XL
Mycobactericidal defect	IFN γ receptor 1 deficiency	AR
	IFN γ receptor 2 deficiency	AR
	IL-12 receptor deficiency	AR
	IL-12 deficiency	AR

AR, autosomal recessive; G6PD, glucose-6-phosphate dehydrogenase; WAS, Wiskott-Aldrich syndrome; XL, X-linked.

**HISTORY**

Pregnancy and birth history may provide information regarding possible congenital infection, intrauterine growth retardation or prematurity, all of which are associated with immune defects. Delayed separation of the umbilical cord, in the absence of local infection, may suggest a neutrophil defect. Most children will present with an infective problem. The

**Table 27.5D** Complement deficiencies (Adapted from Notarangelo et al 2006<sup>14</sup>)

Component	Inheritance	Main clinical associations
C1q	AR	SLE, MPGN, pyogenic infections
C1r*	AR	SLE
C1s*	AR	SLE
C4	AR	SLE
C2	AR	SLE, MPGN, HSP, pyogenic infections
C3	AR	Severe pyogenic infections
C5	AR	Neisserial infections, SLE
C6	AR	Neisserial infections, SLE
C7	AR	Neisserial infections, SLE
C8	AR	Neisserial infections, SLE
C9	AR	Neisserial infections (less marked than for C5-8 deficiency)
Factor D	AR	Neisserial infections
Properdin	XL	Neisserial infections
C1 esterase inhibitor	AD	Hereditary angioedema
Factor H	AR	Hemolytic uremic syndrome, MPGN
Factor I	AR	Pyogenic infections
MBP deficiency	AR	Pyogenic infections, usually asymptomatic
MASP2 deficiency	AR	SLE, pyogenic infections

AD, autosomal dominant; AR, autosomal recessive; HSP, Henoch-Schönlein purpura; MPGN, membranoproliferative glomerulonephritis; SLE, systemic lupus erythematosus; XL, X-linked; MBP, mannose-binding protein; MASP2, mannose-binding protein-associated serine protease 2. NB SLE is the most common immune complex disorder in complement deficiencies.

\* C1r and C1s deficiency usually occur together.

**Fig. 27.10** Relative distribution of primary immunodeficiencies, based on combined experience from Japan, Switzerland and USA, excluding cases of asymptomatic selective IgA deficiency. The T cell deficiency group includes patients with combined cell-mediated and antibody deficiencies.

**Table 27.6** Incidence of some primary immunodeficiencies

Immunodeficiency	Incidence
Severe combined immunodeficiency	1 in 66 000
DiGeorge syndrome	1 in 4000
Common variable immunodeficiency	1 in 50 000
Chronic granulomatous disease	1 in 181 000
Selective IgA deficiency	1 in 500
X-linked agammaglobulinemia	1 in 250 000

age of onset of infections, their site, proven or suspected organisms and time to recovery with conventional treatments are all important considerations. An immunodeficient child is likely to have more infections which take longer to resolve or have an atypical course compared to other children. The type of organism involved, including the occurrence of atypical infections, should direct further investigations (Table 27.7). The occurrence of frequent upper respiratory tract infections (URTI) alone in a young child is not indicative of an underlying immune defect unless associated with frequent bacterial infections. There are a few studies on the frequency of URTI, but clinical experience suggests that up to eight URTI per year is normal in the preschool years. When evaluating the number of infections, other factors such as parental smoking, attendance at daycare and anatomical problems should be considered. Infections with common organisms may run an atypical course in that they are unusually severe, e.g. hemorrhagic chickenpox, or they fail to respond to standard treatments, e.g. a bacterial pneumonia which fails to respond to appropriate antibiotic therapy. Alternatively, infections may be caused by uncommon (atypical) organisms which are in themselves highly suggestive of immunodeficiency, e.g. *Pneumocystis carinii* pneumonia.

The history should include inquiries about related problems associated with immunodeficiency disorders. Failure to thrive is common, and may be associated with diarrhea due to chronic or recurrent infection or autoimmune enteropathy. Evidence of end-organ damage, such as a cough productive of sputum consistent with bronchiectasis, should also be sought. Allergic/atopic problems are common and may be unusually severe. Autoimmune and malignant diseases, though not common, have an increased incidence. Taking a careful family history may reveal other children with unusual or fatal infectious complications in keeping with an autosomal recessive or X-linked pattern of inheritance. A history of consanguinity should be sought. Some tactful inquiries to ascertain whether the parents have any risk factors for infection with the human immunodeficiency virus should be made as infection with this virus is often a differential diagnosis. In some disorders, e.g. IgA deficiency, there may be a family history of collagen vascular or other immune mediated disease. Older relatives who are carriers of or who are affected by milder variants of primary immune defects may have autoimmune manifestations [e.g. mouth ulcers and systemic lupus-erythematosus variant in chronic granulomatous disease, (CGD)] or

have a history of malignant disease [lymphoma in X-linked lymphoproliferative disease, XLP, or Wiskott–Aldrich syndrome, (WAS)].

## EXAMINATION

General physical examination should be directed towards potential sites of infection, including the throat, ears and sinuses and examination of the oral cavity and napkin area for candidiasis. The presence or absence of lymphoid tissue should be noted, as should cutaneous problems consistent with an immune defect. In more severe antibody states such as X-linked agammaglobulinemia, there is a lack of tonsils and lymphoid tissues. Signs of end-organ damage from infections, such as clubbing and respiratory abnormalities, must be sought. Some diseases may have specific physical signs, such as oculocutaneous albinism in Chediak–Higashi syndrome, typical facies and/or cleft palate in DiGeorge syndrome, telangiectasia or neurological abnormalities in ataxia telangiectasia, and disproportionate short stature in some forms of combined immunodeficiency (see cartilage–hair hypoplasia, p. 1160).

## DIAGNOSTIC IMAGING

Radiological evaluation, directed by findings from history and examination, may be useful. The exception is in DNA repair defects (see below) where the effects of exposure to ionizing radiation may be harmful, and X-ray and computerized tomography (CT) evaluation should be limited as much as possible. Magnetic resonance imaging (MRI) and ultrasound are safe alternatives.

Evidence of bony abnormalities may support a diagnosis of adenosine deaminase deficiency, Shwachman–Diamond syndrome or other dysplasias associated with immune defects. Dilatation of the common bile duct may be suggestive of sclerosing cholangitis, associated with a number of combined immunodeficiencies especially CD40 ligand deficiency.<sup>15</sup> Careful review of chest radiographs may suggest bronchiectasis, and should prompt high resolution CT imaging. Although thymic absence on anterior posterior and lateral chest radiographs is consistent with a combined immune defect in infants and young children, thymic atrophy may also occur in response to stress (e.g. infection) and this finding is not diagnostic.

## LABORATORY INVESTIGATION

Two main questions need to be addressed: which children to investigate, and how extensively to investigate selected children. The following should trigger investigation: family history consistent with immune deficiency, single infection with an unusual/opportunistic organism, single infection which is atypically severe, has an atypical course or occurs at an atypical age, recurrent minor bacterial infections [e.g. otitis media > two per year despite appropriate ear, nose and throat (ENT) management, resulting in significant school absence], or more than one episode of serious bacterial infection.

Laboratory investigations can be directed to a certain extent by the organism causing infection (Table 27.7) and the age of the child.

The laboratory investigations range from those readily available in all centers, to highly specialized tests performed in a few research centers. Only a small proportion of children presenting with recurrent infections require complex investigation; most can be adequately investigated using a few relatively straightforward tests.

## Hematology

Much can be learnt from a full blood count and blood film examination. Modern analyzers rapidly perform a white count and differential. Neutropenia is readily detected. If cyclical neutropenia is suspected, twice weekly counts should be performed for 8 weeks as the nadir may be brief and easily missed. Bone marrow aspiration should be considered in neutropenic children to distinguish between failure of production and increased peripheral destruction, and to exclude a myelodysplastic or

**Table 27.7** Examples of association between infecting organisms and most likely type of immune defect

Organism	Candidate immune defect
<i>Pneumococcus</i> , <i>Haemophilus influenzae</i>	Antibody, complement
<i>Staphylococcus</i>	Neutrophil
<i>Meningococcus</i>	Complement
Gram negative bacteria	Neutrophil
<i>Salmonella</i>	Type 1 cytokine defects, cell-mediated
<i>Cryptosporidium</i>	Cell-mediated
<i>Giardia lamblia</i>	Antibody, cell-mediated*
<i>Mycoplasma</i> spp.	Antibody
<i>Candida albicans</i>	Cell-mediated, neutrophil, monocyte
<i>Aspergillus</i> spp.	Neutrophil
Herpes viruses (e.g. CMV)	Cell-mediated
Enteroviruses	Antibody, cell-mediated
Other viruses (e.g. measles)	Cell-mediated
Mycobacteria (typical and atypical)	Type 1 cytokine defects
Bacille Calmette–Guérin (BCG)	Cell-mediated, type 1 cytokine defects

\* particularly patients with HIV.

malignant process. Neutrophilia in the absence of overt infection suggests a neutrophil adhesion defect or functional problem (e.g. CGD). Lymphopenia, using appropriate age related ranges (see Appendix), is highly suggestive of a combined immunodeficiency of primary or secondary etiology,<sup>16</sup> although SCID can occur in the presence of a normal lymphocyte count. Nucleated red cells in infants and abnormal leukocyte morphology in sick children may render a manual differential necessary. Abnormal leukocyte granules are characteristic of Chediak–Higashi syndrome. Platelet volume is universally low in Wiskott–Aldrich syndrome, and is a rapid and very reliable diagnostic pointer.<sup>17</sup>

## TESTS OF INNATE IMMUNITY

### Complement

C3 and C4 can be routinely measured in pathology departments using nephelometry (see below); reference ranges for C3 are well defined. However, null alleles for C4 are present at a relatively high frequency in the population so that the significance of an isolated low C4 in an individual with recurrent infections is less certain. Furthermore, normal levels of C3 and C4 do not exclude deficiencies of other complement components. It is therefore better to assess the functional integrity of the complement pathway using assays which test the ability of patient serum to lyse sensitized erythrocytes. All assays measure the intactness of one activation pathway plus the final common effector pathway (formation of the membrane attack complex). The species of erythrocyte used in the assay and chelation of magnesium and/or calcium determines whether components of the classical pathway (CH50/CH100 or THC) or alternative pathway (AP50) are assayed. Deficiency in any one component will result in a failure of lysis. However the most common reason for failure of lysis is active infection, with consumption of complement components, or degradation of complement components if the sample is not separated and frozen within 2 h of venesection. If repeat testing shows a persistent abnormality, evaluation of individual complement components should be performed.

Assays for the activity of the lectin pathway are not widely available, although assay of serum concentrations of mannose binding lectin by enzyme linked immunosorbent assay (ELISA) is available in some centers. Polymorphic variants within the MBL gene affect serum concentrations of the protein.<sup>18</sup>

### Neutrophil function tests

Neutrophil function has three main components: chemotaxis, phagocytosis and activation of the respiratory burst. Neutrophil function tests are difficult as neutrophils rapidly activate upon venesection and also die quickly. Historically, a wide range of neutrophil function tests have been performed, although their validity is questionable. This particularly applies to assays of neutrophil chemotaxis.

### Chemiluminescence

This test evaluates the opsonizing capacity of patient serum, the ability of neutrophils and monocytes to phagocytose and activation of the respiratory burst. The use of autologous or third party serum can be used to distinguish defects in opsonization from defects in the respiratory burst. Phagocytosis of organisms by neutrophils and monocytes results in the activation of the respiratory burst and the production of oxygen free radicals. These react with oxidizable substances on microbes, such as unsaturated lipids, nucleic acids and peptides, to form unstable intermediates. When these intermediates return to their original state, light energy is emitted. This chemiluminescence is readily measured with a spectrophotometer or chemiluminometer. Such assays are being superseded by flow cytometric assays (see below).

### Nitroblue tetrazolium reduction test

Nitroblue tetrazolium (NBT) is a yellow dye readily taken up by phagocytes and, upon stimulation [for example with phorbol myristate acetate (PMA)], is reduced to the purple dye formazan by the oxidative burst. In normal individuals, at least 95% of neutrophils should contain a purple deposit in stimulated cells. In CGD, less than 1% of neutrophils reduce NBT.

Carrier mothers of the X-linked disease can be detected by this method; they show an intermediate level of NBT reduction (20–80%) (Fig. 27.11). In experienced hands, this is a rapid and sensitive test for CGD.

## Flow cytometric assays of neutrophil function

### Phagocytosis

Fluorescently labeled organisms or inert agents can be used to assess the phagocytic ability of neutrophils. This assay is still primarily a research tool, but has the advantage of being able to study the phagocytic capability of the neutrophil to different organisms, and may help define the defect in undefined immunodeficiencies. Comparison of phagocytosis with autologous and control serum can be used to assess opsonization.

### Oxidative burst

Neutrophils take up dihydrorhodamine, and activation of the respiratory burst by preincubation with PMA or other stimuli results in fluorescence within cells, which can be assessed using the flow cytometer. As with an NBT, carriers for CGD can also be detected.

### Enzyme assays

Neutrophil killing defects may also occur in deficiency states of myeloperoxidase and glucose-6-phosphate dehydrogenase (G6PD), which can be assayed separately.

## TESTS OF ADAPTIVE IMMUNITY

### Test of humoral immunity

#### Immunoglobulins

IgG is the predominant circulating immunoglobulin. Smaller amounts of IgA, IgM, IgD and IgE are found in serum. A reduced or absent gamma globulin portion may be seen in serum electrophoresis in significant hypogammaglobulinemia. IgG, A and M are routinely quantified by nephelometry. This technique involves mixing of a known quantity of antibody to the test protein (in this case IgG, A or M) with serum containing an unknown quantity of the protein. Immune complexes form which will scatter light, the amount of light scattered being proportional to the quantity of protein within the sample. Results must be evaluated with reference to age-specific normal ranges, as production of all five classes of immunoglobulin is low at birth and gradually matures over the first 5 years of life. Immunoglobulin can be lost through the gut or urinary tract. Thus, low Ig levels can only be attributed to a production defect if gut or renal losses have been excluded and the serum albumin is within the normal range. A number of catabolic states, such as myotonic dystrophy, can also lower total immunoglobulin levels.

IgE is measured using a variety of techniques, including ELISA and automated solid-phase ELISAs. Measurement of IgE is indicated if hyper-IgE syndrome is included in the differential diagnosis.

IgD is present in the serum in very low concentrations. It may be non-specifically increased as a part of multiple inflammatory reactions, but is not used as part of the routine assessment of immune deficiency. IgD is not routinely measured unless a periodic fever syndrome is suspected (see Ch. 28).

#### IgG subclasses

IgG subclasses are commonly measured by nephelometry or radial immunodiffusion. Results should be interpreted in the light of age-specific normal ranges. The utility of measuring IgG subclasses in children under 2 years of age, or if the total IgG is low, is debatable. In addition, approximately 10% of the normal population have undetectable IgG4, and normal ranges should be adjusted to reflect this.

#### Measures of *in vivo* antibody responses

The ability of the immune system to produce functional antibody is more important than the amount of circulating antibody. Functional tests of IgG production rely on measuring antibody titers to antigens to which the child is known to have been exposed either naturally or by vaccination. Responses to protein antigens such as tetanus, diphtheria and the conjugated Hib vaccine are widely available. However, although normal ranges

Fig. 27.11 Slide nitroblue tetrazolium (NBT) reduction test. (a) Normal subject. Neutrophils have taken up and reduced NBT to form a dense brown/black deposit. (b) Patient with chronic granulomatous disease. None of the cells has produced the deposit due to failure to reduce the NBT.

for antibody titers exist these are not well validated for antigens other than Hib, and may not be a true reflection of immunological memory. If antibody titers are low, booster vaccinations should be given to assess the memory response. In children over 2 years of age, administration of 23 serovalent polysaccharide vaccine (Pneumovax®) is useful to assess the ability to respond to carbohydrate antigens. Loss of this response may be the first sign of an evolving immunodeficiency in patients with common variable immunodeficiency or WAS. However, with the introduction of heptavalent conjugated pneumococcal vaccine into the national immunization program, assessment of pneumococcal polysaccharide antibodies is difficult as the Pneumovax® assay result is not possible to interpret if the child has received conjugate pneumococcal vaccine. Assessment of antibody responses to common respiratory viral pathogens and varicella zoster may provide useful additional information, although negative tests in the absence of microbiologically proven disease are difficult to interpret.

The optimal test of *in vivo* antibody production is assessment of IgM and IgG responses and rate of clearance to a novel antigen whose clearance is dependent on opsonization by a specific antibody. The harmless bacteriophage  $\phi$ X174 can be administered intravenously for this purpose, but this investigation is rarely used in current practice.<sup>19,20</sup>

### Cell-mediated immunity

Humoral and cell-mediated immunity do not exist in isolation. Cell-mediated defects are likely to result in a degree of humoral immunodeficiency as the latter is dependent on the former for help in making an antibody response with memory.

#### Quantification of cell numbers

Cell-mediated immunity can be assessed by measuring the number and function of cells. Lymphocytes can be enumerated using flow cytometry, which uses fluid dynamics to separate cells into a single cell stream, passing through beams of laser light to scatter the light with a pattern determined by their size and granularity. The scattered light is detected by photon multiplier tubes. The different light scatter properties of cells enable populations of neutrophils, monocytes and lymphocytes to be differentiated. Lymphocytes can be characterized further by

cell surface markers, tagged with monoclonal antibodies, whose fluorescent labels are excited by incident light beams (Fig. 27.12, Table 27.8). The number of cells staining with a particular monoclonal antibody can be expressed as a percentage of the lymphocyte pool or as an absolute number. Proportions of different lymphocytes and absolute numbers vary with age, and reference should be made to published age-related normal ranges.<sup>21,22</sup> Approximately 60–80% of circulating lymphocytes are T lymphocytes, with 10–20% B lymphocytes and 5–15% NK cells.

#### Functional tests of cell-mediated immunity

**In vitro lymphocyte proliferation assays.** When lymphocytes encounter antigen *in vivo*, they upregulate activation markers and proliferate, without which an effective immune response cannot occur. This can be mimicked *in vitro* by culturing lymphocytes for a defined time period with appropriate stimuli and using the incorporation of tritiated thymidine or a nonradioactive marker such as bromodeoxyuridine into the DNA of dividing cells as a surrogate measure of cell proliferation. A range of stimuli can be used. Plant lectins, e.g. PHA and concavalin A, act as potent T lymphocyte mitogens and cause high levels of proliferation in normal cells. A more physiological assessment of proliferative capacity can be obtained using a monoclonal antibody to the T lymphocyte surface protein, CD3, which results in direct receptor stimulation, or by using a recall antigen such as tetanus. Proliferation tests of *in vitro* B lymphocyte function, e.g. using pokeweed mitogen and EBV, are rarely indicated in modern clinical practice. The results of responses to recall antigens need to be interpreted in the light of previous exposure, which reduces their clinical utility in children. Mixed lymphocyte cultures (MLC) are a modification of lymphocyte proliferation assays where the stimulating cells are irradiated lymphocytes from an HLA disparate donor. MLC responses may be useful in assessing the suitability of donors prior to HSCT.

**Other measures of lymphocyte function.** As well as dividing upon stimulation, T lymphocytes produce a range of cytokines (e.g. IFN- $\gamma$ , IL-2) and express activation markers on their surface (e.g. CD69, CD25, MHC II). The latter may be detected after only a few hours of incubation with an appropriate stimulus. Neither of these assays provides the same

**Fig. 27.12** Flow cytometric lymphocyte assay. Both plots show isotype control and staining for common gamma chain using flow cytometry. The control has normal levels of expression, represented by a shift in the histogram peak. Surface expression is lacking in the patient, enabling rapid molecular diagnosis of gamma chain deficient SCID.

information as that given by formal proliferation assays. Rare immune defects have been described with aberrant cytokine production, and cytokine assays may be useful in this context.

**In vivo tests: delayed hypersensitivity skin tests.** Delayed hypersensitivity skin tests can be performed using a number of common antigens, including those derived from candida, streptococcus, mumps and tetanus toxoid. Induration at the site is indicative of an intact cell-mediated immune response to the test antigen and makes it unlikely that the patient has a significant cell-mediated immune defect. Responses are dependent on established memory. Corticosteroids and some intercurrent viral infections may abrogate the response, which limits their clinical utility in children. They may, however, be useful in circumstances where in vitro lymphocyte proliferation assays are not readily available.

**Definition of molecular defects**

**Protein assays.** The genetic basis of an increasing number of immunodeficiencies is well defined; many occur because a surface or cytoplasmic signaling protein is absent or defective. In most cases a defect in the gene

coding for the protein results in either no protein expression, expression of low amounts, or expression of abnormally sized protein. These abnormalities can be detected using a combination of Western blotting (Fig. 27.13) and flow cytometry.<sup>23</sup> These are highly specialized investigations available in a limited number of centers.

**Table 27.8** Common markers used to identify cell types

Cell type	Detected with fluorescent monoclonal light antibody to
All T lymphocytes	CD3
T helper cells	CD4
Cytotoxic T lymphocytes	CD8
B lymphocytes	CD19 or CD20
Natural killer cells	CD16 and CD56 or CD57
Memory T lymphocytes	CD45RO
Naive T lymphocytes	CD45RA

**Fig. 27.13** Western blotting for btk protein, defective in X-linked agammaglobulinemia. Protein lysates are made from mononuclear cell extracts from peripheral blood. Btk is concentrated by immunoprecipitation with a btk specific antibody. Immunoprecipitates are then subjected to electrophoresis, which separates the proteins on the basis of size. Gels are incubated with a second anti-btk antibody to allow specific detection. Btk is seen in the control and patient 1, who lacked B cells but did not have X-linked agammaglobulinemia. Patient 2 lacked btk expression, and a mutation in btk was later defined.

**Genetics.** In the presence of an appropriate history or abnormal protein expression, genetic analysis may be undertaken. Genes can be screened using SSCP analysis or direct sequencing of genes. However, not all genetic differences between individuals result in clinical problems. Significant numbers of polymorphisms exist within the human genome which may have no clinical effects.

**Carrier testing.** Appropriate genetic counseling should be offered to all families. Once mutations have been defined, parents can be tested for carrier status. In a number of conditions nongenetic tests may be useful in determining carrier status. These include the NBT, in which intermediate numbers of neutrophils will reduce NBT in mothers who carry the mutation for X-linked CGD, and intermediate levels of adenosine deaminase (ADA) in carriers of ADA deficiency. Females randomly inactivate one of their X chromosomes in all cells. If a gene that is critical for the development of a particular cell lineage is carried on the X chromosome, this will result in apparent nonrandom X inactivation as cells where the good gene is inactivated will fail to develop. Detection of nonrandom X activation was historically a powerful tool for carrier detection, but as the X-linked immune deficiencies have now had their genetic basis defined, the need to rely on nonrandom X inactivation in the mother for carrier detection has been largely superseded. Carrier testing of siblings raises a number of ethical issues, and children should usually reach the age of informed consent before any tests are undertaken (see Ch. 10).

**Antenatal diagnosis.** Appropriate counseling by an individual conversant with the outcome of immunodeficiencies in the modern era should be undertaken before antenatal diagnosis is undertaken. Due to the small risk of miscarriage, screening should only be offered to mothers in whom the result would determine whether the mother would terminate the pregnancy. The gestation at which antenatal diagnosis can be undertaken is influenced by the nature of the immunodeficiency. Defined mutations can be screened for on CVS at 10–12 weeks' gestation. Fetal blood sampling at 18–20 weeks can be used where there is a clear phenotype, e.g. absent T lymphocytes, absent respiratory burst.

## DISORDERS OF CELL-MEDIATED IMMUNITY: COMBINED IMMUNODEFICIENCIES

### SEVERE COMBINED IMMUNODEFICIENCY (SCID)

Failure to develop normal T lymphocytes leads to lymphocyte-mediated immunodeficiency. T lymphocytes are also critical for the maturation

and function of B lymphocytes and so the more severe T lymphocyte deficiencies are nearly always accompanied by defective antibody responses resulting in a combined (lymphocyte-mediated and humoral) deficiency. In other combined immunodeficiencies single gene defects affect both B and T lymphocyte development. The severity of the humoral deficiency varies from a subtle defect of specific antibody response to complete hypogammaglobulinemia. Thus, it is unusual to find a significant primary T lymphocyte deficiency syndrome accompanied by normal humoral immune function. Combined immunodeficiency results from a large number of disorders with X-linked or autosomal recessive inheritance.<sup>24</sup> The molecular basis of many combined immunodeficiencies has now been elucidated (Table 27.9). The most severe phenotype, SCID, is associated with a profound T lymphopenia and panhypogammaglobulinemia with early death from infection. Whilst the usual clinical features of this group of diseases are well characterized, atypical presentations and 'leaky' forms with an attenuated phenotype are increasingly recognized. Circulating T lymphocyte numbers are usually low or absent but may be normal. In the classic SCID presentation, lymphocyte responses to mitogen are absent, but may be present in attenuated forms where immunoglobulin may also be produced. However, tests of antigen-specific T lymphocyte proliferation and antibody production are defective and there is cutaneous anergy. Patients usually have a limited diversity of T lymphocyte receptor and immunoglobulin gene rearrangements. Diagnosis may be more difficult in atypical patients. Identifying the molecular defect in specific patients with combined immunodeficiency or SCID is important for prognosis, treatment, genetic counseling and increasing our knowledge about these rare diseases. When identified, the name of the underlying molecular defect should be used.

### General features of severe combined immunodeficiency

The presenting clinical features are characterized by early onset, persistent respiratory tract or gut infection and failure to thrive.<sup>25</sup> Affected babies appear well at birth but within the first few months of life fail to clear infection and fall progressively away from their birth centile. Chronic diarrhea and failure to thrive are due to persistent and sometimes multiple gastrointestinal viral infections, often with associated food intolerance. Persistent respiratory tract infections with respiratory syncytial virus or parainfluenza viruses are common, with failure to clear virus accompanying persistent bronchiolitic-like signs. An insidiously progressive persistent respiratory infection with radio-

Nonhost T lymphocytes (MFE or transfusion GvHD)	+	+/-	+/-	

ADA, adenosine deaminase; AR, autosomal recessive; CgC, common interleukin gamma chain; GvHD, graft versus host disease; IL-7R $\alpha$ , interleukin 7 receptor alpha; JAK-3, janus-associated kinase 3; MFE, maternofetal engraftment; RAG, recombination activating genes; WHN, winged-helix-nude; XL, X-linked; ZAP-70, zeta-associated kinase-70.

\* RS, radiosensitive.

logical evidence of interstitial pneumonitis should raise the suspicion of *Pneumocystis carinii* infection, often a co-pathogen with respiratory viruses. Other presentations include prolonged otitis media and invasive bacterial infections, particularly staphylococcal or pseudomonas septicaemia and pneumonia, which may respond poorly to appropriate treatment. Severe invasive fungal infection is rare, but often fatal. Extensive, persistent superficial candidiasis is more common. Occasionally babies present with disseminated BCG or vaccine-strain poliomyelitis virus. Children presenting within the first 6 months or so of life are more likely to have SCID or a severe T lymphocyte defect.

Non-infectious manifestations mainly result from graft versus host disease (GvHD) caused by the inability to reject foreign lymphocytes acquired either from the mother in utero or from un-irradiated blood transfusion. Engraftment of transplacentally acquired maternal lymphocytes (maternofetal GvHD, MFGvHD) sometimes, but not always provokes GvHD, typically with a mild reticular skin rash with or without slightly deranged liver function tests. Its role in the gastrointestinal symptoms is not known. Fatal GvHD can follow transfusion with non-irradiated blood or with white lymphocyte or platelet concentrates. In these cases the skin rash is more severe and lymphadenopathy and hepatosplenomegaly may be present; here cases may be clinically indistinguishable from Omenn syndrome (see below), but identification of maternal cells by karyotype or DNA fingerprinting will distinguish MFGvHD from Omenn syndrome. EBV infection may lead to uncontrolled B lymphoproliferative disorders, similar to that seen in solid organ transplant recipients.

Examination usually reveals a wasted child (Fig. 27.14) who has dropped through the growth centiles, with evidence of candidiasis and other infections. Skin rashes may be indicative of infection or GvHD. There is no clinically detectable lymphoid tissue. There may be hepatomegaly.

Investigations show severe lymphopenia from birth; in infancy a normal lymphocyte count is  $> 2.7 \times 10^9/L$ , and if the normal adult lower limit of  $1.0 \times 10^9/L$  is quoted, the lymphopenia will be missed. Lymphocyte phenotyping shows severely depleted T lymphocyte numbers; B lymphocytes and NK cells may be present, or absent. Occasional variants show unusual patterns of mature T lymphocyte markers; in such cases maternal engraftment should be excluded. Mitogen responses, MLC reaction, and in vitro antigen specific responses are usually absent. Immunoglobulin estimations show low levels of IgG, IgA and IgM but may be misleading as residual maternal IgG may give a falsely reassuring result and it can be difficult to distinguish IgA and IgM levels in SCID from the low levels seen in normal infants; furthermore some SCID infants make IgM, but this is not functionally active. Isohemagglutinins are a useful measure of in vitro IgM production and absence is significant. If SCID is suspected, lymphocyte phenotyping is more reliable than immunoglobulin estimation. Chest radiographs show an absent thymus, and hyperinflation and/or interstitial pneumonia, if infection is present. Typical cupping and flaring

Fig. 27.14 Wasting in a child with severe combined immunodeficiency (SCID).

of the costochondral junction is also evident in patients with ADA deficient SCID.

In children who die, postmortem examination reveals severely depleted lymphoid tissue, with nodes and thymus showing no lymphoid lymphocytes and absent Hassall's corpuscles in the latter. Plasma lymphocytes are absent.

Without treatment, patients die from infection by about 12 months of age. Currently, the only curative treatment is hemopoietic stem cell transplantation (HSCT), although clinical gene therapy trials for common gamma chain deficiency and ADA deficiency are in progress. Supportive interim treatments include antibiotic prophylaxis with co-trimoxazole as antipneumocystis treatment, antifungal prophylaxis and immunoglobulin replacement. Live vaccines should be avoided. The diagnosis of SCID is a pediatric emergency, and suspected cases should be urgently referred to a designated treatment center for further assessment and treatment.

## TYPES OF SEVERE COMBINED AND COMBINED IMMUNODEFICIENCIES

### T negative B positive SCID

#### *Common gamma chain deficiency (X-linked SCID)*

The most common form of SCID is characterized by severe lymphopenia, absence of mature T and NK lymphocytes, but normal numbers of circulating B lymphocytes. It is caused by a deficiency of the gamma chain common to the IL-2, -4, -7, -9, -15 and -21 receptors. The easiest form of SCID to treat, the first successful gene therapy was performed for this condition. Carriers show nonrandom skewed X inactivation of T lymphocytes.

#### *JAK-3 deficiency*

This autosomal recessive form of SCID is phenotypically identical to the X-linked common gamma chain deficiency. It is due to mutations in the gene encoding Janus-associated-kinase 3, a protein which binds to the intracellular tail of the common gamma chain, and through which signals are transduced following cytokine binding.

#### *IL-7R alpha deficiency*

This autosomal recessive form of SCID is characterized by a T<sup>-</sup> B<sup>+</sup> NK<sup>+</sup> phenotype, and is due to mutations in the gene encoding the IL-7R alpha.

### T negative B negative SCID

Four forms of this autosomal recessive disorder have been described. Phenotypically they are identical, with absent T and B lymphocytes, but normal numbers of NK lymphocytes present. The first form is due to defects in the recombination activating genes (RAG) which are necessary for the development of diverse T and B lymphocyte antigen receptors. In the second form cells cannot repair DNA normally following radiation damage and patients' fibroblasts show in vitro radiosensitivity. The defect is in the artemis gene, which is necessary for rejoining DNA following TCR and B cell receptor (BCR) recombination. Two other DNA repair defects, DNA ligase 4 deficiency and cernunnos-XLF, can also present with a T<sup>-</sup> B<sup>-</sup> NK<sup>+</sup> phenotype, sometimes associated with microcephaly. Whilst treatable by HSCT, results are not as good as in the T<sup>-</sup> B<sup>+</sup> form of SCID. 'Leaky' RAG and artemis defects have been shown in some patients with Omenn syndrome.

### Omenn syndrome

Omenn syndrome is characterized by a generalized erythematous rash, often with scaling and erythroderma, lymphadenopathy, hepatosplenomegaly, increased serum IgE levels with a marked eosinophilia and combined immunodeficiency.<sup>26</sup> Children usually present in early infancy but atypical forms may present towards the end of the first year of life, with the clinical features described, as well as diarrhea, failure to thrive and persistent infection. There are normally high numbers of oligoclonal activated poorly functional T lymphocytes of the T<sub>H</sub>2 phenotype but few if any B lymphocytes and low levels of immunoglobulin. The syndrome has

been called a 'leaky' form of SCID in that small numbers of very abnormal T lymphocytes 'leak' past the block in T lymphocyte development. The underlying defect, at least in some cases, is a mutation in the RAG or artemis genes. Other cases with defects in IL-7R alpha are described.

In some families, one affected individual has presented with T<sup>-</sup> B<sup>-</sup> NK<sup>+</sup> SCID whilst another has presented with Omenn syndrome. The clinical picture may resemble SCID with maternofetal engraftment, when maternal T lymphocytes crossing the placenta cause a GvHD-like reaction in an immunocompromised patient. Molecular genetic studies to identify the origin of the dermal infiltrative T lymphocytes can differentiate the two disorders. Activated oligoclonal lymphocytes in skin seemingly provoke Langerhans' cells to migrate to lymph nodes, liver and spleen where lymphoid tissue architecture is severely disrupted. It has been suggested that IFN-gamma may ameliorate the clinical symptoms, but HSCT is the only curative treatment.

### Reticular dysgenesis

This rare form of SCID, inherited as an autosomal recessive trait, is characterized by defective lymphoid and myeloid differentiation. Bone marrow examination confirms the absence of myeloid precursors. Platelets and erythrocytes are formed normally. There is some evidence that this is not a discrete entity, but due to other forms of SCID, complicated by severe maternal engraftment and bone marrow GvHD.<sup>27</sup> The absence of the innate cellular elements of the immune system makes the immunodeficiency even more severe than in other forms of SCID. Clinical presentation often occurs earlier, as does the inevitable fatal outcome if immune reconstitution cannot be achieved.

### Lymphocyte metabolism defects

#### ADA deficiency

This variety of SCID is due to a single gene defect which results in absence of the purine metabolic pathway enzyme, ADA.<sup>28</sup> Although the enzyme is expressed widely throughout the body, accumulation of adenosine and 2-deoxyadenosine in immature lymphocytes is particularly damaging resulting in cell death. Patients typically present earlier than with other forms of SCID, with very low numbers of T, B and NK lymphocytes. Skeletal abnormalities (cupping deformities of the ends of the ribs, as well as abnormalities of the transverse vertebral processes and the scapulae) are reported in up to 50% of cases and can be correlated with histological changes.<sup>29</sup> Neurodevelopmental problems may also occur in some patients.<sup>30</sup>

Partial forms of ADA deficiency are associated with a milder immunodeficiency. Occasional cases of ADA deficiency have been described where, inexplicably, immune function is normal. The diagnosis is confirmed by finding very low erythrocyte ADA activity and high levels of deoxyadenosine triphosphate in the urine. First trimester antenatal diagnosis can be made by assaying ADA activity in chorionic villus sampling. Treatment is by HSCT or by use of replacement polyethylene glycol-coupled ADA (PEG-ADA). Over several weeks immune function improves considerably, and although not to full normality, often to a degree sufficient to keep the child free of infections and thriving. PEG-ADA has been used on a long term basis in those without a suitable donor. The disadvantages of this include the enormous cost, the continuing dependence on intensive medical input and concerns that the beneficial effects will not be maintained in the long term. Patients can develop antibodies against the bovine ADA but to date in most cases these have not been of great clinical significance.<sup>31</sup> Gene therapy is being offered for some patients with this condition.

#### Purine nucleoside phosphorylase (PNP) deficiency

Deficiency of the purine metabolic pathway enzyme, PNP, which results in combined immunodeficiency, is initially less severe than ADA deficiency though there is progression with age. It is an autosomal recessive condition, the gene for which is found on chromosome 9. The metabolites deoxyguanosine and deoxyguanosine triphosphate are particularly toxic for thymocytes resulting in a T lymphocyte deficiency with relatively preserved B lymphocyte function.<sup>32</sup>

The onset of symptoms is usually later than in ADA deficiency, and can be delayed for several years though most cases present in infancy with recurrent and severe infections, particularly with viruses and fungi, diarrhea and failure to thrive. There is a marked tendency to autoimmune disease, especially hemolytic anemia which can progress to red cell aplasia and a predisposition to GvHD following non-irradiated blood transfusion. Skeletal abnormalities do not occur, but neurodevelopmental problems are found in over half of all patients, particularly spastic paresis, disequilibrium and ataxia. There may also be more general neurodevelopmental and behavioral problems. In one series 20% of patients presented primarily with neurological disorder.<sup>33</sup>

Laboratory tests show a progressive fall in T lymphocyte numbers and function with time, poor in vitro mitogen responses and negative delayed hypersensitivity skin tests. Immunoglobulin levels and antibody responses are initially normal but in the late stages levels fall. Serum uric acid levels are very low. The diagnosis is confirmed by demonstrating absent PNP activity in erythrocytes or fibroblasts and deoxyinosine and deoxyguanosine in the urine. Asymptomatic forms of the deficiency have not been reported. Prenatal diagnosis can be made by enzyme activity assays on chorionic villus samples.

The prognosis without corrective treatment is poor with most cases dying in early childhood. The risk of development of malignancy is high. Treatment with HSCT is therefore indicated as early as possible. If successful this corrects the immunodeficiency but its effect on the neurological disease is uncertain. Enzyme replacement therapy with fresh irradiated red blood cells and other biochemical manipulations have not met with sustained success.

### Other combined immunodeficiencies

Other rare immunodeficiencies have been described in only a few patients to date, with defects in other surface and signaling molecules (Table 27.10). It is likely that these will become increasingly recognized as more laboratories are able to offer diagnostic testing. Other atypical or unusual presentations may be due to defects in molecules already described, or to as yet unidentified molecules or mutations.

#### ZAP-70 kinase defect (CD8 deficiency)

Defective signal transduction in T lymphocytes results from this autosomal recessive condition.<sup>34</sup> The defective kinase is important in T lymphocyte activation via the CD3/TCR complex. There is a marked effect on CD8<sup>+</sup> lymphocyte development, resulting in a profound CD8<sup>+</sup> lymphopenia which is the hallmark of this condition. Though CD4 lymphocytes are present in normal numbers, they are nonfunctional.

#### Idiopathic CD4 lymphocytopenia

A marked depression in the CD4 positive lymphocyte count characterizes this condition. Most reports have been on adult patients, but it can be seen in children. It is best regarded as a primary immunodeficiency disorder<sup>35</sup> as strenuous efforts to look for a retroviral cause have proved negative and the epidemiology of the condition does not fit with a viral infection. Affected individuals may be highly susceptible to opportunistic infections. The nature of the defect is poorly understood. There may well be a number of different causes.

Table 27.10 Other forms of severe combined immunodeficiency

Defect	Phenotype
IL-2Rβ/IL-15Rβ deficiency	T <sup>LOW</sup> B <sup>+</sup> NK <sup>-</sup>
CD45 deficiency	T <sup>LOW</sup> B <sup>+</sup> NK <sup>LOW</sup>
IL-2Rα deficiency	T <sup>LOW</sup> B <sup>+</sup> NK <sup>+</sup>
CD3γ deficiency	T <sup>LOW</sup> B <sup>+</sup> NK <sup>+</sup>
CD3δ deficiency	T <sup>-</sup> B <sup>+</sup> NK <sup>+</sup>
CD3ε deficiency	T <sup>LOW</sup> B <sup>+</sup> NK <sup>+</sup>

Immunoglobulin levels and antibody responses may be normal. The natural history of this condition is not well understood. The CD4 cell count remains stable for a prolonged period in most patients rather than progressively declining as in HIV infection. Prophylaxis against *Pneumocystis carinii* infection should be given. HSCT has been successfully performed.

## MHC ANTIGEN DEFICIENCY

### MHC CLASS II DEFICIENCY

Major histocompatibility complex (MHC) class II antigens (HLA DR, DP, DQ) are expressed on a limited repertoire of cells and present antigen to CD4+ T lymphocytes, which, following an appropriate second signal, activate T helper lymphocytes specific for that antigen and initiate an effective immune response. Expression of MHC II in the thymus is essential for positive selection of CD4+ T lymphocytes, and lack of MHC II expression, previously described as a variant of the 'bare lymphocyte syndrome', results in a profound susceptibility to viral, bacterial, fungal and protozoal infections.<sup>3</sup>

The disease is rare and is inherited in an autosomal recessive manner. The MHC II genes are normal and MHC II deficiency results from mutations in several different genes which code for a complex of regulatory factors controlling transcription of MHC II genes. The genes involved include MHC2TA, RFX5 and RFXAP.<sup>36</sup> The clinical and laboratory variability does not correlate with genotype.

The clinical picture resembles SCID, although often infections develop slightly later. Intestinal and hepatic complications due to cryptosporidial infections are more common than in other immune defects. Neurological manifestations due to a range of viral infections are also well described. Coxsackie virus, adenovirus and poliovirus were the most frequently reported causes of meningoencephalitis.

The laboratory phenotype is variable, but most patients have CD4 lymphopenia and hypogammaglobulinemia, with normal lymphocyte proliferation responses. The diagnosis can be confirmed flow cytometrically by showing absent or significantly reduced levels of class II molecules, e.g. DR, on cells that constitutively express class II (B lymphocytes and monocytes).

Affected children require treatment with replacement immunoglobulin, co-trimoxazole and antifungal prophylaxis pending HSCT, which is the definitive treatment although this has had limited success in comparison to other types of SCID.<sup>37</sup>

### MHC CLASS I DEFICIENCY

Although described before MHC II deficiency, SCID due to abnormal expression of the A, B and C components of the MHC I complex is much less common. MHC I is required for development of CD8 positive T lymphocytes, and affected children have low numbers of these cells. Mitogen responses are frequently normal. The genetic basis for the disease is mutations in TAP1 or 2.<sup>38</sup> These proteins are required for transport of antigen from the cytoplasm into the endoplasmic reticulum where they associate with MHC I. If the assembly of the antigen/MHC I complex cannot be completed due to antigenic lack, then the MHC is destroyed in the cytoplasm.

Clinically this disease has a milder phenotype than MHC II deficiency with symptoms often not beginning until late childhood. Recurrent respiratory tract infections leading to bronchiectasis and sinus problems are common. Gastrointestinal disease is rare. Unusual skin lesions thought to be due to vasculitis have been reported in a few patients.

Diagnosis is confirmed by showing absent HLA class I expression in peripheral blood. Treatment is directed towards prevention/limitation of lung disease with judicious use of antibiotics (directed by sputum cultures), physiotherapy and bronchodilators as required. Prophylactic continuous antibiotics are of unproven benefit, but may be helpful. The majority of cases do not require replacement immunoglobulin therapy or bone marrow transplantation.

## COMBINED IMMUNODEFICIENCY FORMING PART OF OTHER SYNDROMES

### DiGEORGE ANOMALY

This condition results from abnormal cephalic neural crest cell migration into the third and fourth pharyngeal arches in early embryological development. A microdeletion at chromosome 22q11.2 is present in 90% of cases whilst others are associated with other chromosomal anomalies, including 10p-. The 22q microdeletion is also found in velocardiofacial or Shprintzen syndrome, as well as some cases of Opitz G/BBB, a syndrome which should now be considered as a part of the same spectrum. In a few families with the DiGeorge phenotype, mutations have been identified in *Tbx1*, a gene within the 22q11 deleted region. *Tbx1* is required for the development of the pharyngeal arches, which are important for the development of the thymus and parathyroid glands. DiGeorge anomaly is sporadic in occurrence, though familial cases, some associated with 22q chromosomal deletions, have been reported with a prevalence of 1 in 3000–4000 live births. The syndrome is extremely heterogeneous: partial forms are more common than the complete phenotype. Whilst it is classically recognized by the triad of congenital heart defects, immunodeficiency secondary to thymic hypoplasia and hypocalcemia secondary to parathyroid gland hypoplasia, an expanded phenotype is increasingly recognized with dysmorphic facies [low set, abnormally formed ears, hypertelorism and antimongoloid slant, micrognathia, short philtrum to the upper lip and high arched palate; (Fig. 27.15)], palatal abnormalities (cleft palate, velopharyngeal insufficiency), autoimmune phenomena, learning difficulties (particularly speech delay), renal anomalies, neuropsychiatric disorders and short stature. Conotruncal heart defects are classically associated with the syndrome, but other defects are seen including tetralogy of Fallot, septal defects, pulmonary atresia and aberrant subclavian vessels (see Ch. 21). Some patients have normal cardiac anatomy.

Severe T lymphocyte immunodeficiency presenting with a SCID phenotype of profound lymphopenia and poor lymphocyte proliferation is rare (< 1.5% of cases). Humoral immunodeficiency is more common, presenting with recurrent sinopulmonary infection, which may improve with time. Occasionally significant lung damage may occur due to repeated infection. Autoimmune features are increasingly recognized, including juvenile chronic arthritis, autoimmune thyroiditis and autoimmune cytopenias. The long term immunological outlook is not well defined.

All children diagnosed with 22q11.2 deletion should have an immunological evaluation including lymphocyte subset analysis, T lymphocyte proliferative responses, immunoglobulin levels and specific antibody responses to vaccination antigens. Laboratory findings may show severe T lymphocyte depletion with poor mitogen responses or relatively normal findings. Previously considered a T lymphocyte defect, recent studies have shown that antibody responses, particularly to polysaccharide antigens, may be impaired. Immunoglobulin levels may be normal but hypogammaglobulinemia may develop, and minor humoral abnormalities are common. Chest radiographs show absence of a thymic shadow.

In the severe phenotype, the cardiac problems are the main prognostic determinant. Blood products should be irradiated if T lymphocyte mitogen responses are poor. Patients with severe immunodeficiency have been successfully treated with fetal thymus implants. In the partial phenotype with normal T lymphocyte function, the usual infant vaccination schedule can be followed and it is safe to give live vaccines such as measles, mumps, rubella vaccine or varicella zoster vaccine as long as the CD4 count exceeds 400/mm<sup>3</sup> and there are normal T lymphocyte mitogen responses. Demonstration of good antibody responses to tetanus and Hib vaccination gives further reassurance that live vaccines can be safely administered.<sup>39</sup> Prophylactic antibiotics and occasionally intravenous immunoglobulin can be helpful, particularly for young children with recurrent infection due to humoral deficiency.

Some infants with CHARGE syndrome (coloboma; heart anomaly; atresia, choanal; retardation of mental and somatic development;

Fig. 27.15 Facies of a child with DiGeorge syndrome. (Reproduced with permission of the Bubble Foundation and the family.)

microphallus; ear abnormalities and/or deafness) due to a defect in the CHD7 gene can also present with severe immunodeficiency.<sup>40</sup> Treatment is the same as that for severe immunodeficiency in DiGeorge syndrome.

### WISKOTT–ALDRICH SYNDROME (WAS)

Immunodeficiency, thrombocytopenia, eczema and an increased risk of autoimmune disorders and malignancy characterize this X-linked recessive condition. The gene codes for a novel 501 amino acid protein, the Wiskott–Aldrich syndrome protein (WASP), only found in bone marrow derived cells. Mutations in the same gene are found in patients with X-linked thrombocytopenia (XLT) and X-linked severe congenital neutropenia.

#### Clinical features

The classic features of thrombocytopenia, recurrent infections and eczema vary in severity and in some patients the eczema is surprisingly mild. The condition usually presents in early life with bruising, petechiae and bleeding: thrombocytopenia and bleeding episodes may require platelet transfusions. In XLT, thrombocytopenia with small platelet volume is the only symptom, perhaps with mild eczema. In WAS, bacterial and/or viral infections of the upper and lower respiratory tract are common and opportunistic infection, such as *Pneumocystis carinii*, may occur. Herpes viruses, including herpes simplex and varicella zoster

virus, are poorly handled and may cause severe and recurrent disease. Impetigo, cellulitis and skin abscesses are common; molluscum contagiosum and viral warts may be very extensive. Infection exacerbates the bleeding tendency, and early death may result from bleeding. With increasing age, infective problems replace bleeding as the major cause of death. Immunization with polysaccharide vaccines is ineffective and can cause severe, even fatal, reactions. The median survival is between 3 and 15 years. Autoimmunity, particularly autoimmune hemolytic anemia and vasculitis, and lymphoreticular malignancy become more common with increasing age and in many cases are related to abnormal persistence of EBV infection.<sup>41</sup> Scoring systems have been used to distinguish the milder phenotype of XLT from classic WAS. Heterozygous female carriers are clinically normal and demonstrate random X inactivation in all hemopoietic cells.

#### Laboratory tests

Thrombocytopenia with an abnormally small mean platelet volume (mean platelet volume < 5 fl) is pathognomonic. The severity of immunodeficiency is variable, but affects cellular and humoral responses. T lymphopenia is progressive with depressed responses to mitogens and antigens and negative delayed hypersensitivity skin tests. Serum immunoglobulins show a characteristic pattern with a very low IgM, normal IgG and raised IgA and IgE. Antibody responses to tetanus, *Haemophilus influenzae* type B and pneumococcus are often low, as are isohemagglutinin titers. The direct Coombs test is frequently positive, with or without a hemolytic anemia. In vivo neutrophil and monocyte chemotaxis is impaired. Electron microscopy shows greatly reduced numbers of microvilli on lymphocytes and platelets due to failure of the normal binding of actin bundles which is critical to the organization of the cytoskeleton. Lymphoid and myeloid cell lines are all affected so that phagocytes migrate poorly to sites of inflammation and do not put out normal filopodia, dendritic cells do not present antigen effectively, lymphocytes do not signal to each other normally and platelets form imperfectly from megakaryocytes.<sup>42</sup> WASP has a number of unique domains, suggesting multiple functions, which may explain the complex phenotype of a single gene mutation. Mis-sense mutations in exons 1–3 which lead to normal or truncated sized protein result in the milder phenotype of XLT, whereas most other mutations result in the classic WAS phenotype.

#### Treatment

Acute bleeding episodes may be controlled by platelet transfusions (irradiated to prevent GvHD). Splenectomy and systemic steroids should be avoided if possible as they will increase the risk of infection. Topical steroids are required for the eczema. Immunoglobulin replacement, with or without prophylactic antibiotics, reduces bacterial sinopulmonary infections and in high dose may help treat autoimmune phenomena.

With only these supportive measures the prognosis remains poor. Immunological and hematological reconstitution can be achieved by HSCT, and despite a higher risk of EBV-driven lymphoproliferative disorders 5-year survival is 87% after HLA identical sibling donor HSCT and 71% after unrelated donor HSCT.<sup>43</sup> Partial chimerism may lead to the presence of autoimmune features, but the risk of lymphoid malignancy should be diminished.

### X-LINKED HYPER-IgM SYNDROME (CD40 LIGAND DEFICIENCY)

X-linked hyper-IgM syndrome is a T lymphocyte immunodeficiency due to a defect in the gene encoding for the CD40 ligand glycopeptide (CD154) expressed on activated T lymphocytes. CD40L binds to CD40, expressed on B lymphocytes and monocyte/macrophage derived cells. Lack of binding prevents immunoglobulin isotype switching from IgM to IgA, IgG and IgE as well as activation of Kupffer cells and pulmonary macrophages. Lack of IgA and IgG results in a similar clinical picture to X-linked agammaglobulinemia (XLA) with sinopulmonary and invasive

Fig. 27.16 Chest radiograph of a 6-month-old boy, presenting with *Pneumocystis carinii* pneumonia. The underlying immune deficiency was found to be CD40 ligand deficiency.

bacterial infection but in contrast to XLA, opportunistic infections also occur; failure of T lymphocytes to activate pulmonary macrophages results in *Pneumocystis carinii* pneumonia (Figs 27.16 and 27.17) whilst ineffective Kupffer cell function allows repeated infections of bowel, pancreas and biliary tree with *Cryptosporidium parvum* and similar organisms leading to sclerosing cholangitis, cirrhosis, pancreatitis and hepatic malignancy which becomes clinically apparent in the second or third decade. Neutropenia with oral ulceration is common, and when combined with low or absent IgA and IgG and normal or raised IgM should suggest the diagnosis. Fatal CMV infection or enteroviral meningoencephalitis can occur. Autoimmune phenomena are relatively common and include hemolytic anemias, thrombocytopenia, hypothyroidism, arthritis and liver disorders.<sup>15</sup>

Patients should receive co-trimoxazole as *Pneumocystis carinii* pneumonia prophylaxis and high doses of immunoglobulin replacement therapy are often required. With adequate replacement the rising IgM levels may normalize. The neutropenia sometimes responds to granulocyte colony stimulating factor (G-CSF) and immunoglobulin replacement. All drinking water should be boiled. Azithromycin prophylaxis may lessen the risks of *Cryptosporidium parvum* infection. Despite conventional treatment, many patients do not survive beyond the second decade of life, but a few patients with a common variable immunodeficiency-like clinical course are relatively well in middle life. HSCT is increasingly recommended for this condition<sup>44</sup> and combined HSC and liver transplantation has been successful.

### X-LINKED LYMPHOPROLIFERATIVE DISEASE

An X-linked immunodeficiency associated with fulminant fatal EBV-driven infectious mononucleosis was first recognized in the Duncan kindred.<sup>45</sup> There are three common clinical presentations: fulminant infectious mononucleosis (58%), dysgammaglobulinemia, often evolving to common variable immunodeficiency (CVID) (31%) and EBV-driven B lymphocyte lymphoma, usually extranodal, and affecting the gastrointestinal tract or central nervous system (20%). Less commonly patients present with vasculitis, aplastic anemia, hemophagocytic lymphohistiocytosis or pulmonary lymphomatoid granulomatosis.<sup>46</sup> The prognosis is poor with 45–96% mortality, depending on the clinical presentation, and registry data indicate no survivors after 40 years of age. Most patients are well until infected with EBV, although other viruses may act as triggers. The gene responsible for the disease, SH2D1A in the Xq25 region of the X chromosome, was identified in 1998.<sup>47</sup> The gene encodes a small protein, signaling lymphocyte activation molecule (SLAM) associated protein (SAP), which appears critical for T lymphocyte and NK cell control of EBV-infected B lymphocytes but why this causes the clinical features is not yet understood.

(a)

(b)

Fig. 27.17 Lung histology following open lung biopsy in the patient whose chest radiograph is shown in Figure 27.16. (a) Hematoxylin and eosin stain showing marked inflammatory infiltrate. (b) Grocott methenamine stain showing *Pneumocystis* organisms (arrowed).

Confirmation of the diagnosis involves demonstrating EBV genome in blood by PCR, together with the immune defects outlined above and an abnormal serological response to the virus with absent antibody response to EB nuclear antigen. Mothers of affected boys also have abnormal EBV serology, with persisting very high titers against viral capsid antigen. Whilst the majority of cases appear to be triggered by EBV infection, EBV negative clinical cases have been described.<sup>48</sup> Protein analysis reveals absent or abnormal SAP protein in many cases, although a gene mutation is not apparent in up to 40% of patients, raising the possibility of mutations in intrinsic elements or other control proteins. Regular treatment with immunoglobulin replacement as passive immunization against EBV is recommended in affected patients, particularly

if hypogammaglobulinemia is present. Hemophagocytic lymphohistiocytic episodes may be treated with immunosuppression with ciclosporin. Correction of the disorder by HSCT has been achieved and is the only curative treatment. Other family members may be diagnosed from the index case and should be offered HSCT.

### IMMUNODEFICIENCY AND SHORT-LIMBED DWARFISM

T and B lymphocyte function abnormalities are seen in a number of osteochondrodysplasias, including Shwachman syndrome, where there is neutropenia and pancreatic insufficiency, and Schimke immuno-osseous dysplasia which features radiographic changes of spondyloepiphyseal dysplasia, nephrotic syndrome and cellular immunodeficiency. Other short-limbed dwarfisms associated with immunodeficiency are less clearly delineated.

Cartilage-hair hypoplasia is the most well described variant, inherited in an autosomal recessive manner, and mutations in the RMRP gene, which encodes mitochondrial RNA-processing endoribonuclease RNA, have been described. Severe short-limbed short stature ( $-11.8$  SD to  $-2.1$  SD) with radiographic appearances of metaphyseal and spondyloepiphyseal dysplasia is always present, accompanied by sparse light hair in most patients. Severe anemia and Hirschsprung disease are well recognized associations, as are malignancies, notably lymphoma and skin carcinoma. The immunodeficiency is surprisingly variable; most have T lymphopenia and impaired *in vitro* mitogen proliferative responses, but only half suffer recurrent infection.<sup>49</sup> However, some have IgA and/or IgG subclass deficiencies with frequent ear infections. Patients are excessively vulnerable to viral infections, particularly varicella zoster, EBV and other human herpes virus infections and the risk of infective death is 300 times greater than normal.<sup>50</sup> Severely affected patients should be assessed for HSCT, which has been successful in correcting the immunodeficiency.

### DNA REPAIR DEFECTS AND IMMUNODEFICIENCY

Recognition of a wide array of foreign antigens requires a huge number of genetically diverse lymphocytes, each bearing a unique receptor. These are created by rearranging the variable (V), diversity (D) and joining (J) gene segments that code for T or B lymphocyte receptor genes (VDJ recombination). This is initiated by introducing DNA double strand breaks between the gene segments, and then rejoining the rearranged segments using the cells' ubiquitous DNA repair machinery. Without the ability to repair DNA damage, cells may apoptose or undergo malignant proliferation and so individuals with defective DNA repair mechanisms have a predisposition to neurodegeneration, developmental anomalies and cancer as well as defective immunity. The mechanisms are complex with scope for many single gene defects to give rise to distinct clinical entities.<sup>51</sup>

#### Ataxia telangiectasia (AT)

This multisystem autosomal recessive disorder, the best known of the DNA repair disorders, is characterized by progressive cerebellar ataxia, oculocutaneous telangiectases, variable immunodeficiency and an increased risk of lymphoid malignancy and is associated with chromosomal instability and cellular radiosensitivity. Diagnosis, in the absence of a family history, is usually by a pediatric neurologist on the basis of gait anomalies. Before telangiectases appear it may be difficult to distinguish from other ataxia syndromes (see also Ch. 22). Ataxia and cerebellar signs are always present and usually appear in the second year, but may be delayed. Neurological degeneration is progressive, resulting in severe disability by late childhood. Mental function is usually preserved though retardation has been described. Telangiectases appear later, usually between 2 and 8 years of age, first on the bulbar conjunctivae (Fig. 27.18) but later elsewhere, particularly on the nose, the ears, and in the antecubital and popliteal fossae. Other cutaneous manifestations include patches of hypo- or hyperpigmentation, cutaneous atrophy and atopic dermatitis.

Fig. 27.18 Ataxia telangiectasia.

Gonadal atrophy occurs in both sexes, and growth failure is also prominent in the later stages. Cellular and humoral immunodeficiency affects 60–80% of cases but clinical manifestations are extremely variable. Recurrent sinopulmonary infection is common and may lead to bronchiectasis and clubbing. Recurrent pulmonary infection may be exacerbated by aspiration, common as the disease progresses. Lymphoreticular malignancies and, unusually for immunodeficiency, carcinomas, occur with increased frequency. Radiosensitivity means that treatment with radiotherapy is toxic and often lethal. Irrespective of the development of malignancy, survival beyond early adult life is unusual. Heterozygosity for the AT gene mutation confers an increased risk of developing breast cancer.

#### Laboratory features

Immunological findings are extremely variable. Low or absent levels of IgA, IgE, IgG, IgG2 and IgG4 subclasses are frequently found and antibody responses are particularly poor to polysaccharide and viral antigens. IgM may be raised and autoantibodies are sometimes found. Cellular immunodeficiency is characterized by defective thymic development and lymphopenia, predominantly of CD4+ T lymphocytes with an increase in the number of T lymphocytes bearing the gamma/delta receptor. Decreased mitogen and antigen responses can be demonstrated due to defective cytoplasmic to nuclear signaling. A raised alpha-fetoprotein (abnormal in 90%) supports the diagnosis, as does evidence of increased chromosome breakage on exposure to ionizing radiation. Patients are efficient at V(D)J rejoining, but have a high incidence of translocations at the sites of the T lymphocyte receptor and immunoglobulin heavy chain genes (chromosome 7:14 translocations). The ATM gene on chromosome 11q22.23 codes for a phosphatidyl kinase involved in meiotic recombination and cell cycle control.<sup>52</sup> The protein detects DNA damage and signals to proteins involved in DNA repair and cell cycle control;<sup>53</sup> it is absent or inactive in AT patients.

#### Treatment

Prophylactic antibiotics or immunoglobulin replacement can reduce the morbidity of sinopulmonary infection in some patients. As the immunodeficiency is often progressive, the need for such treatment should be reviewed intermittently.

#### Nijmegen breakage syndrome

Nijmegen breakage syndrome (NBS), an autosomal recessive disorder, is characterized by microcephaly with mild to moderate mental retardation, 'bird-like' facies, immunodeficiency, predisposition to malignancy, radiation sensitivity and chromosomal instability. Bacterial sinopulmonary infection is common. Hypogammaglobulinemia is the most common immunological abnormality and a third of patients make no

immunoglobulin. A CD4+ T lymphopenia with diminished T lymphocyte proliferative responses is also found.<sup>54</sup> Alpha-fetoprotein levels are normal. Patients have an increase in chromosome 7:14 translocations on karyotype analysis. Mutations in the gene encoding nibrin cause NBS.<sup>55</sup> Nibrin is a component of a protein complex which is part of the ATM signal transduction cascade. Treatment with antibiotic prophylaxis or immunoglobulin replacement can be helpful, and patients should be monitored carefully for development of lymphoid malignancy. In rare cases HSCT may have a role in improving immunodeficiency, although the long term effects on malignancy are not known.

### Ataxia-telangiectasia-like disorder

Patients with similar features to AT patients but with no mutation in the ATM gene have been described. In some, mutations have been found in the Mre11 protein, part of the complex with which nibrin associates and which is one of the complexes downstream from ATM. Some patients are microcephalic.

Other disorders associated with DNA repair (artemis, DNA ligase IV, cernunnos-XLF) have been described in the section on SCID. Patients with artemis and DNA ligase IV deficiency can present with CID. Microcephaly has been described in some of these patients.

### Bloom syndrome

This rare autosomal recessive disorder is associated with increased sister chromatid exchange, severe growth failure, increased malignancy and immunodeficiency. Affected individuals may develop facial telangiectases and facial photosensitivity. Recurrent bacterial sinopulmonary infections associated with hypogammaglobulinemia, most often low IgM, are the most common clinical manifestation of immunodeficiency, and may lead to bronchiectasis. The Bloom protein, mutated in the disease, unwinds the DNA helix. The mechanism of the immunodeficiency is unclear.

### Fanconi anemia (see also Ch. 23)

Progressive bone marrow failure leading to pancytopenia is the main problem in this condition. There may also be skeletal malformations. Immunodeficiency can occur, and selective IgA deficiency and T lymphocyte abnormalities have been recorded. At least 11 genes are implicated in the disorder, encoding for proteins which form a complex involved in sensing crosslinking DNA damage and facilitating repair.<sup>56</sup> A subgroup of patients with defects in the FANCD2 gene show similarity to patients with NBS and fibroblasts exhibit sensitivity to ionizing radiation as well as DNA crosslinking agents.

### Xeroderma pigmentosa

Immune deficiency, predominantly involving NK cells, may occur but is not a prominent feature. The mechanism of the immunodeficiency is unclear.

## DEFECTS ASSOCIATED WITH OTHER SYNDROMES

### Immunodeficiency, centromeric instability, facial anomalies (ICF) syndrome

Immunodeficiency, centromeric instability, facial anomalies syndrome is an autosomal recessive disorder in which there are characteristic structural abnormalities in chromosomes 1, 9 and 16 in lymphocytes. Affected children develop severe recurrent infections and have immunoglobulin deficiency, often with agammaglobulinemia but with normal T and B lymphocyte numbers.<sup>57</sup> T lymphocyte immunity is not normal and *Pneumocystis carinii* infection, severe viral warts and cutaneous fungal infection are described. The differential diagnosis is CVID. Mental retardation may occur but there is no increased risk of malignancy. Mutations in the DNMT3B gene have been identified in some patients, leading to hypomethylation of their DNA. The immunodeficiency may be due to lymphogenesis-associated gene dysregulation caused by indirect effects on gene expression that interfere with normal lymphocyte signaling, maturation and migration. HSCT has corrected the immunodeficiency in some patients who are able to discontinue immunoglobulin replacement.

## OTHER IMMUNODEFICIENCIES

A number of syndromes have been described which include primary immunodeficiency as part of the phenotype. In some, the syndrome is well described, and in a few the underlying molecular defect has recently been elucidated. Most lack clear definition.

### Hoyeraal-Hreidarsson syndrome

This X-linked disorder is characterized by microcephaly, cerebellar hypoplasia, aplastic anemia and growth retardation. A progressive combined immunodeficiency with hypogammaglobulinemia and lymphopenia is a well recognized association. Mutations in the dyskeratosis congenita gene (DKC1) have been found in some patients.

### Netherton syndrome

This triad of generalized infantile erythroderma, diarrhea and failure to thrive may be associated with variable immunodeficiency including mild lymphopenia. The clinical features are similar to those seen in Omenn syndrome and SCID with maternofetal engraftment. Distinguishing these entities is important as the other conditions are treated by HSCT, whereas Netherton syndrome is not. Hair shaft abnormalities are diagnostic (bamboo hairs), and mutations in the serine protease inhibitor (PI) gene SPINK5 have been described.

## DISORDERS OF IMMUNE REGULATION

### AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME (ALPS)

Apoptosis, or programmed cell death, downregulates immune responses once an infection has been countered. Defects in this process lead to marked autoimmune and lymphoproliferative features which characterize ALPS.<sup>58</sup> Apoptosis can be induced by a number of pathways; one of the most important is initiated through a cell surface molecule, Fas (CD95). Ligation of Fas initiates a cascade of intracellular reactions culminating in apoptosis induced by proteolytic enzymes including caspases. Mutations in several molecules in this cascade result in molecularly distinct but clinically similar forms of ALPS (Table 27.11).

Most of the cases described have been heterozygotes though a few homozygous cases are also reported. The variability of clinical severity and the occurrence of asymptomatic individuals make estimation of the incidence of this condition very difficult.

### Clinical features

Many cases present in early childhood, often co-incident with the first encounter of human herpes virus infection (CMV, EBV, HHV6), but adult presentation is also described. Asymptomatic cases may occur in the families of symptomatic individuals. Autoimmune disease most commonly affects the hemopoietic system causing hemolytic anemia or thrombocytopenia but the CNS, kidney and skin can be involved. Lymphoproliferation often results in characteristically massive lymphadenopathy in the anterior triangle of the neck, together with splenomegaly in nearly all cases and hepatomegaly in some. Fever is a common feature. Lymphoreticular malignancy (Hodgkin and non-Hodgkin) is reported with increased frequency but has probably been overdiagnosed because the histological picture of proliferation resembles malignancy:

Table 27.11 Different molecule types of ALPS

Type	Molecule affected
Ia	Fas (CD95)
Ib	Fas ligand
II	Caspase 10
III	Caspase 8
IV	Unknown

clonality studies distinguish the two.<sup>59</sup> Homozygous Fas deficiency has a more severe clinical phenotype, sometimes with prenatal onset resulting in hydrops.

### Laboratory features

Affected individuals usually have high lymphocyte counts and normal or high immunoglobulin levels. Autoantibodies are usually present; the direct Coombs test is often positive. A universal feature is the occurrence of circulating CD3 positive T lymphocytes expressing the alpha/beta receptor but not expressing CD4 or CD8 (so-called 'double negative T lymphocytes') and usually constituting 5–20% of the total CD3 cell count. Many of these cells also express HLA DR (normally only expressed on activated T lymphocytes). CD95 is not normally constitutively expressed on lymphocytes but is after activation with mitogens, and failure of this expression can be demonstrated in type 1a ALPS after appropriate cellular activation. Apoptotic assays involving artificial ligation of CD95 with an antibody and then measurement of cell death can be used to confirm an ALPS defect. Mutation analysis of Fas, Fas L and the appropriate caspase genes will confirm the precise molecular diagnosis.

### Treatment and prognosis

Autoimmune phenomena usually respond to treatment but there is a tendency for recurrence or the emergence of new autoimmune problems. Splenectomy for the control of hematological problems should be avoided if possible since there are reports of severe infective complications following this. However it may prove unavoidable, in which case penicillin prophylaxis should be given. The immune dysregulation can often be 'reset' with a course of rituximab in combination with a 6 month course of high dose intravenous immunoglobulin (IVIG) (2 mg/kg fortnightly) and steroids (initially 2 mg/kg/day prednisolone, tapering with response). Malignant disease is treated along standard lines but at the moment there are insufficient data to determine whether the response to treatment differs from non-ALPS patients. HSCT has been successful in patients with homozygous Fas deficiency but currently not enough is known of the long term prognosis to justify elective HSCT in (milder) heterozygous cases, especially as some patients improve with age.

### CHRONIC MUCOCUTANEOUS CANDIDIASIS

Chronic mucocutaneous candidiasis (CMC) describes a group of disorders characterized by chronic infection of skin, nails and mucous membranes by organisms of the genus *Candida*, most commonly *Candida albicans*. Recurrent and persistent candida of the mouth, napkin area, skin and nails is the hallmark of this condition, but the severity varies considerably and invasive disease almost never occurs. Failure of usually effective antifungal drugs to clear candida distinguishes CMC from other conditions that predispose to candida such as secondary immunodeficiency, steroid treatment or systemic antibiotics. Candidiasis is usually first noticed early in infancy and in severe cases gross esophageal involvement causes dysphagia, gastroesophageal reflux and failure to thrive whilst skin lesions may be extremely disfiguring and distressing (Fig. 27.19). As a patient becomes older, candida may become less severe. Nail dystrophy and dental enamel hypoplasia are associated.

In some patients there is an associated endocrinopathy (hypoparathyroidism, Addison disease, pernicious anemia, hypothyroidism, diabetes mellitus) which suggests that CMC is part of autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy (APECED), inherited in an autosomal recessive manner. In some of these, a defect in the AIRE (AutoImmune REgulator) gene has been identified. This codes for a protein expressed in thymus that is critical for the deletion of autoreactive T lymphocytes. A minority of patients suffer from invasive bacterial sepsis, opportunistic infection, autoimmune hemolytic anemia, malabsorption and chronic active hepatitis. Bronchiectasis and restrictive lung disease can occur.<sup>60</sup>

The underlying non-autoimmune immunodeficiency is poorly defined and variable. There may be diminished T lymphocyte

Fig. 27.19 Chronic mucocutaneous candidiasis. (Reproduced with permission of the Bubble Foundation.)

proliferation and cytokine production in response to candida antigens with impaired antibody production to polysaccharide antigens, and sometimes IgG2 subclass deficiency.<sup>61</sup>

Treatment with azole antifungals such as fluconazole can be very effective, even in severe cases, but often does not completely eradicate infection, or infection recurs on stopping treatment. Continuous treatment is necessary in severe cases.

### THE IMMUNE DYSREGULATION, POLYENDOCRINOPATHY, ENTEROPATHY, X-LINKED (IPEX) SYNDROME

The IPEX syndrome is characterized by infantile ichthyosiform dermatitis, protracted diarrhea, insulin dependent diabetes mellitus and thyroiditis; other autoimmune features may be apparent, particularly autoimmune cytopenia. Gut biopsies show autoimmune enteropathy. Mutations in the FOXP3 gene have been described in some affected patients. FOXP3-expressing T lymphocytes are regulatory T cells with a role in preventing autoimmunity. HSCT is the only curative treatment, and short term results are encouraging. Whilst the initial response is often dramatic, with rapid resolution of diarrhea and the disappearance of autoantibodies, the long term prognosis following HSCT is unknown.

### DEFECTS OF ANTIBODY PRODUCTION

#### X-LINKED AGAMMAGLOBULINEMIA (XLA, BRUTON DISEASE)

First described by Bruton in 1952,<sup>62</sup> this X-linked condition is due to an intrinsic defect in the normal differentiation of B lymphocytes beyond the pre-B lymphocyte stage. The defective gene encodes a cytoplasmic enzyme, Bruton tyrosine kinase (btk). Affected boys classically show a complete failure to produce immunoglobulins and antibody responses, but cell-mediated immunity is normal. Milder phenotypes have been found although it has not proved possible to correlate severity with the many different mutations that have been found.

#### Clinical features

Typically, recurrent pyogenic infections commence in the latter half of the first year of life, after maternal IgG levels have declined. The diagnosis is often made surprisingly late; in one series, the average age at diagnosis was 3.5 years without, and 2.5 years with, a positive family history.<sup>63</sup> The situation may not have improved since then as a more recent audit of all forms of immunoglobulin deficiency in adults and children in the UK found an average delay of 6.26 years between onset of symptoms and diagnosis.<sup>64</sup>

**Table 27.12** Presenting features in 96 patients with X-linked agammaglobulinemia (From Lederman Et Winkelstein 1985<sup>63</sup>)

Presenting feature	%
Ear, nose and throat infections (otitis media)	75 (59)
Lower respiratory tract infections (pneumonia)	65 (56)
Gastrointestinal infections (diarrhea)	35 (32)
Pyoderma	28
Arthritis (septic)	20 (8)
CNS infections (meningitis)	16 (10)
Septicemia	10
Neutropenia	10
Positive family history	26
Others: Failure to thrive; fever of uncertain origin; complications of immunization; osteomyelitis and dermatomyositis	<5% each

Diagnoses and figures in brackets indicate the predominant type of infection in each system and its overall incidence in the 96 patients.

Sinopulmonary infections are most common, but gastroenteritis, pyoderma, arthritis, meningitis and osteomyelitis may be presenting features (Table 27.12).<sup>63</sup> Common gastrointestinal pathogens include *Campylobacter jejuni* and *Giardia lamblia*.<sup>65</sup> Chronic conjunctivitis caused by *Pseudomonas* species may also occur. Recovery from viral infections is normal with the notable exception of those caused by enteroviruses (especially echoviruses) which can cause a chronic meningoencephalitis or dermatomyositis-like picture. Vaccine-associated paralytic poliomyelitis has been reported with live vaccine. Pathogens in which cell-mediated immunity is thought to be important are not usually a problem, though occasional cases of *Pneumocystis carinii* infection have been reported. Other complications include a nonpurulent arthritis affecting predominantly large joints. In some cases this has been shown to be due to mycoplasma infection. Neutropenia, alopecia totalis and amyloidosis are infrequent complications.

**Laboratory findings**

Once maternal IgG has declined, the usual pattern is absence or severe depletion of all serum immunoglobulin classes. It is not possible to demonstrate any antibody response to vaccines or to bacteriophage ΦX174. Circulating lymphocyte markers show a normal number of T lymphocytes, but absence of B lymphocytes. Bone marrow aspirate shows pre-B lymphocytes (containing cytoplasmic mu chains). Lymph nodes show absent follicles and germinal centers. Plasma cells cannot be demonstrated at any site. An associated neutropenia is found in some cases. Confirmation of the diagnosis can be made rapidly in over 90% of cases by demonstrating absence of the btk protein in cell lysates.<sup>66</sup> The finding of absent or abnormal btk in boys with partial antibody deficiency means that the condition should be considered in the presence of any form of antibody deficiency in boys, particularly if circulating B lymphocyte numbers are low. Foremost in the differential diagnosis of XLA is CVID. Table 27.13 lists some of the important differences between the two.

The mainstay of treatment is immunoglobulin replacement therapy (p. 1172). Infections may still occur, especially giardiasis and chronic conjunctivitis. Chronic lung damage and sinus disease may also progress on treatment and for this reason vigorous and early antibiotic therapy should be used for respiratory tract infections. If the problems are recurrent despite increased doses of immunoglobulin, continuous prophylactic antibiotics may be required. A large series of patients treated before IVIG was available revealed a high incidence of chronic lung disease (75% of those over 20 years) even with treatment with intramuscular immunoglobulin, and 17% of patients had died with a mean age of 16.9 years. With the widespread use of IVIG, lung disease seems less common and a recent sizable retrospective study<sup>67</sup> found that the patients developing progressive lung and sinus disease while on treatment tended to

**Table 27.13** Comparison of X-linked agammaglobulinemia (XLA) and common variable immune deficiency (CVID)

	XLA	CVID
Inheritance	X-linked	Mostly unknown (some may be AR or AD)
Age of onset	Infancy	Any age
Immunological defect	Antibody	Antibody ± cell-mediated
Immunoglobulin classes	All decreased	One (usually IgM) or more often preserved
B cell numbers	Absent	Usually present
T cell numbers and function	Normal	Normal or decreased
Pyogenic infections	Yes	Yes
Opportunistic infections	Very rare	Yes
Autoimmune phenomena	Very rare	Yes
Chronic gastrointestinal problems	Rare	Common

AD, autosomal dominant; AR, autosomal recessive.

be those with damage sustained before immunoglobulin therapy was commenced. These data emphasize the importance of early diagnosis and treatment for this condition. The same study also found that maintaining patients at higher IgG levels reduced the risk of lung disease but not of sinus problems.

**RELATED VARIANTS**

**X-linked agammaglobulinemia and sensorineural hearing loss**

Three unrelated boys with XLA have been described with mutation confirmed XLA and progressive sensorineural hearing loss.<sup>68</sup> They all had large deletions in the terminal part of the btk gene which were believed to involve a contiguous gene coding the deafness, dystonia protein, DDP. Mutations in the latter gene have been associated with the Tranebjaerg syndrome of deafness, dystonia and mental retardation. At the time of reporting the patients did not exhibit the other features.

**Hypogammaglobulinemia with growth hormone deficiency**

Very rarely hypogammaglobulinemia with low/absent B lymphocytes consistent with XLA has been described associated with isolated growth hormone deficiency. In the first case described no btk mutation was identified. In subsequent cases mutations in btk have been identified but the same mutations have also been found in boys without growth hormone deficiency. The relationship between the two conditions therefore remains enigmatic.

**AUTOSOMAL RECESSIVE FORMS OF AGAMMAGLOBULINEMIA**

When hypogammaglobulinemia is found in girls or when a patient's parents are consanguineous, autosomal recessive genetic defects affecting B lymphocyte differentiation should be considered. Mutations have been described so far in genes coding for: mu heavy chain, Ig-alpha (part of the signal transduction complex of the B lymphocyte antigen receptor), lambda<sub>5/14.1</sub> light chain, BLNK (B lymphocyte linker protein). These proteins are required for early B lymphocyte development from pro-B lymphocyte to pre-B lymphocyte stage. Unlike XLA, pre-B lymphocytes are therefore not detectable in marrow samples. Other families have also been described in whom the molecular defect is yet to be identified. In all cases the defect is B lymphocyte specific. The number of cases described is too small to draw firm conclusions but the clinical picture would seem

to be similar to XLA, although patients with mu heavy chain deficiency may have more serious life-threatening infections than those with XLA with an earlier onset of symptoms.<sup>69</sup>

### IMMUNOGLOBULIN DEFICIENCY WITH TRANSCOBALAMIN II DEFICIENCY

Hypogammaglobulinemia due to a failure of terminal (antigen driven) B lymphocyte differentiation can result from congenital absence of one of the vitamin B<sub>12</sub> carrier proteins, transcobalamin II. There is associated pernicious anemia. Parenteral high dose vitamin B<sub>12</sub> corrects the immunological defect.

### COMMON VARIABLE IMMUNE DEFICIENCY

CVID is a poorly defined entity characterized by the presence of quantitative or qualitative hypogammaglobulinemia. The incidence is between 1:10 000 and 1:100 000 of the population and although the onset of symptoms is typically seen within the second or third decade of life it is increasingly being diagnosed in childhood.

Familial inheritance is seen in up to 25% of cases, but the variability of phenotype both within and between families suggests a polygenic inheritance. Selective IgA deficiency appears to be one end of the spectrum of this disease.<sup>70</sup> Autoimmune diseases such as rheumatoid arthritis also have an increased incidence in these kindreds. As with all patients with humoral immune defects, patients with CVID present with recurrent sinopulmonary and gastrointestinal infections. They are particularly susceptible to *Giardia lamblia*. They are also at risk from enteroviral infections, causing choriomeningitis in particular, and arthritis may result from chronic mycoplasma infection. Other clinical manifestations exemplify the inherent immune deregulation with an increased incidence of autoimmune disease, particularly autoimmune hemolytic anemia, thrombocytopenia and neutropenia. Nonmalignant granulomatous lymphadenopathy, hepatosplenomegaly and involvement of the gastrointestinal tract is a frequent finding in a subgroup of patients,<sup>71</sup> and clinical differentiation from malignancy may be difficult although histologically lesions resemble those seen in sarcoidosis. These granulomata are normally sensitive to steroid treatment. Patients with CVID also have a significantly increased risk of lymphoreticular and gastrointestinal malignancies.

### Laboratory findings

Hypogammaglobulinemia is the hallmark of these patients. This may vary from a failure of specific vaccine responses to panhypogammaglobulinemia. B lymphocyte numbers are frequently normal. A significant proportion of patients have T lymphocyte abnormalities, in particular a reversed CD4/8 ratio and a generalized lymphopenia.<sup>72</sup> Such abnormalities at presentation should prompt a search for other defined immune defects. As the molecular basis of other immune deficiencies is being defined, it is clear that a number of patients with CVID have milder phenotypes of other immunodeficiencies such as X-linked agammaglobulinemia, CD40 ligand deficiency or X-linked lymphoproliferative disease.<sup>73,74</sup> Additionally, defects in ICOS, TACI, BAFF-R and CD19 have been described in a few individuals, but for the majority of cases the genetic basis is unknown.

### Treatment

The aim of treatment is prevention of further infections and consequent end-organ damage such as bronchiectasis. Mild phenotypes may require only prophylactic antibiotics. Significant degrees of hypogammaglobulinemia should be treated with immunoglobulin replacement therapy. If patients have significantly abnormal cell-mediated immunity, they should be given prophylactic co-trimoxazole. Granulomatous lesions and autoimmune phenomena may respond to treatment with steroids.

### IgA DEFICIENCY

Studies on healthy blood donors have shown that 1 in 600–700 Caucasians have no demonstrable serum IgA. Deficiency of serum IgA is usually associated with a lack of salivary IgA. The clinical significance of low IgA in isolation is unclear as the majority of affected individuals are asymptomatic. However, in populations of patients with chronic lung disease and autoimmune diseases there is an increased incidence of IgA deficiency. As the majority of patients with IgA deficiency are well, the pathophysiology of disease in these individuals is probably multifactorial; other contributory elements may include IgG subclass deficiency and reduced levels of mannan-binding lectin. Selective IgA deficiency is part of the spectrum of CVID; both may be present in the same family and rarely patients with IgA deficiency progress to CVID. In an infant, low IgA may be the last manifestation of transient hypogammaglobulinemia to resolve. Acquired IgA deficiency (usually reversible) may occur as a result of drug therapies (e.g. penicillamine, phenytoin, sodium valproate, captopril). It has also been described in congenital infections and after hepatitis C infection.

### Assessment of patients with IgA deficiency

If it is an incidental finding without a history of recurrent infections, an isolated low IgA is unlikely to be of clinical significance. If recurrent infections are present, further investigation should be undertaken, including assessment of IgG subclasses and specific vaccination responses. IgG subclass deficiencies occur in approximately 15% of cases. True IgA absence should be differentiated from low levels, which are common in childhood, by performing an Ouchterlony test, which will detect IgA in those patients with low levels.

### Symptoms

**Infective.** Recurrent sinopulmonary infections are the commonest symptoms in young children. Middle ear infections can be troublesome, and recurrent lower respiratory tract infections may result in lung damage. In the majority of children the frequency and severity of infections improve with age, regardless of the IgA level. Gastrointestinal infections, in particular with *Giardia lamblia*, have an increased incidence.

**Autoimmunity.** There is a strong correlation between autoimmune disease of all types and IgA deficiency,<sup>75</sup> whether or not the latter is associated with infections. Mechanisms are poorly understood, but may include abnormalities in antigen handling.

**Gastrointestinal disease.** The increased incidence of gastrointestinal infection has been discussed above. There is also an increase in celiac disease in IgA deficiency, which may give a false negative test if the diagnosis of celiac disease is based on the presence of IgA anti-gladiadin and endomysial antibodies.

**Malignancy.** There are multiple reports of lymphomas and gastric malignancies in patients with IgA deficiency, although the true incidence of this problem has not been well defined.

### Treatment

Patients with significant symptoms may respond to prophylactic antibacterial treatment, particularly over the winter. Very occasionally patients may require replacement immunoglobulin therapy. If they have a total IgA deficiency, they may have anti-IgA antibodies, which can result in severe anaphylactoid reactions if given IgA-containing preparations (including IVIG or blood). The risks can be minimized by choosing an immunoglobulin preparation with the lowest IgA content.

### IgG SUBCLASS DEFICIENCY

Many individuals with isolated subclass deficiencies are completely healthy. Immunoglobulin subclass deficiency is more likely to be associated with infection in patients who make poor specific antibody responses, particularly to polysaccharide antigens. The utility of IgG subclass measurement is therefore questioned by some authorities and

assessment of results should occur in the context of clinical features and specific antibody responses.<sup>76</sup>

Criteria for diagnosis should include a normal total IgG with a subnormal level of one or more IgG subclasses.<sup>14</sup> As IgG1 is the predominant IgG subclass, low levels of IgG1 will result in low total IgG, and this should be defined as CVID. Although deletions of the corresponding gamma genes have been demonstrated in a few cases, a majority of patients suffer from a regulatory dysfunction, and the deficiencies are most often relative rather than absolute.<sup>77</sup>

IgG3 is the most common subclass deficiency in adults, with IgG2 predominating in children. IgG4 levels vary widely in normal individuals, with up to a fifth of the population having very low levels. The clinical significance of selective IgG1 deficiency is difficult to assess. IgG subclass deficiencies may be associated with IgA deficiency, be a part of the spectrum of the immune defect in combined or T lymphocyte immunodeficiency such as AT, or be an early manifestation of CVID.

Recurrent sinopulmonary infections are the usual clinical presentation of a significant subclass defect. Most children can be effectively treated with prophylactic antibiotics, such as co-trimoxazole or a macrolide, over the winter months. Hearing loss and lung damage should be monitored. Very occasionally children may require treatment with replacement immunoglobulin.

## SELECTIVE ANTIBODY DEFICIENCY WITH NORMAL IMMUNOGLOBULINS

A small number of individuals have normal immunoglobulin levels, but fail to respond to specific antigens. The most frequent defect is a failure to respond to polysaccharide antigens (e.g. the polysaccharide pneumococcal vaccine, Pneumovax®). The majority of individuals are normal, and clearly have other immune mechanisms that can compensate for this defect. A number, however, have recurrent sinopulmonary infections.

Lack of polysaccharide responses may also be seen in Wiskott–Aldrich syndrome, be normal in the first 2 years of life, or be an early manifestation of CVID. Children over the age of 3 years who are found to lack pneumococcal responses should be followed up until it is clear that they are not developing an immune defect.

## DISORDERS OF PHAGOCYtic CELLS

### CHRONIC GRANULOMATOUS DISEASE

Chronic granulomatous disease (CGD) is an inherited defect of the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex which generates superoxide and other reactive oxygen species that are toxic to organisms ingested into phagosomes. The commonest X-linked gene defect, accounting for up to 60% of cases, is in the major membrane component gp91phox. Defects in the cytoplasmic components p67phox and p47phox are inherited in an autosomal recessive pattern, as are mutations in the second membrane component p22phox, the latter being very rare.

The disease has protean clinical manifestations, but the hallmark is acute, and potentially fatal, bacterial or fungal infection.<sup>78</sup> A subgroup of patients with some residual enzyme function may not present until adult life. A common manifestation is acute suppurative lymphadenitis in the neck, axilla or groin. Other frequent pyogenic infections include liver abscesses, osteomyelitis, arthritis, pneumonia, skin sepsis and perianal abscesses. Pathogens such as *Staphylococcus aureus*, *Burkholderia cepacia*, *Aspergillus* species and *Serratia marcescens* are common because they are catalase positive: this enzyme destroys any hydrogen peroxide produced by the organism within the phagosome. Infections with catalase negative organisms, such as *Streptococcus pneumoniae*, are rare. Fungal infection often manifests as pneumonia, but disseminated infection is frequently seen, with osteomyelitis and hepatic involvement. Once established, fungal infection is hard to treat and frequently fatal.

The occurrence of non-infectious granulomatous complications is increasingly recognized. These include inflammatory bowel disease, restrictive lung defects, genitourinary obstruction and cutaneous

granulomata. Many children have colitis, which may be subclinical, manifested only as a persistent iron deficiency anemia and which histologically may be mistaken for Crohn disease. These non-infective manifestations respond well to corticosteroid treatment.<sup>79</sup> Female carriers of the X-linked form may have a number of manifestations including skin abscesses and an increased incidence of autoimmune diseases and mouth ulcers.

Diagnosis is suggested by failure of reduction of nitroblue tetrazolium or dihydrorhodamine by neutrophils (see diagnosis section). In the X-linked form, mothers may have intermediate levels of dye reduction.

### Treatment

The use of prophylactic antibiotics, in particular co-trimoxazole which is concentrated in neutrophils, has significantly reduced morbidity and mortality from bacterial infections in this disease. Children should also receive oral prophylactic antifungal agents such as itraconazole or voriconazole which help reduce the incidence of fatal fungal disease in these patients.<sup>79</sup>

Infections or unexplained fevers should be treated aggressively. IFN-gamma is a useful adjunctive treatment in severe bacterial or fungal infections, and in Europe is mainly used for prophylaxis only after documented failure of oral antibacterial and antifungal agents.<sup>80</sup> White cell infusions may be used as adjunctive therapy in severe infection. Registry data suggest that the outlook in early childhood has improved considerably in recent years,<sup>81</sup> but considerable morbidity and mortality occurs and consideration should be given to HSCT when a suitable donor is available.<sup>82</sup> Clinical gene therapy trials are in progress.

## ENZYMATIC DEFICIENCIES RESULTING IN NEUTROPHIL KILLING DEFECTS

Myeloperoxidase (MPO) deficiency is the commonest inherited disorder of neutrophils. Almost half of those affected have a complete deficiency, the rest have structural or functional defects in the enzyme. MPO is the primary component of azurophilic (primary) granules. The majority of patients with MPO deficiency are asymptomatic, a notable exception being diabetic patients with MPO deficiency, who appear to have a particular susceptibility to candidiasis.

Other enzyme defects are less common and include glutathione synthetase deficiency, pyruvate kinase deficiency and complete neutrophil G6PD deficiency (note: in the common red cell G6PD deficiency there is sufficient enzyme present in neutrophils for normal killing to occur). The phenotypes may be very mild, with variable numbers of bacterial infections. G6PD deficiency will result in an abnormal NBT test; otherwise the diagnosis is established by measurement of specific enzyme levels.

## NEUTROPHIL-SPECIFIC GRANULE DEFICIENCY

This rare disorder is characterized by recurrent skin and lung infections with staphylococci and enteric bacteria. The diagnosis can be confirmed by electron microscopy of patient neutrophils, which show reduced or absent primary granules. Specific stains will also demonstrate lack of the proteins that constitute the granules, including lactoferrin and vitamin B<sub>12</sub> binding protein. Proteins that reside in azurophilic (primary) granules, such as lysozyme and myeloperoxidase, are present. Neutrophils also show abnormalities in migration and nuclear morphology. Mice lacking the transcription factor CCAAT/enhancer binding protein have a similar phenotype, and patients with mutations in this gene have been reported.<sup>83</sup>

The clinical course of patients is variable. Treatment options include prompt institution of antibiotic therapy for infections and prophylactic antibiotic treatment. HSCT should be considered in patients with a severe phenotype

## OTHER NEUTROPHIL DISORDERS

### Neutropenia

This includes cyclical neutropenia and severe congenital neutropenia, which are covered in Chapter 23.

### Shwachman–Diamond syndrome

This rare autosomal recessive disorder is characterized by exocrine pancreatic insufficiency, skeletal abnormalities, bone marrow dysfunction and recurrent infections. Neutropenia occurs in all patients, whilst 10–25% of patients also have pancytopenia. There is an increased incidence of malignancy. The genetic defect has recently been identified. HSCT may be indicated in some patients.

## HEMOPHAGOCYTIC SYNDROMES

### Chediak–Higashi syndrome

Chediak–Higashi syndrome (CHS) is a rare autosomal recessive disease with partial oculocutaneous albinism, recurrent bacterial infections and the development of an accelerated lymphocyte and macrophage activation syndrome [similar to that seen in hemophagocytic lymphohistiocytosis (HLH) and X-linked lymphoproliferative disease (XLP)] in approximately 85% of patients, which is usually fatal. Variable neurological manifestations are also recognized. Characteristic giant lysosomal granules are seen in the cytoplasm of all cells containing these organelles, and are easily detected on a peripheral blood film. A characteristic pattern of hair pigment can be seen by light microscopy. The gene for this disease (*Lyst*) codes for a regulator of lysosomal transport;<sup>84</sup> proteins normally transported through lysosomes enter these organelles but cannot exit, with subsequent lysosomal hypertrophy. In melanocytes this is thought to result in abnormalities of melanin transport and consequent albinism. In neutrophils degranulation of lysosomes cannot occur, with failure of release of bactericidal proteins into the phagosome and defective intracellular killing. The impaired NK cell function is not fully elucidated, whilst monocyte function is probably impaired because giant lysosomes interfere with intracellular motility systems leading to abnormal processing of MHC II in endosomes, and thus defective antigen presentation. The activation syndrome may result from failure to transport inhibitory molecules such as CTLA4 to the surface of leukocytes, with consequent failure of negative feedback mechanisms after T lymphocyte and macrophage activation. Common pathogens in CHS include *Staphylococcus aureus*, streptococci and pneumococci. Hemophagocytosis may be triggered by viral infection, particularly human herpes virus infection.

#### Treatment

Prophylactic co-trimoxazole should be given to prevent bacterial infection. The accelerated phase cannot be predicted, and patients should be closely monitored, particularly if febrile. Symptoms, signs, laboratory and clinical findings and diagnosis and treatment of the accelerated phase are as for HLH (see below). The only definitive treatment for the hematological problems is HSCT. This should be considered early if there is a matched sibling donor. Successful HSCT will not prevent late onset neurological sequelae however.

### GrisCELLI syndrome

Individuals with GrisCELLI syndrome resemble those with CHS in that they have variable hypopigmentation of the skin. The hair is characteristically silvery grey from birth, and recurrent pyogenic infections associated with absent delayed type cutaneous hypersensitivity and impaired natural killer cell function should suggest the diagnosis. Hypogammaglobulinemia can be seen as a secondary phenomenon. In contrast to CHS, large lysosomal granules are not seen and examination of hair by electron microscopy shows large clumps of pigment, with the accumulation of mature melanosomes in melanocytes. This provides a rapid diagnostic test. Three distinct types of GrisCELLI syndrome have been identified, but only patients with mutations in *Rab27a* have an accelerated phase.<sup>85</sup>

### Hemophagocytic lymphohistiocytosis (familial)

Hemophagocytic lymphohistiocytosis (HLH) may be primary (familial) or secondary to a viral infection or an immune deficiency (e.g. GrisCELLI syndrome, CHS and XLP) or other immune dysregulation (macrophage

activation syndrome in juvenile arthritides). The primary form is universally fatal without treatment. Patients present with high swinging fevers, hepatosplenomegaly and pancytopenia, and may appear septic. Laboratory findings include an acute phase response, elevated ferritin and elevated fasting triglycerides. Examination of bone marrow, cerebrospinal fluid, pleural effusions or ascitic fluid may demonstrate hemophagocytosis. This may be very difficult to find, and repeated sampling may be required. Diagnosis of familial HLH should be suspected in an infant with an appropriate clinical picture.<sup>86</sup> Older children are more likely to have secondary HLH.

Of patients with familial HLH, 20–30% will have a mutation in perforin and a similar proportion in *munc13-4*. Mutations in *syntaxin 11* have also been identified, particularly in Turkish families.<sup>87</sup> A group of patients remains in whom the genetic defect remains to be identified. The exact pathophysiology of the disease has not been elucidated, but it is thought that all the identified molecules have a regulatory role, and absence leads to dysregulated immune activation.<sup>88</sup>

Treatment with a combination of chemotherapeutic agents, steroids, and monoclonal antibodies that deplete lymphocytes may induce remission, but HSCT is required for cure.

## LEUKOCYTE ADHESION DISORDERS

To counter infection in tissues, leukocytes egress from the circulation toward sites of inflammation as described earlier in this chapter (p. 1141). Inherited defects in some of the cell surface molecules responsible for the process have been recognized.

### Leukocyte adhesion deficiency type I

Deficiency of the 95 kd beta chain (CD18), common to the beta-2 integrin family of cell surface adhesive molecules, leads to a profound immunodeficiency affecting the function of neutrophils, monocytes and certain lymphocytes, including T and NK cytotoxic cells.<sup>89</sup> Inheritance is autosomal recessive. Chemotaxis, adherence and phagocytosis are markedly depressed. Different mutations result in phenotypes of variable severity depending on the number of surface molecules that can be expressed. Occasional patients have also been described whose cells express normal levels of CD18 but have a mutation affecting the function of the molecule. This can be demonstrated by showing failure of expression of an activation epitope on the molecule. Although these molecules are involved in the lymphocyte interactions necessary for specific immune responses, these responses are preserved. Even the impaired lymphocyte cytotoxicity, which can be demonstrated very clearly in the laboratory, is of uncertain clinical significance. The clinical picture is almost entirely explained by the way in which leukocytes are attracted to areas of infection and can become fixed to the vessel walls at sites of inflammation in the usual way but cannot pass out into the tissues. This leads to blockage of small vessels and rapidly expanding necrotic lesions without pus. The beta-2 integrin family is also involved in the platelet function molecule Gp 2b3a, and patients with a combined leukocyte and platelet defect have been found.<sup>90</sup>

Individuals affected by the most severe phenotype (<1% expression) present in the first weeks of life with delayed umbilical cord separation (the cord fails to shrink down and may not separate until 3–4 weeks of age), together with rapidly progressive erosive perianal ulcers. Delayed umbilical cord separation does not seem to occur in patients with some expression of the molecule (usually in the range 2–10% of normal expression). In all forms there is excessive susceptibility to bacterial and fungal infections. Gingivitis and periodontitis are common and more deep seated infections of bone, respiratory and gastrointestinal tracts are often seen. Non-infective inflammatory lesions, particularly affecting the skin and resembling pyoderma gangrenosum, can occur in the partial forms of the deficiency and are often responsive to steroids.

Investigations almost invariably show a circulating neutrophilia (because of failure of the cells to migrate out of the circulation) and a profound neutrophil chemotactic defect. Diagnosis is confirmed by

demonstrating the absence of the cell surface markers recognized by the anti-CD11/CD18 monoclonal antibodies.

In the severe form, early death from infection is the rule unless a successful HSCT can be performed. In the partial forms supportive and expectant management is pursued in the first instance but HSCT may become necessary.

### Leukocyte adhesion deficiency (LAD) type II

In this extremely rare disorder a defect of fucose metabolism results in a failure of fucosylation to generate sialyl lewis x (CD15s) and other ligand molecules to which the selectin molecules bind. This results in a failure of the 'rolling' type weak adhesion of leukocytes to endothelium which slows down the circulating leukocytes before beta-2 integrin binding can occur. There is a neutrophilia, and neutrophil chemotaxis and migration from the circulation is severely impaired. There is no deficiency in specific immune responses. As in LAD I deficiency, patients have a neutrophilia and suffer repeated bacterial infections and periodontal disease. Delayed umbilical cord separation is, however, not seen. Other features peculiar to LAD II include mental retardation, short stature and the Bombay (hh) blood phenotype.<sup>91</sup>

## CYTOKINE DEFECTS

### Type 1 cytokine defects

Defects in the IL-12 dependent IFN-gamma pathway have been described in patients affected by persistent severe, invasive or intractable mycobacterial infections with bone and soft tissue abscesses complicated by persistent discharging sinuses. Implicated pathogens are usually BCG or poorly pathogenic environmental nontuberculous mycobacteria and are often fatal.<sup>92</sup> Invasive non-typhi salmonella infections have been described, and may be successfully treated with antibiotics. There may also be increased susceptibility to viral infection including human herpes viruses, respiratory viruses including respiratory syncytial virus and parainfluenza type 3. Infections result from a failure of upregulation of macrophage killing. The clinical picture depends on the precise molecular defect that is present. Defects have been described in a number of constituents of the IL-12/IFN-gamma pathway, including complete or partial IFN-gamma-R1 deficiency, IL-12p40 subunit deficiency, and complete IL-12bn1 deficiency. The outcome of patients with complete IFN-gamma-R1 deficiency is poor, but HSCT has been successfully attempted.

### HYPER-IgE SYNDROME

This complex disorder is characterized by extreme elevation of the serum IgE level (usually in the range 2000–40 000 units/L), chronic dermatitis and repeated lung and skin infections.<sup>93</sup> The predominant organism is staphylococcus, although infections with other organisms and secondary fungal infections may occur. The total IgE levels may fall in adulthood, sometimes to the normal range. Autosomal dominant and autosomal recessive forms occur: the former (Job syndrome) is characterized by the formation of pneumatoceles and multiple systemic problems, including coarse facies, delayed loss of primary dentition and a variety of skeletal abnormalities including an increased fracture rate and joint hypermobility.<sup>94</sup>

While the immunological features can be explained as the consequence of a T cell regulatory defect, the other features are not easily explained. Abnormal bone and connective tissue turnover as a consequence of abnormal cytokine profiles has been postulated as a possible way of tying all the features together. The mode of inheritance is thought to be autosomal dominant with incomplete penetrance. The gene for the disorder has not been identified but studies on the autosomal dominant cases have found linkage to the proximal part of chromosome 4q.<sup>95</sup>

The autosomal recessive form was more recently described.<sup>96</sup> Although these children have skin and lung infections and very high IgE, they do not develop pneumatoceles or have any of the soft tissue or skeletal markers of the autosomal dominant form.

The mainstay of treatment is long term antistaphylococcal antibiotic prophylaxis, usually with flucloxacillin. HSCT failed to correct the IgE levels in the one patient in whom it was reported as being attempted despite successful engraftment of donor myeloid and lymphoid cells.<sup>97</sup> Subsequent follow-up has demonstrated less frequent and severe infections.

## ANHYDROTIC ECTODERMAL DYSPLASIA, INCONTINENTIA PIGMENTI AND DEFECTS IN THE NEMO GENE, AND RELATED DISORDERS

X-linked anhydrotic ectodermal dysplasia has been associated with immunodeficiency. Patients present with sparse scalp hair, conical teeth and absent sweat glands. Some suffer from recurrent sinopulmonary infection, often with encapsulated organisms, and have poor antibody responses to polysaccharide antigens, or frank hypogammaglobulinemia. Incontinentia pigmenti is a rare X-linked dominant condition characterized by developmental abnormalities in skin, hair, teeth and the central nervous system. Previously thought lethal in male fetuses, rare male infants with a progressive combined immunodeficiency have been described.

Hypofunctional mutations in the NEMO gene encoding a protein required to activate the transcription factor NF-kappaB have been described in male patients with both X-linked anhydrotic ectodermal dysplasia and incontinentia pigmenti, suggesting that these conditions represent variants of the same disorder.<sup>98</sup>

Similar presentations have been described in patients found to have defects in I-kappa-B-alpha, with recurrent Gram positive and Gram negative bacterial infections and raised IgM. Other rare patients with similar bacterial infections but no ectodermal dysplasia have been described with IRAK-4 deficiency.

## COMPLEMENT DISORDERS

### PRIMARY INHERITED DEFICIENCIES

The main inherited deficiencies of complement components are listed in [Table 27.5D](#) (p. 1149). Severe disease is inherited in an autosomal recessive manner with absolute deficiency of a complement component due to gene defects in both alleles. However, heterozygosity results in approximately half normal levels of the protein which can sometimes be clinically important. A number of clinical patterns can occur depending upon which factor is deficient.

### Autoimmune disease

A predisposition to autoimmune disease, particularly systemic lupus erythematosus and the other immune complex disorders, is a feature of most of the complement deficiency syndromes. Deficiency of C1q carries a very high risk with over 90% of patients in one series developing either systemic lupus erythematosus (SLE) or discoid LE.<sup>99</sup> Evidence, based on the finding that null alleles for a number of complement components (notably C2 and C4) occur with greater frequency in patients with autoimmune diseases such as SLE, suggests that heterozygosity for deficiency is also a risk factor. In general, the course of these diseases is similar to that in patients without complement deficiency.

### Pyogenic infections

Recurrent pyogenic infections are a feature of complement deficiencies. Organisms such as streptococci and *Haemophilus influenzae* are the main problem as opsonization/binding of antibody and complement to bacteria is critical for their elimination. C3 deficiency is the most severe. Deficiency of the classical pathway components C1q and C2 and of factor D in the alternative pathway also predisposes to infection and the first two also carry a predisposition to autoimmune phenomena. Deficiencies of the alternative pathway control proteins, factors H or I lead to uncontrolled consumption of C3 resulting in increased susceptibility to pyogenic infections.

## Neisserial infections

Deficiency of one of the later complement components, C5–C9 (leading to failure of membrane lysis), or of the control factor properdin (the only deficiency inherited in an X-linked manner) leads to a specific deficiency in handling neisserial species (*Neisseria meningitidis* and *N. gonorrhoeae*) but not to a generalized increase in susceptibility to pyogenic infections. There is a predominance of disease caused by rare serogroups of meningococci (W135, X, Y and Z) in these patients. In a Dutch study<sup>100</sup> complement deficiency (most commonly late components or properdin) was found in 33% of survivors of meningococcal disease due to rare serogroups compared to 2, 0 and 7% in patients who suffered Group A, B and C disease respectively. The disease is said to run a milder course in these patients. Recurrent attacks of meningococcal septicemia/meningitis and severe invasive gonococcal disease are also associated with late complement deficiencies in factors 6–9. Late complement deficiencies are more common in individuals from the Middle East and Japan; C9 deficiency in Japan affects up to 0.1% of the population.<sup>101</sup> Screening for deficiencies should be undertaken in patients and their immediate families where there has been recurrent meningococcal disease due to common serogroups or single episodes caused by a rare serogroup. In the UK, screening children with single episodes of meningococcal disease due to common serotypes is unlikely to reveal a complement defect.<sup>102</sup>

## Hereditary angioedema

Deficiency of the control protein, C1 esterase inhibitor (C1INH), leads to spontaneous episodes of localized edema (angioedema) without urticaria due to excessive release of proinflammatory breakdown products of complement. C1INH is also a negative regulator of the kallikrein pathway and edema may be due to the increased release of kinins. These occur spontaneously anywhere in the body but those affecting the upper airway are most serious and can be life threatening. Precipitating factors can include local trauma (including surgical procedures, endoscopy and dental work), exposure to extreme cold and emotional stress. Intra-abdominal swelling can occur causing pain and swelling which can be misdiagnosed as a surgical condition. There is a high incidence of SLE and related diseases. C4 levels are also persistently low due to excessive consumption (which occurs even between attacks) although C3 levels are normal. In most cases C1INH assay shows very low levels or absent protein but in approximately 15% of cases the protein is present but functionally defective. The condition is inherited in an autosomal dominant fashion. Episodes of visible swelling do not usually occur until the second decade of life, but younger children suffer from attacks of abdominal pain. Infusions of purified C1INH are effective in terminating attacks and should be used for all attacks affecting the head and neck and for intra-abdominal attacks which are running a protracted course. The concentrate should also be given prophylactically to cover surgical and dental procedures. For prevention of attacks, the treatment of choice after puberty is one of the 'retarded' androgenic steroids, such as danazol. In prepubertal children prophylactic use of tranexamic acid, a fibrinolytic agent which inhibits plasmin formation, is recommended. This raises functional C1INH levels sufficiently to prevent attacks and is relatively free of virilizing side-effects. Monitoring of liver function tests should be performed with long term usage.

## SECONDARY COMPLEMENT DEFICIENCIES

Many immunopathological diseases can result in excessive complement activation and consumption. In SLE and other immune complex diseases, low levels of C3 and the early classical pathway components can occur. In acute nephritis, C3 levels are acutely depressed, while in membranoproliferative glomerulonephritis a more persistent depression of C3 levels occurs due to the presence of an autoantibody – C3 nephritic factor – directed against C3bBb, the alternative pathway C3 convertase. This autoantibody can also be associated with the condition partial lipodystrophy, with or without membranoproliferative glomerulonephritis. An increased susceptibility to pyogenic infections occurs when C3 levels are reduced

below approximately 10%. Gram negative sepsis, acute pancreatitis and acute vasculitis can all be associated with complement consumption.

## INTERACTION OF ANTIBODY AND COMPLEMENT DEFICIENCIES

Deficiency of the early classical pathway complement components has been shown to be associated with poor antibody responses, presumably because of some immunoregulatory role of the complement factors. Later components are not implicated.

Alternative pathway opsonization is less efficient in the absence of specific antibody to bacterial surfaces. There is evidence that antibody may 'neutralize' surface molecules, such as sialic acid, which otherwise inhibit alternative pathway activation.

## MANNAN-BINDING LECTIN (MBL) DEFICIENCY

MBL provides another antibody independent mechanism for opsonization of microorganisms by binding to mannose residues common on the surface of a number of different microorganisms.<sup>103</sup> Several allelic variants of the molecule are found and appear to be common findings in different populations. The variant affecting codon 54 is found in up to 20% of Caucasians while a variant at codon 57 has a frequency of 20–30% in West Africans.

The variant alleles affect the stability of MBL protein structure and so result in low serum levels of MBL in the heterozygous state and extremely low levels in those who are homozygous. Two promoter region polymorphisms also cause low levels of MBL.<sup>104</sup> It has been suggested that the persistence of such high frequencies of MBL deficiency in humans occurs because low levels may protect against certain parasitic infections.<sup>2</sup> Individuals with low levels have an increased incidence of bacterial infections, particularly in early childhood before the ability to make high affinity antibodies is fully developed. They also have an increased incidence of autoimmune disease.<sup>105</sup> The true significance of MBL deficiency is much debated and may only be important when other 'minor' immunodeficiencies coexist, or in early childhood, when other immune pathways are not fully developed.

## DEFICIENCIES OF C3 RECEPTORS

The distribution and function of cell surface receptors for C3b and its derivatives have been described (p. 1140). Specific clinical syndromes have been attributed to deficiencies of some of these receptors. A dominantly inherited CR1 deficiency is associated with SLE and other immune complex disorders, presumably related to failure of the immune complex clearing function of this molecule.

Deficient expression of the CR3 receptor occurs as part of the leukocyte adhesion deficiency type I syndrome (p. 1166) since it is a member of the beta integrin family affected in this disorder though what contribution this makes to the overall clinical picture in that condition is unclear.

## PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

The membrane bound complement regulatory proteins DAF (CD55) and CD59 prevent the activation of complement on host cells. They are part of a family of proteins which are attached to the cell surface by a glycosylphosphatidylinositol anchor. A clonal defect in stem cells can result in abnormal expression which increases the susceptibility of cells, especially red blood cells, to complement mediated lysis. This can result in paroxysmal nocturnal hemoglobinuria.

## MANAGEMENT OF COMPLEMENT DEFICIENCIES

Apart from C1 esterase inhibitor there are no specific replacement factor preparations. Fresh plasma infusions have been used prophylactically or can be reserved for the treatment of serious episodes of infection. Life-long prophylactic penicillin and meningococcal vaccination are advised in those complement deficiencies resulting in susceptibility to

neisserial infections. A polyvalent vaccine (A, C, W135 and Y) should be given. Prophylactic co-trimoxazole can be used in deficiencies which result in an increased susceptibility to a wider range of organisms. Clinical monitoring may allow earlier diagnosis and treatment of autoimmune disorders should they emerge.

## SECONDARY IMMUNODEFICIENCY

Secondary immunodeficiencies are more common than primary disorders and are easily overlooked. Increasing success in treating cancer and transplantation mean that more and more children receive immunosuppressive drugs (Table 27.14). Children with autoimmune disease also receive immunosuppressive treatment, and newly available biological agents, e.g. etanercept, are associated with infection. Viral infections also depress immune function and specific aspects of immunity may be lost in other conditions, e.g. immunoglobulin deficiency secondary to protein-losing states, or complement consumption states. The causes of more generalized, and sometimes less well-defined, secondary immunodeficiency are discussed here.

## INFECTION-INDUCED IMMUNODEFICIENCY

Many different infections have been shown to depress immunity. This is seen most commonly after viral infection<sup>106</sup> but chronic infection with

other organisms can have similar effects. Examples include the depressed antibody responses in malaria infected children which correlate with the parasite load, or the T lymphocyte depression that complicates advanced mycobacterial disease and which may be due to the immunosuppressive effects of specific mycobacterial cell wall products.

### Acute viral infection

Decreased numbers of circulating lymphocytes associated with markedly reduced T lymphocyte proliferative responses and cutaneous anergy are a 'normal' reaction to a wide variety of common acute viral infections. This was first recognized in measles infection by Von Pirquet in 1908. It has also occurred after live viral vaccines, including measles and oral polio. In some cases, it is due to direct infection of lymphocytes and/or macrophages. In others, there is an alteration in immunoregulation, most marked in acute infectious mononucleosis due to EBV infection in which there is B and T lymphocyte proliferation and a reversal of the normal helper:suppressor T lymphocyte ratios. Influenza and measles virus infections also have nonspecific depressive effects on neutrophil and monocyte function. The clinical importance of these observations is not always certain but in resource limited countries they probably account for the very high incidence of secondary bacterial infection after measles and the fatal downward spiral of infection and malnutrition that is commonly seen after measles.

### Chronic viral infection

Congenital viral infection (and toxoplasmosis) results in an immune depression with specific failure of T lymphocyte reactivity, or tolerance, to the relevant agent and in some cases a more generalized depression of antibody responses and even hypogammaglobulinemia, sometimes of a pattern which mimics the hyper-IgM syndrome. Congenital cytomegalovirus and rubella infections can result in prolonged excretion of these viruses for several years. Other chronic viral infections, e.g. subacute sclerosing panencephalitis or persistent EBV infection, are associated with an ill-defined immune suppression, possibly partly due to an element of pre-existing immune incompetence. Hepatitis C virus infection is associated with acquired IgA deficiency.<sup>107</sup>

## IMMUNODEFICIENCY DUE TO DRUGS AND RADIATION

### Specific immunosuppressive agents

Antibodies to human lymphocytes (antilymphocyte globulin) or specific T lymphocyte subpopulations are used to treat idiopathic aplastic anaemia, GvHD and graft rejection. They induce prolonged, profound lymphopenia and depress primary antibody and delayed hypersensitivity responses. B lymphocyte monoclonal antibodies have been used in the treatment of B lymphoproliferative disease in transplant patients with some success but deplete the B lymphocyte population for many months and can lead to hypogammaglobulinemia.

The newer biologic monoclonal antibody agents such as etanercept (soluble TNF-alpha receptor), infliximab (anti-TNF-alpha), basiliximab (anti IL-2R-alpha), and others are increasingly used in transplantation settings, and to treat inflammatory disorders such as juvenile idiopathic arthritis and Crohn disease. Their use is associated with an increased infection risk, particularly tuberculosis associated with the use of TNF-alpha blockade.

Ciclosporin and tacrolimus are reversible calcineurin antagonists used in organ and bone marrow transplantation, affecting predominantly T lymphocytes, but also B lymphocytes and other cell types. They inhibit antigen processing as well as diminishing IL-1 and IL-2 production, and IL-2 receptor expression.

Corticosteroid drugs are less specific, but potent, immunosuppressive drugs.<sup>108</sup> The degree of immunosuppression induced is related to the dose and length of treatment course and probably varies between individuals. An equivalent dose of prednisolone 2 mg/kg/day for more than a week, or 1 mg/kg/day for greater than a month is generally considered immunosuppressive. Lymphopenia results from a diminution of recirculation of long-lived T lymphocytes. Cytotoxic function, mitogenic

Sarcoidosis	
Surgery and anesthesia	

responses and delayed hypersensitivity responses are all depressed. With high dose treatment for prolonged periods antibody responses, especially primary responses, also become impaired. Corticosteroids also affect recirculating monocytes and polymorphs, and microbicidal ability is depressed.

Cytotoxic drugs used in the treatment of leukemia and solid tumors have major immunosuppressive side-effects. Cyclophosphamide particularly affects B lymphocyte function and antibody production, but T lymphopenia (especially of CD4+ T lymphocytes) also occurs.

Azathioprine, mycophenolate mofetil and 6-mercaptopurine suppress antibody production, particularly primary responses. T lymphocyte functions including delayed hypersensitivity responses are also depressed.

Methotrexate has potent anti-inflammatory activity and may also suppress antibody responses in higher doses.

Radiation therapy, particularly total body or total lymphoid irradiation, has profound and long-lasting effects on lymphocyte-mediated immune function and on antibody responses.

The most severe immunosuppressed states occur during HSCT for malignant disease. In these cases, a combination of radiotherapy and chemotherapy is often used.

### Clinical effects

The immunosuppressed child is susceptible to opportunistic infection, especially fungal infections and *Pneumocystis carinii* pneumonia (see Figs 27.16, 27.17). After HSCT, there is a recognized pattern of susceptibility to different pathogens, depending on the elapsed time since the procedure (Fig. 27.20). In the absence of neutropenia, susceptibility to pyogenic infections is less of a problem. 'Live' vaccines should be avoided, as should contact with cases of measles and chickenpox. Postexposure prophylaxis should be given when inadvertent exposure to these viruses occurs. Co-trimoxazole is effective as prophylaxis against *Pneumocystis carinii* pneumonia.

### Other drugs

A variety of miscellaneous drugs may cause immunosuppression as part of their side-effect profile. The effects of phenytoin and other agents on IgA production are discussed in the section on IgA deficiency. Moderate or severe depression of neutrophil counts is a side-effect of a large number of drugs including antibiotics such as sulfonamides and flucloxacillin and results in a susceptibility to bacterial disease.

## MALNUTRITION

Nutritional status, infection and immunity are closely linked, and nutritional deficiency can have profound effects on all aspects of the immune system. The most profound and wide-ranging effects are seen in protein/

Table 27.15 Main immunological effects of severe malnutrition

<i>Cell-mediated immunity</i>
T cell lymphopenia
Reduced CD4 cell numbers
Reduced CD4:CD8 ratio
Reduced delayed hypersensitivity responses
Reduced proliferative T cell responses to mitogens and antigens
Reduced lymphokine production
<i>Antibody production</i>
Polyclonal hypergammaglobulinemia
Decreased IgA in secretions
Increased serum IgE
Defective antibody responses
Reduced antibody affinity
Depressed function of antigen-presenting cells
<i>Nonspecific immune system</i>
Depressed neutrophil bactericidal capability
Depressed levels of complement factors, especially C3

calorie deficiency (Table 27.15), with changes in lymphocyte number and function, antibody production and quality, complement synthesis and phagocytosis.<sup>109</sup> There is increased susceptibility to TB, measles, *Pneumocystis carinii* as well as staphylococcal pneumonia, and Gram negative sepsis.

Specific nutritional deficiencies also affect immune function. Zinc deficiency in autosomal recessive acrodermatitis enteropathica or secondary to nutritional deficiency causes thymic atrophy, T lymphopenia, anergy, impaired cytotoxicity and decreased immunoglobulin production. Many immunological effects of zinc deficiency may be related to the critical role of zinc in intracellular zinc-finger-dependent transcription factors, and in DNA synthesis and lymphocyte proliferation. Treatment with zinc supplements reverses most effects. Iron deficiency, even without anemia, has subtle effects on T lymphocyte and phagocytic lymphocyte function. The clinical importance of this is not clear. Some studies have shown an increased frequency of infections which reverses with iron therapy, but others have not confirmed this. Vitamin A deficiency is associated with depressed T lymphocyte and humoral responses, and a dominant  $T_H2$  pattern of response. In populations at risk from malnutrition, vitamin A supplementation improves antibody responses to vaccines. In similar populations treatment with vitamin A during measles infection reduces mortality and has been shown to reverse some of the induced abnormalities in lymphocyte numbers and function.

## VACCINATION OF THE CHILD WITH A POTENTIALLY IMPAIRED IMMUNE RESPONSE

Immunocompromised children are often more in need of the protection vaccination can offer because of their greater risk from infection, and yet are less likely to be vaccinated because of concerns about the underlying immunodeficiency. In general, live vaccine should be avoided in children with malignancy who are being treated with or have received chemotherapy within 6 months. Booster vaccines may be appropriate after completion of treatment. Children who have undergone HSCT should be reimmunized 12–18 months post HSCT, providing immunosuppression has been stopped for 6 months or more and they do not have GvHD. Measles, mumps and rubella (MMR) vaccine should be given 6 months after commencement of the vaccination schedule. Vaccinations should be up to date before transplantation in those receiving solid organ transplants. As they remain on life-long immunosuppression following transplantation, live vaccines should be avoided. HIV infected children should receive killed polio vaccine, but MMR seems safe to give. Children with primary immunodeficiency should be immunized. Those with lymphocyte-mediated immunodeficiency should not receive live vaccines; in all other forms

Fig. 27.20 Timeline showing periods of maximal risk for various infectious complications after bone marrow transplantation with immunosuppression/marrow ablation. (Courtesy of the Bubble Foundation).

of immunodeficiency live vaccine can safely be administered, except BCG in patients with CGD. Children on pharmacological doses of steroids (an equivalent dose of prednisolone 2 mg/kg/day for > 1 week, or 1 mg/kg/day for > 1 month) or other immunosuppressive therapy should not be given live vaccines. Conjugate pneumococcal vaccine should be given to children with asplenia, hyposplenism or nephrotic syndrome, although from late 2006 it is part of the routine UK primary vaccination schedule. Zoster-specific immunoglobulin should be given to those with significant immunosuppression who are chickenpox contacts and non-immune. Children receiving immunoglobulin replacement should not be vaccinated, as protective antibody is present in the immunoglobulin given.<sup>110</sup>

## HYPOSPLENISM

Congenital asplenia, splenectomy and sickle cell disease are the major causes of hyposplenism in childhood. Finding Howell–Jolly bodies on a blood film or absence of a spleen on ultrasound are helpful when it is unclear whether the spleen is absent. Patients are at risk of pyogenic infection including pneumonia, septicemia or meningitis with polysaccharide encapsulated bacteria such as *Streptococcus pneumoniae* or *Neisseria meningitidis*. The absolute risk of infection of 0.42% per year is significant when viewed over a lifetime, and the risk is four times higher in young children with congenital asplenia where other aspects of immunity are less well developed. Young asplenic children also suffer infection with a greater range of pathogens including *Haemophilus influenzae* and Gram negative organisms. The immunodeficiency is multifactorial and probably largely functional. Factors thought to contribute include failure of clearance of opsonized bacteria in the spleen, lack of the B lymphocyte reservoir function, and low activity of the alternative pathway of complement. Defective alternative pathway complement activity was found in 10% of splenectomized and 16% of sickle cell patients. In older patients, IgG antibody responses to pneumococcal vaccine are similar to normal individuals although low serum IgM levels have been reported. Antipolysaccharide IgG levels decay more quickly.<sup>111</sup>

As pneumococcal infection is the most common severe infection, prophylaxis with penicillin is used in the UK, but alternative treatment may be necessary where penicillin-resistant pneumococci are common. In children below 4 years of age, the risks from other infections mean a broader spectrum antibiotic such as amoxicillin (or co-trimoxazole) is recommended. Vaccination with conjugated pneumococcal, *Haemophilus influenzae* type B and meningococcus C vaccines may diminish the risk but does not remove the need to give penicillin. Immunization should be performed prior to elective splenectomy. Antipneumococcal antibody levels should be measured annually, and patients revaccinated if levels are low.<sup>112</sup>

Much, but not all, of the increased susceptibility to infection in sickle cell disease stems from the hyposplenism which develops as the spleen is infarcted. In addition, sickle cell patients have impaired reticuloendothelial clearing capacity (due to chronic hemolysis) and focal tissue ischemia (as a result of sickling). As well as being susceptible to pneumococcus, these patients are also prone to Gram negative sepsis, including salmonella osteomyelitis. The risk of these problems is less in the variant form, hemoglobin S, hemoglobin C disease, but is still higher than background so prophylactic measures are still indicated.

## TREATMENT OF IMMUNODEFICIENCY

### SUPPORTIVE CARE

Children with immunodeficiency disorders often require the full spectrum of pediatric care. Particular attention needs to be paid to nutritional status and the management of dietary intolerances secondary to the gastrointestinal problems which frequently occur. Supporting the emotional needs of the family is also very important. Prevention and treatment of infections is the mainstay of supportive care.

## GENERAL MEASURES FOR PREVENTION OF INFECTIONS

Newborns suspected of having a severe immunodeficiency disorder should be protected using isolation techniques, including limitation of the numbers of persons involved with care; individuals with respiratory or gastrointestinal symptoms of infection should avoid contact. Breast-feeding should be encouraged. Wherever the child is managed the importance of strict hand washing procedures cannot be overemphasized. If HSCT with conditioning chemotherapy is embarked upon (see below), isolation in facilities with positive pressure filtered air supply is necessary, mainly to reduce the risk of aspergillosis and droplet borne viral infections.

## SPECIFIC MEASURES FOR PREVENTION OF INFECTIONS

Co-trimoxazole as prophylaxis against *Pneumocystis carinii* should be given for defects involving cell-mediated immunity mechanisms. For *Pneumocystis carinii* pneumonia prophylaxis only, co-trimoxazole need only be given on 2 or 3 days a week. If this is not tolerated, alternatives include dapsone or atovaquone. Inhaled pentamidine can be used in older children. Injectable pentamidine should not be used prophylactically because of the potential side-effects and possible reduced efficacy. Co-trimoxazole probably also reduces the incidence of pyogenic infections in these patients and those with phagocytic or humoral immune deficiencies and for this purpose it is usually given daily (dose 30 mg/kg/day in one or two doses). In circumstances of poor nutrition, increased bone marrow turnover and in all cases after HSCT, weekly folic acid supplements are given to lessen the risk of bone marrow depression without compromising the antimicrobial efficacy. Antifungal prophylaxis should be used in combined immunodeficiencies or phagocytic cell defects. In chronic granulomatous disease and other conditions where the risk of aspergillus infection is high, itraconazole is preferred. Otherwise fluconazole or non-absorbed agents such as nystatin are used.

Where the immune deficiency predisposes to infection with relatively few organisms, prophylaxis with a narrow spectrum antibiotic can be used, e.g. penicillin prophylaxis for the terminal complement deficiencies where only neisserial infection is a risk. Prophylactic antibiotics are most commonly used for patients with relatively minor humoral deficiencies such as symptomatic IgA deficiency. There is no scientific basis for the choice of antibiotic in these circumstances because of the great difficulty in performing a trial looking at efficacy. Co-trimoxazole has been widely used but concerns over potential side-effects have led to the use of other agents such as azithromycin which, because of its long half-life, can be given on 3 days out of every 14 and provides continuous prophylaxis against sinopulmonary bacterial infections. This is attractive, but less is known of its effects when given over many years. Cefixime is a further alternative given as a single daily dose. Antiviral prophylaxis with aciclovir is used in patients with cell-mediated immunodeficiency and previous herpes simplex infection. It is also used in the context of HSCT to prevent herpes simplex and CMV reactivation.

Immunizations may be used judiciously if sufficient immune function is judged to be present to give an antibody response. 'Live' vaccines are contraindicated in combined immunodeficiencies and in the more severe antibody deficiency states. Passive immunization is the basis of immunoglobulin replacement therapy (see below) and specific hyperimmune globulins are available for postexposure prophylaxis in patients with primary or secondary immunodeficiency exposed to chickenpox or hepatitis B. For measles exposure, standard immunoglobulin is used. The role of immunoglobulins with high titers of anti-respiratory syncytial virus (RSV) or of monoclonal anti-RSV antibodies in protecting against RSV in children with primary immunodeficiencies during the winter season has not been evaluated and is unlikely to be formally investigated because of the rarity of these conditions. They may have a role in SCID patients before and during transplant, particularly as common cold symptoms in carers may be caused by this virus.

The prevention of complications of recurrent infections is most important. Evidence of middle ear disease which might lead to deafness should be sought and treated. Chronic lung disease leading to bronchiectasis is a serious complication, particularly of antibody deficiency states. Regular physiotherapy with sputum cultures to direct appropriate antibiotic therapy and monitoring of pulmonary status are useful. Breakthrough infections threatening organ damage despite prophylactic antibiotics may be an indication for starting immunoglobulin therapy even if the tests show relatively minor abnormalities of humoral immunity. Serial measurements of lung function tests and judicious use of high resolution CT (HRCT) scanning may detect early damage or progression of existing damage. HRCT scans are relatively contraindicated in disorders associated with increased radiosensitivity such as ataxia telangiectasia.

## TREATMENT OF INFECTIONS

A policy of vigorous and early antimicrobial treatment of infections should be observed. Unusual agents may cause infection, and broader spectrum antimicrobial cover may therefore be needed. In neutrophil disorders it is important to cover *Pseudomonas* and other Gram negative bacilli. Early treatment of an infection may be life saving, but its initiation should not detract from full attempts at identification of the causative agent. Invasive diagnostic procedures, such as bronchoalveolar lavage or, if this fails to produce a diagnosis, open lung biopsy, will facilitate precise and optimal therapy. The mainstay of treatment for systemic fungal infection remains amphotericin B, mostly used in its liposomal form to reduce toxicity and enable larger doses to be given. New agents increasingly used for treating invasive aspergillosis include voriconazole and caspofungin.

Antivirals such as the broad spectrum agent, ribavirin, and the anti-cytomegalovirus agents, ganciclovir and foscarnet, are particularly useful in the immunocompromised infant. Newer antivirals include cidofovir for resistant CMV, adenovirus and severe molluscum contagiosum and pleconaril for enteroviral infections. The role of zanamivir in immunocompromised children with influenza has not been assessed.

## BLOOD PRODUCT SUPPORT

Blood product infusions may be necessary in some disorders. In combined deficiencies and in patients undergoing heavy immunosuppression (as for HSCT), all such products except intravenous immunoglobulin and fresh frozen plasma may contain viable leukocytes and should be irradiated with 2000–3000 rad to prevent possible GvHD. In those with no evidence of previous exposure to CMV, blood products should be obtained from CMV-antibody-negative donors. White cell infusions have a role in specific situations such as adjunctive therapy in poorly responding infections in patients with CGD and other neutrophil function disorders particularly if they are harvested from G-CSF primed donors.

## SUPPORT FOR FAMILIES AND PATIENTS

Patient support organizations which are established in most resource rich countries are very helpful in providing information and advice and in helping families to meet others with the same (rare) diagnoses. In the UK the organization is the Primary Immunodeficiency Association (PIA) (<http://www.pia.org.uk/>). Further information may be generally available on the Web but families should be warned that sometimes this is produced without reference to expert advice. Other specific diseases may have their own organizations.

## REPLACEMENT IMMUNOGLOBULIN THERAPY

This is the mainstay of treatment for the more severe antibody states and various combined immunodeficiencies. The need for immunoglobulin must be evaluated on an individual patient basis. Absolute indications include quantitative defects (IgG less than the 95th percentile for age or less than 3 g/L in an older child) and qualitative defects (failure of response to booster vaccinations). Other indications include failure of

antibiotic prophylaxis in a child with quantitatively minor Ig abnormalities (e.g. IgA and IgG subclass deficiency) and risk of end-organ damage (e.g. bronchiectasis) in a child with any degree of antibody deficiency. As immunoglobulin is a blood product, and there is a limited supply, new and existing uses should be carefully evaluated.

## Risks of replacement therapy

Replacement immunoglobulin must contain the full range of protective antibodies in order to provide effective prophylaxis against infections. Unlike coagulation factors where the invariant protein needed can be made using molecular techniques, a polyclonal product cannot be generated by recombinant technology and human plasma has to be used as a source. To ensure that immunoglobulin contains the full spectrum of protective antibody, preparations are made from pooled (5–100 000 donors) plasma donations, which increases the risk of transmission of an infectious agent.<sup>113</sup> Pools are screened for known agents (e.g. hepatitis B and C) and the process of cold ethanol precipitation, universally used for the fractionation of plasma, effectively kills some viruses, including HIV. New intravenous and subcutaneous products must include a further viral inactivation step such as pasteurization or nanofiltration before they are licensed. The risk of transmission of variant Creutzfeldt – Jakob disease (vCJD) is theoretical and not quantifiable using modern techniques, but plasma is no longer sourced from the UK in an effort to minimize the risk. Taken together, these precautions have reduced the risk of infection to a very low level. Patients should be evaluated by PCR for hepatitis B and C prior to commencement of therapy, and require regular monitoring of immunoglobulin levels and liver function tests. Any elevation in liver function tests should prompt re-evaluation of their hepatitis status. Batch numbers of all products administered must be recorded to facilitate patient tracing if there is a problem with an individual batch. Switching between different preparations should be avoided unless there are good clinical reasons.

## Mode of administration

The efficacy of replacement immunoglobulin therapy was established in the 1950s using i.m. preparations. However, this is painful and only limited volumes can be given so that adequate serum levels of IgG were rarely achieved. Improvements in manufacturing techniques in the 1980s meant IMIG was superseded by IVIG preparations. Large volumes of the latter could be given, achieving better symptom control and trough IgG levels well within the normal range. Doses are in the range of 0.3–0.5 g/kg/3 weeks, infused over 2–3 h. Immediate reactions to IVIG are more common than to the i.m. preparation and include nausea, vomiting, flushing, rigors and occasionally hypertension. These can normally be controlled by slowing the infusion rate. Rarely, anaphylactoid reactions occur, particularly in IgA-deficient patients who may have anti-IgA antibodies.<sup>114</sup> Patients with known anti-IgA antibodies should be given a preparation with a low IgA content. In the 1990s subcutaneous (s.c.) administration of immunoglobulin was shown to be efficacious in adults with far fewer side-effects, other than local reactions, and specific products are now licensed for use in children. Advantages include lack of need for venous access and ease of training parents for home therapy. However, given that only a limited volume can be given in one site, frequency of administration is normally increased, and ScIg should be given weekly.

## REPLACEMENT THERAPY FOR COMBINED DEFICIENCIES

### REPLACEMENT OF THYMUS FUNCTION

Fetal thymus and/or fetal liver (as a source of stem cells) transplants have been used for SCID with some limited success. Delayed immune reconstitution, severe infection, GvHD and lack of availability of fetal tissues together with significant improvement in HSCT techniques have led to these procedures being abandoned. However, fetal thymus transplantation appears to be effective in patients with severe DiGeorge anomaly who have normal hemopoietic stem cells but who lack the thymic machinery to undergo

T lymphocyte receptor gene rearrangement. Thymic transplant in these patients is still being evaluated, but early results look promising.<sup>115</sup>

## HEMOPOIETIC STEM CELL TRANSPLANTATION

Virtually all primary T lymphocyte and phagocyte immunodeficiency disorders are potentially correctable by HSCT.<sup>116</sup> Patients with immediately life-threatening conditions, mainly SCID, are treated by HSCT. Improving results from HSCT, together with an increasing understanding of the basis of the immunodeficiencies, and international registry data on their long term outcome have led to more conditions such as Wiskott–Aldrich syndrome, CD40L deficiency and CGD being treated by HSCT (Table 27.16).

Early attempts at HSCT using poorly matched donors were largely unsuccessful and so only transplants using HLA matched sibling donors were performed, an approach available only to about 20% of patients. Since the early 1980s, techniques have been developed to allow parent-to-child (haploidentical) grafts, by removing mature T lymphocytes that would otherwise cause fatal GvHD. These have become the most common HSCT procedure for patients with SCID.<sup>117,118</sup> Matched unrelated donor transplants are being increasingly used, particularly for non-SCID immunodeficiencies. Overall results are improving, probably due to a combination of factors (Table 27.17).

**Table 27.16** Primary immunodeficiency disorders which have been treated with bone marrow transplantation

<i>Lymphocyte disorders</i>
Severe combined immunodeficiency (including adenosine deaminase deficiency)
Wiskott–Aldrich syndrome
Omenn syndrome
Major histocompatibility antigen class II deficiency
DiGeorge syndrome
Purine nucleoside phosphorylase deficiency
Cartilage–hair hypoplasia syndrome
X-linked lymphoproliferative disease
Hyper-IgM syndrome (CD40 ligand deficiency)
Mucocutaneous candidiasis
Immunodeficiency with partial albinism (Griscelli syndrome)
<i>Phagocytic cell disorders</i>
Chronic granulomatous disease
Leukocyte adhesion defect type I
Congenital agranulocytosis
Chediak–Higashi syndrome
Familial hemophagocytic lymphohistiocytosis
IL-12-dependent interferon-gamma pathway defects
Hyper-IgE syndrome

**Table 27.17** Factors associated with improvement in results of HSCT in primary immunodeficiency

- Use of new stem cell sources (peripherally mobilized blood stem cells, umbilical cord blood stem cells)
- Development of low toxicity (reduced intensity) conditioning chemotherapy
- Improved HLA matching with high resolution molecular DNA techniques
- Improved early detection of viral infection by PCR enabling preemptive treatment
- Development of new antiviral and antifungal agents
- Development of new immunosuppressive agents to treat GvHD, e.g. infliximab
- Early use of aggressive supportive care including intensive care

## Complications of HSCT

The five main complications of HSCT are toxicity from conditioning agents, graft failure, graft rejection, GvHD, and infection which may be pre-existing due to immunodeficiency or be acquired after HSCT. Rejection is less likely following transplantation with replete rather than T lymphocyte depleted marrow, but the risk of GvHD after replete marrow is greater. Graft rejection is unusual in SCID, but more likely in the NK+ phenotypes, or if clinically evident maternal engraftment is present. Myeloablation with chemotherapy helps reduce the chance of rejection and may result in better engraftment quality. The risk of infectious complications is greatest in T lymphocyte depleted grafts where there is a prolonged period before functioning immunity develops.

GvHD primarily affects skin, gut and liver causing an erythematous maculopapular rash, watery diarrhea and jaundice. Diagnosis is clinical, but should usually be confirmed by biopsy of the affected organ. GvHD is rarely fatal but the associated severe acute inflammatory changes may be life threatening. The process itself causes further immunosuppression and bone marrow depression, which may cause delay or failure of graft maturation which, in turn, increases the risk from infection. Cyclosporin A (ciclosporin) is generally given as prophylaxis against GvHD with or without methotrexate. Corticosteroids and intravenous immunoglobulin are also sometimes used as GvHD prophylaxis, the latter also reducing the risk of infection. Acute GvHD is treated with immunosuppressive agents including high dose steroids, mycophenolate mofetil and increasingly biologic agents such as infliximab and basiliximab. In extreme cases antithymocyte globulin may be needed, which further increases the infection risk. Chronic, ongoing GvHD is rarely a problem following HSCT for immunodeficiency. Recalcitrant GvHD may respond to extracorporeal phototherapy.

Infection after transplantation is discussed above (see secondary immunodeficiencies and Fig. 27.20).

## Matched related donor HSCT

Usually only sibling donors are matched, but when parents are consanguineous, other family members may be a full match. For severe combined immunodeficiency, HLA-matched grafts are relatively straightforward. Prior immunosuppression ('conditioning') is not usually required or can be minimal. GvHD can occur but is usually mild and self-limiting and prophylaxis is not usually given. Full and long-lasting immune reconstitution is usually achieved though in some cases B lymphocyte engraftment and therefore reconstitution of humoral immunity does not occur, necessitating continuing immunoglobulin therapy. In recent years, the success rate in the European experience has been of the order of 90%.<sup>116</sup> Failure is usually related to the pre-existing condition of the child, rather than the technique.

Matched transplants for other conditions (where a residual immune system is capable of graft rejection) have a lower success rate, at least in part because of the need to give conditioning treatment, with the consequent risks of lung and liver toxicity and infection. Nevertheless, encouraging results have been reported<sup>116</sup> with overall survival of 81% since 1995. The use of lower intensity chemotherapy conditioning regimens has enabled sick patients with pre-existing lung and liver damage to undergo successful treatment.<sup>119</sup>

## Mismatched bone marrow transplantation

By removing all T lymphocyte lineage cells (back to the prethymic stage) from harvested bone marrow, GvHD can be prevented even in an HLA-mismatched situation. At first, T lymphocytes were removed by their propensity to bind to plant lectins, but now specific monoclonal antibodies are used that either remove T lymphocytes or positively select HSC in a semiautomated system. The resulting T lymphocyte-depleted, stem cell-enriched marrow will reconstitute T lymphocyte immunity by producing precursor T lymphocytes which are 'educated' into a state of tolerance towards the foreign HLA haplotype in the recipient thymus. The fact that there is half matching of human leukocyte antigen allows most immune functions to proceed normally.

However, successful mismatched bone marrow transplants are not as easily achieved as matched ones. Even in SCID, the T lymphocyte depleted bone marrow can be rejected (or fail to take), and to prevent this conditioning therapy (marrow ablation) is often needed. Development of immune function is often slow (120 days before the appearance of T lymphocytes versus 42 days following matched antigen HSCT), and full immune reconstitution will take months. B lymphocyte function (antibody responses) is generally good following fully conditioned HSC transplantation,<sup>120</sup> although polysaccharide responses may remain poor. Failure to remove all the T lymphocytes can result in severe GvHD, which may require the use of immunosuppressive drugs. On the other hand absolute deficiency of T lymphocytes inhibits engraftment. The adding back of small numbers of T lymphocytes has been attempted to overcome this problem but it increases the risk of GvHD. Clinical trials are in progress investigating the co-infusion of mesenchymal stem cells, which may facilitate engraftment and modulate GvHD. The prolonged period of immunodeficiency greatly increases the risk of opportunistic infections. In this group of transplants the use of high technology isolation facilities (such as laminar air flow) improves the outcome.

Despite these problems, refinements of the technique over recent years have resulted in continuing improvement in results, with success rates for SCID of around 78% for T lymphocyte depleted grafts, and >90% for matched sibling donors.<sup>116</sup> Success is dependent on type of SCID, with better results for B+ SCID than the B- phenotype.<sup>117</sup> Age at presentation also influences outcome, with very good results for those transplanted in the neonatal period, before they have contracted infections.<sup>121</sup>

The problems and risks of mismatched bone marrow transplantation have meant that it has been used less for non-SCID conditions. Nevertheless results are improving<sup>116</sup> with 47% survival in the post-1995 period in Europe.

### Matched unrelated donor bone marrow transplantation

For many years there have been national and international registries of tissue typed volunteers willing to donate bone marrow, allowing the option of using phenotypically matched unrelated donors. There is considerable experience of this approach in the hematological field. Early results in SCID suggested that using mismatched haploidentical donors gave better results. However, with the increased sophistication of tissue typing techniques this may no longer be the case and unrelated donors are increasingly being used with similar results to those following mismatched bone marrow transplantation.

Storage of screened umbilical cord donations is also performed. Advantages to using cord blood include high stem cell dose, no risk to the donor, less GvHD and 'instant' availability of a suitable unit. This is particularly important in treating infants with SCID where the delay involved in identifying, screening and harvesting an unrelated donor may mean new or worsening infection, decreasing the chance of successful transplantation. Relatively low stem cell dose/kg is less of a problem than for adult transplantation, particularly for infants with SCID. Immune reconstitution appears to be as good as for other stem cell sources.<sup>122</sup>

### Transplantation technique

This is relatively straightforward for donor and recipient. Under general anesthesia marrow is harvested by multiple punctures along the posterior iliac crest. If it is to be given unfractionated it is passed through a coarse filter to remove bone particles, the nucleated cells are counted and if necessary the volume adjusted. T lymphocyte depletion, if required, is done under strict aseptic conditions (details of this are beyond the scope of this chapter). Another approach which avoids the need for bone marrow harvest is the technique of peripheral stem cell harvest which is increasingly being used and is under evaluation. Umbilical cord blood is harvested at time of delivery, and in families with known immunodeficiencies, directed cord donation is possible, targeted for potential future affected family members.

## OTHER REPLACEMENT THERAPIES

### Enzyme replacement

Some reconstitution of immunological function can be achieved by administering replacement enzyme in ADA deficiency. Purified bovine ADA is conjugated with polyethylene glycol (PEG-ADA) and given by intramuscular injection. In the severe SCID phenotype this can significantly improve immune function, but regular treatment is needed and the long term outcome is not known. If a suitable donor is available, HSCT seems the best treatment. However PEG-ADA may be useful in partial forms of the condition. Its role as an adjunct to transplantation is unclear.

### Cytokines

Several cytokines and growth factors are available in recombinant synthetic form. Their widespread use in immunodeficiency disorders awaits evaluation. IFN-gamma and IL-2 have been useful in improving cell-mediated immune function in deficiencies where their production was demonstrably absent.<sup>123</sup> Growth factors such as G-CSF or granulocyte-macrophage colony stimulating factor may be of benefit in phagocytic series defects. The use of IFN-gamma in chronic granulomatous disease has been discussed under the description of this disorder.

### Somatic gene therapy

This has been attempted in adenosine deaminase deficiency using ADA transfected CD34 positive autologous cells, with improvement in immunological and clinical parameters.<sup>124</sup> Successful gene therapy has also been performed for common gamma chain deficiency.<sup>125</sup> Although early results were encouraging, leukemia has subsequently occurred in some cases.<sup>126</sup> It is not yet clear how widespread this risk is, and it may be confined to specific disorders. Preclinical gene therapy trials for RAG deficiency in animal models have demonstrated a malignancy risk. A number of other conditions may be amenable to gene therapy. Clinical trials are currently planned for selected patients with X-linked chronic granulomatous disease or Wiskott-Aldrich syndrome who have no suitable donor. At present HSCT remains the treatment of choice for all but a handful of patients.

## MORTALITY AND MORBIDITY IN INFECTIOUS DISEASE

### THE GLOBAL PERSPECTIVE

Worldwide, infections are responsible for the majority of deaths and loss of good health in children. In 2005, infectious diseases were estimated to have caused about 6.7 million of a total of 10.1 million deaths among the estimated global child population of under-5-year-olds of 616.2 million.<sup>1,2</sup> These deaths occurred disproportionately in resource limited countries, where it is also estimated that five groups of infections caused the death of more than 7 million children: acute respiratory infections (ARIs); diarrheal diseases; congenital infections including human immunodeficiency virus (HIV) and hepatitis B; malaria; and vaccine-preventable diseases including measles.<sup>1,2</sup> Although there has been improvement worldwide in the all cause under-5 child mortality rate from 1990 to 2005 (from 95 to 76 per thousand) there is little reason to believe the proportion of deaths attributable to infection has changed much over this time, except that the numbers of children dying as a result of HIV have considerably increased.<sup>2,3</sup> This and other factors means that there has been far less improvement in under-5 mortality in sub-Saharan Africa where the decline between 1990 and 2005 has been only from 188 to 169 per thousand. Indeed there are countries most heavily affected by HIV such as Botswana and South Africa where HIV has reversed previous trends with the estimated under-5 mortality rising from 58 to 120 per thousand and 60 to 68 per thousand respectively.<sup>3</sup> The relationship between infection, malnutrition and socially determined factors such as wars and orphanhood is subtle but important, as poor nutrition, poverty and social dislocation greatly multiply the impact of infections. To a considerable extent this explains why infections are so much more important as a cause of death and disability in resource limited compared to resource rich countries.<sup>4</sup> The rising incidence of HIV infection in resource limited countries has added another multiplier and these relations are shown schematically in Figure 28.1, contrasting sub-Saharan Africa with South Asia in the early years of the new millenium.<sup>2,3</sup>

Malnutrition underlies a substantial proportion of the deaths from diarrheal diseases, respiratory infections, measles and malaria, while HIV is of particular importance in sub-Saharan Africa and some parts

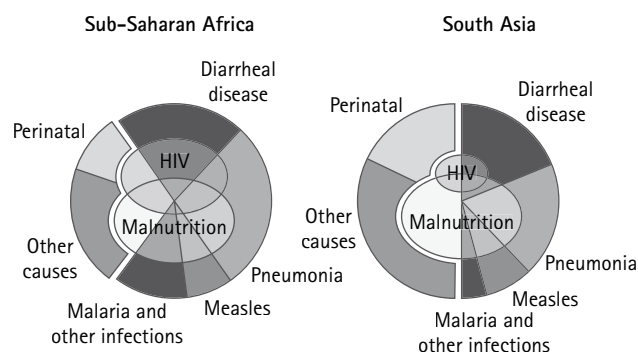

Fig. 28.1 Principal causes of death in children under age 5, sub-Saharan Africa and South Asia, circa 2000.

of Asia.<sup>2,3</sup> In contrast, in Western Europe and other resource rich countries, malnutrition plays little role as a cofactor for the effects of infection, except in children with serious constitutional diseases such as malignancies or congenital immunodeficiencies. However, a growing population of immunocompromised children (very low birth weight babies, children with congenital immunodeficiencies or HIV infection and children on powerful immunocompromising therapies) represents an increasingly important source of deaths due to infections, often with organisms that are usually innocuous for immunocompetent children. It has been estimated that infections are responsible for around 17% (37 000) of 214 000 deaths under 5 years old that take place among 78 million children annually in resource rich countries.<sup>1,2</sup> Proportionately, the burden of infections is far higher in primary care. In England and Wales, infectious diseases are responsible for 40% of all new episodes of illness presenting to general practitioners with annual rates of around 730 episodes per 1000 population. Rates are even higher for infants (children before their first birthday).<sup>5</sup> Mortality statistics and data on acute consultations need to be supplemented by estimates of the burden of disability (morbidity) and to allow for the varying implications of the disability or death of an individual at different ages. This can be done by use of a measure such as disability adjusted life years (DALYs).<sup>1,6</sup> Combining estimates of chronic disability and mortality statistics, this measure calculates the likely numbers of healthy years of life lost because of specific diseases and conditions and, by 'weighting', an allowance is made for the different significance of ill-health and mortality among infants, elderly persons and adults providing for dependants. Estimates of the burden of disease experienced (Table 28.1 and Figure 28.1)<sup>1</sup> further emphasize the importance of infectious disease in resource limited

Table 28.1 Estimated distribution of burden of disease (combined mortality and chronic morbidity) in children in resource limited countries – 1990. (Source World Bank 1993<sup>1</sup>)

	Total DALYs lost (million)	
	Age under 5 years	Age 5–14 years
Perinatal conditions	13.5	Nil
Communicable disease	63.3	33.9
Congenital STDs (HIV and syphilis)	(2.0%)	(4.0%)
Diarrheal diseases	(32%)	(15%)
Tuberculosis	(1.0%)	(11%)
Other vaccine-preventable disease	(20%)	(18%)
Malaria	(8%)	(9%)
Intestinal helminths	Nil	(27%)
Respiratory infections	(35%)	(16%)
Noncommunicable disorder	20.8	16.9
Injuries	6.2	9.7
Total	103.8	60.5

countries and the particular contribution to mortality in children under age 5 played by respiratory disease, diarrheal disease, the five vaccine-preventable diseases (diphtheria, measles, pertussis, polio and tetanus), and in older children by tuberculosis and intestinal helminths.<sup>1</sup>

### HIV AND AIDS

Since the 1990s there has been an inexorable rise in the global importance of HIV. In 2006, the United Nations AIDS program and WHO estimated that 39.5 million persons worldwide were infected with HIV, of whom 2.3 million were children under the age of 15, and 530 000 children became infected with HIV.<sup>2,3</sup> The majority of childhood infections occur through mother-to-child transmission, with a smaller number from unscreened blood transfusions in resource limited settings. The distribution of deaths varies dramatically by global region, with the highest numbers and rates in sub-Saharan Africa where the rates have reversed previous improving trends in child mortality rates (Figs. 28.2 and 28.3). HIV rarely kills children directly, but by lowering the child's immunocompetence it leaves the infected child increasingly vulnerable to other infections. In addition, HIV infection affects children by making them lose their parents to HIV prematurely and it is estimated

that 15.2 million children (under age 18) were living having lost one or more parents to HIV.<sup>3</sup> Since the appreciation that the risk of mother-to-child transmission of HIV infection can be reduced to under 2%, screening for HIV infection has resulted in a fall in early AIDS cases in France, Italy, Spain and the UK, the countries most affected in Western Europe (Fig. 28.4).<sup>7</sup> The fall in early paediatric AIDS has taken place despite rising levels of HIV infection in mothers in the UK, notably in London, but also in the rest of the UK (Fig. 28.5).<sup>8</sup>

### THE UK

Infections remain an important cause of death in UK children. Conventional death registration data indicate that in 2005 infections (including infections of the central nervous and respiratory systems) were the main cause of death in 127 children in England and Wales (Table 28.2). The figure rises to 199 if sudden infant death syndrome is included. This represents a considerable change over time. In 1995 there were 193 deaths where infections were the main cause, with the figure including SIDS being 537.

Recent trends in a number of important infections in the UK are shown in Figures 28.4–28.14. Trends in vertically acquired HIV

infection (Figs 28.4 and 28.5) have already been mentioned.<sup>7,8</sup> The introduction of immunization against *Haemophilus influenzae* type b (Hib) in 1992 led to a dramatic decline in invasive infections attributed to this organism (Fig. 28.6). However, a booster dose of Hib was added when it became clear that primary immunization alone was insufficient and numbers began to rise again after 2000 (Fig. 28.6).<sup>9</sup> There has been heightened awareness of meningococcal infections as the most important single cause of septicemic and meningitic infections in immunocompetent children. The introduction of a conjugate vaccine against type C meningococcal infections has resulted in a fall in cases attributed to this infection in the earliest targeted groups, the under-1-year-olds and teenagers (Fig. 28.7).<sup>10</sup> Immunization was highly effective in reducing the incidence of measles in the 1970s (Fig. 28.8). However, measles vaccination coverage is incomplete. Sero-epidemiological investigations in England in the early 1990s indicated a growing number of susceptible (antibody negative) older children and hence an increasing risk of a substantial measles epidemic in school age children, with its inevitable morbidity and mortality, and more recently there have been significant

outbreaks.<sup>11,12</sup> To pre-empt further larger epidemics a UK-wide initiative immunized 8 million schoolchildren (90% of those eligible) in 1994. Transmission of indigenous measles was almost entirely interrupted and confirmed notifications fell dramatically. Hence the risk of an epidemic was averted, at least temporarily.<sup>12</sup> Subsequent declines in measles, mumps and rubella (MMR) vaccination following unwarranted parental concern over the safety of vaccine left more children under-protected (Fig. 28.9) and substantial outbreaks of measles followed in the late 1990s and early 2000s.<sup>13,14</sup> Trends in whooping cough (pertussis) in the late 1980s and early 1990s, following the collapse of professional and public confidence in pertussis vaccine, had provided earlier evidence of what can happen if myths about immunization are allowed to prevail over science (Fig. 28.10).<sup>15,16</sup> The rate of diphtheria and poliomyelitis declined dramatically in the UK following the introduction of immunization in the 1940s and 1950s rather as it did for *Haemophilus* in the 1990s. In contrast, control of another illness for which there is a vaccine, tuberculosis,<sup>17</sup> has been less successful with an overall rise in notifications in the 1990s, which particularly reflects trends in London

and imported cases (Fig. 28.11). Influenza epidemics occur every winter though they vary in their severity and the proportion of infections that occur among children (Fig. 28.12). Food poisoning has become the commonest notifiable infection in children. Sharply increasing trends in notified numbers of cases of food poisoning in the 1980s and 1990s were mirrored by trends in national laboratory reporting of salmonellosis. Since 1997, however, salmonella reports have declined while reports of *Campylobacter* spp. have risen (Fig. 28.13). Though numbers are far less than for campylobacter or salmonella, the emergence of *Escherichia coli* O157 since the 1980s is of concern because of the severe disease and specific renal pathology that often follows this infection. Not all countries see this subtype of verocytotoxigenic *E. coli* (VTEC): in Australia for example the predominant subtype is *E. coli* O111.<sup>18</sup>

Sexually transmitted diseases are now appreciated to be a substantial problem among adolescents in the UK. Rates of gonorrhoea rose by over 50% between 1995 and 2000 (Fig. 28.14) with the highest percentage rise among adolescents.<sup>19</sup> The highest incidences of gonorrhoea and chlamydia seen among genitourinary medicine clinic attenders are in females aged 16–19 years.<sup>8,19</sup> After intensive campaigns the rates of gonorrhoea are now declining.<sup>8</sup> Chlamydia is the more important, because of its widespread distribution and serious sequelae of pelvic inflammatory disease, infertility and ectopic pregnancies. It is clear that the chlamydia infections seen in genitourinary medicine clinics are only

a fraction of those prevalent in the teenage population and campaigns in the UK are now aiming to control this infection through opportunistic screening in primary care.<sup>20</sup>

General practitioner (GP) reporting provides the least-selected surveillance data in the UK on the nature and burden of infectious disease in children in the community, particularly on conditions such as chickenpox or influenza that are unlikely to be investigated microbiologically or to lead to hospital admission. These data show that respiratory tract infections (mainly upper tract infections) account for over 80% of new GP consultations for infectious diseases in children.<sup>5</sup>

## EMERGING AND RE-EMERGING INFECTIONS

In the 1960s and 1970s it was often stated that improving social conditions and medical treatments were leading to a relentless decline in the importance of infectious diseases. Emerging and re-emerging infections such as HIV and tuberculosis (Figs. 28.1 and 28.11), high profile nosocomial outbreaks of legionnaires' disease and food poisoning in the UK, and most recently the appearance of severe acute respiratory syndrome (SARS) and highly pathogenic avian influenza (H5N1) have changed medical opinion. In addition, the deliberate release of organisms such as anthrax in the USA has brought a new threat to health from infections.<sup>21</sup> It is now realized that infections remain important threats to the health

Fig. 28.11 Tuberculosis notification rates per 100 000 population in England and Wales 1993–2005. Fig. 28.14 Rates of uncomplicated gonorrhoea seen in genitourinary medicine clinics by age group in the UK 1995–2005.

Of particular importance to children are HIV, diphtheria, pertussis, *E. coli* O157 causing hemolytic uremic syndrome (HUS) and avian influenza (A/H5N1), and sexually transmitted infections in adolescents.

The reasons for emergence and re-emergence are almost as varied as the organisms themselves (Table 28.4).<sup>25</sup> Failure of public health programs can be an important cause. Diphtheria reappeared in the 1990s as an epidemic in Russia because of a collapse in vaccine production and the emergence of mistaken reasons among the public and professionals for refusing immunization. A similar phenomenon affecting pertussis occurred in the UK in the 1970s and 1980s from the mistaken impression that the vaccine was more dangerous than the disease (see Fig. 28.10).<sup>13,26</sup> Both *E. coli* O157 and various salmonellas have been spread efficiently through industrialized production and distribution of foods.<sup>27</sup> An outbreak of HUS due to contaminated commercial hamburgers occurred in the USA in 1993<sup>28</sup> and in 1995 an outbreak of gastrointestinal disease in children due to *S. agona* in north London was traced to defective production in a factory in Israel. Changes in behavior can result in disease emergence. International trends towards earlier menarche and sexual debut are causing younger females to be exposed to STDs with a consequent rise in pelvic inflammatory disease, ectopic pregnancy and secondary infertility.<sup>20,29</sup>

## EFFECTIVE INTERVENTIONS

In 1990, at a World Summit for Children, government leaders including that of the UK committed their administrations to 27 goals to improve the health and lives of children. There have been some major

achievements towards these goals and subsequent aspirational targets such as the Millennium Goals.<sup>2</sup> More than 60 countries have reached their national goals of reducing mortality rates of children < 5 years by a third or more. Polio has been eradicated in more than 175 countries and deaths from diarrheal illnesses have been more than halved.<sup>2</sup>

Interventions designed to prevent or treat infections may be assessed by measuring their resulting health gain as healthy years of life and comparing their costs relative to other interventions. Thus it is possible to come up with 'best buys' for countries, and this has been undertaken for resource limited countries by the World Bank using the 'DALY' measure.<sup>1,6</sup> Interventions targeted against acute respiratory infections, diarrheal disease, malaria and the six vaccine-preventable diseases represent four of the six top interventions for health gain in children under age 5, and five out of six of those targeted at children aged 5–14 years<sup>30</sup> (Tables 28.5 and 28.6). While new technologies and developments are necessary, greater health gains can come from the application of established interventions of proven effectiveness such as the early detection and treatment of acute respiratory infections, and the use of oral rehydration therapy (ORT) for gastrointestinal infections.<sup>30</sup> Immunization represents a success story. By 1990, the Expanded Program of Immunization (EPI) reached a goal of immunizing 80% of children in most countries with an estimated benefit of 3 million lives saved in 1995. A particular priority has been polio immunization. The EPI, supported by Rotary International, had, by 1995, eliminated wild polio from 145 countries, including all of the Americas.<sup>30</sup> However, the 80% target remains unachieved in sub-Saharan Africa where overall immunization rates are static and there have been outbreaks extending out of West Africa into

Table 28.4 Factors in infectious disease emergence and re-emergence relevant to child and adolescent health (Adapted from Morse 1995<sup>26</sup>)

Factor	Example of specific factors	Examples of disease (more than one factor may be driving the emergence of an infection)
Ecological changes including: those due to economic development and land use, distribution of animal populations and climate changes	Agriculture: dams, changes in water ecosystems; deforestation/reforestation; flood/drought; famine; changes in animal distribution; climate changes	Schistosomiasis (dams); Rift Valley fever (dams, irrigation); Argentine hemorrhagic fever (agriculture); West Nile virus (bird movement), highly pathogenic avian influenza Hantaan–Korean hemorrhagic fever (agriculture); hantavirus pulmonary syndrome, southwestern US, 1993 (weather anomalies)
Human demographics, behavior	Societal changes and events: population growth and migration (movement from rural areas to cities); practices of keeping animals and contact with wild animals, war or civil conflict; urban decay; sexual behavior; intravenous drug use; preference for 'fast foods'; use of high-density facilities	Introduction of HIV; spread of dengue; spread of HIV and other sexually transmitted diseases, appearance of zoonoses [highly pathogenic avian influenza (H5N1), SARS (corona virus)], meningococcal disease, cholera, increases in food poisoning ( <i>Salmonella enteritidis</i> )
International travel and commerce	Worldwide movement of goods and people; air travel	'Airport' malaria; dissemination of mosquito vectors; rat-borne hantaviruses; antibiotic-resistant gonorrhoea; introduction of cholera into South America; dissemination of O139 <i>V. cholerae</i>
Technology and industry	Globalization of food supplies; changes in food processing and packaging; organ or tissue transplantation; drugs causing immunosuppression; widespread use of antibiotics	Hemolytic uremic syndrome ( <i>E. coli</i> contamination of hamburger meat), <i>S. agona</i> in kosher snacks; transfusion-associated hepatitis (hepatitis B, C), opportunistic infections in immunosuppressed patients, Creutzfeldt–Jakob disease from contaminated batches of human growth hormone (medical technology)
Microbial adaptation and change	Microbial evolution, response to selection in environment	Antibiotic-resistant bacteria (multiply resistant <i>M. tuberculosis</i> ), 'antigenic drift' in influenza virus; zidovudine-resistant HIV
Breakdown in public health measures	Curtailement or reduction in prevention programs; inadequate sanitation and vector control measures, immunization myths	Whooping cough in the UK, resurgence of tuberculosis in the US; cholera in refugee camps in Africa; resurgence of diphtheria in the countries of the former Soviet Union

**Table 28.5** Main cause of disease burden in children in demographically developing countries in 1990 and the cost-effectiveness of the interventions available for their control. (Adapted from Morse<sup>25</sup>)

Disease and injuries	Number of DALYs lost* millions (% total)	Main intervention	Cost-effectiveness (\$ per DALY)
Respiratory infections	98 (14.8) <sup>†</sup>	Integrated management of the sick child	30–100
Perinatal morbidity and mortality	96 (14.6)	a. Prenatal and delivery care b. Family planning	30–100 20–150
Diarrheal disease	92 (14.0)	Integrated management of the sick child	30–100
Childhood cluster (diseases preventable through immunization)	65 (10.0)	Expanded Program on Immunization (EPI) EPI-plus <sup>†</sup>	12–30
Congenital malformation	35 (5.4)	Surgical operations	High (unknown)
Malaria	31 (4.7)	Integrated management of the sick child	30–100
Intestinal helminths	17 (2.5)	School health program	20–34
Protein-energy malnutrition	12 (1.8)	Integrated management of the sick child	30–100
Vitamin A deficiency	12 (1.8)	EPI-plus <sup>†</sup>	12–30
Iodine deficiency	9 (1.4)	Iodine supplementation	19–37
Subtotal	467 (71.0)	–	–
Total DALYs lost	660 (100)	–	–

\*DALYs lost (for specific diseases and the total) are taken from the 1993 World Development Report (World Bank 1993).

<sup>†</sup>EPI-plus includes the six vaccines of the Expanded Program on Immunization (EPI), plus the vaccine against hepatitis B and vitamin A supplementation.

**Table 28.6** The global balance sheet – child health 1990–2000. (Source WHO 2001<sup>22</sup>)

Goal	Gains	Unfinished business
Infant and under-5 mortality (U5MR): reduction by one third in infant mortality and U5MR	More than 60 countries achieved the goal of U5MR At the global level, U5MR declined by 14%	U5MR rates increased in 14 countries (nine of them in sub-Saharan Africa) and were unchanged in 11 others Serious disparities remain in U5MR within countries: by income level, urban vs. rural, and among minority groups
Polio: <i>global eradication</i> by 2000	More than 175 countries are polio free	Polio is still endemic in 20 countries
Routine immunization: <i>maintenance of a high level of immunization coverage</i>	Sustained routine immunization coverage at 75% [three doses of combined diphtheria/pertussis/tetanus vaccine (DPT3)]	Less than 50% of children under 1 yr of age in sub-Saharan Africa are immunized against DPT3
Measles: <i>reduction by 95% in measles deaths and 90% in measles cases by 1995 as a major step in global eradication in the longer run</i>	Worldwide reported measles incidence has declined by nearly two thirds between 1990 and 1999	In more than 15 countries, measles vaccination coverage is less than 50%
Neonatal tetanus: <i>elimination</i> by 1995	104 of 161 resource limited countries have achieved the goal Deaths caused by neonatal tetanus declined by 50% between 1990 and 2000	27 countries (18 in Africa) account for 90% of all remaining neonatal tetanus
Deaths due to diarrhea: <i>reduce them by 50%</i>	This goal was achieved globally, according to World Health Organization (WHO) estimates	Diarrhea remains one of the major causes of death among children
Acute respiratory infections (ARIs): <i>reduction of ARI deaths by one third in children under 5</i>	ARI case management has improved at health center level The effectiveness of <i>Haemophilus influenzae</i> type b and pneumococcus vaccines is established	ARI remains one of the greatest causes of death among children Vertical, single-focus ARI programs seem to have had little global impact

other parts of Africa. Because of economic or social reasons there are at least some war-torn countries where polio elimination looks difficult or impossible. The infection is also proving hard to eradicate in India.<sup>31,32</sup> This makes the goal of global polio elimination, and its prize of release of resources currently committed to polio immunization, look difficult.<sup>2</sup>

### SURVEILLANCE TO INFORM PUBLIC HEALTH ACTION

Given adequate resources and will, many infectious diseases can be prevented or contained, but eradication of all infection-related morbidity

and mortality is unachievable as many microorganisms have extensive animal and environmental reservoirs. Interventions can prevent infections or ameliorate the effects of disease. Knowledge as to which interventions are effective must be combined with timely surveillance data on the epidemiology of infection and susceptibility so as to allow rational decisions to be made on resource allocation for public health action. Equally, surveillance provides the basis for health protection, for example in detecting and directing action on deliberate release of biological agents.<sup>21</sup>

Data for surveillance of the commoner infectious diseases in the UK are derived from mortality statistics, disease notifications and

laboratory reporting although in recent years enhanced surveillance to answer specific public health questions has become far more important (Table 28.7).<sup>7-14,19,24,33</sup> An infection may be made statutorily notifiable in the UK, either because there is a need for rapid information for effective local control or for the purpose of monitoring national immunization programs. Often taken for granted, these systems are among

**Table 28.7** Infectious disease morbidity and mortality: principal sources of data in the UK

Data source	Collected by	Type of information
Mortality data	OPCS, GRS, DHSS	Death entries from medical practitioners
Statutory notifications	OPCS, LGAs, SHHD, DH	Currently (1995) list of 39 IDs; selected because need for rapid local information for control, or to monitor national immunization program; clinical diagnoses
Laboratory reports	Cfi and HPA from routine and specialist laboratories	Wide range of microbiologically confirmed infections
General practitioners	Computerized reporting by GPs including the RCGP from weekly returns from 40 practices	Wide range of infectious diseases presenting in general practice; clinical diagnoses
NHS Direct	Daily outputs from NHS Direct systems	Wide range of infectious diseases presenting as syndromes through the NHS Direct centers
Computerized hospital discharge data	ONS and SHHD from individual hospitals and health boards	All diagnoses categorized by ICD code; combination of clinical and microbiological
Enhanced surveillance systems	From many sources to Cfi, HPS, CDSC-PHS (Wales), CDSC NI	A wide variety of conditions answering specific questions: e.g. levels of MRSA in hospitals, rates of completion of treatment courses by those with tuberculosis, performance of antenatal screening for HIV
Consultant pediatricians	British Paediatric Surveillance Unit	Changing 'menu' of rare infections and infection-related disorders; specified case definitions
Consultant clinicians (genitourinary medicine)	HPA Centre for Infections	HIV and AIDS cases including detailed demographic data
Public health specialists	HPA Centre for Infections	Significant outbreaks and incidents

CDSC-PHS (Wales), Communicable Disease Surveillance Centre of the Public Health Service, Wales; CDSC NI, Communicable Disease Surveillance Centre (Northern Ireland); Cfi, Health Protection Agency Centre for Infections; DH, Department of Health; DHSS, Department of Health and Social Security, Northern Ireland; GRS, General Registrar's Office for Scotland; HA, health authority; HB, health board; HPS, Health Protection Scotland; ID, infectious disease; LGA, local government authority; ONS, Office for National Statistics; OPCS, Office of Population Censuses and Surveys; PHL, Public Health Laboratory Service; RCGP, Royal College of General Practitioners; SHHD Scottish Home and Health Department.

the best in the world. Routine reporting is supplemented by special or enhanced surveillance systems for rare and/or more important infections such as HIV and congenital rubella syndrome. An example of this is active reporting by clinicians through the British Paediatric Surveillance Unit (BPSU) of the Royal College of Paediatrics and Child Health (RCPCH), whereby researchers combine reports from RCPCH members with data from other systems to give optimal coverage.<sup>33</sup> Other innovative mechanisms are using primary care mechanisms through general practice or NHS Direct. Surveillance of infectious disease mortality and morbidity in England and Wales is undertaken by the Office for National Statistics (ONS) and by the Centre for Infections and Local and Regional Services of the Health Protection Agency (HPA) and the Public Health Service-Wales. In Scotland this function is performed by Health Protection Scotland though public health policy is coordinated by national departments of health and enacted by local specialists in public health medicine. In Wales it is performed by the Communicable Diseases Surveillance Centre (CDSC) of the Public Health Service Wales and in Northern Ireland by CDSC (Northern Ireland). The HPA and ONS collaborate closely to obtain, analyze and interpret data from several sources which often overlap, but which are also complementary allowing validation of reports (Table 28.7). From these national reporting centers data and information are routinely reported to the European Centre for Disease Prevention and Control and the World Health Organization. The legal basis of these reporting mechanisms is established under the European Union Legislation and the new (2005) International Health Regulations.<sup>22,34</sup>

## ACKNOWLEDGMENTS

In the preparation of this section the assistance is gratefully acknowledged of a large number of colleagues in the European Centre for Disease Prevention and Control; the United Nations Special Program on AIDS; the European HIV Centre (EUROHIV) at INVS, Paris; the Office for National Statistics; the Registrar General's Office, Scotland; the Department of Health and Social Security, Northern Ireland; the Centre for Infections of the Health Protection Agency; the Royal College of General Practitioners Research Unit; Health Protection Scotland; the Communicable Disease Surveillance Centre of the Public Health Service, Wales; and the Communicable Disease Surveillance Centre (Northern Ireland).

## CLINICAL PROBLEMS

### THE CHILD WITH FEVER

The most useful temperature measurement is the core or central temperature which has a normal range in young adults of 36.4–36.9°C, and fluctuation around these values of up to 0.4°C. Infants have a rectal temperature above 37°C which falls by about 0.8°C during sleep and rises before waking.<sup>35</sup> There is a circadian rhythm in childhood with the highest temperature at 6 P.M. The peripheral temperature is normally 0.5°C lower than that recorded centrally.<sup>36</sup> What is regarded as fever varies. Studies of infants define fever as a central temperature of greater than 38°C. Antipyretic agents have the same effect on fever of either bacterial or viral origin and the response should not be used as a distinguishing feature. There are a number of different devices available for temperature measurement. Electronic probes are widely used in hospital for oral (central), axillary (peripheral) or rectal (central) sites. Tympanic membrane thermometers are moderately accurate providing they are inserted correctly but are not recommended in young infants. Other methods using strips or chemical dots are of variable accuracy. Mercury thermometers, sometimes regarded as the 'gold standard', are not recommended because of the risks from broken glass and the toxic effects of the metal.

Although a central temperature reading is of value in the sick child, and measurement of the temperature difference between core and

periphery is of particular value in the shocked patient, for most purposes a peripheral reading is adequate.

The commonest cause of fever in childhood is viral infection, usually resolving within a week of onset. Persistence of fever demands thorough investigation; the term pyrexia or fever of unknown origin (PUO, FUO) is normally applied when fever has been present for 14 days.

## FEVER IN THE NEWBORN

Fever during the neonatal period may be the presenting sign of bacterial infection. If investigation is delayed until other signs occur, such as lethargy, anorexia or apnea, infection may be far advanced before treatment is started. It is generally accepted that any febrile newborn should have cultures of blood, cerebrospinal fluid (CSF) and urine taken, and then should be started on empirical antibiotics.<sup>37</sup> Other investigations such as a peripheral white blood count (WBC), serum C-reactive protein (CRP) and serum procalcitonin (PCT) may indicate the likelihood of bacterial infection.<sup>38</sup> If an infant is tachypneic then a chest X-ray (CXR) should be performed.

Infections presenting within 48 h of birth are likely to have resulted from maternal transmission with bacteria such as group B streptococcus (GBS, *Streptococcus agalactiae*), *S. pneumoniae* and *Escherichia coli*. Later infections in the neonatal period are more likely to be nosocomial, and are more common in the preterm infant undergoing intensive care. Typical organisms are *Staphylococcus aureus* and *S. epidermidis*. However, maternally acquired infections with organisms such as GBS, and those acquired in the community, are also seen later in the neonatal period.

Viral infections, either congenital or acquired, may also be associated with fever. Babies who acquire herpes simplex virus (HSV) infection from their mothers at birth may present after 2–7 days with fever and nonspecific signs of sepsis, and HSV should be considered in the differential diagnosis. Clinical features may include skin, eye or mouth lesions, pneumonitis, hepatitis, encephalitis and disseminated intravascular coagulopathy (DIC). Other viruses that commonly present with fever in the neonatal period include enteroviruses, influenza and respiratory syncytial virus.

## FEVER DURING INFANCY AND CHILDHOOD

The commonest cause of fever in this group is viral infection, which tends to be short lived. The challenge for the pediatrician is to determine whether the fever is the result of a viral or bacterial infection. In a series of 292 infants < 2 months old admitted to hospital with a history of fever, 19 (6.5%) were described as having serious bacterial infection (SBI), although 5 of the 19 were afebrile at the time of admission.<sup>39</sup> In a prospective study of children 3–36 months of age, pathogenic bacteria were isolated in blood culture from 60/519 (12%) with a fever greater than 39.5 °C (method of temperature measurement not described). The risk of bacterial infection was found to be higher among infants with an elevated white blood count.<sup>40</sup> In the young infant the signs of SBI are relatively nonspecific and it is generally accepted that children < 3 months old require hospital admission. The strategy described by Baraff et al is widely accepted.<sup>41</sup>

The infant is assessed as toxic or nontoxic based on level of activity, responsiveness, feeding and peripheral perfusion. Toxic infants need to be evaluated urgently for bacteremia or meningitis and started on antibiotics. Nontoxic infants should have blood cultures and lumbar puncture and can be classified as low risk if they have normal CSF and urinalysis, and a WBC between 5 and 15 000/mm<sup>3</sup>. The well looking infant in the high risk group should also be started on antibiotics. A CXR should be performed in the presence of abnormal respiratory signs.

Guidance on many aspects of fever in the infant and child is published by the National Institute for Clinical Excellence.<sup>42</sup>

The typical signs of viral upper respiratory infection include coryza, inflamed tympanic membranes, tonsillitis and fever. Bacterial tonsillitis and otitis media are difficult to differentiate from viral causes.

A good history and thorough examination are essential if a speedy diagnosis is to be achieved. Direct questions should be asked about the following:

1. previous immunizations;
2. family members with fever;
3. travel abroad;
4. consumption of unpasteurized milk (to exclude listeriosis, brucellosis), or raw eggs (*Salmonella* spp.);
5. history of congenital heart disease;
6. symptoms of this illness (abdominal pain, urinary frequency and dysuria);
7. signs noticed, e.g. rash, joint swelling.

Examination should take note of rash, lymphadenopathy, hepato- and splenomegaly, chest signs, heart murmurs, abdominal masses and tenderness. The bones and joints should be assessed for swelling and tenderness.

When fever has been persistent – over a week for instance – and no cause has been found, serious consideration should be given to hospital admission to confirm pyrexia and to initiate investigations. The physical signs and investigations required to exclude conditions producing FUO or PUO are given in [Table 28.8](#).

However, certain basic investigations should be performed, of which urine and blood culture are arguably the most important.

## FEVER AND NEUTROPENIA

The neutropenic child with fever is in a similar clinical situation to the neonate with fever, in that there is no time to wait for culture results. Antibiotics should be started after blood cultures have been taken. The antibiotics chosen must cover infections due to staphylococci and Gram negative enteric bacilli. Neutropenic children are also at risk of fungal infection, and empirical antifungal therapy is indicated if fever persists despite antibiotics and negative cultures.

## THE CHILD WITH A RASH

In some cases a rash will be diagnostic, and in others the diagnosis will only be reached in conjunction with the history and appropriate investigations. Failure to recognize certain rashes could cost the life of a child, as in meningococcal infection or varicella in an immunocompromised child.

If an infectious cause is suspected, certain information should be obtained by history: prior infectious disease and/or rashes; recent contact with infectious disease; prior immunization; foreign travel; prodromal illness; fever.

In the general examination, note should be taken of the child's general state, the temperature, appearance of conjunctivae, ears and throat. Careful auscultation of the chest should be performed; all groups of lymph glands as well as liver and spleen should be examined.

Once this has been done, interest should return to the rash, which should be described carefully (e.g. hemorrhagic, macular, papular):

1. macules – flat and impalpable;
2. papules – circumscribed, elevated lesions;
3. vesicles – circumscribed, elevated, filled with clear fluid, and normally less than 0.5 cm in diameter;
4. pustules – elevated lesions containing a purulent exudate;
5. petechiae and other hemorrhagic spots – cannot be blanched by compression and may be flat or raised; the term purpura usually refers to the larger lesions with a diameter greater than 0.5 cm.

The distribution may be an important clue to certain infections, and it may be relevant whether or not the rash is itchy.

## INFECTIOUS RASHES IN THE NEWBORN

Rashes are common in the neonatal period. Neonatal urticaria, or erythema toxicum, is characterized by a mixture of erythematous macules and white or yellow papules that usually develop over the first few

Table 28.8 Causes of pyrexia of unknown origin

Disease	Signs	Investigations
<i>Bacterial</i>		
Brucellosis	Lymphadenopathy, splenomegaly	Antibody titers
Bacterial endocarditis	Murmur, splinter hemorrhages	Blood culture × 3, <i>Brucella</i> , <i>Coxiella</i> titers
Leptospirosis	Hematuria, jaundice, conjunctivitis	Blood culture, serology
Osteomyelitis	Bone swelling, tenderness, redness, immobility	Blood culture, bone aspirate culture, bone radioisotope scan
Pelvic abscess	Abdominal tenderness, tender mass rectally	Leukocytosis on full blood count
Pyelonephritis	Loin tenderness	Urine microscopy and culture
Tuberculosis	Pneumonia, meningitis	Tuberculin test, culture gastric washings ± cerebrospinal fluid, chest X-ray
Typhoid fever	Abdominal tenderness, rose spots, splenomegaly	Blood culture
Septic arthritis	Swelling, tenderness, immobility at single joint	Joint aspirate culture
Psittacosis	Chest crackles, tachypnea	Chest X-ray, serology
Listeriosis	Arthritis, meningitis	Blood culture, cerebrospinal fluid culture
<i>Virus</i>		
Cytomegalic inclusion disease	Lymphadenopathy, hepatosplenomegaly	Urine culture, etc., blood and urine PCR
Human immunodeficiency virus	Lymphadenopathy, failure to thrive, chronic infection, e.g. candida	T4/T8 lymphocyte ratio, HIV antibody, HIV PCR
Infectious mononucleosis	Tonsillitis, hepatosplenomegaly	Paul-Bunnell/Monospot, Epstein-Barr viral antibody
Hepatitis	Icterus, hepatomegaly	Hepatitis A, hepatitis B serology, hepatitis B and C PCR
<i>Parasite</i>		
Malaria	Splenomegaly, hepatomegaly, encephalopathy	Thick or thin blood film
Toxoplasmosis	Cervical, supraclavicular lymphadenopathy	Smear from biopsy specimen, serology
<i>Miscellaneous</i>		
Crohn's disease	Abdominal tenderness and mass	GI endoscopy or barium study of GI tract. Exclude <i>Yersinia</i> and <i>Campylobacter</i> infection
Diabetes insipidus	Polyuria, polydipsia	Dilute urine following water deprivation
Juvenile rheumatoid arthritis		
1. Systemic	Fever, characteristic maculopapular rash, lethargy, arthritis, pericardial effusion	No diagnostic test
2. Monoarticular/polyarticular	Fever not a consistent sign	
Kawasaki disease	Cervical lymphadenopathy, bilateral conjunctival injection, red, fissured lips and tongue, maculopapular rash, swelling and desquamation of hands and feet	No diagnostic test
Malignancy	Includes anemia, lymphadenopathy, splenomegaly, abdominal mass, bone pain	Full blood count, blood film, lymph node biopsy, bone marrow trephine, vanillylmandelic acid
Leukemia		
Lymphoma		
Neuroblastoma		
Factitious fever (Munchausen by proxy)	Pyrexia only recorded by parent	None

days and may persist until the end of the second week. Staphylococcal infection of the newborn may be difficult to distinguish from neonatal urticaria. Although erythematous lesions are seen with staphylococcal infection, pustules and vesicles predominate. When there is uncertainty as to the diagnosis, a Gram stain of vesicle fluid should be performed. Plentiful polymorphs as well as Gram positive cocci should be seen in the presence of staphylococcal infection; eosinophils predominate in neonatal urticaria.

Vesicles are also seen in neonatal varicella and herpes simplex virus (HSV) infection. In the former, a history of maternal varicella will be elicited. In the latter, however, a history of past or current genital herpes is obtained in only a quarter of cases. The vesicles of HSV tend to be larger and less opaque than those of staphylococcal infection. Urgent treatment of neonatal HSV is essential. Rapid diagnosis can be achieved by rapid viral identification tests such as immunofluorescence on vesicle fluid or by electron microscopy if available. PCR of vesicle fluid, if available in a timely way, can also be diagnostic.

Other rashes associated with infection may be petechial or purpuric as a result of thrombocytopenia, as seen in congenital cytomegalovirus (CMV) or congenital rubella infections. In such cases the rash is usually just one of several clinical features of congenital infection.

## INFECTIOUS RASHES IN INFANCY AND CHILDHOOD

These will be described under descriptive headings.

### Vesicular rashes

#### *Varicella*

Lesions normally appear without a prodromal illness, and progress rapidly (within a few hours) from papules to vesicles surrounded by an erythematous base. Crops of vesicles appear over 3 days, predominantly on the trunk and proximal limbs. Vesicles may also develop on mucous membranes.

#### *Herpes zoster*

Lesions similar to those seen in varicella infection may develop over specific dermatomes or cranial nerves. Although the immunosuppressed are at increased risk from zoster, this condition is also seen in normal children.

#### *Herpes simplex virus (HSV)*

HSV infection in childhood may be primary, usually associated with gingivostomatitis, may be secondary (reactivation) as with cold sores

and other recurrent herpetic lesions, or may occur as eczema herpeticum, a spreading vesicular rash in association with eczema (caused by HSV but sometimes confusingly called Kaposi's varicelliform eruption). Pyrexia is followed by the appearance of crops of vesicles on the eczematous skin, which may occur over several days. Rapid diagnosis, e.g. with immunofluorescence, and treatment with antivirals is essential because untreated severe infection may be fatal.

### **Hand, foot and mouth**

This is caused by enteroviruses, the commonest being Coxsackie virus type 16, and occurs in epidemics. It is associated with a papular-vesicular eruption of the mouth, hands, feet and sometimes buttocks.

### **Impetigo**

This condition usually presents as a red macule and then becomes vesicular. The small vesicles burst to leave a honey-colored crust. Both streptococcal and staphylococcal impetigo occur most commonly around the mouth.

### **Molluscum contagiosum**

This is caused by a pox virus. Flesh-colored papules with a central dimple are firm initially, but become softer and more waxy with time. Lesions are 2–5 mm in size and may occur anywhere. Molluscum is more severe in HIV infection.

## **Maculopapular rashes**

### **Measles**

Measles rash is blotchy, red or pink in color, raised in places, and starts behind the ears and on the face, spreading downwards. The lesions tend to become confluent on the upper part of the body and remain more discrete lower down. The rash fades, usually after 2–3 days. The skin becomes brown and although desquamation occurs this is not usually seen on the hands and feet, as it is in scarlet fever.

### **Rubella**

Rubella results in a pink rash which progresses caudally. The lesions are normally discrete and the rash develops more quickly and disappears earlier than in measles. Desquamation is not a characteristic.

### **Scarlet fever**

The eruption is dark red and punctiform. The rash tends to be most prominent on the neck and in the major skinfolds. A distinctive feature is circumoral pallor as a result of the rash sparing the area around the mouth. Desquamation of the hands and feet is common after 1–2 weeks. True scarlet fever is associated with inflammation of the tongue (white and red strawberry tongue). Scarletina refers to the rash, which may occur alone in milder streptococcal infection and is often short lived.

### **Kawasaki disease**

Although several features are required for the diagnosis of this condition, which is of unknown etiology, the rash may be confused with that of scarlet fever. Discrete red maculopapules are seen on the feet, around the knees and in the axillary and inguinal skin creases. Desquamation of the hands and feet is a common feature (Fig. 28.15).

### **Erythema infectiosum or fifth disease**

Infection caused by parvovirus B19 is associated with a rash which develops in two stages. The cheeks appear red and flushed, giving rise to a 'slapped cheek' appearance. A maculopapular rash develops 1–2 weeks later, predominantly over the arms and legs which, as it fades, appears lace-like.

### **Roseola infantum**

The main cause is human herpes virus 6 (HHV-6). Roseola infantum is characterized by a widespread morbilliform (measles-like) rash, seen in its most florid form on the trunk. The lesions tend to be discrete. As the rash appears the fever, which is normally present over the previous

Fig. 28.15 Kawasaki disease: finger desquamation starting at the tips.

4 days, resolves and the child looks well (in contrast to measles, in which the child is febrile and unwell when the rash appears).

### **Viral infections**

Many viral infections, particularly those associated with the enteroviruses, may cause maculopapular rashes.

## **Petechial and purpuric rashes**

### **Meningococcal infection**

The first sign of meningococcal septicemia may be a petechial or purpuric rash anywhere on the body and often localized (Fig. 28.16). On occasions these lesions may be preceded by or accompany a maculopapular rash which may blanch (Fig. 28.17). The petechiae will not blanch, and although it is conventional to make a microbiological diagnosis on blood culture and PCR, bacteria can often be seen on Gram stain and cultured on scrapings of the skin lesions.

Meningococcal petechiae can be confused with those seen on the face around the eyes following events that result in a transient rise in venous pressure such as vomiting. Rarely petechial rashes are associated with septicemia caused by other bacteria, such as *S. pneumoniae*, *S. aureus* and *Haemophilus influenzae* type b.

Fig. 28.16 Purpuric rash of meningococemia. (Courtesy of Department of Medical Illustration, University of Aberdeen.)

Fig. 28.17 Maculopapular/morbilliform rash of early meningococemia. (Courtesy of Department of Medical Illustration, University of Aberdeen.)

### Henoch–Schönlein purpura

This condition often follows an upper respiratory tract infection but no single infective agent has been implicated. Hemorrhagic macules and papules develop on the buttocks and extensor surfaces of the limbs, particularly the knees and ankles. The lesions come in crops and fade over a few days leaving a brown pigmentation.

### Idiopathic thrombocytopenic purpura (ITP)

A purpuric rash sometimes associated with frank bleeding is seen in this condition. Even post-infective cases are often referred to as ITP, and rubella infection is considered to be the commonest infectious cause.

### Leukemia

Children with leukemia may present with a hemorrhagic rash as a result of thrombocytopenia but in addition, the pallor of severe anemia will usually be obvious.

## FEVER AND INCREASED RESPIRATORY RATE

The combination of fever and rapid breathing is a common and important pediatric presentation. While the differential diagnosis is vast (Table 28.9), a serious underlying condition must always be considered, in particular sepsis (bacteremia or septicemia) and bacterial pneumonia.

Table 28.9 Differential diagnosis of the child with fever and increased respiratory rate

Serious infections
Bacteremia/septicemia
Bacterial pneumonia (with or without parapneumonic effusion)
Other focal bacterial infections (including meningitis, osteomyelitis, septic arthritis)
Less serious infections
Viral or <i>Mycoplasma</i> bronchopneumonia
Mild infections
Viral upper respiratory tract infection (URTI)
Viral bronchitis
Viral exanthema
Fever and increased respiratory rate with upper airways obstruction (stridor)
Viral laryngotracheobronchitis (viral 'croup')
Fever and increased respiratory rate with lower airways obstruction (wheeze)
Acute viral bronchiolitis (usually due to RSV)
Asthma triggered by intercurrent viral upper respiratory tract infection

Fortunately, these serious conditions are uncommon and most infants and young children presenting with fever and increased respiratory rate simply have a relatively minor viral upper respiratory tract infection. In this situation, the respiratory rate is only mildly elevated and not associated with any other obvious signs of increased work of breathing (such as intercostal and/or subcostal retractions).

Both the level of the fever and the degree of tachypnea are key indicators of a serious versus minor infection: the higher the level, the greater the likelihood of a serious bacterial infection. In addition, infants and young children with serious infections will have other features, both on history and physical examination, which will assist with the diagnosis. These include signs of marked increased work of breathing, and 'grunting' respirations with extensive bacterial pneumonia. Further, infants and young children with serious bacterial infections will look ill, with signs such as pallor, cyanosis, apathy and altered level of consciousness. On the other hand infants and young children with a viral acute respiratory infection will have a history and physical evidence of a viral/coryzal illness with mild fever, clear rhinorrhea, conjunctival injection, redness of the tympanic membranes, sore throat and dry cough.

Clearly, the source or focus of infection must be thoroughly sought, both when taking the history and when performing the physical examination, in children presenting with this combination of symptoms. Recent contact with other children suffering from a viral infection (including one of the viral exanthemata) is vital information. Symptoms of a viral upper respiratory tract infection, or symptoms which localize the inflammation to a specific area of the respiratory tract, need to be elicited. This includes: a barking cough and inspiratory stridor indicating viral laryngotracheobronchitis (croup); coryzal symptoms plus acute history of significant cough (acute viral bronchitis); coryzal symptoms with acute wheeze, cough and shortness of breath (acute viral bronchiolitis in infants; acute asthma in older children).

A major symptom and sign to look for in children with fever and tachypnea is wheezing. In infants this is most likely to be due to acute viral bronchiolitis (usually due to respiratory syncytial virus), and in older children to an episode of acute bronchospasm (asthma) triggered by an intercurrent viral respiratory tract infection. In both these situations wheeze will be present, either audible with the ear or with a stethoscope. Generally, there will also be hyperinflation of the thoracic cage, tachypnea and other signs of increased work of respiration. In infants with acute viral bronchiolitis, diffuse inspiratory crackles are generally audible throughout the chest plus the loud expiratory, musical wheezing.

Infants and children with viral or *Mycoplasma* bronchopneumonia generally have other coryzal symptoms and signs in the ear, nose and throat plus a marked cough, which is often the major complaint. By contrast bacterial pneumonia presents with high fever, 'grunting' respirations and tachypnea, but no cough, particularly in the early phases of the illness.

The infant and young children with bacterial sepsis will generally have high fever (over 38.5 °C), rapid respiratory rate and rapid pulse and will look ill. On close inspection some of these children may have localized features of serious infection such as meningitis, osteomyelitis, septic arthritis or endocarditis. Infants with a bacterial urinary tract infection will have very few localizing symptoms or signs apart from fever and mild elevation of respiratory rate.

In summary, there is a large differential diagnosis of the infant or young child presenting with a combination of fever and increased respiratory rate. This can range from a severe life-threatening illness to a trivial head cold. The latter is far more likely, and most will have only mildly elevated temperature and respiratory rate plus other symptoms and signs to indicate an intercurrent viral upper respiratory tract syndrome. On the other hand, a markedly elevated temperature and respiratory rate in a very sick child indicates a serious infection, particularly bacteremia/septicemia or bacterial pneumonia.

When in doubt, further investigations and/or a further period of observation are essential. These may include CXR, blood cultures, lumbar puncture and blood or urine for bacterial antigen testing.

In obviously sick infants and children, or those in whom a serious underlying bacterial infection is likely, appropriate antibiotics should be given while waiting for the results of the above testing.

## COUGH AND FEVER

The presence of cough signifies irritation or stimulation of cough receptors in the upper or lower airways. This is most commonly secondary to inflammation from a viral infection of the upper or lower airways and will be accompanied by mild fever. Cough is also a feature of bronchial asthma, which is also often accompanied by fever, since the commonest trigger for an acute exacerbation in young children is an intercurrent viral upper respiratory tract infection.

Thus the combination of fever and cough suggests an infection somewhere in the respiratory tract and this is far more likely to be due to a virus rather than bacteria. Diffuse, mild inflammation is typical of viral infection, while focal, severe inflammation is typical of bacterial infection in the respiratory tract. Indeed, one of the major distinguishing features between streptococcal pharyngitis and a viral upper respiratory tract infection is the absence of cough and coryzal symptoms in streptococcal throat infections.

To determine the likely cause of cough and fever requires a comprehensive history and physical examination. Laboratory investigations may occasionally be required to further elucidate the cause.

If there is a past history of bronchial asthma, the fever and cough are almost certainly due to episodic asthma or 'wheezing associated respiratory infection' (WARI). If there is a past history of chronic bronchitis (frequent episodes of protracted cough with intercurrent viral acute respiratory infections) then it should be obvious from the history that the child is having a further episode of acute viral bronchitis.

Fever and cough due to an upper respiratory tract infection should be readily distinguishable by the coryzal symptoms of rhinorrhea, conjunctival injection and a dry cough but no increased work of breathing and no wheeze. While the child with viral laryngotracheobronchitis will have signs of a coryzal illness, the striking features will be the barking, 'croupy' quality of the cough and probable inspiratory stridor, particularly when the child is upset. When severe this inspiratory stridor will be associated with increased work of breathing (chest wall retractions, tracheal tug). Acute viral bronchitis is characterized by troublesome dry or wet cough in association with an acute respiratory infection. On auscultation there may be scattered coarse crackles (due to excessive airway secretions), which should clear following active coughing. Acute viral bronchiolitis is characterized by coryzal symptoms plus hyperinflation of the chest, loud wheezing, inspiratory crackles throughout both lung fields, and varying degrees of respiratory difficulty in addition to fever and cough. Viral and *Mycoplasma* bronchopneumonia will be characterized by coryzal symptoms, marked cough, increased work of breathing and widespread, scattered, inspiratory crackles.

A less common but important cause of cough and fever is foreign body inhalation, e.g. nuts and peanuts. Initially this is a dry cough, often with wheeze and difficulty breathing. If retained, the cough becomes loose and productive of purulent sputum. A child with a loose, productive cough and fever could also be suffering from chronic suppurative lung disease – bronchiectasis or chronic bronchitis. Most of these children will have some underlying problem (e.g. cystic fibrosis or immune deficiency).

In summary, fever and cough signify some inflammatory process in the airways. This can range from a relatively uncomplicated viral upper respiratory tract infection due to rhinovirus through to viral or *Mycoplasma* bronchopneumonia (Table 28.10). A major differential to consider is whether the fever and cough are due to an exacerbation of asthma in the child with underlying episodic asthma.

## RHINITIS

Rhinitis implies inflammation of the nasal 'mucosa', and in children this is most commonly due to a viral upper respiratory tract infection. The

**Table 28.10** Causes of cough and fever

Acute respiratory tract infections
Viral upper respiratory tract infection (URTI)
Acute viral bronchitis
Acute viral laryngotracheobronchitis (viral croup)
Acute viral bronchiolitis (infants)
Acute viral bronchopneumonia
<i>Mycoplasma</i> (bronchitis and bronchopneumonia)
Asthma syndromes
Classical bronchial asthma
Wheezing associated respiratory infection (WARI)
Less common causes
Foreign body inhalation
Suppurative lung disease (chronic bronchitis/bronchiectasis)

inflammation normally results in a combination of rhinorrhea and nasal obstruction. Sneezing is commonly associated with these symptoms.

The major differential diagnosis of rhinitis secondary to a viral upper respiratory tract infection is allergic rhinitis. In children allergic rhinitis is generally perennial rather than seasonal and is characterized by its persistence for weeks or months rather than the short term nasal symptoms of an acute viral infection. The symptoms of allergic rhinitis have a typical diurnal pattern (classically worse in the mornings) and there is absence of fever and other signs suggesting a viral upper respiratory tract infection. Nasal itch and sneezing are common as are clear rhinorrhea and nasal obstruction. There is often an associated allergic conjunctivitis which can simulate a viral rhino-conjunctivitis. The child with allergic rhinitis generally has other signs of clinical atopy, particularly atopic eczema or bronchial asthma.

Vasomotor rhinitis is uncommon in young children and typically causes sudden onset (and sudden cessation) of clear rhinorrhea – often for only hours – but with recurrent episodes.

Other rarer causes of rhinitis include:

- Foreign body – particularly small parts of toys and polystyrene beads. Causes unilateral nasal symptoms.
- Unusual infections (e.g. nasal diphtheria).

The distinction between acute viral rhinitis secondary to a viral infection and acute sinusitis is subtle and arbitrary. Most definitions base the distinction on duration of symptoms. Conventionally, acute sinusitis is the appropriate diagnosis if the nasal discharge is severe and persists for more than 10 days. These symptoms would generally be associated with cough and possibly bad breath.

Chronic sinusitis is arbitrarily defined as a persistent, mucopurulent nasal discharge for over 30 days. This is most commonly seen in children with underlying abnormalities of mucus, mucociliary clearance or immune function (e.g. cystic fibrosis, primary ciliary dyskinesia, agammaglobulinemia).

Drug therapy for rhinitis associated with a viral upper respiratory tract infection is generally not required. However, in small infants the nasal obstruction and rhinorrhea may interfere with feeding and saline drops followed by suctioning of the drops ('nasal lavage') may be helpful, particularly immediately prior to feeds. Acute sinusitis is generally viral although secondary bacterial infection may occur. While there is some uncertainty as to whether or not antibiotics are indicated in this situation, there is little doubt that the color of the nasal discharge changes promptly with administration of antibiotics, but such treatment is best reserved for those who are more severely affected by the symptoms. Chronic sinusitis should be treated with antibiotics and prolonged courses (three weeks) may be necessary.

Perennial allergic rhinitis in children warrants treatment, particularly if the symptoms are severe. The most effective treatment is regular nasal topical corticosteroid (e.g. budesonide nasal spray).

In summary, while there are many possible causes for rhinitis (Table 28.11), most commonly it is the result of either a respiratory virus or allergic rhinitis.

Table 28.11 Causes of rhinitis

Common
Viral upper respiratory tract infection (acute viral nasopharyngitis – most commonly due to rhinovirus)
Perennial allergic rhinitis
Uncommon
Acute viral or bacterial sinusitis
Vasomotor rhinitis
Rare
Retained foreign body
Uncommon infections (e.g. nasal diphtheria)

## NOISY BREATHING

Audible noises of respiration are common in children. Clarification of the type of noise is critical with respect to identifying the most likely underlying cause. In general, noisy breathing signifies some obstruction to airflow, and the specific type of noise – especially which phase of respiration – can greatly assist in determining the anatomic site of the airflow obstruction.

The types of noises identifiable are listed below in Table 28.12, together with the phase of respiration in which they are most audible, and the usual anatomic site for the noise.

An important principle is: the noise is predominantly inspiratory when the obstruction is outside the thoracic cage (upper airways), and predominantly expiratory when the obstruction is inside the thorax (lower airways).

If a child has the noise when being examined then there is no difficulty determining its features. However, when the noise is from history alone this can create difficulties with respect to the terminology used by parents. In such instances, mimicking these noises will often assist with the accurate diagnosis. Alternatively, asking the parents to obtain tape recordings will enable clear identification of the type of noise.

There will generally be associated symptoms and signs with these noises, which will assist clinically in determining the exact site and

Table 28.12 Types of identifiable noises

Noise	Inspiration	Expiration	Site of obstruction
Snuffliness	++	±	Nasal
Snoring	++	±	Oronasopharynx
Stridor	+++		Extrathoracic trachea (subglottis/larynx)
Rattliness	++		Central tracheobronchial tree (trachea)
Wheeze		++	Small and medium sized intrathoracic airways
Grunting		+++	Alveoli

Table 28.13 Causes of obstruction

	Causes of noise	
	Acute	Persistent
Snuffliness	Viral upper respiratory tract infection	Perennial allergic rhinitis
Snoring	Acute tonsillitis/upper respiratory tract infection	Chronic enlargement of tonsils and adenoids
Stridor	Viral croup	Congenital subglottic stenosis or other fixed upper airway malformations
Rattle	Acute viral bronchitis	Cerebral palsy/CNS disorders ('sputum retention')
Wheeze	Asthma	Chronic small airways obstruction (e.g. cystic fibrosis)
Grunt	Acute bacterial (lobar) pneumonia Hyaline membrane disease (neonate)	Chronic interstitial lung disease (e.g. pulmonary fibrosis)

cause for the obstruction. For example, a child with acute onset inspiratory stridor and a barking cough in association with an URTI has acute viral 'croup' (laryngotracheobronchitis). On the other hand, a child with grunting respirations and high fever who looks toxic and unwell is probably suffering from acute (bacterial) pneumonia.

The causes of obstruction are numerous and are summarized in Table 28.13.

In summary, the child presenting with the problem of noisy breathing requires a comprehensive history and examination to determine the exact nature of the noise and to determine whether there are any associated symptoms or signs. By accurately determining the nature of the noisy breathing, the likely anatomical site of the obstruction can usually be determined, and this will greatly assist with the final diagnosis.

## SUSPECTED MENINGITIS

Over the last five years, notified cases of bacterial meningitis have fallen to less than 1500 cases a year in England and Wales (Table 28.14). The mortality from these infections has also declined in recent years, but there is evidence that the long term consequences of meningitis are considerable, particularly when the disease occurs early in life.

### ETIOLOGY AND PATHOPHYSIOLOGY OF BACTERIAL MENINGITIS

The commonest route of meningeal infection is from the bloodstream, so the spectrum of pathogens causing meningitis is similar to that seen in bacteremia and sepsis. The introduction of the *Haemophilus influenzae* type b (Hib) polysaccharide-conjugate vaccine into the UK vaccination program has had a dramatic effect.<sup>43</sup> The incidence of Hib meningitis has dropped from around 2500 cases per year to 44 per year, with *Neisseria meningitidis* now the commonest cause of community acquired bacterial meningitis in the UK, followed by *Streptococcus pneumoniae*. The relative importance of these pathogens varies considerably with age (Table 28.14) and the nature of the immunization programs in operation. In the neonatal period, group B streptococcus is the prominent meningeal pathogen, followed by Gram negative bacilli, *S. pneumoniae* and *Listeria monocytogenes*. In children older than 3 months and in young adults, the most frequent cause of bacterial meningitis is *N. meningitidis* followed by *S. pneumoniae*. Infants between 1 and 3 months old are susceptible to *N. meningitidis* and *S. pneumoniae*, as well as the neonatal pathogens. The propensity of neonates to get meningitis is in part due to their immunological immaturity. Older children with congenital or acquired deficiencies in complement, immunoglobulin production, lymphocytes, neutrophils or splenic function are at increased risk from meningitis, sometimes due to atypical pathogens. A rare but serious form of bacterial meningitis is caused by *Mycobacterium tuberculosis*. This organism can affect patients of all ages and should be considered in any atypical presentation of meningitis, particularly patients presenting with an insidious illness.<sup>44</sup>

Table 28.14 Statutory notifications of meningitis cases in 2000 and 2005 (data from Health Protection Agency)

	Year	Age group				
		1–11 months	1–4 years	5–9 years	10–14 years	15–24 years
<i>Haemophilus influenzae</i>	2005	11	15	3	2	3
	2000	5	10	1	1	2
<i>Neisseria meningitidis</i>	2005	163	121	42	26	92
	2000	231	220	105	86	219
<i>Streptococcus pneumoniae</i>	2005	63	32	10	7	5
	2000	53	27	4	9	14

While meningitis often occurs in the context of systemic infections, it can also follow bacterial invasion from a contiguous focus of infection, such as the mastoids or paranasal sinuses, or from osteomyelitis of the skull. Skull fractures, craniospinal dermal sinuses, neurenteric or dermoid cysts, occult intranasal encephaloceles, or transthemoid meningoceles are also potential portals of entry for pathogens into the subarachnoid space.<sup>45</sup> The possibility of a cranial defect should be considered in children with recurrent meningitis. Neurosurgical procedures and the presence of ventriculoperitoneal shunts also provide routes for meningeal infection. In such cases, *Staphylococcus aureus* and coagulase negative staphylococci are more likely pathogens.

Bacterial invasion of the cerebrospinal fluid (CSF) is followed by an outpouring of inflammatory cells which cross the blood–brain barrier and enter the CSF. Inflammatory cytokines such as tumor necrosis factor and interleukins 1, 6 and 8 are central to the inflammatory response. These mediators increase adhesion molecule expression on endothelial cells and leukocytes, which act in concert to facilitate the migration of cells into the CSF. Antibodies to adhesion molecules limit leukocyte migration and the consequences of meningeal infection.<sup>46</sup> The meninges become inflamed, swollen and covered by fibrino-purulent exudate. The thickest exudate is usually at the base of the brain. This leads to obstruction of the exit foramina of the fourth ventricle or the subarachnoid basal cisterns, restricting the CSF circulation to produce hydrocephalus. The ependymal lining of the cerebral ventricles may also be a site of intense inflammation (ventriculitis), causing ventricular enlargement and subsequent subependymal gliosis. A combination of cerebral vasculitis, thrombosis, cerebral edema and raised intracranial pressure leads to globally reduced cerebral blood flow and focal ischemia. This results in neuronal injury and cerebral damage, manifest clinically as coma, seizures and focal neurological signs.

## CLINICAL FEATURES

The fully developed clinical picture of acute meningitis in children is sufficiently characteristic to be recognized without difficulty. More than 80% of children will have fever, vomiting, severe headache and signs of meningeal irritation. However, in the early stages of disease, and in young children, the symptoms and signs are often nonspecific. Fever may be absent in up to 30% of individuals, and 20–30% do not have signs of meningism at presentation. Previous antibiotic therapy may also mask the significance of the presenting illness.<sup>47</sup>

Older children will often complain of headache or pain at the back of the neck, nausea and photophobia. The physical signs of meningeal irritation are neck stiffness and a positive Kernig test, which reflect inflammation of nerve roots of the spinal canal and adjacent sensory nerves. The most comfortable position for the patient is to lie with an extended neck and flexed hips and knees to reduce tension on the nerves emanating from the spinal cord. Neck stiffness can be detected by placing a palm of the hand on the supine child's occiput. Any attempt at flexing the child's neck will result in the lifting of the whole trunk. Kernig's sign is elicited with the child supine. The hip and knee joints are bent 90 degrees and then an attempt is made to extend the knee fully. In the presence of meningitis, there is resistance and severe pain as the sciatic

nerve is stretched. A positive Brudzinski sign is involuntary muscular contraction causing leg flexion upon passive flexion of the neck, but this is a less reliable sign of meningitis. Additional evidence of neurological involvement includes convulsions, which occur in 30% of children within 3 days of presentation, cranial nerve palsies (particularly III, IV, VI, and VII), delirium, drowsiness and coma.

In infants and toddlers, the symptoms are often those of a generalized illness. Irritability, lethargy, convulsions, refusal of feeds, vomiting, a high pitched cry and a bulging fontanelle should all alert the physician to the presence of meningitis. The 'typical' features of meningitis may be absent or difficult to interpret or elicit. When present they are often indicative of advanced disease.

*Neisseria meningitidis* is the commonest cause of bacterial meningitis in the UK (Table 28.14). More than 50% of patients infected with this organism will have a petechial rash, so a vigilant search for petechiae should be made in any child with features suggesting a diagnosis of meningitis. The whole skin surface should be carefully examined, since there may initially be only one or two petechiae. However it is also important to note that initially the rash of *N. meningitidis* may be maculopapular or urticarial in nature, and so an atypical rash should not be taken as evidence to exclude the diagnosis. In all age groups, the clinical manifestations of bacteremia and sepsis may be the earliest evidence of infection (see section on sepsis and meningococcal infection). If the condition can be picked up at this stage and treated appropriately, meningitis can be prevented.

## DIAGNOSIS

If meningitis is suspected, the diagnosis should be confirmed by lumbar puncture and examination of CSF. Over the last 10 years, there has been a move away from performing diagnostic lumbar punctures (LP) in patients presenting with suspected meningitis, since it is frequently argued that an LP will not affect patient management and may be hazardous. However, an LP offers immediate confirmation of the diagnosis and allows appropriate treatment to be started, which may be particularly important in neonates and immunocompromised patients in whom the differential diagnosis is wide. Identifying the etiological agent and its antibiotic sensitivities may be crucial to administering the most appropriate antibiotics and providing important prognostic information.<sup>47</sup>

There are, however, specific and clear contraindications to LP in patients with meningitis.<sup>48</sup> These are:

1. signs of raised intracranial pressure with changing level of consciousness, focal neurological signs or severe mental impairment;
2. cardiovascular compromise with impaired peripheral perfusion or hypotension;
3. respiratory compromise with tachypnea, an abnormal breathing pattern or hypoxia;
4. thrombocytopenia or a coagulopathy.

An LP should also be avoided if it will result in a significant delay in treatment. The association between LP and cerebellar tonsillar herniation has not been shown to be causal, and has not been reported in the absence of the specific contraindications listed above.

Lumbar puncture should be performed in the third to fourth lumbar space using a needle with a stylet, since use of a needle alone has been associated with the development of implantation dermoid cysts. CSF should be collected for microscopy and culture, bacterial and viral polymerase chain reaction (PCR), latex agglutination tests for bacterial antigens, protein and glucose. Blood cultures may also identify the etiological agent if an LP is not performed or fails to establish the cause of meningitis.

Analysis of the CSF leukocyte count, glucose and protein can usually establish a positive diagnosis of meningitis, but normal results do not necessarily exclude meningitis. The absence of cells may indicate very early meningitis before the migration of leukocytes into the CSF. Very high white cell counts of up to 20 000/mm<sup>3</sup> can be observed in bacterial meningitis, although the number of cells is usually less than 3000/mm<sup>3</sup>. There is a broad association between a predominance of polymorphonuclear leukocytes in the CSF and bacterial meningitis. However, lymphocytes may predominate in early or partially treated bacterial meningitis, in tuberculous meningitis and in neonates. In bacterial meningitis, CSF glucose is usually low with a CSF: blood ratio of less than 0.5, and protein is frequently raised to more than 0.4 g/L. Numerous studies have now shown that even after the administration of intravenous antibiotics, the diagnostic cellular and biochemical changes in the CSF may persist for at least 48 h. In the context of a negative Gram stain and CSF culture, the presence of bacterial antigens and PCR tests may prove invaluable for establishing a diagnosis of bacterial meningitis.

## THE USE OF CT SCANS

Following the clinical diagnosis of bacterial meningitis, it has become common practice to arrange a computerized tomographic (CT) brain scan to exclude raised intracranial pressure prior to undertaking a lumbar puncture. This approach has three important drawbacks. First, raised intracranial pressure (ICP) is very common amongst children with meningitis and clinically significant raised ICP cannot be ruled out by brain CT. Second, it is hazardous to transport patients to a CT scanner before they have been adequately stabilized. Third, the inevitable delay in undertaking the CT scan requires that empirical antibiotics be given while awaiting the procedure, therefore impairing the diagnostic yield from a subsequent LP. Patients presenting with clinical signs of raised ICP are the minority, and these children should not undergo LP, regardless of their CT findings. CT scans can exclude lesions requiring neurosurgical intervention and identify conditions such as cerebral abscess or hydrocephalus requiring shunting. The diagnostic yield from a CT scan in children is, however, low and should not be allowed to compromise the procedures required for diagnosis and to initiate appropriate treatment.<sup>47</sup>

## ANTIBIOTICS

Except in cases where the patient is well and the diagnosis very uncertain, antibiotics should be administered empirically while awaiting the result of the LP. The selection of the optimal antibiotic for the treatment of bacterial meningitis should be based on the following criteria: the spectrum of pathogens known to cause meningitis in different age groups (Table 28.14); the changing pattern of antimicrobial resistance;<sup>49,50</sup> the pharmacological properties of the antibiotics available and the results of therapeutic trials. In infants up to 3 months of age, a combination of ampicillin and cefotaxime is a logical choice, as cefotaxime provides cover for both neonatal and infant pathogens, and ampicillin is effective against *Listeria monocytogenes*. For the same reason, ampicillin should be included as part of empirical therapy for immunocompromised patients. Penicillin-resistant meningococci are emerging worldwide, as are chloramphenicol-resistant strains, but these have not yet resulted in treatment failures. Fortunately, almost all strains in the UK remain sensitive to the third generation cephalosporins.

In the USA and some countries in Europe including Spain, France and Romania, more than 25% of pneumococcal isolates are resistant to

penicillin and this proportion exceeds 50% in South Africa. Penicillin-insensitive strains of pneumococci are more likely to be resistant to third generation cephalosporins, and there have been documented cases of microbiological failure in the treatment of pneumococcal meningitis with third generation cephalosporins. In the UK, the level of penicillin resistance is stable at less than 5%.<sup>50</sup> In most UK cases, penicillin resistance is low level and cephalosporin resistance is rare and so a third generation cephalosporin (cefotaxime or ceftriaxone) is adequate for most community acquired meningitis in children over 3 months. The routine use of vancomycin for community acquired meningitis is not justified in the UK at the present time. However, vancomycin should be added to the treatment regimen for any patient coming from an area where high levels of penicillin resistance are endemic. The addition of rifampicin to vancomycin or the administration of vancomycin intraventricularly has been recommended by some authorities.<sup>51</sup>

## THE ROLE OF CORTICOSTEROIDS

It is now widely accepted that much of the cerebral damage which occurs in bacterial meningitis is not caused by the invading organism itself but by the host mediated inflammatory response.<sup>52</sup> While a number of adjunctive anti-inflammatory agents have been suggested, only corticosteroids have been extensively tested in clinical trials. Several studies have shown some improvement in morbidity (deafness or neurological deficit), although these studies were largely conducted in children with *Haemophilus influenzae* type b meningitis, and this approach requires administration of corticosteroids either before antibiotic administration or at the same time.<sup>53</sup> Fewer data are available in children with pneumococcal and meningococcal meningitis. However, a recent systematic review of 18 studies in children and adults supports the use of steroid administration as a means of reducing the mortality and morbidity associated with meningitis.<sup>54</sup> These data imply that, at least at the present time, concerns that limiting meningeal inflammation could actually delay sterilization of the CSF by agents such as vancomycin, since these antibiotics cross the blood-brain barrier poorly, have not been substantiated.

## NEUROLOGICAL AND FLUID MANAGEMENT

Hyponatremia is frequently observed in patients with bacterial meningitis. While this is associated with elevated serum antidiuretic hormone (ADH), possibly suggesting inappropriate ADH secretion (SIADH), more recent studies indicate that SIADH is overdiagnosed and the patients are hypovolemic.<sup>55</sup> Treatment of suspected SIADH with fluid restriction could potentially compromise circulating volume and therefore cerebral blood flow. Circulatory shock should be treated aggressively, significant dehydration corrected carefully, fluid balance monitored frequently and maintenance fluids given with care.

Patients presenting with clinical signs of raised ICP require very careful fluid balance monitoring to help maintain adequate cerebral blood flow. Intubation and mechanical ventilation should be instituted early to facilitate oxygenation, allow adequate sedation and permit normalization of PaCO<sub>2</sub>. Such patients should be nursed head up and central venous catheters should not be placed in the neck. Intravenous mannitol may be useful for managing acute changes in intracranial pressure, and anticonvulsants for control of fits.<sup>47</sup>

## COMPLICATIONS

Convulsions occur in 20–30% of children, usually within 72 h of presentation. The onset of late or persistent fits is associated with a poor prognosis. Subdural collections of fluid are common, particularly during infancy. They are usually sterile and rarely require aspiration unless there is evidence of increasing ICP, the presence of focal neurological signs, convulsions or persistent fever due to subdural empyema. Cerebral abscesses are rare outside the neonatal period. More frequent causes of persistent fever include intercurrent viral infection, ongoing

inflammation and drug fever. In the absence of a definitive microbiological etiology, the combination of persistent fever and poor clinical condition may indicate that the meningitis is due to organisms resistant to the prescribed antibiotic therapy. A repeat LP should then be performed.

The commonest long term complication of meningitis is sensorineural deafness. This appears to develop early in the course of the disease and may occur in spite of early recognition and appropriate treatment. All children should undergo audiological assessment after recovery from infection. The overall rate of permanent deafness following meningitis may be less than 5% but is higher in cases of pneumococcal meningitis than in meningococcal infections. However, reversible hearing loss is seen in many more children, with reports of up to a third of children showing some impairment during the early phase of infection. In a study of morbidity after an episode of meningitis in infancy, almost a fifth of patients had some degree of disability.<sup>56</sup> This figure is higher if subtle defects are included, such as behavioral problems, middle ear disease and squints. Morbidity was highest following neonatal meningitis and also after meningitis caused by *S. pneumoniae*, group B streptococcus and atypical pathogens.

## PREVENTION

Conjugate vaccines against *H. influenzae* type b (Hib), *N. meningitidis* group C and *S. pneumoniae* are now routinely given in the UK as part of the primary course of immunization and as a booster in the second year of life. An effective vaccine against *N. meningitidis* group B is not yet available.

When a child presents with meningococcal or Hib meningitis, other family members and close contacts are at increased risk of infection. Rifampicin (rifampin) is currently recommended for contacts of meningococcal disease (four doses of 10 mg/kg per dose 12 hourly) and *H. influenzae* type b (20 mg/kg per dose daily for 4 days). Decisions on who should receive prophylaxis can be difficult, and advice should be sought from the Consultant in Communicable Disease Control.

## SEPTIC SHOCK

Despite the vast array of potential pathogens, the human host is remarkably resistant to life-threatening infection. Most pathogens are restricted by host defenses to their primary sites of invasion, with minimal clinical consequences. These first line defense mechanisms successfully intercept invading organisms in the majority of cases. On occasion, however, microbial invasion of the bloodstream can and does occur, even in apparently immunocompetent children, with potentially devastating consequences. The sequence of events following successful entry of microbes or microbial products to the circulation is complex, and depends both upon the virulent properties of the offending microorganism and the host response. Initial microbial invasion may be clinically silent and indeed may resolve without antimicrobial therapy. If, however, bacterial proliferation ensues, a systemic response is initiated in the host. This is referred to as the systemic inflammatory response syndrome (SIRS) and is defined by the presence of abnormalities in two or more of the following: temperature, heart rate, respiratory rate and white blood count, of which one must be temperature or white count. SIRS can follow any severe insult including infection, trauma, major surgery, burns or pancreatitis, but when SIRS occurs in the context of infection, the patient is described as *septic*.

The term *severe sepsis* can be used to describe a state characterized by hypoperfusion, hypotension and organ dysfunction, while the term *septic shock* is restricted to patients with persistent hypotension despite adequate fluid resuscitation and/or hypoperfusion even following adequate inotrope or pressor support.<sup>57</sup> In practice it can be difficult to divide patients neatly into these defined states, but the use of these terms serves to highlight the sequential nature of the events associated with microbial invasion, and will help in the evaluation of future clinical trials in septic patients.

## MICROBIAL ETIOLOGY OF SEPSIS

In view of the multitude of potential pathogens with the capacity to cause disease, it is perhaps surprising that a very limited range of microorganisms is responsible for invasive infections in healthy children beyond the neonatal period. Three organisms predominate: *Streptococcus pneumoniae*, *Neisseria meningitidis* and *Haemophilus influenzae* type b.

The incidence of sepsis due to vaccine preventable organisms has been drastically reduced in countries with appropriate vaccination programs. However, even in these countries, otherwise healthy children who are not yet fully vaccinated, children in whom the vaccine has not provided adequate cover (vaccine failures), and children with infections caused by *N. meningitidis* group B continue to present with severe and life-threatening infections. Rarer causes of sepsis in healthy children include *Staphylococcus aureus*, group A, C and G streptococci and *Salmonella* spp., and these may be associated with wound and skin infections or a history of diarrhea respectively. In vulnerable patient groups other pathogens are implicated. In neonates, group B *Streptococcus*, *Escherichia coli*, other Gram negative bacteria, and *Listeria monocytogenes* are the usual causes of sepsis. In immunocompromised patients, Gram negative organisms such as *Pseudomonas aeruginosa*, and fungi may be responsible. Any patient with an indwelling catheter is particularly at risk of sepsis from coagulase negative staphylococci and enterococci as well as methicillin resistant *Staphylococcus aureus* (MRSA). With all of these organisms, the onset of bacteremia is a crucial event in the pathogenesis of sepsis, but invasion of the bloodstream is not necessary for bacteria to induce features of septic shock. Enterotoxins from staphylococci and streptococci are potent stimulators of T cell proliferation and activation, and can produce toxic shock syndromes even in patients with an apparently localized focus of infection. Some viruses, including herpes viruses, enteroviruses and adenoviruses, can produce diseases which may be indistinguishable clinically from bacterial sepsis, particularly in neonates and infants.

## PATHOPHYSIOLOGY OF SEPSIS

Over the last three decades it has emerged that it is the host response to microbial invasion which is predominantly responsible for the clinical features of sepsis and septic shock. Lipopolysaccharides (LPS) from Gram negative bacteria, and a variety of other microbial products have the capacity to stimulate the production of mediators from many cells within the human host. Tumor necrosis factor, interleukin 1 and interleukin 6 are just a few of the many inflammatory mediators reported to be present at high levels in septic patients. It has now been established that families of pattern recognition receptors exist which are able to transduce cellular signals in response to microorganisms, including bacteria. One important family, the human Toll-like receptors (hTLR), consists of at least ten proteins, with hTLR4 acting as the principal mediator of LPS signaling, while other members of the family, such as hTLR1, hTLR2 and hTLR6, can mediate signals induced by lipoproteins of mycobacteria and Gram positive bacterial peptidoglycans. The cytokines and inflammatory mediators produced in response to microbial stimuli activate neutrophils, endothelial cells and monocytes and influence the function of vital organs, including the heart, liver, brain and kidneys. The net effect of excessive inflammatory activity is to cause the constellation of pathophysiological events seen in patients with sepsis and septic shock.

## PRO- VERSUS ANTI-INFLAMMATORY MECHANISMS IN SEPSIS

The proinflammatory mediators produced in response to microbial invasion prime and activate cells to fight infection. However, the host also responds to proinflammatory stimuli by producing antagonists, known collectively as anti-inflammatory mediators. Interleukin 10 and soluble cytokine receptors or antagonists such as interleukin 1 receptor antagonist occur naturally and act to limit the effects of proinflammatory cytokines. The balance between pro- and anti-inflammatory mediators

is probably more critical than the levels of either alone. Patients who survive the initial inflammatory insult, but who still require assisted ventilation and intravenous support, have high levels of anti-inflammatory mediators. These patients are resistant to further proinflammatory stimulation and may be more susceptible to nosocomial infections. Such patients may actually benefit from immune stimulation<sup>58</sup> to provoke the production of more inflammatory mediators, and the balance of pro- and anti-inflammation may prove crucial in therapeutic interventions. In the future, a clear characterization of the inflammatory status of septic patients may therefore be essential before adjuvant therapy is instituted (see below).

## CLINICAL PRESENTATION AND DIAGNOSIS

The symptoms and signs of the initial phase of bacteremia are dependent upon the age and pre-existing health of the patient and the duration of the illness, as well as the causative organism. Bacteremia, with little inflammatory response, can be very difficult to diagnose clinically because of the overlap in clinical presentation with common viral illnesses. A number of clinical parameters have been examined to try to estimate the probability of bacterial rather than viral infection: children with a bacteremic illness are more likely to have a fever  $> 39^{\circ}\text{C}$  and a white blood cell count (WBC)  $> 15 \times 10^9/\text{L}$  or  $< 2.5 \times 10^9/\text{L}$ . However, the specificity and sensitivity of these parameters for diagnosing bacteremia is low and does not greatly add to the physician's general assessment of the child's condition.<sup>59</sup> Therefore frequent reassessment of the patient may be necessary if impending severe sepsis is to be recognized at an early stage. Nonspecific signs, including lethargy, irritability, hypotonia, poor feeding, nausea and vomiting, may be the earliest features of impending severe sepsis. Fever is not invariably present and hypothermia may also occur, particularly in neonates and infants. Cardiovascular involvement with tachycardia or bradycardia, inadequate peripheral perfusion, prolonged capillary refill, cold extremities, peripheral edema, decreased urine output and evidence of shock may all be manifest as the systemic response to bacterial invasion progresses. Respiratory, gastrointestinal and neurological derangement may indicate systemic disease or involvement of these specific organs in the infectious process. A petechial rash may be indicative of meningococcal disease, and in staphylococcal and streptococcal toxin-mediated shock, erythroderma, conjunctival and mucosal erythema and edema are usually present.

In all patients with suspected sepsis, blood cultures should be taken. The success of this procedure is dependent upon adequate blood inoculation of the culture media. If only a small volume of blood is available for culture, this should be added to the aerobic bottle, as few of the causative organisms will be anaerobes. Samples from potential sources of infection should be collected where appropriate. These include indwelling catheters, urine microscopy and culture, diagnostic radiology and aspiration for intra-abdominal sepsis, and lower respiratory tract secretions in ventilated patients, preferably by bronchoalveolar lavage. A lumbar puncture should be considered in patients with suspected meningeal involvement but is contraindicated in the presence of shock, coagulopathy, reduced conscious level or focal neurological signs. Samples can also be analyzed by molecular microbiological techniques for bacteria, fungi and viruses, although these investigations are not always routinely available. In patients with suspected toxic shock syndrome, analysis of staphylococcal and streptococcal isolates for the presence of toxin production and of V beta T cell receptor repertoires may be instructive. WBCs, high or low, and markers of inflammation including C-reactive protein (CRP), procalcitonin and proinflammatory cytokine levels may be useful. However, none of these investigations is specific or diagnostic. Coagulation studies, hemoglobin, urea and electrolytes, glucose and liver function tests should be performed to help inform further management and guide fluid and electrolyte replacement and general support.

## MANAGEMENT OF SEPSIS

### Recognition

Most cases of sepsis begin with the invasion of the bloodstream by a limited number of microbes. As the organisms multiply, often logarithmically, the host response intensifies and the condition of the patient deteriorates. The chances of a favorable outcome are greatly enhanced by initiating treatment at the earliest possible stage, so the most important aspect of sepsis management is the earliest possible recognition of the condition. In view of the diagnostic difficulties described above, it is imperative that otherwise healthy children presenting with nonspecific features are observed carefully. Even if a health care professional considers the risk of impending sepsis to be low and the patient well enough to be at home, a detailed plan of management should be discussed with the family. The parents or guardians should have a clear understanding of the clinical features to observe and what actions to take if there is deterioration or failure to improve and a plan agreed for the clinician to review the child's condition. In patients at increased risk of bacteremia, such as neonates, immunocompromised children and children with neutropenia or sickle cell disease, there should be a low threshold for initiating antimicrobial therapy.

### Antimicrobial therapy

The choice of antibiotics is dependent upon the most likely pathogens and the particular antibiotic resistance patterns of the community or hospital. In otherwise healthy children without an obvious source, a third generation cephalosporin such as cefotaxime or ceftriaxone is appropriate. The emergence of antibiotic resistance precludes penicillin as adequate initial therapy. In more vulnerable populations, other considerations apply. For example, in neonates, a third generation cephalosporin is frequently used together with ampicillin to treat *Listeria monocytogenes*, sometimes with the addition of an aminoglycoside for additional Gram negative bacterial cover.

Immunocompromised patients are vulnerable to infection with a wider spectrum of pathogens. Children with B cell and antibody deficiencies or with reduced or absent splenic function are at increased risk from encapsulated bacterial infections. Neutropenic patients are particularly susceptible to staphylococcal and Gram negative bacteria including pseudomonal infections. A combination of an antipseudomonal penicillin (e.g. piptazobactam) with an aminoglycoside (e.g. gentamicin) is usually prescribed for this population. However, a glycopeptide (e.g. vancomycin) and antifungal therapy may be required if initial therapy fails to control the infection. Patients with sickle cell disease are at risk of salmonella septicemia and may require treatment with ciprofloxacin. In patients with staphylococcal toxic shock syndrome, treatment with antistaphylococcal therapy is advisable, even though the total number of bacteria may be small. These are general guidelines, and advice about local antimicrobial prescribing policies should always be sought.

### Subsequent management

The details of the emergency treatment of shock are covered in Chapter 36. Children will usually require transfer to a pediatric intensive care unit. Hypovolemia is invariably present due to fluid maldistribution, which occurs as a result of the release of vasoactive mediators by host inflammatory and endothelial cells. The loss of circulating volume is compounded by a loss of intravascular proteins and fluid due to endothelial dysfunction (capillary leak). Continuous monitoring of central venous pressure and urine output is required to guide fluid replacement. Large volumes of plasma or blood are normally required, and mechanical ventilation may be necessary to manage capillary leakage of fluid into the lungs.<sup>60</sup> The net effect of the host response to infection frequently leads to myocardial depression, necessitating the use of inotropic support. Severe peripheral vasodilatation compounds hypotension, and vasopressors may be required. Dysregulation of the coagulation and thrombotic pathways leads to widespread microvascular thrombosis and consumption of clotting factors. Treatment of disseminated intravascular coagulation (DIC) is largely symptomatic, with

administration of fresh frozen plasma and platelets if bleeding occurs. While administration of antibiotics will prevent further bacterial proliferation, the concentration of microbial components such as LPS and outer membrane proteins may persist for some time. These will continue to cause inflammation and further deterioration in the patient's condition. Continuous reassessment and adjustment of supportive therapy is therefore required to optimize further management.

### Adjuvant therapy

The recognition that much of the pathology seen in sepsis is due to host-derived mediators has led to the development of numerous antagonists to offending bacterial and host components. Initial attempts to reduce the inflammatory response in sepsis used steroids. However, high doses of methylprednisolone were found to be detrimental in sepsis, and as a result routine use of high dose steroids in sepsis was abandoned. More recent data have shown that physiological doses of glucocorticoids may shorten the duration of shock and improve survival rates.<sup>61</sup> More selective agents have been developed, including antagonists of tumor necrosis factor, interleukin 1, platelet activating factor and endotoxin. None of these has proved to be beneficial in large clinical trials. However, it is too early to discard these new forms of treatment, since a clearer understanding of the sequence of events in sepsis may identify subgroups of patients who might benefit from these interventions.

The use of high doses of intravenous immunoglobulin may be beneficial in toxic shock syndromes and may be useful in other septic populations.<sup>62</sup> There is also evidence that administration of activated protein C (APC) can reduce mortality in adults with sepsis-induced organ failure.<sup>63</sup> This suggests that downstream inflammatory pathways, such as the protein C anticoagulation pathway, critical in thrombosis and hemostasis, may present potential targets for future interventions. However, in a trial of APC in children, no beneficial effect was observed. Perhaps the most important recent development in critical illness concerns the modulation of endocrine pathways. The administration of growth hormone to critically ill adults was found to significantly increase mortality, whilst low doses of steroids and tight glycaemic control appear to be advantageous.<sup>64</sup> The role of the endocrine axis in children with sepsis is still unclear but is currently under investigation.

## CONGENITAL AND NEONATAL INFECTIONS

### SPECIFIC INFECTIONS

#### Congenital rubella

The association between rubella infection during pregnancy and congenital cataracts in the newborn was first made by an Australian ophthalmologist, Norman Gregg, in 1941.<sup>65</sup> The introduction of effective rubella vaccination programs has made congenital rubella syndrome (CRS) an uncommon disorder in resource rich countries such as the UK. Falling vaccine coverage and immigration of nonvaccinated women was the likely cause of a small resurgence in the number of reported cases of CRS over the period 1996–2000.<sup>66,67</sup>

Both the risk of fetal infection and the risk of sequelae vary with the gestation when maternal infection occurs. Transmission of the virus to the fetus occurs in 90% in the first 11 weeks, 50% from 11 to 20 weeks' gestation, 37% from 20 to 35 weeks, and 100% during the last month of pregnancy.<sup>68</sup> However, the risk of serious sequelae to the fetus after confirmed maternal rubella infection is greatest in early pregnancy, being 90% if infected <11 weeks, 30% at 12–20 weeks and none thereafter, aside from some mild growth retardation.<sup>68</sup> The majority of infants with congenital rubella disease result from primary maternal rubella infection, although maternal reinfection may rarely result in an infant with anomalies.<sup>69</sup>

#### Clinical manifestation

The common manifestations of congenital rubella infection are shown in Table 28.15. Important clinical manifestations are disorders of the eye (microphthalmia, cataract, congenital glaucoma, retinitis), congenital

**Table 28.15** Clinical features of rubella, cytomegalovirus and toxoplasmosis

	Cytomegalovirus	Rubella	Toxoplasmosis
<b>CNS</b>			
Hydrocephaly	+	–	+++
Microcephaly	+	+++	–
Calcification	+++	+	++
Deafness	++	+++	++
Encephalitis	–	–	+
<b>Eyes</b>			
Microphthalmia	+	+	+++
Cataracts	–	++	+
Chorioretinitis*	+	+	+++
Intrauterine growth retardation	+	+++	+
Cardiac lesion	–	++	+
Purpuric rash	++	+++	–
Pneumonia	+++	++	++
Hepatosplenomegaly	++	+++	++++
Lymphadenopathy	–	–	+
Bony lesion	+	+++	–

\*The chorioretinitis caused by *Toxoplasma gondii* and *Treponema pallidum* has been confused with the Aicardi syndrome, in which the lesions are always bilateral, rarely peripheral, and lack pigments, in contrast to that due to these two organisms.

Infecting organisms are listed alphabetically and not in order of likelihood.

heart disease (patent ductus arteriosus, peripheral pulmonary artery stenosis), and neurological sequelae (mental retardation, behavioral disorders, meningoencephalitis, convulsions). There may also be intra-uterine growth retardation, microcephaly, thrombocytopenia, hepatosplenomegaly, purpuric skin lesions, pneumonitis and linear bone lesions. Only 68% of infected infants show signs at birth and up to 20% of these may die in infancy. A number of manifestations, however, present much later in life. These include hearing loss 87%, congenital heart disease 46–60%, mental or psychomotor retardation 30–50%, cataract or glaucoma 30–40%, diabetes mellitus and thyroid dysfunction.

#### Diagnosis

Virus isolation, either from nasopharyngeal washing, urine or cerebrospinal fluid (CSF) is the most direct method of diagnosis, but may take many weeks. A positive rubella-specific immunoglobulin M (IgM) in a neonate and/or the detection of rubella RNA in urine or nasopharyngeal secretions by polymerase chain reaction (PCR) usually indicates recent postnatal or congenital infection, although false positive results do occur. A number of sensitive immunoassays are available for the detection of rubella-specific IgG. Rising or persistently stable levels of IgG from the newborn period to beyond 9 months of age confirm perinatal or congenital infection.

#### Management

There is no specific treatment for rubella infection. In countries where routine rubella vaccination has been used, the infection rate has been considerably reduced. Seronegative women of childbearing age should be offered vaccination either after a pregnancy test or immediately postpartum. Rubella immunization of 13-year-old girls, which started in the UK in 1970, reduced the incidence considerably and the use of the measles, mumps and rubella (MMR) vaccine in the UK from 1988 has made congenital rubella rare.<sup>66</sup> Most new reports of congenital rubella in the UK are of infants born to mothers who were themselves born abroad and came to the UK after the age of schoolgirl immunization. In 2004, the World Health Organization adopted a strategy to improve global control of rubella and CRS by 2010 by increasing vaccination coverage of women of childbearing age using the combined measles–rubella vaccine, and by improving surveillance for CRS.<sup>70,71</sup>

## Cytomegalovirus (CMV)

Cytomegalovirus (CMV) infection is the most common congenital infection in Europe with a prevalence of 3–4 per 1000 births. CMV is a member of the herpes virus family and, as such, establishes a latent infection after the initial infection and reactivates, especially under states of altered cellular immunity. It is ubiquitous in the community, although not highly infectious. It may be transmitted transplacentally or through genital secretions, saliva, breast milk or blood transfusion.

About 50% of women of childbearing age in the UK remain susceptible to CMV infection and 1% of those susceptible at the beginning of pregnancy will have a primary infection during pregnancy. Like rubella, the greatest risk of fetal damage occurs after primary maternal infection. In about 50% of primary infections of the mother, the fetus will be infected, but only 10% of these infants will display symptoms at birth or through childhood. After a recurrent maternal CMV infection, there is a low risk of transmission to the infant ( $\leq 1\%$ ), with an equally low risk of sequelae.<sup>72</sup> However, some cases of infants with severe, symptomatic congenital CMV disease due to either maternal reinfection with a new CMV strain or reactivation of latent CMV infection during pregnancy have been reported.<sup>73</sup> Unlike rubella, fetal damage may follow primary infection or recurrent infection at any stage of pregnancy.

### Clinical manifestations

The majority of infants with congenital CMV infection are asymptomatic. When symptomatic, the main clinical features are as shown in Table 28.16. The risk of neurological sequelae and intrauterine growth retardation in the fetus is greatest after infection in the first 20 weeks of pregnancy, but infants of mothers with pre-existing immunity to CMV can have clinical sequelae.<sup>74</sup> Such effects include microcephaly, chorioretinitis, mental retardation, sensorineural hearing loss and intracerebral periventricular calcification. Infection in the second half of pregnancy usually results in visceral disease such as hepatitis, purpura, hyperbilirubinemia and thrombocytopenia. Other effects include dental abnormalities and inguinal hernias. Pneumonitis is a common feature of postnatally acquired CMV infection, especially in the premature infant, but rarely follows true congenital infection. Those infants who have symptoms in the newborn period nearly always have subsequent handicap. The presence of microcephaly at birth is the strongest predictor of poor cognitive outcome in later life.<sup>75</sup> Of the infected infants who are asymptomatic at birth, up to 10% will have CMV-related problems by 3 years of age, the most common problem being sensorineural hearing loss.<sup>76,77</sup> High CMV viral blood load ( $10^4$  viral DNA copies per  $10^5$  poly-

morphonuclear leukocytes) in the newborn has recently been identified as a strong predictor for adverse long term clinical sequelae.<sup>78</sup>

### Perinatal CMV infection

Many infants acquire CMV infection through breast-feeding or by contact with other infected secretions in the first weeks of life or, in hospitalized babies, through blood products. This usually results in an asymptomatic infection. The exception is premature infants, especially those with extremely low birth weight, or infants with cellular immunodeficiency in whom CMV infection may result in pneumonitis, hepatitis, thrombocytopenia, neutropenia and, uncommonly, gastroenteritis. In general, postnatal CMV infection does not result in long term sequelae, with the possible exception of babies less than 2000 g.<sup>79</sup>

### Diagnosis

Diagnosis is based on isolation of the virus in throat washings or urine or by detection of CMV DNA in these specimens by PCR. Cultures must be obtained within the first 3 weeks of life to distinguish congenital CMV infection from perinatally acquired infection. Demonstration of CMV-specific IgM antibody in neonatal serum is also suggestive of congenital infection, but it can only be detected in about 70% of infected newborns. Later in infancy, in the absence of clinical signs suggestive of congenital infection, laboratory methods alone will not make the distinction between CMV acquired during intrauterine life and postnatal infection. Retrospective diagnosis of congenital CMV infection can be made by detection of CMV DNA in dried blood on the filter paper from newborn screening cards.

### Treatment and prevention

Ganciclovir therapy may be used to treat some congenitally infected infants with life-threatening CMV-related organ disease or retinitis involving the macula. Work is in progress towards production of a vaccine. Intravenous ganciclovir has also been used in a series of small clinical trials to try to reduce the risk and extent of central nervous system damage after symptomatic congenital CMV infection.<sup>80,81</sup> However, no firm conclusions about the efficacy of this treatment could be drawn due to the small sample sizes, and until more efficacy data are available it is not routinely recommended. Some groups nevertheless recommend ganciclovir therapy for infants with signs of disseminated disease without severe hearing loss [ $\geq 100$  dB by brainstem auditory evoked response (BAER)] due to the high risk of late progression,<sup>82</sup> and others prescribe prolonged therapy with oral valganciclovir.<sup>83</sup> However, there is a lack of clinical trial data to support these opinions.

**Table 28.16** Lesions that may be caused by prenatally acquired viral infections

Pathogen	Clinical sequelae
1. Coxsackie virus	Abortion, mild febrile disease, rash, meningitis, hepatitis, gastroenteritis, myocarditis, congenital heart disease and neurological deficits
2. Cytomegalovirus	Microcephaly, hydrocephaly, microphthalmia, retinopathy, cerebral calcification, deafness, psychomotor retardation, anemia, thrombocytopenia, hepatosplenomegaly, jaundice and encephalopathy
3. ECHO virus	Same as coxsackie virus
4. Hepatitis B virus	Low birth weight, asymptomatic hepatitis carrier, acute hepatitis, chronic hepatitis
5. Herpes simplex virus	Abortion, microcephaly, cerebral calcification, retinopathy, encephalitis, multiple organ involvement
6. Human immunodeficiency virus	Abortion, hydro/microcephaly, limb deformities, intrauterine growth retardation, failure to thrive, rash, hepatosplenomegaly, pneumonia
7. Influenza virus	Abortion
8. Measles virus	Abortion, congenital measles
9. Polio virus	Abortion, congenital poliomyelitis with paralysis
10. Rubella virus	Abortion, microcephaly, cataract, microphthalmia, congenital heart disease, deafness, low birth weight, hepatosplenomegaly, petechiae, osteitis
11. Vaccinia virus	Abortion, congenital vaccinia
12. Varicella-zoster virus	Abortion, limb, cerebral and skin malformation
13. Variola virus	Stillbirth, low birth weight, chorioretinitis, congenital chickenpox, or disseminated neonatal varicella or zoster

In alphabetical order and not in order of frequency or seriousness.

CMV is spread by intimate contact with infected secretions. Pregnant caregivers and hospital personnel should employ careful hand washing after exposure to the secretions of a CMV-infected infant. Passive immunotherapy with CMV hyperimmune globulin of women with primary CMV infection during early pregnancy has been shown in an open labeled phase I trial to be safe and possibly effective at reducing transmission to and sequelae in the offspring.<sup>84</sup> Results have yet to be confirmed in a randomized clinical trial.

## Varicella-zoster (chickenpox)

### *Congenital infection*

Maternal varicella-zoster infection during the first 20 weeks of pregnancy may result in spontaneous abortion or fetal death in utero, or in an embryopathy characterized by dermatomal skin scarring and limb hypoplasia. There may also be disorders of the central nervous system (microcephaly, cortical atrophy) and eyes (cataracts, chorioretinitis), of the gastrointestinal tract and of the genitourinary tract. It is hypothesized that the damage results from in utero reactivation of varicella-zoster virus (VZV) or disseminated fetal infection.

Maternal infection in the second half of pregnancy may result in an asymptomatic primary fetal infection followed by herpes zoster in the first years of life in about 1% of exposed infants. A large prospective study from the UK and Germany of the effects of maternal VZV infection in pregnancy estimated the overall risk of embryopathy during the first 20 weeks of pregnancy to be 1%, with the highest risk of transmission of 2% being in the period 13–20 weeks.<sup>85</sup> Occasional cases resulting from maternal infection at 23 weeks have been reported.<sup>86</sup> Administration of varicella-zoster immunoglobulin (V-ZIG) to the mother may modify the course of chickenpox, but it has not been shown to alter the risk of transmission to the fetus.<sup>87</sup>

### *Perinatal infection*

Maternal varicella that occurs in the period 5 days before delivery to 2 days after delivery may result in life-threatening, disseminated VZV infection in the infant due to transplacental passage of the virus in the absence of maternal antibody. If the onset of maternal infection is more than 7 days prior to delivery, there is usually sufficient passive transfer of antibody, unless the infant is less than 28 weeks' gestation. Administration of V-ZIG to the infant has been shown to prevent or modify the course of the illness in most cases. However, as a significant number of infants will develop systemic VZV despite the administration of V-ZIG,<sup>88</sup> all infants with perinatal VZV exposure should be monitored closely for systemic disease, with prompt initiation of intravenous aciclovir should vesicles appear. Hospitalized infants with chickenpox should be placed in respiratory and contact isolation until the lesions have crusted, but breast-feeding can continue.

## Herpes simplex virus (HSV)

Neonatal HSV infection carries a high mortality if untreated. The incidence of disease ranges from 1:2500 live births in some parts of the USA<sup>89</sup> to 1:60 000 live births in the UK.<sup>90</sup> In the past, up to 75% of cases of neonatal infection were due to HSV type 2 and the rest due to type 1. More recently, the proportion of cases due to neonatal HSV-1 infection is increasing in the UK and elsewhere around the world, possibly due to an increase in genital HSV-1 disease.<sup>90</sup> The infection is acquired from passage through an infected birth canal in 85% of cases, and is postnatally acquired from the oral lesions of an infected caregiver in 10–15% of cases. A true congenital syndrome is seen in < 5% of cases. The greatest risk for transmission (about 50%) is from a primary maternal infection when there has been insufficient time for seroconversion and transplacental transfer of antibody.<sup>91</sup> If a woman with a recurrent infection is shedding virus at delivery, the risk may be 5% or less. Cesarean delivery is not completely effective in preventing transmission to the infant.

### *Clinical manifestations*

Neonatal HSV disease may manifest as lesions localized to the skin, eye or mouth (SEM), as encephalitis, as pneumonitis or as a disseminated multiorgan infection with or without central nervous system involvement.

The age of presentation varies with the category of disease. In general, neonatal HSV disease usually presents in the first 3 weeks of life, but it may manifest at any time from day 1 to 4 weeks of life. About 50% of cases now present as SEM disease, possibly due to better awareness of the condition. The typical vesicular, ulcerative lesion usually occurs on the presenting part. Up to 70% of SEM disease will spread to the central nervous system or elsewhere without treatment, but is rarely fatal. Infants with SEM disease have 10% long term morbidity, with higher rates seen if there are frequent cutaneous recurrences in early life.

The disseminated form typically commences at about 1 week of age with a shock-like syndrome in the absence of positive bacterial cultures with thrombocytopenia, disseminated intravascular coagulation, hepatitis, jaundice, and sometimes encephalitis and seizures. Skin lesions appear in 50% of these cases. Disseminated HSV infection may also present as an interstitial pneumonitis, usually presenting about day 3 of life. The mortality in this group is as high as 50% even with treatment, and over half of the survivors are left with long term sequelae (mental retardation, blindness, seizures, learning defects). The third group presents with central nervous system symptoms such as poor feeding, apnea, lethargy and seizures without visceral involvement, typically in the second to third week of life. It has been hypothesized that this group represents reactivation of an earlier asymptomatic infection. They have a 15% mortality, with severe long term central nervous system effects seen in 65%.<sup>92</sup>

### *Congenital infection*

Intrauterine HSV infection may manifest as the presence of vesicles or scarring at birth, chorioretinitis, microphthalmia, microcephaly, hydranencephaly or cerebral atrophy on CT scan in the first week of life, organ calcification or organomegaly. The majority of reported cases are due to HSV-2. There is a high rate of early neonatal death and long term central nervous system sequelae.

### *Diagnosis*

If neonatal HSV disease is suspected, viral swabs of skin vesicles, eyes, nasopharynx and rectum should be sent for HSV culture and immunofluorescence or HSV PCR, CSF collected for routine examination, HSV PCR and culture, blood sent for liver function tests, platelet count and coagulation screen, and empirical therapy with systemic intravenous aciclovir promptly commenced. A chest radiograph may be indicated if respiratory distress is present. Imaging of the head by ultrasound or CT scan should be performed. Serologic assays are usually not helpful in the acute diagnosis of neonatal HSV disease.

### *Treatment and prevention*

Mothers with primary lesions should be delivered electively by Cesarean section while mothers with recurrent lesions, if they have a negative culture and do not have lesions or prodrome of infection, may be delivered vaginally. The use of invasive fetal monitoring and vacuum delivery should be avoided where possible in women with known genital HSV disease. Some suggest that the infant should be screened for infection by surface viral swabs at 48 h of life.

Aciclovir 60 mg/kg/d in three divided doses given intravenously should be commenced as soon as neonatal HSV disease is suspected. Many suggest it should be commenced empirically in the offspring of women with known primary genital HSV infection due to the high attack rate. The duration of therapy is 14 days for SEM disease and 21 days for all other categories or where a lumbar puncture could not be performed.<sup>93</sup> Topical therapy may be given in addition to systemic therapy for HSV eye disease under the direction of an ophthalmologist. The prognostic significance of persistence of HSV DNA at the end of therapy is currently under evaluation.

Prevention of neonatal HSV disease demands a vaccine to prevent maternal infection and/or reactivation. Recently a recombinant HSV type 2 glycoprotein subunit vaccine has been shown to be partly effective at reducing the risk of infection and development of clinical disease in women without prior immunity to HSV types 1 or 2.<sup>94</sup> Its efficacy is currently being evaluated in HSV-1 seronegative girls prior to the onset of sexual activity.<sup>95</sup> Other prevention strategies include the use of an

oral antiviral in late pregnancy in women with primary HSV infection during pregnancy or in HSV-seropositive women with frequent clinical recurrences in the genital area.<sup>96</sup>

The shock-like syndrome associated with the disseminated form of neonatal HSV disease has been associated with signaling through Toll-like receptor (TLR)-2,<sup>97</sup> raising the possibility that future therapeutic strategies for this condition may target TLR signaling pathways.

## PARASITIC INFECTIONS

### Toxoplasmosis

Toxoplasmosis is a worldwide disease. In the UK between 20 and 40% of the population have been infected with this protozoan by adult life. The incidence of congenital toxoplasmosis in Europe is 1–10 in 10 000 newborns.<sup>98,99</sup>

Congenital toxoplasmosis infection usually occurs as a result of placental infection after a primary infection in a pregnant woman. Parasites form small focal lesions in the placenta, proliferate and are released as active forms into the fetal bloodstream. Rare cases of fetal transmission have been reported after preconception maternal infection in immunocompetent women,<sup>100</sup> presumably due to myometrial infection. It is generally accepted that women who bear a congenitally infected child do not have infected children in subsequent pregnancies, probably owing to persistence of immunity after the primary infection. Exceptions to this rule do occur, and it is suggested that the persistence of *Toxoplasma gondii* as cysts in the myometrium with liberation of active forms during pregnancy is one of the main infectious causes of repeated abortion in women. Congenital toxoplasmosis has been reported following reactivation in women with HIV infection, although it is a rare event as shown by a European Collaborative Study.<sup>101</sup>

The risk of transmission and the clinical outcome after maternal toxoplasmosis infection vary with the trimester of pregnancy. Recently, up-to-date risk estimates of maternal transmission of toxoplasmosis during pregnancy have come from a large study of women with confirmed infection who were referred to a toxoplasmosis reference laboratory in France.<sup>98</sup> Infection in early pregnancy carried a low risk of transmission; this rose to 6% by 13 weeks, thereafter rising sharply to 40% at 26 weeks, and 72% at 36 weeks. If a fetus is infected, the risk of developing clinical signs (and the severity of disease) is greatest the earlier in pregnancy the infection occurs, falling from 61% at 13 weeks, to 25% at 26 weeks, to 9% at 36 weeks.<sup>98</sup>

### Clinical manifestations

Infection of the fetus with virulent strains early in pregnancy may produce fetal death and abortion; still later, severe fetal damage or stillbirth; and later still, a liveborn infant with stigmata of congenital toxoplasmosis. However, up to 70% of infants with congenital toxoplasmosis are asymptomatic at birth. The most common single presenting feature is chorioretinitis and both eyes are involved in 40% of cases. Other important clinical features are given in Table 28.15. They include hydrocephalus, intracranial calcification, hepatosplenomegaly, jaundice, thrombocytopenia and a maculopapular rash. Clinical sequelae of congenital infection, including visual disturbance, seizures and mental retardation, may not manifest until later in life. A recent long term follow-up study of visual sequelae from congenital toxoplasmosis infection has confirmed that late onset retinal lesions and relapse in existing visual lesions can occur many years after birth. The prognosis for patients with central nervous system involvement must be extremely guarded.

### Diagnosis

This is usually based on *Toxoplasma* IgM and/or *Toxoplasma* IgA antibody test. The sensitivity of the IgM-ISAGA test is probably the highest. Persistently elevated *Toxoplasma* IgG beyond 12 months of life, and detection of *Toxoplasma* DNA by PCR in the placenta, neonatal blood or CSF may also be used to make the diagnosis. In the infant with suspected congenital toxoplasmosis, ophthalmological examination, hearing

assessment and central nervous system examination and imaging should also be performed.

### Treatment

Infants diagnosed with symptomatic or asymptomatic congenital toxoplasmosis infection should be treated to reduce the incidence of long term sequelae such as chorioretinitis. Two synergistic antimicrobials, either sulfadiazine or sulfadiazine together with pyrimethamine, are used in various combinations. Prolonged treatment for up to 12 months is required to reduce the risk of late reactivation in the eye.<sup>102</sup> Corticosteroids should be used in the presence of chorioretinitis or raised CSF protein. Many advise treatment of pregnant women with primary toxoplasmosis. A recent systematic review suggests that there are still insufficient data on whether this treatment is effective in preventing neonatal infection.<sup>103</sup>

Pregnant women should be educated to avoid ingestion of *Toxoplasma* cysts by adequate cooking of meat, washing of garden produce, and washing hands after contact with soil.

## ENTEROVIRUSES (NON-POLIO)

Intrauterine, perinatal and postnatal transmission of enteroviruses [coxsackie viruses group A and B, enteric cytopathogenic human orphan (ECHO) viruses, enteroviruses 68–71] has been documented, although there are no data available on the risks of transmission to the fetus or of sequelae should this occur. While maternal enterovirus infection during pregnancy has not been conclusively proven to cause an embryopathy, there have been links between some specific maternal enteroviral infections and anomalies in the infant (coxsackie B virus infection with urogenital anomalies, coxsackie B3 and B4 viruses with cardiac anomalies, coxsackie A9 with digestive anomalies).

Perinatal enteroviral infections generally cause asymptomatic infection or mild, nonspecific illness, particularly if the baby acquires infection 'horizontally' from other babies. However, if a woman is infected just before or after delivery, severe disease may develop in the 'vertically' infected newborn, in the first week after birth. The mother may present with severe abdominal pain mimicking abruption, or with respiratory or gastrointestinal symptoms. The baby may present with one or more of the following: a sepsis-like syndrome [fever or hypothermia, anorexia, vomiting, lethargy, disseminated intravascular coagulation (DIC)], gastrointestinal (vomiting, diarrhea, fulminant hepatitis, pancreatitis), neurological (aseptic meningitis, encephalitis or paralysis), respiratory (pneumonitis, pharyngitis, laryngotracheobronchitis), skin or mucosal manifestations (erythematous, maculopapular rash, herpangina, hemorrhagic conjunctivitis) or cardiac disease (myocarditis, pericarditis). Some specific enteroviruses are associated with particular syndromes (see Enteroviruses). Severe ECHO virus infections are more likely to cause hepatitis with massive hepatic necrosis, DIC and death, while coxsackie viruses are more likely to cause myocarditis and meningitis. Neonatal outbreaks of enterovirus 71 (EV 71) have recently been associated with neurological manifestations such as encephalitis, Guillain-Barré syndrome and neurogenic pulmonary edema.<sup>104,105</sup>

### Diagnosis

Enteroviruses may be cultured from the nasopharynx, throat swab or feces. Serology is rarely helpful due to poor sensitivity. Detection of enterovirus nucleic acid in the CSF by PCR can be useful in the diagnosis of enteroviral meningitis.

### Treatment

The antiviral agent pleconaril has been shown to have in vitro activity against a number of enteroviruses, but not EV 71.<sup>106</sup> In a small case series, treatment of severe neonatal enterovirus infection with oral pleconaril was associated with both virological and clinical improvement, but the sample size was too small to determine if this outcome was significant. Intravenous immunoglobulin has also been used to treat life-threatening disease, but its efficacy is unproven for this use.

## HOSPITAL INFECTION CONTROL

Nosocomial infections are defined as infections acquired by hospitalized patients which were not present or incubating at the time of their hospital admission.<sup>107</sup> Infection control developed as a formal discipline during the 1950s and 1960s primarily as a response to nosocomial staphylococcal infections. Today infection control, enhanced by the application of epidemiological methods and the use of statistical analysis, has a major role in identifying and analyzing adverse outcomes in the health care setting. The central role of an infection control program is to reduce the risk of nosocomial infection with resulting protection of patients, health care workers, students and visitors.

All hospitals should have in place a multidisciplinary infection control committee with members who are interested and knowledgeable in infection and infection control and represent areas of the hospital where infection is either a potential problem or are involved in controlling these infections. The infection control committee must have the delegated authority of the hospital executive to efficiently and tactfully implement actions to control infection. It is recommended that the committee should consist of a medical microbiologist, medical virologist, infection control practitioner and an infectious disease physician and, in addition, personnel from medical and nursing and administration as well as pharmacy, operating theaters, housekeeping, engineering and maintenance. Ideally the chair of the committee should have expertise in hospital epidemiology and infection control.

Nosocomial infections are predominantly transmitted via contact, primarily by the contaminated hands of health care workers who have touched a colonized patient or something in the patient's environment. Hand washing with soap and water remains the single most important method in the prevention of nosocomial infections, but numerous studies have shown that hand washing compliance by health care workers is poor and often less than 50%. To improve the situation, there has been a recent increase in use of alcohol-based hand antiseptics. The application of these alcohol-based hand antiseptics, a process called hand hygiene, kills bacteria (except *Clostridium difficile*) very rapidly. Hand hygiene takes much less time than traditional hand washing and is gentler on the skin of the hands than repeated use of soap and water. In addition, hand lotions and moisturizers should be available to health care workers to decrease skin irritation which may result from frequent hand washing and hand hygiene.<sup>108</sup>

Isolation of patients is done to prevent the spread of microorganisms from infected or colonized patients to other patients or health care workers, thus interrupting transmission. The current isolation guidelines are based on our understanding of the mechanisms of disease transmission. There is essentially a two-tiered approach to isolation. The first is the use of **standard precautions**, the basis of infection control, which applies to all patients. The second approach is **transmission-based precautions**, contact, droplet and aerosol, which apply to patients with documented or suspected infections (see Table 28.17).

Standard precautions involve hand washing before patient contact and after leaving the patient's environment. In addition, personal protective equipment, masks, gowns, gloves and eye protection, provides a barrier to reduce the opportunities for transmission of infectious agents if there is contact with body fluids. A fluid resistant gown or apron made with impervious material, fluid repellent mask or face shield and protective eyewear should be worn when performing any procedure where there is the likelihood of splashing or spreading of blood or other body substances.<sup>109</sup> Gloves are worn as a barrier to protect the health care worker's hands from contamination and prevent the transfer of microorganisms. The type of gloves selected should be appropriate to the type of risk of the procedure. Sterile gloves are worn if the procedure involves contact with tissues that would be sterile under normal circumstances. Medical examination gloves, which are clean but not sterile, are used in all procedures that may involve direct skin or mucous membrane contact with blood or fluids capable of transmitting blood-borne pathogens. General purpose gloves are used for housekeeping activities and cleaning instruments. The gloves must be changed and discarded as soon as they are torn or punctured, after contact with an individual is completed and before care is

Table 28.17 Isolation and types of precautions

Isolation precautions	Requirements	Examples of infections
Standard	Hand washing before and after patient contact Personal protective equipment (PPE): Gloves, gown and mask should be worn by staff when touching or handling blood or body substances Hands must be washed before attending patients and after removal of gloves	All patients require standard precautions
Contact	Standard precautions plus: Single room if possible and cohorting of patients with like illness if possible	Respiratory syncytial virus Rotavirus Impetigo Herpes zoster (shingles) Hepatitis A Methicillin-resistant <i>S. aureus</i> (MRSA) Extended-spectrum beta-lactamase (ESBL) positive Enterobacteriaceae Carbapenem-resistant <i>Acinetobacter baumannii</i>
Droplet	Contact precautions plus: Use of a mask if within 1 meter of the patient The room door must remain closed	Influenza virus Adenovirus <i>N. meningitidis</i> (invasive) <i>B. pertussis</i>
Airborne	Droplet precautions plus: Single negative pressure room with 6–12 air changes per hour	Measles Chickenpox Tuberculosis

provided to another individual or when performing separate procedures on the same patient where there is a risk of transmitting infection from one part of the body to the other. It should be emphasized that hands must be washed and cleaned after the removal and disposal of gloves.

Health care workers are susceptible to infectious diseases and may therefore be infected by, or transmit infection to, patients. It is therefore strongly recommended that health care workers working in clinical areas be protected against those infectious diseases where vaccination is possible. It is recommended that health care workers be vaccinated against diphtheria, tetanus, pertussis, measles, mumps, rubella, varicella, influenza and hepatitis B.<sup>109</sup> Other vaccinations such as meningococcal, typhoid and hepatitis A virus vaccines may be indicated in special circumstances.<sup>110</sup>

The potential transmission of blood-borne diseases is greatest where a needle, scalpel blade or other sharp instrument is used. All health care workers are responsible for the management and disposal of the sharps they have used and should take care to ensure they are disposed of in a safe manner. Particular care should be taken in removing disposable scalpel blades from scalpel handles. In addition, needles should not be removed from disposable syringes and should not be purposefully bent or broken. Needles should not be re-sheathed after use, if possible. All sharps should be disposed of immediately after use into a sharps container which is puncture resistant and waterproof.<sup>111</sup>

It is generally agreed that antimicrobial resistance is driven by antibiotic use, and excessive and unnecessary use of antimicrobials can be expected to increase the prevalence of resistant microorganisms. Infection

of patients with multiresistant organisms leads to increased morbidity and mortality as well as increased financial costs. All health care institutions need to develop policies for the control of antimicrobial use by developing guidelines and authorization for their use in specific situations. Advice from the medical microbiologist or infectious diseases physician may assist general clinicians in more appropriate selection of antimicrobial agents.<sup>112</sup>

Routine surveillance for selected pathogens may be a method to assess the efficacy of infection control policy and procedures and determine if an outbreak occurs. A nosocomial infection outbreak may be described as an epidemic, or an increase above normal of the expected level of an infection in the clinical setting. The main goal of managing an outbreak is to prevent a further increase in the incidence of health care associated infection by identifying factors which may have contributed to the outbreak. This also allows for the development and implementation of measures to prevent future outbreaks. General management of an outbreak involves first determining a case definition and, second, confirming an increase in cases by the infectious agent above the background rate. It is then necessary to collect information regarding cases as descriptive epidemiology to determine if there are any recognized modes of transmission.<sup>113</sup> Implementation of appropriate infection control measures as described in Table 28.17 should be undertaken to contain the outbreak.

Managing infection control in a pediatric hospital presents some unique challenges. Young children usually have poor personal hygiene and require significant adult supervision to ensure this practice. They are also mobile and quite impulsive and may require isolation to prevent contact spread of infecting organisms to other patients. Isolation of small children can often distress them and it is essential to provide adequate supervision for their safety and suitable age-related activities to relieve their distress.

## BACTERIAL INFECTIONS

### THE USE OF THE BACTERIOLOGY LABORATORY BY THE PEDIATRICIAN

A proficient and well managed microbiology laboratory is essential for any health care institution.<sup>114</sup> Pivotal to the function of the microbiology laboratory is excellent communication between the physician and the laboratory personnel. After considering the clinical and epidemiological circumstances of the patient infection, the physician must collect appropriate samples for culture. Ideally specimens should be obtained directly from the site of infection before commencement of antibiotic therapy. However, this may not always be possible in patients who are critically ill, when antimicrobial therapy may need to start immediately. It is critical that all specimens submitted to the laboratory be correctly collected, labeled and transported as well as being of sufficient quality and quantity for adequate microbiological testing. They should be submitted promptly to the laboratory along with all relevant clinical and epidemiological data to assist the laboratory in selection of appropriate testing protocols.

### DIRECT MICROSCOPY

Gram stain is one of the most useful and rapid diagnostic tests offered by the microbiology laboratory. It can be performed on exudates, tissue smears, fluids and aspirates to detect bacteria and fungal elements. In addition to bacteria, the presence and type of inflammatory cells is also detected. Information about bacterial morphology, i.e. cocci or rods, and the staining appearance, Gram positive or Gram negative, can give important preliminary information about the possible genus of the infecting microorganism and thus guide empiric antimicrobial therapy. If infection with mycobacteria or *Nocardia* spp. is suspected, the acid-fast or modified acid-fast stains respectively can be performed to detect these microorganisms.

### BLOODSTREAM INFECTIONS

Blood cultures are among the most important specimens processed by the microbiology laboratory. Bloodstream infections can be considered to

be transient, intermittent or continuous, and diagnosis of a bloodstream infection is very important in managing sick patients.

An example of transient bacteremia is that which occurs following cleaning one's teeth; transient bacteremia is rarely of clinical significance. An intermittent bacteremia occurs in patients who have serious bacterial infections such as pneumonia, urinary tract infections or osteomyelitis, where organisms may be isolated from the bloodstream but this is not uniformly the case. Continuous bacteremia occurs in patients who have infection within the vascular space and this includes patients with bacterial endocarditis or septic thrombophlebitis.

Because diagnosis of a bloodstream infection may be critical for patient care, it is essential that these specimens are collected correctly. Optimal collection of a blood culture starts with proper skin preparation. The skin must first be cleaned with 70% alcohol followed by tincture of iodine for 1 min or alternatively povidone-iodine for 2 min. It is important to allow these disinfectants to dry as killing bacteria takes time. Alcohol should not be used as a second antiseptic agent when an iodophor is used as it may inactivate these compounds. It is also recommended to clean the septum of the blood culture bottle with 70% alcohol and allow this to dry before injecting blood. The blood must be injected without changing needles.

It is important to take the volume of blood which is recommended for the blood culture system being used. Optimal blood volume enhances recovery of agents as blood is an important component of the culture media itself. The maximum amount of blood that can be taken from a child will depend on the weight and the clinical status of the child and it is usual for 1–3 ml to be obtained from a child younger than 6 years, whereas the neonate may only be able to afford 0.5–1 ml. When collecting blood cultures from children it is advisable to use a pediatric blood culture system which is optimized to function with much smaller volumes than adult blood culture systems. Addition of extra blood can often lead to a false positive signal due to blood cell metabolism, as modern automatic blood culture systems detect carbon dioxide production, and additional blood does not enhance bacterial detection. Blood culture media also contain an anticoagulant, sodium polyanethole sulfonate (SPS), which in addition to its anticoagulant action has an anticomplement and antiphagocytic effect that prevents intracellular killing of microorganisms by neutrophils following injection of the blood into the culture bottle and thus enhances sensitivity. However, SPS may inhibit recovery of organisms such as *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *Gardnerella vaginalis*, *Streptobacillus moniliformis* and *Peptostreptococcus anaerobius*. Ideally blood cultures should be obtained before the start of antibiotic therapy to prevent inhibition of microorganism growth.

More recently, bacteremias have been associated with the increased use of indwelling intravenous catheters for a variety of vascular access needs.<sup>115</sup> Where the use of indwelling catheters is common, institutions have seen an increase in organisms such as coagulase negative staphylococci, corynebacteria, bacilli, yeasts and a variety of uncommon but opportunistic Gram negative rods. When collecting blood cultures through an indwelling catheter, it is strongly recommended that blood cultures are collected simultaneously from a peripheral noncannulated site, to determine if a positive culture represents true bacteremia or infection of the central venous line. While it is recommended not to take blood cultures through central venous lines, this practice is usually quite common because of the ease of drawing blood through these catheters with little discomfort to the patient. Identification of a contaminated catheter may result in treating patients with antibiotics for a period of time, possibly preventing more serious systemic infection and also obviating the need to remove the catheter.

Blood cultures are usually incubated for 5–7 days before being declared negative. The length of culture may be extended in specific situations, for example when fastidious organisms are anticipated as in subacute bacterial endocarditis or in prolonged fever of unknown origin.

## URINARY TRACT INFECTIONS

The commonest site of clinically significant bacterial infection in infants and children is the urinary tract. Urinary tract infections may occur within the renal parenchyma, in the tubules or pelvis, or at any point along the ureters, urinary bladder or urethra. Studies relating clinical infection to the number of bacteria in a voided urine specimen demonstrated that at least 100 000 variable bacteria on culture per milliliter of urine correlated strongly with infection in the upper urinary tract. Most urinary tract pathogens grow easily and quickly and include *Escherichia* spp., *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp., *Pseudomonas* spp., *Enterococcus* spp. and *Staphylococcus* spp. Bacteria that are generally considered contaminants and disregarded include lactobacilli, diphtheroids, non-enterococcal alpha-hemolytic streptococci and coagulase negative staphylococci, other than *Staphylococcus saprophyticus* which is a common cause of urinary tract infection in pubertal girls and young women.

Yeasts, particularly *Candida* spp., may cause urinary tract infections. Determination of true urinary tract infection due to the yeast is more complex than with bacteria as there is no correlation with colony number and formal diagnosis may require an invasively obtained specimen, e.g. catheterization of the bladder, to avoid genital colonization which may contaminate the culture. Urine specimen may on occasions be used to detect *Mycobacteria* spp. and leptospirosis.

In addition to culture information, with identification of the bacterium and provision of antibiotic sensitivity results, the cell count per high power field is also helpful in determining the significance of results. The presence of a high white blood cell count, greater than 100 per high power field, indicates the presence of a significant inflammatory reaction occurring within the upper urinary tract. Where there is sterile pyuria, consideration must be given to whether the patient has already received an antibiotic rendering the sample sterile or whether there is some other non-infectious inflammatory lesion of the upper urinary tract. Some laboratories will also test the urine to see if it contains antibacterial activity, indicating the presence of antibiotic in the urine and thus warning the clinician of possible false negative results.

The presence of greater than 10 epithelial cells per high power field in the urine specimen is indication of significant contamination from the terminal urethra or vulva, so culture results need to be interpreted with great caution. Collection of the urine specimen should be done so as to minimize possible contamination by external colonizing bacteria in the urogenital tract. Suprapubic bladder aspiration of urine is the procedure least likely to result in contaminated urine. Alternatively, urine obtained by insertion of a catheter through the urethra into the bladder, collection of the urine specimen and removal of the catheter is also much less likely to be contaminated than voided specimens. If a voided specimen is to be collected, careful cleaning of the urethral meatus with sterile water in both males and females is strongly recommended prior to collection of a mid-stream urine specimen. It is desirable to ask the patient to void a small volume first (about 5 ml) and then collect the next urine passed, a mid-stream urine specimen. The initial voiding helps clean any colonizing bacteria from the terminal urethra prior to collection of the specimen for culture.

## RESPIRATORY TRACT INFECTION

Respiratory tract infections can be divided into upper respiratory and lower respiratory. Common upper respiratory tract specimens include throat swabs and nasopharyngeal swabs or aspirates. Aspirates from sinuses or the middle ear are submitted only occasionally, because they are difficult to collect and empiric therapy without culture is usually effective. Throat swabs are cultured only for group A streptococci (*Streptococcus pyogenes*) unless there is a specific request to look for other agents.<sup>116</sup> Group C and group G beta-hemolytic streptococci can also cause throat infection, but there is no association with rheumatic fever or acute post-streptococcal glomerulonephritis. If diphtheria (*Corynebacterium diphtheriae*) or whooping cough (*Bordetella pertussis*) is suspected, the laboratory should be contacted so that the specimens

are collected in the correct way and cultured on appropriate media for detection of these organisms.

Expectorated sputum is the most common specimen for diagnosis of lower respiratory tract infections (primarily pneumonia). In addition to sputum culture, more invasive methods for collection of specimens from the lower respiratory tract include bronchial washes, bronchial brushes, transbronchial biopsy and bronchoalveolar lavage. In difficult and serious clinical situations a surgical open lung biopsy may be indicated.<sup>117</sup>

Microbiology laboratories routinely use screening microscopy guidelines to reject sputum specimens of poor quality and thereby minimize unnecessary and potentially misleading culture results. The quality of the specimen is assessed by the number of squamous epithelial cells present per high power field with numbers exceeding 25 per low power field indicating that the specimen is heavily contaminated with saliva (oropharyngeal contamination) and unlikely to produce reliable results. The presence of polymorphonuclear leukocytes indicates a sputum specimen usually of apparent good quality. These criteria are not suitable and have not been validated for rejection of specimens where *Legionella* spp., fungi or *Mycobacteria* spp. are being cultured. The range of microorganisms that can cause lower respiratory tract infections is very diverse and it is important to provide an appropriate history to the laboratory so that testing can be targeted to the most relevant causes. Lower respiratory tract infection may be community acquired or nosocomial and other relevant clinical information including the type of infiltration seen on chest X-ray, the immunological status of the patient, any underlying diseases such as cystic fibrosis, a history of exposure to tuberculosis or travel, occupational or other exposures may be very helpful to the laboratory in identifying the causative organism.

## CENTRAL NERVOUS SYSTEM INFECTION

Cerebrospinal fluid (CSF) must be transported to the laboratory promptly, because fastidious organisms such as *Neisseria meningitidis* may become nonviable if the specimen cools. In addition, cells in the specimen begin to degenerate and are difficult to identify morphologically in specimens greater than 6 h old.

It is customary to collect at least three tubes of CSF to send to the laboratory and it is important that a sufficient quantity is collected for all testing that is requested. In addition to culture, all CSF specimens are examined for cell count including red cells and white cells, with the white cells differentiated into polymorph lymphocytes and monocytes, as well as determining the biochemical parameters of protein and glucose concentration.<sup>118</sup>

Gram stains must be performed on all spinal fluids and any microorganism seen immediately reported to the responsible clinician as this may be of critical assistance in managing the patient and optimizing antibacterial coverage. Bacterial antigen tests for *Neisseria meningitidis*, *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, group B streptococcus (*Streptococcus agalactiae*) and *Escherichia coli* are not routinely performed by many laboratories as the sensitivity of these tests does not exceed that of Gram stains. More recently, polymerase chain reaction (PCR) testing for *Neisseria meningitidis* and *Streptococcus pneumoniae* has become available, and these tests have been particularly helpful in the early management of cases of acute bacterial meningitis, especially when antibiotics have been given before taking cultures.<sup>119</sup> However, culture remains essential as the infecting organism can be tested for antibiotic susceptibility to guide therapy.

In addition to bacterial cultures, cultures for mycobacteria and fungi may also be indicated in specific clinical situations. However, cultures for both these types of organisms require reasonable volumes of CSF, at least 2 ml per sample and preferably 5–10 ml.

## DIARRHEAL DISEASES

Acute diarrhea can be caused by a broad range of microorganisms including bacteria, viruses and parasites. Ideally stool specimens are preferred

to rectal swabs and should be transported to the laboratory promptly. Most laboratories will reject a stool specimen which is not diarrheal, i.e. the specimen must take up the shape of the container, unless one is specifically looking for *Salmonella* spp. carriage. Most laboratories routinely culture for *Salmonella*, *Shigella* and *Campylobacter*. In addition, white and red cells are often looked for by direct microscopy as an indication of colitis. It is important to provide a good history to complement the specimen, such as any history of travel, ingestion of seafood or recent antibiotic therapy, and it is necessary to inform the laboratory if the clinician is looking for *Vibrio* spp., *Aeromonas* spp., *Plesiomonas* spp., *Yersinia* spp. or enterohemorrhagic *Escherichia coli*, as specific techniques in the laboratory will be needed to detect these organisms.<sup>120</sup> Parasites can be a common cause of diarrhea in young children, including *Cryptosporidium* and *Giardia*, and microscopy or antigen detection is required to detect these.

## GENITAL TRACT INFECTIONS

Genital specimens are usually collected on pediatric patients when looking for evidence of sexually transmitted disease following alleged sexual assault and child abuse. The genital tract contains many nosocomial organisms including coagulase negative staphylococci, lactobacilli, corynebacteria, streptococci, anaerobes and yeasts. Some genital tract infections not associated with sexually transmitted disease may be caused by endogenous bacteria, for example *Gardnerella vaginalis* or group B streptococci or rarely *Staphylococcus aureus*.

The common sexually transmitted diseases which need investigation are *Neisseria gonorrhoeae*, *Chlamydia trachomatis* and *Treponema pallidum* (syphilis). Both gonorrhea and chlamydia can be confirmed by culture. It is important to ensure that the cultures are collected with the correct type of swabs, as both organisms are extremely fastidious and the method of specimen collection and transport to the laboratory are critical. More recently, detection of these microorganisms using PCR on first void urine specimen has proved both sensitive and specific as well as having increased patient acceptance. It should be noted that PCR for gonorrhea should not be performed on any other specimen other than the urogenital specimens as there is a high rate of false positive results if eye or throat specimens are collected, due to cross-reaction with nonpathogenic nosocomial *Neisseria* spp. It is important to have culture evidence if at all possible as antibiotic susceptibility testing can be done for gonorrhea and these results are more reliable if legal proceedings arise from the case. Syphilis can be detected by dark field examination of exudate from any ulcerative lesion, but is more commonly diagnosed serologically.

## ANTIMICROBIAL SUSCEPTIBILITY TESTING

Antimicrobial susceptibility testing is advisable for presumed pathogens where response to antimicrobial agents is not predicted from identification alone. It is becoming increasingly needed with dissemination of resistance genes amongst bacteria. The aim of antimicrobial susceptibility testing is to demonstrate that in vitro growth inhibition of an infecting microorganism by a specific antimicrobial agent correlates with clinical response to that agent. Most testing is performed to detect the minimal inhibitory concentration (MIC), which is the lowest concentration of a specific antimicrobial agent that prevents visible growth of the test organism. Minimal bacterial concentration (MBC) is the lowest concentration of a specific antimicrobial agent that kills most (greater than 99.9%) of the inoculum of the organism and is rarely performed except under specialized circumstances. The more common and non-fastidious organisms can be tested. There need to be adequate data substantiating the clinical response of a species, and a minimal inhibitory concentration (MIC) for that agent, to provide interpretive data. There are many organisms for which these data are not available, examples being *Bacillus* species other than *Bacillus anthracis*, *Corynebacterium* spp. and many fastidious or unusual species, e.g. *Eikenella*, *Capnocytophaga*, *Leuconostoc*. It is also important to know that there are some specific organism-antimicrobial agent combinations where results are not reported because in vitro data are often misleading.

## PRINCIPLES OF ANTIMICROBIAL THERAPY

Antimicrobial therapy is indicated when there is clinical or culture evidence of an infection and the use of an antimicrobial agent would be expected to significantly shorten the duration of illness or lower the incidence of complications. However, not all bacterial infections need specific antimicrobial treatment, including minor skin infections and some gastrointestinal infections, e.g. *Salmonella* spp., where host defense mechanisms usually effect cure.

## INITIAL MICROBIOLOGICAL EVALUATION

Patients in whom an infectious illness is suspected should always be investigated to establish a microbiological diagnosis as this will aid ongoing therapeutic decisions. Initial microscopic examination of a Gram stained specimen from a sterile site often shows excellent correlation with the cause of the infection. However, if the specimen must pass through an area which is normally colonized with commensal bacteria, such as wound cultures or the mouth with sputum specimens, then the Gram stain should be evaluated carefully. In these situations, the bacterial culture report should be interpreted cautiously and contamination with commensal bacterial flora and the pathogenic potential of the isolated organism carefully considered. With sputum specimens, the presence of many polymorphs compared to epithelial cells on Gram stain and microscopy can be used to quality control the specimen, with predominance of polymorphs supporting purulent sputum while predominance of epithelial cells indicates heavy salivary contamination and probable invalid and contaminated culture results.

When there are clinical signs suggestive of a systemic infection, blood cultures should always be collected. Positive cultures from normally sterile fluid such as blood, CSF, pleural and synovial fluid should always be considered accurate, unless there is strong evidence to suggest otherwise. Bacteria such as *Neisseria meningitidis* and *Streptococcus pneumoniae* growing on cultures from sterile sites are never contaminants and the *Enterobacteriaceae* are rarely contaminants. However, when normal skin flora, such as alpha-hemolytic streptococci, *Propionibacterium acnes* or coagulase negative staphylococci are isolated, their significance and the clinical picture must be carefully reviewed to decide whether the isolated bacteria are indeed pathogens.

## CHOICE OF ANTIBACTERIAL AGENT

The optimal antibiotic for treating a bacterial infection is one with action against the infecting agents, the narrowest possible spectrum of antibacterial activity, the fewest side-effects and the lowest toxicity.

The microbiology laboratory reports bacteria as susceptible or resistant to a particular antibacterial agent, depending on the amount of antibiotic that corresponds to achievable serum concentrations with standard dosage and schedule. Many infections occur at sites other than the bloodstream where there may be issues of antibiotic penetration (e.g. the CSF) or activity (e.g. aminoglycoside activity is decreased in pus). The antibiotic should be administered in a dose, at a dose interval and by a route that achieves an antibacterial level at the site of infection at least equal to, or preferably several times higher than, the level of that agent required to inhibit bacterial growth in vitro.

The choice of an empiric antibiotic agent for a suspected or proven infection is based upon (1) the site(s) of infection, (2) those bacteria that are most likely to cause that particular infection, (3) the bacteria presumptively identified by Gram stain of a specimen from the infected site, (4) the predicted susceptibility of the organism to the antibiotic, (5) the pharmacological properties of the antibiotic, and (6) the cost.

## TREATMENT WITH MORE THAN ONE ANTIBIOTIC

The indications for using more than one antibiotic in the treatment of an infection are: (1) to treat infection due to more than one microorganism if they are not susceptible to the same drug; (2) to treat empirically

a life-threatening infection where the causative bacterium is unknown and broad spectrum coverage of potential infecting bacteria must be achieved immediately; (3) to treat difficult organisms or infections for which synergy of an agent has been demonstrated or is postulated, e.g. enterococcal endocarditis; (4) to prevent the emergence of resistance during treatment.

### DURATION OF ANTIMICROBIAL THERAPY

The appropriate duration of an antibacterial treatment course is defined as the shortest period necessary to prevent bacteriological or clinical relapse, i.e. produce a cure. The duration of treatment for a bacterial infection depends on the site and extent of the infection, the bacterium and the host response. The duration of treatment for cure has been reliably established for some infections, e.g. streptococcal pharyngitis, but it has not been established for many others. Response to therapy in patients with infections is best monitored clinically rather than bacteriologically. Repeat cultures are usually unnecessary and not helpful in the patient who has a good clinical response.

### FAILURE OF ANTIMICROBIAL THERAPY

Failure of antibiotic therapy is defined as detection of bacteria beyond the expected time of clearance, usually accompanied by clinical failure of response to therapy. It is self-evident that antibiotics cannot be expected to cure a nonbacterial disease. If there is a failure of therapy with antibiotic therapy then details of the regimen should be examined, such as the susceptibility of the bacterium, dosage, route of administration, dosage interval and penetration into the site of infection. When there is an abscess, drainage is often far more effective than antibiotic treatment in resolving the infection. Common reasons for antibiotic treatment failure are: (1) failure of the patient to take medication as directed; (2) deficiency in host defense mechanisms including poor nutritional status; (3) inability to clear respiratory or other secretions; and (4) poor penetration of the antibiotic to the site of infection, e.g. poor tissue perfusion. The development of antibiotic resistance by an initially susceptible bacterium during treatment occurs but is uncommon.

### ANTIBACTERIAL PROPHYLAXIS

Antibiotic prophylaxis is the use of an antibacterial agent to prevent infection and is most efficacious when attempting to prevent infection for a relatively brief period. The administration of antibiotics to prevent postoperative wound infection is now well established. The risk of contamination of the wound occurs at the beginning of the operation, so if prophylaxis is to be effective the antibiotic must be administered immediately prior to the operation to maintain high effective blood and tissue levels throughout the procedure. The use of prophylactic antibiotics has resulted in a significant decrease in the incidence of infections in procedures involving areas that are heavily contaminated with bacteria, such as the head and neck, and in gynecological and colonic surgery. Factors that predispose to contamination in surgery are long operations and the placement of prosthetic devices. Preventing infection of a prosthesis can be achieved with a short duration of therapy, up to 12 h. However, in specific situations such as cardiac surgery or placement of orthopaedic prostheses, prophylactic antibiotics are frequently continued for 2 days.

### CLINICAL PHARMACOLOGY OF ANTIMICROBIAL AGENTS

#### Absorption

Many antimicrobial agents are well absorbed after oral administration while others are very poorly absorbed, e.g. vancomycin and aminoglycosides are very rapidly degraded in the intestinal tract so they must be administered parenterally to treat systemic infections. With few exceptions, oral administration of antibiotics results in lower serum

concentrations of antibiotics than when using identical parenteral dosing, exceptions being metronidazole and chloramphenicol.

Serum concentrations achieved by the usual oral doses of agents such as ampicillin, first generation cephalosporins and tetracycline are generally not high enough to inhibit Gram negative enteric bacteria susceptible to these drugs. However, they may be used in urinary tract infection, because they are concentrated in the urine. In hospitalized patients with severe infection, antimicrobial therapy is generally administered parenterally to ensure adequate levels.

#### Distribution

After administration and absorption, antimicrobial agents are bound to plasma proteins to varying degrees. The time of serum decline relates to excretion and inactivation and is measured as serum half-life, i.e. the time required for a 50% decrease in serum concentration, which is a measure of the duration of the pharmacological effect. Serum half-life is an important determinant of a dosage schedule, in both normal patients and those in whom the half-life is prolonged because of decreased drug excretion or metabolism.

The initial rise in serum concentration after drug administration is followed by a decrease as the drug is distributed to body tissues. The tissue concentration of antibiotic depends on the degree of protein binding, the concentration gradient from serum to tissue, and the drug diffusibility. Most antibiotics penetrate well into pleural, peritoneal, pericardial and synovial fluid. Penetration into brain, CSF, eye and placenta is more variable. In general, penetration of antibiotics into body compartments increases with the presence of inflammation, e.g. penicillin penetrates into the CSF much more easily in an inflammatory state.<sup>121</sup>

#### Inactivation and excretion

There are several mechanisms of excretion and inactivation of antimicrobial agents, which include excretion by the bowel, removal by the kidney, inactivation by the liver, or inactivation by other unknown means. Antimicrobial agents may be inactivated by more than one mechanism.

Renal excretion is the major means of clearance of most antimicrobials, exceptions being chloramphenicol, erythromycin, clindamycin, doxycycline, ceftazidime and metronidazole. Renal failure results in accumulation of antimicrobials normally excreted by the kidney and dosage changes are essential for such agents as aminoglycosides and glycopeptides which have a low therapeutic-to-toxicity ratio and a single means of excretion or inactivation.

### MECHANISM OF RESISTANCE

Bacteria acquire resistance to antibiotics most commonly by one of three main mechanisms:

1. Inability to reach the site of action due to decreased cell wall permeability or increased action of efflux pumps. Examples of this type of mechanism occur in *Pseudomonas* spp. and *Enterobacteriaceae* as a mechanism of resistance to aminoglycosides.
2. Alteration in the antimicrobial target. An example is alteration in the penicillin-binding protein 2 in staphylococci to PBP-2a encoded by the *mec A* gene, which renders all beta-lactam antibiotics, including the penicillinase-resistant penicillins, inactive, i.e. MRSA.<sup>122</sup>
3. Production of an enzyme that inactivates the antibiotic. Examples are beta-lactamases, which cleave the beta-lactam ring and render these antibiotics inactive.<sup>123</sup> Beta-lactamases have co-evolved with the increased use of beta-lactam antibiotics over the last 50 years, and are a major mechanism of defense by Gram negative bacteria against beta-lactam antibiotics. The introduction of penicillin saw a very rapid increase in prevalence of beta-lactamase production by staphylococci which inactivate penicillin but not penicillinase-resistant penicillins (see below) which are stable and therefore remain active.<sup>122</sup> Beta-lactamases have spread to organisms which previously did not have them, including *Haemophilus influenzae* and *Neisseria gonorrhoeae*.

Hundreds of beta-lactamases have been described and can be assigned to one of four groups, A to D. Class A beta-lactamases are usually plasmid-mediated and can spread easily between bacteria of different genera. They occur commonly in *E. coli* and other *Enterobacteriaceae*. More recently, mutants have emerged with an 'extended spectrum', which can attack not only penicillins but many of the first, second and third generation cephalosporins, called extended-spectrum beta-lactamases or ESBLs.<sup>124-126</sup> The class A beta-lactamases can be inhibited by beta-lactamase inhibitors such as clavulanic acid (see below). On the other hand, class C beta-lactamases, which have a broader spectrum than class A enzymes and mediate resistance to penicillins and most cephalosporins, are chromosomal, intrinsically produce a beta-lactamase, and are confined to specific bacterial species such as *Enterobacter* spp., *Serratia marcescens*, *Citrobacter freundii*, *Acinetobacter* spp., *Aeromonas* spp., indole positive *Proteus* spp. and *Morganella morganii*, often referred to as the ESCAAMP group. The class C beta-lactamases cannot be inhibited by clavulanic acid. Both class A and class C beta-lactamases inactivate penicillins and cephalosporins but do not inactivate carbapenems. However, more recently, metallo-beta-lactamases, which are usually class B and inactivate all beta-lactams including carbapenems, have become more prevalent by spreading on plasmids among Gram negative bacteria.<sup>123</sup>

Aminoglycosides, which are very potent bactericidal antibiotics with a broad range of activity especially against Gram negative bacteria, can induce enzymes which catalyze phosphorylation, acetylation or adenylation of this class of antibiotics causing covalent modifications leading to poor ribosomal binding resulting in high-level resistance to these agents.<sup>127</sup>

## CLASSES OF ANTIMICROBIAL AGENTS

### Beta-lactams

The antimicrobial agents of most value in treating infants and children are the beta-lactams, including penicillins, cephalosporins, monobactams and carbapenems, which have in common a beta-lactam ring.

The bacterial targets of beta-lactam antibiotics are penicillin binding proteins (PBPs), which are vital for bacterial cell division, shape and structural integrity. The exact mechanism of action of beta-lactams remains elusive. Recent evidence suggests it is a complex process involving both inhibition of cell wall synthesis and activation of endogenous autolytic systems. Their action is usually bactericidal. Some bacteria have a deficiency in this system of autolytic enzymes that results in inhibition but not killing of the bacteria by the beta-lactam. This phenomenon is called tolerance and is demonstrated, *in vitro*, by a minimal inhibitory concentration (MIC) in the susceptible range but a minimal bacterial concentration (MBC):MIC ratio of 32 or greater.

The nature of the bactericidal activity of beta-lactam has been described as time-dependent killing. The important determinant of bactericidal activity for beta-lactams is the length of time during the dosing interval that the concentration of the antibiotic exceeds the MIC of the infecting microorganism. Bactericidal activity is thought to be greatest when the concentration of the beta-lactam antibiotic at the site of infection is 4–10 times greater than the MIC of the infecting microorganism. The rapidity and extent of bacterial killing are not increased when concentrations exceed this ratio.

Resistance to beta-lactam antibiotics is either by production of a beta-lactamase or by alterations in the PBPs.

### Penicillin

The penicillins can be classified into four groups based on their antimicrobial activity. There are some overlaps in activity. The four groups are the natural penicillins, the amino-penicillins, the penicillinase-resistant penicillins and the extended-spectrum penicillins. The mechanism by which most bacteria have acquired resistance to penicillins G is beta-lactamase production. Resistance to penicillin by *Streptococcus pyogenes* (group A streptococcus) and *Streptococcus agalactiae* (group B streptococcus) has not emerged. Resistance caused by altered PBPs occurs less commonly, but the increasing resistance of *Streptococcus pneumoniae* to penicillin is a result of altered PBPs.

1. *Aqueous penicillin G* produces high peak concentrations of antibacterial activity in the serum within 30 min of administration. The drug is rapidly excreted by the kidneys resulting in low serum concentrations within 2–4 h. When treating severe disease such as meningitis, pneumonia or endocarditis, penicillin G should be administered usually every 4 h until the infection has been cured.
2. *Procaine penicillin G* given intramuscularly produces serum levels of approximately 10–30% of those of aqueous penicillin, but the activity persists in serum for as long as 4 h. IM procaine penicillin is very painful and can cause injection site abscesses. It is only recommended for short term treatment of children with mild to moderate disease when IV access cannot be achieved.
3. *Benzathine penicillin G* is given intramuscularly as a depot preparation that provides for low continuous concentrations approximately 1–2% of those achieved by the aqueous penicillin G. Penicillin is detectable in the serum for 3 weeks or more following injection. Benzathine penicillin G can be used for the treatment of group A streptococcal pharyngitis, impetigo or prophylaxis of streptococcal infections in children who have rheumatic carditis, although pain at the injection site is a major deterrent to the use of this antibiotic.
4. *Phenoxyethylpenicillin* (oral penicillin or penicillin V) is well absorbed from the gastrointestinal tract with peak concentrations in serum approximately 40% of that of the same dose of aqueous penicillin G. Oral penicillin is satisfactory for treating mild to moderate infections with susceptible organisms.

All penicillins are excreted by both glomerular filtration and tubular secretion. Concomitant use of probenecid, a drug that blocks tubular secretion of organic acids, can produce higher peaks and more sustained serum concentrations resulting in greater antimicrobial activity. Dosages and dosing intervals will need adjustment when penicillins are administered to persons with decreased renal function.

### Penicillinase-resistant penicillin

Penicillinase-resistant penicillins are the drug of choice for the initial management of patients with suspected staphylococcal disease, as most strains of *S. aureus* produce a beta-lactamase, penicillinase. Common penicillinase-resistant penicillins are cloxacillin, dicloxacillin, flucloxacillin, oxacillin and nafcillin. These agents are active against streptococci and can be used for treatment of infections commonly caused by both staphylococci and streptococci, e.g. impetigo. However, as these agents are less active than penicillin G against streptococci, penicillin G should be used if streptococci alone are isolated from culture. It should be noted that penicillinase-resistant penicillins have no activity against Gram negative bacteria or enterococci.

Disease caused by methicillin-resistant *Staphylococcus aureus* (MRSA) was reported shortly after the introduction of methicillin in the 1960s. Methicillin resistance is caused by alterations in PBP-2 rather than by production of a beta-lactamase, so MRSA is resistant to all currently available beta-lactam agents including penicillins, cephalosporins and carbapenems.

Coagulase-negative staphylococci, most commonly *Staphylococcus epidermidis*, a skin commensal, may be a pathogen in neonates or cause infections of prosthetic devices such as heart valves, CSF shunts and intravenous lines. Many strains of coagulase-negative staphylococci produce beta-lactamase and have altered PBPs making them methicillin resistant. Vancomycin is the drug of choice for diseases known to be caused by MRSA or methicillin-resistant *Staphylococcus epidermidis* (MRSE).

### Amino-penicillin

The amino-penicillins include ampicillin and amoxicillin which have extended activity compared with penicillin, with activity against some Gram negative organisms, including *H. influenzae*, *E. coli*, *Proteus mirabilis*, *Salmonella* spp. and *Shigella* spp. The amino-penicillins can also retain activity against penicillin-susceptible Gram positive bacteria. Amino-penicillins are the drug of choice for treatment of infections

caused by *Listeria monocytogenes* and the enterococci. These drugs are used frequently in the treatment of susceptible pathogens causing (1) lower respiratory tract infection, (2) acute otitis media, (3) urinary tract infections, and (4) acute diarrheal disease when therapy is indicated. It should be noted that amoxicillin is significantly less effective than ampicillin for the treatment of shigellosis. Ampicillin is associated more frequently with diarrhea than amoxicillin.

### Extended-spectrum penicillins

Extended-spectrum penicillins are semisynthetic derivatives of ampicillin and have better activity against Gram negative bacteria because of high affinity for PBPs and greater penetration to the Gram negative outer membrane. The carboxypenicillins include carbenicillin and ticarcillin while the ureidopenicillins include piperacillin and mezlocillin. These extended-spectrum penicillins have activity against *Pseudomonas aeruginosa* but are significantly less active against Gram positive cocci than ampicillin.

Extended-spectrum penicillins (often combined with an aminoglycoside) have been used for the treatment of intra-abdominal and upper urinary tract infections as well as for sepsis in neutropenic patients. They are only available as parenteral formulations.

### Beta-lactamase inhibitor/beta-lactam combinations

Beta-lactamase inhibitors, such as clavulanic acid, sulbactam and tazobactam, are compounds that have weak intrinsic antibacterial activity but bind irreversibly to many beta-lactamases rendering the beta-lactamases inactive. Beta-lactamase inhibitors are combined in a fixed ratio with a beta-lactam antibiotic, e.g. amoxicillin/clavulanic acid or piperacillin/tazobactam. The spectrum of activity of the combination is determined primarily by the spectrum of activity of the beta-lactam. The main indication for use of these combination antimicrobial agents is the treatment of infections caused by susceptible beta-lactamase producing pathogens.

Ampicillin/sulbactam or amoxicillin/clavulanic acid can be used to treat beta-lactamase producing strands of *Staphylococcus aureus* (but not methicillin-resistant *Staphylococcus aureus*), *Haemophilus influenzae*, *Moraxella catarrhalis*, *Neisseria gonorrhoeae*, *Escherichia coli*, some *Proteus* spp., *Klebsiella* spp. and some anaerobic bacteria including *Bacteroides fragilis*.

### Adverse effects and allergies of penicillins

The penicillins have very little dose-related toxicity. Adverse reactions include electrolyte disturbance of sodium and potassium, gastrointestinal problems with diarrhea, and hematological changes with hemolysis, neutropenia or platelet dysfunction. Drug-induced hepatitis can occur determined by elevated aspartate aminotransferase (AST), neurological abnormalities are rare and include seizures, while renal problems can occur with interstitial nephritis.

Allergy, however, is an important factor and can occur quite frequently with penicillin compounds.<sup>128</sup> The penicillin are haptens, low molecular weight compounds too small to induce an immune response but which bind to host proteins and are highly immunogenic. The four types of immune-mediated reactions that can occur after the administration of penicillins are: (1) immediate hypersensitivity (IgE mediated); (2) cytotoxic antibody reactions; (3) immune complex reactions (Arthus reactions); and (4) delayed cell-mediated hypersensitivity. It is estimated that serious immediate reactions will occur in 2 of every 10 000 cases and fatal reactions in 1 in 100 000 treatment cases of penicillin administration. Identifying patients who will have a significant reaction to penicillin remains difficult. At present, physicians must rely on the patient's history of reactions after administration of penicillin to identify those likely to be allergic and avoid administration of penicillin in these patients for anything other than very serious infections, e.g. endocarditis, where desensitization may be necessary. All penicillins are cross-reactive with regards to sensitization, and allergy to one implies sensitization to all, although this cross-sensitivity is less than 100%.

### Cephalosporins

The cephalosporins have a very broad range of activity which includes Gram positive, Gram negative and anaerobic bacteria. Cephalosporins are categorized as first, second, third and fourth generation depending on their pattern of in vitro activity. Cephalosporins have no activity against enterococci or methicillin-resistant staphylococci.

**First generation cephalosporins.** The first generation cephalosporins are effective against Gram positive cocci including beta-lactamase producing *Staphylococcus aureus*. They have variable activity against Gram negative enteric bacilli, such as *Escherichia coli*, *Proteus mirabilis* and *Klebsiella* species, with minimal if any activity against *Haemophilus influenzae* and *Moraxella catarrhalis* and are inadequate against penicillin-sensitive *Streptococcus pneumoniae*. They should therefore not be used for treatment for respiratory tract infection.

**Second generation cephalosporins.** The second generation cephalosporins in common use are cefuroxime and cefaclor. When compared with the first generation cephalosporins, second generation cephalosporins have similar or somewhat less activity against Gram positive cocci with better activity against *Haemophilus influenzae*, *Moraxella catarrhalis*, *Neisseria meningitidis* and *Neisseria gonorrhoeae* and some members of the *Enterobacteriaceae*.

**Third generation cephalosporins.** The common parenteral third generation cephalosporins used in children are cefotaxime, ceftriaxone and ceftazidime. There are oral third generation cephalosporins and cefixime is the most commonly used. Third generation cephalosporins are very potent against Gram negative and enteric bacteria and have excellent activity against *Haemophilus influenzae*, *Moraxella catarrhalis*, *Neisseria gonorrhoeae* and *Neisseria meningitidis*, group A streptococci and penicillin-susceptible pneumococci. They have relatively poor activity against staphylococci. Ceftazidime is the only third generation cephalosporin used in children with activity against *Pseudomonas aeruginosa*. The increasing prevalence of extended-spectrum beta-lactamases (ESBL) in the *Enterobacteriaceae* is increasing the prevalence of resistance to these agents. The parenteral third generation cephalosporins achieve high levels in the serum and adequate concentration in CSF.

**Fourth generation cephalosporins.** The fourth generation cephalosporin, cefepime, exhibits very rapid entry into the bacterial cell and stability against a range of beta-lactamases as well as increased binding affinity to multiple PBPs. These factors explain cefepime's expanded spectrum of activity and improved efficacy against Gram negative pathogens compared with third generation cephalosporins.<sup>129</sup>

**Adverse reactions.** The safety profile of cephalosporins is similar to penicillins with hypersensitivity reactions being the most frequent.

### Monobactams

Aztreonam is the prototype monobactam. It has aerobic Gram negative antibacterial activity similar to that of ceftazidime but has no significant Gram positive activity.

### Carbapenems

The carbapenem class of antimicrobial agents exhibits the broadest spectrum of activity of all beta-lactam antibiotics. They include imipenem-cilastatin and meropenem and have activity against most clinically significant Gram positive and Gram negative pathogens including anaerobic organisms.

### The glycopeptides

The glycopeptides, vancomycin and teicoplanin, exhibit time-dependent bactericidal activity against most clinically significant Gram positive bacteria except that they are only bacteriostatic for enterococci. The glycopeptides interfere with the development of the peptidoglycan cell wall at a site of action distinct from that of beta-lactams, so there is no cross-resistance or competitive inhibition between these drug classes.

Vancomycin is not metabolized significantly and is excreted by glomerular filtration. In patients with severe renal failure the half-life may extend 7 or more days, and furthermore vancomycin is not removed effectively by either peritoneal or hemodialysis. The dosing interval

needs to be adjusted when using vancomycin in patients with impaired renal function.<sup>130</sup>

**Adverse effects.** Ototoxicity and nephrotoxicity have been considered serious adverse effects of vancomycin therapy in the past, but these serious events are much less frequent than previously thought. Infusion-related side-effects are the most common side-effect seen with vancomycin with the rapid onset of a widespread erythematous rash. This can usually be managed by slowing the infusion rate or premedicating the patient with antihistamines.

### Aminoglycosides

The aminoglycosides, gentamicin, tobramycin and amikacin, demonstrate rapid concentration-dependent bactericidal activity with a post-antibiotic effect, i.e. killing of bacteria continues in the absence of any detectable serum antibiotic.<sup>131</sup> The higher the peak concentration of the aminoglycoside, the longer the duration of the post-antibiotic effect. The mechanism of the bactericidal action is binding to the bacterial ribosome and interfering with bacterial protein synthesis by inducing translational errors. The uptake of aminoglycosides by bacteria can be facilitated by concomitant therapy with a cell wall-active antibiotic such as vancomycin or a beta-lactam. Aminoglycosides have activity against a range of facultative aerobic bacteria, but their activity is reduced in infections at sites with reduced oxygen tension, e.g. abscesses. Anaerobic bacteria and fermentative bacteria such as streptococci are inherently resistant to aminoglycosides. Aminoglycosides penetrate the blood-brain barrier very poorly in the absence of inflammation and thus are not very successful in the treatment of Gram negative meningitis. Aminoglycosides are not metabolized after parenteral administration and are excreted unchanged in the kidney by glomerular filtration.

Resistance to aminoglycosides can evolve in a number of ways: (1) alteration in the bacterial target affecting binding; (2) decreased cell permeability making it more difficult for the drug to reach the ribosomal target; and (3) breakdown of the drug by bacterial enzymes.

The major use of aminoglycosides in children is for serious infections caused by Gram negative enteric infections, neonatal sepsis, sepsis in a child with immunodeficiency, especially neutropenia, abdominal and systemic infections associated with fecal contamination of the peritoneum, and complicated urinary tract infections.

**Adverse effects.** All aminoglycosides can damage the proximal renal tubules, the cochlea, the vestibular apparatus or a combination of these, and rarely can cause neuromuscular blockade. To avoid toxicity and ensure therapeutic levels, the concentration of aminoglycoside in serum should be monitored in all patients.

### Macrolides

The macrolides, erythromycin, clarithromycin and azithromycin, have similar antibacterial spectra, mechanism of action and mechanism of resistance but they differ in their pharmacokinetic characteristics. They all bind reversibly to the 23S component of the 50S ribosomal subunit and inhibit protein synthesis. The macrolides are bacteriostatic but clarithromycin and azithromycin are bactericidal against *Streptococcus pyogenes*, *Streptococcus pneumoniae* and *Haemophilus influenzae*.

The newer macrolides have a spectrum of activity similar to that of erythromycin, but clarithromycin has greater activity against *Moraxella catarrhalis*, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Chlamydia trachomatis*, *Legionella pneumophila*, *Ureaplasma urealyticum* and *Neisseria gonorrhoeae*. Clarithromycin also has activity against organisms that are resistant to erythromycin, including *Toxoplasma gondii*, *Mycobacterium leprae*, *Mycobacterium chelonae* and *Mycobacterium avium-intracellulare* (MAC).

Azithromycin is effective in vitro against a diverse group of microorganisms including *Bordetella pertussis*, *Legionella pneumophila*, *Corynebacterium diphtheriae*, spirochetes including *Treponema pallidum*, the mycoplasmas (except *M. hominis*), chlamydiae, and aerobic and anaerobic Gram positive cocci.<sup>132</sup> Azithromycin is highly active against *Campylobacter jejuni*. When compared with erythromycin, azithromycin has less activity against Gram positive bacteria and greater activity

against Gram negative bacteria including some *Enterobacteriaceae* such as *Shigella* and *Salmonella* species.

**Adverse effects** These include local gastrointestinal irritation with nausea, vomiting and abdominal pain. Cholestatic hepatitis occurs rarely but is a serious reaction requiring cessation of therapy. Erythromycin has been associated with infantile hypertrophic pyloric stenosis.

### Miscellaneous antibacterial agents

#### Clindamycin

Clindamycin is a semisynthetic derivative of lincomycin and has much better oral absorption and greater antimicrobial activity. It has action against Gram positive bacteria as well as Gram positive and Gram negative anaerobes including *B. fragilis*. Clindamycin penetrates well into most tissues including bone but has poor penetration into the CNS. It is inactivated in the liver and excreted in bile with very little renal excretion. It is useful in the treatment of staphylococcal infections in penicillin-allergic individuals and MRSA.

**Adverse effects.** Clindamycin can often cause diarrhea and less commonly the more serious *Clostridium difficile* associated pseudomembranous colitis. The occurrence of pseudomembranous colitis is a strong indication to cease this agent. Clindamycin is also associated with allergic reactions and rashes and rarely causes erythema multiforme and anaphylaxis.

#### Trimethoprim-sulfamethoxazole (co-trimoxazole)

Trimethoprim is active against many Gram positive and Gram negative bacteria, except *Pseudomonas aeruginosa*. Trimethoprim is often combined with sulfamethoxazole because the two drugs act synergistically. The drug is widely distributed in tissues including the CNS, and a significant amount is excreted unchanged in the urine giving high concentrations which makes it useful for treating urinary tract infections. Trimethoprim-sulfamethoxazole also has activity against *Haemophilus influenzae* and *Pneumocystis carinii*.

**Adverse effects.** The most common side-effects are nausea, vomiting, diarrhea and hypersensitivity reactions. Prolonged administration may be associated with a megaloblastic bone marrow or leukopenia; thrombocytopenia and anemia may also occur.

A discussion of the mechanisms of action, clinical indications and modes of resistance of antiviral agents and antifungal agents is beyond the scope of this chapter. The reader is referred to other publications for this information.<sup>133-135</sup>

Management of infections is complex. The clinician needs a good understanding of infectious clinical syndromes, likely pathogens, antimicrobial resistance patterns, and knowledge of antimicrobial agents, their spectrum of activity, penetration to the site of likely infection and possible adverse effects, to effectively and safely treat common childhood illnesses.

## BACTERIAL INFECTIONS: BOTULISM

The name botulism derives from the Latin *botulus* for sausage, and was coined following an outbreak in Germany in 1793 in which 13 people who shared a large sausage became ill and 6 died.

Classical botulism is a paralytic disease caused by ingestion or absorption of one or more preformed neurotoxins produced by the soil organism, *Clostridium botulinum*. Cases occur singly or in small clusters following consumption of home-canned or prepared foods in which the heat-resistant spores of *C. botulinum* have germinated under anaerobic conditions. Canned or bottled foods, especially soil-contaminated vegetables, smoked fish and continental sausage, are classic food vehicles. High temperatures are required to inactivate spores. If toxin production does occur, poisoning can be avoided by adequate cooking or reheating of the food, because the toxin is inactivated by moderate heat. Raw fish or fish products are also potential sources of botulinum toxin.

Infant botulism is a different condition from the botulism due to preformed toxin. Infant botulism results from multiplication of *C. botulinum* in the baby's intestine, and causes an indolent presentation. The median age of onset is 2 months, with a range of less than 3 weeks to

12 months.<sup>136–138</sup> Infant botulism is more common in babies living in rural areas or on a farm: in Australia cases occur when it is hot, dry and windy and spores may blow into the baby's mouth or into the water supply.<sup>136</sup> There is a particular association with babies whose pacifiers were dipped in honey, although only 11 of 68 US babies reported with infant botulism had honey exposure.<sup>137,138</sup> Corn syrup ingestion (20 of the 68 babies) and breast-feeding were other risk factors. Breast milk is thought to generate favorable conditions for germination of spores.

## CLINICAL FEATURES AND DIAGNOSIS

### Classic botulism

Typically, after an interval of 12–36 h, patients present acutely with malaise, nausea, vomiting, dizziness, weakness and dry mouth. After hours or days cranial nerve palsies develop, causing ptosis, blurred vision, diplopia, dysphagia and dysarthria. Paralysis may progress over a period of hours or days to involve many muscle groups and the patient may require respiratory support. Recovery occurs over weeks to months.

### Infantile botulism

This is characterized by an insidious onset of severe, progressive hypotonia, poor suck, constipation and bilateral ptosis. The pupils are often dilated and there may also be pooling of oral secretions, reduced facial movements and ophthalmoplegia. The gag reflex is often weak. Peripheral tendon reflexes are normal or diminished, but not usually absent. Paralysis may progress to involve the respiratory muscles and the infant may require respiratory support.<sup>138</sup>

The differential diagnosis includes spinal muscular atrophy (absent reflexes, fasciculations), myotonic dystrophy [myotonia, electromyogram (EMG) pattern], wild-type or vaccine-associated paralytic poliomyelitis (asymmetric paralysis, CSF pleocytosis) and Guillain-Barré syndrome (ascending paralysis, raised CSF protein). The EMG in infant botulism shows denervation. The diagnosis is primarily based on clinical findings and EMG, and can be supported by detecting *C. botulinum* toxin in stools (by PCR or animal inoculation) and/or by growing *C. botulinum* from stool culture. An association between infant botulism and sudden infant death syndrome (SIDS) has been proposed but is unproven.

## TREATMENT

Infant botulism is managed by protecting the airway and using artificial ventilation if required. Babies who require artificial ventilation recover after 3–4 weeks. With proper supportive care the outcome is excellent, with complete recovery the rule.

Tracheostomy prolongs hospitalization.<sup>138</sup> Nasogastric tube feeds are usually well tolerated. Antibiotics such as penicillin do not speed recovery and gentamicin may exacerbate neuromuscular problems. Antibiotics are only indicated for complications such as pneumonia. Botulism antitoxin, harvested from hyperimmune adults (hBIG) and available only to investigators in the USA, halves the mean time to resolution of symptoms in infant botulism.<sup>139,140</sup> Equine antitoxin made in horses (eBIG) has long been used in the treatment of adult botulism but has not been shown to be effective in infant botulism.<sup>141</sup> A new intravenous botulinum immunoglobulin, produced in the USA, reduced the duration of mechanical ventilation and hospitalization significantly in infant botulism.<sup>142</sup>

In older children, circulating toxin needs to be neutralized with antitoxin, in the form of botulinum immune globulin, as soon as possible. This has no effect on bound toxin but it is always indicated as toxin may circulate for days. The remainder of the care is supportive of respiration, as for infant botulism.

## BACTERIAL INFECTIONS: BRUCELLOSIS; UNDULANT FEVER

Brucellosis is usually caused by one of three organisms: *Brucella abortus*, *Brucella melitensis* or *Brucella suis*. All three are primarily dis-

eases of domesticated animals (cattle, goats and pigs, respectively). The clinical picture ranges from clinically asymptomatic infection via acute brucellosis (with septicemic manifestations) to chronic brucellosis.

## EPIDEMIOLOGY

Human brucellosis is mostly a disease of those who come into contact with infected animals in rural areas. Spread of infection from animal to animal occurs readily and the resulting illness is often chronic with long term excretion of the organism. Infection is transmitted to humans by infected milk or milk products and, less frequently, by direct contact or entry through skin. Person-to-person spread rarely occurs. Elimination of brucellosis in animal populations (by vaccination or slaughter policies) will eliminate new infections in humans. World Health Organization sources estimate that there are 500 000 cases worldwide each year (childhood infections accounting for less than 10% of cases). In the UK there are about 20 patients each year, most with disease caused by imported *B. melitensis* infection or laboratory accident. The low incidence of brucellosis in children which results from milk-borne infection is unexpected and some have suggested that environmental exposure may be more relevant.

## PATHOLOGY

Acute brucellosis is a septicemic illness, with seeding of organisms in the body, which may become apparent immediately or later after the systemic features have resolved. There is widespread reticuloendothelial system hyperplasia and focal manifestations may occur in many organs, particularly in the liver or spleen. Chronic brucellosis may follow acute brucellosis or begin insidiously. In chronic brucellosis the organisms usually remain intracellularly where they are relatively protected against host defenses and antibiotics.

*B. melitensis* often produces more invasive manifestations and debility than *B. abortus*, an important point to realize when generalizing about brucellosis. Those with low gastric acid levels are thought to be at particular risk of infection.

## CLINICAL FEATURES

The incubation period of acute brucellosis is from a few days to a month.

With acute brucellosis symptoms develop rapidly with high fever, rigors, arthralgia and profuse sweating: patients often feel much more ill than signs suggest but recovery follows in most. Fever has no particular pattern. Weight loss and secondary anemia may develop. If the patient does not recover then a state of chronic brucellosis ensues with vague irritability, malaise, fatigue, musculoskeletal aches and pains, headaches and depression. Fever may be intermittent, occurring every few weeks – hence the name 'undulant fever'.

Although chronic brucellosis is rarely life threatening the morbidity may be significant.

With both acute and chronic brucellosis suggestive signs may be prominent or absent, constituting a pyrexia of unknown origin. There may be hepatomegaly, splenomegaly or lymph node enlargement. Particularly with *B. melitensis* infection lymph nodes may suppurate and osteomyelitis or arthritis may develop.

Other rare, but potentially life-threatening manifestations include meningitis, endocarditis, peritonitis and encephalitis.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Clinical diagnosis may be easy in areas where animal infection is endemic. In non-endemic areas clinical diagnosis may be difficult unless it is realized that patients have visited endemic areas or ingested milk products from endemic areas.

In acute brucellosis blood cultures may be positive, but the organisms are difficult to culture and cultures may take up to 2 weeks to

become positive. Agglutination tests to detect IgM and IgG antibodies may be helpful but may be positive in asymptotically infected patients in endemic areas. Nevertheless increasing titers are almost certainly diagnostic. Agglutination titers of greater than 1:160 in a patient with appropriate clinical features are very suggestive.

In chronic brucellosis blood cultures are rarely positive and bone marrow culture or, less often, liver or splenic biopsy culture may be necessary. If there is renal involvement urine cultures may be positive. Biopsy shows noncaseating granulomas.

If available, the presence of *Brucella*-specific IgM is diagnostic of acute brucellosis or of chronic brucellosis in an acute relapse, whilst *Brucella*-specific IgG indicates infection at some stage. Lymphocytosis with neutropenia may be found.

The differential diagnosis of acute brucellosis includes malaria, salmonellosis (including typhoid fever), tuberculosis, tularemia, rheumatic fever, infective endocarditis, Q fever, leptospirosis and non-infective conditions. If malaise and debility predominate, depression enters the differential diagnosis, as well as being a complication in its own right.

## TREATMENT<sup>143</sup>

In acute brucellosis antibiotic treatment probably shortens the illness and reduces the risk of progression to chronic brucellosis. Opinions differ as to the optimal treatment: comparison of treatment results of *B. abortus* and *B. melitensis* infection is not necessarily valid. Most studies of children with brucellosis deal with children with *B. melitensis* infection. Regimens advocated include (either alone or in combination) co-trimoxazole, rifampicin or streptomycin. In chronic brucellosis suppression of intracellular infection may be attempted in the hope that the host's immunity will eventually eliminate or contain infection. Regimens advocated include protracted courses of the antibiotics used in acute brucellosis. Tetracyclines are useful but obviously cannot be used in children unless there is no alternative.

Single agent treatment carries a relapse rate of 5–40%, thought to be caused by inadequate killing rather than development of resistance.

Antipyretics, analgesics and antidepressant treatment may be indicated. Vaccination of humans with the live attenuated organisms used in animals is not practicable and would certainly make subsequent interpretation of serological tests very difficult.

## BACTERIAL INFECTIONS: CHOLERA

Cholera is an acute bacterial enteric disease characterized in its severe form by sudden onset, profuse, painless, watery stools, occasional vomiting, and, in untreated cases, rapid dehydration, acidosis, hypoglycemia and circulatory collapse. Cholera is caused by infection with toxin-producing strains of *Vibrio cholerae*: O1 (includes two biotypes – classical and El Tor) and O139 (non-O1). The clinical picture is similar, because the organisms elaborate a similar enterotoxin that is critical in the pathogenesis. In any single epidemic, one particular biotype tends to be dominant.

## EPIDEMIOLOGY

From the nineteenth century, pandemic cholera has spread repeatedly from the Gangetic delta of India to most of the world. Since 1961, *V. cholerae* of the El Tor biotype has spread through most of Asia into Eastern Europe, Africa and Latin America, assuming a worldwide distribution in resource limited countries. Sporadic imported cases occur among returning travelers or immigrants to high-income countries. Humans are the main reservoir of infection, but other environmental reservoirs such as small crustaceans exist in brackish water or estuaries. Outbreaks occur as a result of ingestion of infected water due to poor sanitation and hygiene and occasionally as a result of ingestion of infected food, especially shellfish.

The arrival of cholera in a region may be heralded by an epidemic of severe disease among all age groups: the presentation of large numbers

of adults (as well as children) with severe dehydrating diarrhea should alert to the possibility of a cholera epidemic. The initial outbreak may be explosive due to the short incubation period (1–5 days) and the ease of fecal–oral transmission in areas where standards of environmental sanitation and personal hygiene are low. Cholera may then become endemic, causing disease mainly in young children of less than 5 years. This is particularly likely with the El Tor biotype, which has a longer carrier period (up to 2–4 weeks) than classical, a longer viability in water and a higher infection:case ratio. El Tor cholera has largely replaced classical cholera as the major pathogen of public health importance worldwide. *V. cholerae* O139 has been a cause of severe outbreaks in the Bay of Bengal region since 1992.

## ORGANISM AND PATHOPHYSIOLOGY

*V. cholerae* are Gram negative curved rods measuring 1.5–3.0 μm × 0.5 μm. In culture, they may assume other forms such as spiral shapes. They possess somatic (O) antigens and flagellar (H) antigens that may be used to distinguish serological strains such as Ogawa, Inaba and Hikojima. In hanging-drop preparations, they are highly motile. Diarrhea is mediated via an enterotoxin that consists of A and B subunits. The B subunit binds the toxin to surface receptors on the enterocyte and activates arachidonic acid metabolism. Once binding has occurred, the A subunit activates the enzyme adenylate cyclase to produce cyclic adenosine monophosphate (cAMP) which inhibits the absorption of sodium chloride and water. cAMP also stimulates secretion of sodium chloride and bicarbonate from the crypt epithelial cells. The excessive intestinal secretions accumulate in the intestinal lumen and are then expelled in the diarrheal stools. The severity of disease depends on the size of the infecting dose, and the organism is easily destroyed by gastric acid. Most patients with cholera are infected with large inocula of the organism or have relative achlorhydria. Breast-feeding is protective.

The electrolyte content of stools of patients with adult cholera, cholera in children and diarrhea due to other organisms is summarized in Table 28.18. Generally, stool osmolarity in pediatric cholera is isotonic with plasma. The stool sodium content of children with cholera is intermediate (~100 millimoles/litre) between that found in childhood diarrhea due to other organisms such as rotavirus (~30 mmol/L) or *Shigella* (~60 mmol/L) and that found in adult cholera (130–150 mmol/L). Stool potassium is higher in pediatric cholera (~30 mmol/L) compared to adult cholera (~15 mmol/L) and bicarbonate losses (~45 mmol/L) are also high. Cholera does not invade the gut mucosa, but colicky abdominal pain and ileus can occur due to electrolyte disturbances such as hypokalemia and hypocalcemia with acidosis.

## CLINICAL FEATURES

The majority of infections with *V. cholerae* are asymptomatic or mild and clinically indistinguishable from other causes of acute watery diarrhea. The typical presentation of severe disease is of acute frequent diarrhea with copious, odorless, virtually colorless (described as 'rice-water') stools. Vomiting is common but fever is unusual. A similar presentation can occur in infants with rotavirus gastroenteritis. In older age groups, the presentation of acute diarrhea among a family group may be confused with food poisoning but severe vomiting which precedes diarrhea and marked abdominal pain are characteristics of food poisoning that are unusual with cholera.

Table 28.18 Relative electrolyte constituents of stools

	Sodium	Potassium	Chloride	Bicarbonate
Cholera in adults	+++	+	+++	+++
Cholera in children	++	++	++	++
Noncholera infantile diarrhea	+	++	+	+

The main clinical features of cholera are those due to severe water and electrolyte loss. Dehydration is commonly isotonic or hypotonic with typical sunken eyes, reduced skin turgor, thirst and dry mucous membranes. Hypovolemic shock may occur within hours of onset. Hypoglycemia is not uncommon and, along with acidosis and hypovolemic shock, leads to deterioration in level of consciousness and occasional convulsions. Hypokalemia and hypocalcemia may also develop and cause colicky abdominal pain, paralytic ileus, muscle cramps and arrhythmias. In severe untreated cases, death may occur within a few hours, and the case-fatality rate may exceed 50%. With proper treatment, the mortality is < 1%.

## DIAGNOSIS

Infection with *V. cholerae* is confirmed microbiologically by culture of stools or rectal swabs. Isolates should be serogrouped, and tested for toxin production and antibiotic susceptibility. If laboratory facilities are not nearby, specimens should be transported in special medium such as Cary-Blair transport medium.<sup>144</sup> Traditional culture techniques usually take over 48 h to complete. For clinical purposes, a quick, presumptive diagnosis can be made by dark field or phase microscopic examination of wet preparation showing the vibrios moving like 'shooting stars' and inhibited by serotype-specific antiserum. Rapid dipstick tests that could be used by non-laboratory trained health workers show promise.<sup>145</sup> Earlier confirmation of a cholera outbreak could reduce the case-fatality rate, usually highest at the beginning of an outbreak, and lead to earlier implementation of infection control measures.

## MANAGEMENT

The basis of therapy is replacement of water and electrolyte losses from the stool. In cases with no dehydration or mild dehydration, oral solutions will suffice but ongoing review is important. The World Health Organization oral rehydration solution (WHO-ORS) was developed for cholera management and the electrolyte content is appropriate replacement for the above mentioned stool losses. Absorption is dependent on the glucose-facilitated membrane transport of sodium. Other more complex substrates with a lower osmolality such as in cereal-based ORS (e.g. rice-based) are more effective at reducing fluid losses in children with acute watery diarrhea.<sup>146</sup> Stool sodium content is higher in cholera than in noncholera diarrhea, yet a meta-analysis<sup>147</sup> concluded that reduced osmolarity ORS (sodium 75 mEq/L, glucose 75 mmol/L, osmolality 245 mmol/L) is safe and at least as effective as WHO-ORS (sodium 90 mEq/L, glucose 111 mmol/L, osmolality 311 mmol/L). The WHO now recommends low osmolarity ORS and zinc supplementation for all children with acute watery diarrhea.<sup>148</sup>

Patients with moderate dehydration have a fluid deficit of between 5 and 10% with decreased skin turgor, thirst, sunken eyes and tachycardia but an intact sensorium. Rehydration and maintenance may be oral or intravenous. Those with severe dehydration, with fluid deficits of more than 10%, will show all the above signs together with peripheral cyanosis, drowsiness or coma, and weak or absent peripheral pulses. Such patients require rapid rehydration with intravenous (or intraosseous) fluids. Ringer's lactate is the most appropriate, widely available intravenous fluid for rehydration but normal saline can also be used. Provision must be made for ongoing stool losses and frequent review of fluid management is essential. Electrolytes and blood sugar should be assessed at intervals to guide ongoing therapy. Potassium will need to be added (at least 20 mmol/L) if normal saline is used during the maintenance phase.

Antibiotics can shorten the duration of diarrhea, reduce fluid losses and requirements and reduce vibrio excretion. Alternatives include doxycycline, erythromycin, azithromycin or ciprofloxacin. Antibiotic-resistant strains are increasingly common, and treatment protocols should be guided by in vitro susceptibility testing. Chemoprophylaxis for contacts has never succeeded in markedly limiting spread but is justified for close household contacts of an index case or if the outbreak is

in a closed group, e.g. aboard ship. Mass chemoprophylaxis of whole communities is never indicated and encourages antibiotic resistance.

## CONTROL AND PREVENTION

During an outbreak, a coordinated response is important.<sup>144</sup> An emergency treatment center should be established that is accessible to the community and appropriately supplied and staffed. Standardized treatment regimens and frequent review are essential for effective therapy. Early case-finding and management of household contacts should be organized. Educate the population at risk concerning the need to seek appropriate treatment without delay. Initiate a thorough investigation designed to find the vehicle and circumstances of transmission (time, place, persons). Support with laboratory examination of implicated water or food sources and sewage, and plan control measures accordingly. It may be necessary to educate the community by dissemination of important, factual information relating to water safety, food preparation and human waste disposal, and to obtain public support for control activities. Adopt emergency measures to ensure a safe water supply. Chlorinate public water supplies and chlorinate or boil water used for drinking, cooking and washing dishes and food containers. Provide appropriate safe facilities for sewage disposal.

Cholera will ultimately be brought under control only when water supplies, sanitation and hygienic practices attain such a level that fecal-oral transmission of *V. cholerae* becomes an improbable event. Active immunization with a cheap, oral killed whole-cell vaccine that provides a moderate level of protection is gaining recognition as an effective control strategy.<sup>149,150</sup> Indirect herd protection to nonvaccinated neighbors improves effectiveness<sup>151</sup> and the vaccine may provide protection for 3–5 years.<sup>152</sup>

## BACTERIAL INFECTIONS: DIPHTHERIA

Diphtheria is an acute infectious disease caused by exotoxin-producing *Corynebacterium diphtheriae*. Although local disease at the primary site of infection, usually the respiratory tract, may be severe, the most significant clinical manifestations are often those at distant sites following systemic absorption and dissemination of the extremely potent diphtheria toxin. Having been one of the leading causes of pediatric mortality in Europe and the USA in the early twentieth century, a combination of improved social welfare and the introduction of mass immunization programs resulted in a dramatic decline in the incidence of diphtheria in resource rich countries by the 1980s (Table 28.19). However, a major resurgence occurred in the newly independent states of the former Soviet Union during the 1990s,<sup>153</sup> emphasizing the potential for rapid re-emergence of the disease in situations where overcrowding, lack of basic infrastructure, natural disasters and/or social unrest disrupt immunization programs and increase exposure to the organism.<sup>154</sup> Nowadays, diphtheria is encountered most frequently among children in South and Southeast Asia, where it remains endemic. Worldwide, more than 5000 deaths from the disease were reported in 2002.<sup>155</sup> Imported cases continue to occur in Europe, particularly among inadequately vaccinated travelers to or from the Indian subcontinent.<sup>156–158</sup>

Table 28.19 Diphtheria – England and Wales

	Cases	Deaths
1920	69 481	5648
1930	74 043	3497
1940	44 281	2480
1950	962	49
1960	49	5
1970	22	3
1980	5	0

## BACTERIOLOGY AND PATHOGENESIS

*Corynebacterium diphtheriae* is a nonmotile unencapsulated nonsporulating Gram positive bacillus. It grows readily on ordinary nutrient agar but is more easily identified by early growth on the nutritionally inadequate Loeffler's medium or on blood tellurite agar, on which growth of other throat organisms is inhibited. Conventionally, three biotypes (gravis, intermedius and mitis) are recognized on the basis of differences in colonial morphology, fermentation reactions and hemolytic potential. Toxin production, the major virulence factor of *C. diphtheriae*, depends on the presence of a lysogenic phage carrying the tox structural gene and is not related to biotype. Highly toxic strains may carry two or three *tox*<sup>+</sup> genes inserted into the genome. Strains lacking the phage do not produce toxin, although conversion to toxigenicity by transfer of a *tox*<sup>+</sup> phage can occur. An immunoprecipitation assay was traditionally used to demonstrate toxigenicity of individual strains, but both PCR for the gene and rapid enzyme immunoassays for the toxin are now available.<sup>159-161</sup>

In the absence of toxin production, *C. diphtheriae* is not particularly invasive, usually remaining in the superficial layers of the respiratory mucosa and inducing only a mild inflammatory reaction. The toxin, a 58 kDa polypeptide, consists of two fragments; fragment B binds to specific receptors on susceptible cells allowing fragment A to enter the cell and catalyze the inactivation of elongation factor 2, thereby inhibiting protein synthesis and leading to cell death.<sup>162</sup> At the site of infection, local toxin production induces tissue necrosis and the formation of a dense, necrotic mass of fibrin, leukocytes, dead epithelial cells and organisms, closely adherent to the underlying mucosa (Fig. 28.18). Attempts to remove this 'pseudomembrane' often result in bleeding from the edematous submucosal layers. Systemically absorbed toxin can affect all organs in the body, but the major clinical consequences generally involve the heart, kidneys and nervous system. Renal involvement is seen in persons with massive toxin absorption, most of whom die within the first week of illness. In contrast there is often a latent period before cardiac and neurological complications become apparent. The severity of these late complications usually reflects the severity of the initial infection and the extent of the membrane.

Reports of endocarditis and osteomyelitis caused by invasive nontoxic strains indicate that other virulence factors may exist.<sup>163,164</sup> A related microorganism, *Corynebacterium ulcerans*, is also able to produce diphtheria toxin and has occasionally been isolated from patients with otherwise classical diphtheria, as well as from individuals with milder symptoms.<sup>165,166</sup>

## CLINICAL MANIFESTATIONS

### Acute disease

The incubation period is typically between 2 and 5 days. The clinical manifestations depend on the site of the primary infection, the immunization status of the host, and the degree to which systemic absorption of toxin has occurred. The disease is conveniently classified into several clinical phenotypes according to the site of primary infection.

Nasal diphtheria is characterized by a serosanguinous or seropurulent nasal discharge associated with a subtle membrane inside the nostrils, and sometimes excoriation of the external nares and upper lip.

Fig. 28.18 Typical 'pseudomembrane' in a child with faucial diphtheria.

If the infection is limited to the anterior nares, the acute illness is often mild, absorption of toxin is limited and systemic complications rare.

Faucial diphtheria is usually a more severe presentation. Anorexia, malaise, sore throat and low grade fever are followed after one or two days by the development of membrane, typically on one or both tonsils, extending variously up to the uvula and soft palate, or down to the larynx and trachea and compromising the patency of the airway. Local soft tissue edema and lymphadenitis give rise to the 'bull-neck' appearance seen in severe cases (Fig. 28.19). The extent of the membrane correlates with the severity of the bull-neck, the degree of airway obstruction and the signs of acute systemic toxicity. In very severe cases massive toxin absorption occurs resulting in cardiac and respiratory collapse, renal failure and death within a few days. However, with appropriate treatment and good supportive care the membrane sloughs off after 5–7 days and the patient recovers from the local infection, although remaining at risk of the delayed toxin-mediated problems.

Laryngeal involvement generally represents downward extension of the membrane from the pharynx and is correspondingly severe. In some cases the membrane extends to involve the whole of the tracheobronchial tree and death is virtually inevitable. Occasionally, however, isolated laryngeal disease occurs and the membrane is limited to the larynx alone; hoarseness, a brassy cough, and rapidly progressive stridor and respiratory distress develop after a short prodromal illness. Relief of the airway obstruction by emergency tracheostomy provides dramatic relief and late complications are unusual as absorption of toxin tends to be limited in such cases.

Cutaneous, ocular, aural and genital diphtheria may all occur, but are rarely associated with significant toxin-mediated disease. The indolent ulcers of cutaneous diphtheria are common in the tropics and may serve as a reservoir for the organism, whilst at the same time inducing good immunity in the host. Cutaneous diphtheria is also seen among alcoholics, the indigent and the homeless in resource rich countries.<sup>167,168</sup>

### Late complications

Characteristically cardiac complications become evident during the second, or occasionally third, weeks of illness and are often insidious in onset. ECG abnormalities such as subtle ST–T wave changes, increased rates of ectopy and/or first-degree heart block are detectable in many patients, but clinical dysfunction is apparent in only 10–25%.<sup>169-171</sup> In these patients, the initial ECG abnormalities tend to progress to more complex conduction abnormalities, notably complete heart block, as clinical myocarditis develops. Findings at this stage include profound bradycardia, diminished heart sounds, a gallop rhythm, and varying degrees of congestive failure. A hypotensive low output state is a very poor prognostic sign, usually associated with major conduction disturbances, and suggests extensive myocardial damage. Ventricular and supraventricular tachyarrhythmias may also occur and are often fatal.

Neurological complications occur in around 10–20% of patients overall. Bulbar involvement is sometimes seen during the first or second week, although minor dysfunction can be difficult to identify in children during the acute stage. In general neurological symptoms are identified later, usually arising between the third and eighth weeks of illness. In some cases there may be a biphasic course with initial partial recovery

Fig. 28.19 Severe diphtheria showing brawny erythematous swelling of the neck (bull-neck) and serosanguinous nasal discharge.

from early bulbar symptoms, followed by late secondary deterioration with bulbar and peripheral manifestations.<sup>172</sup> The early symptoms are likely due to local effects of toxin on the nerve endings in bulbar muscles, while the later effects reflect systemic absorption and dispersion of the toxin. The neurological manifestations are typically bilateral and motor rather than sensory, and electrophysiological studies indicate an underlying demyelinating process. Difficulty in swallowing with nasal regurgitation due to palatal paralysis is often the first symptom, followed by ocular and other cranial nerve palsies, and later a peripheral polyneuropathy similar to but usually more severe than Guillain-Barré syndrome.<sup>173</sup> If diaphragmatic or respiratory muscle paralysis occurs, the course may be severe and prolonged.

**DIAGNOSIS**
