Pediatric Cardiovascular Medicine

SECOND EDITION

SENIOR EDITORS:

James H. Moller, MD

Adjunct Professor of Medicine
Emeritus Professor and former Head of Pediatrics
University of Minnesota
Minneapolis, MN
USA

Julien I. E. Hoffman, MD, FRCP

Emeritus Professor of Pediatrics
University of California
San Francisco, CA
USA

ASSOCIATE EDITORS:

D. Woodrow Benson, MD, PhD

Professor of Pediatrics
Division of Cardiology
University of Cincinnati School of Medicine and
Cincinnati Children's Hospital Medical Center
Cincinnati, OH
USA

George F. Van Hare, MD

Professor of Pediatrics
Washington University and
St. Louis Children's Hospital
St. Louis, MO
USA

Christopher Wren, MBChB, PhD

Consultant Paediatric Cardiologist
Senior Lecturer in Paediatric Cardiology
Freeman Hospital
Newcastle upon Tyne
UK

Preface

With the expansion of knowledge and methods of diagnosis and treatment of cardiac abnormalities occurring in childhood, the major textbooks on the subject have also expanded, often beyond a single volume. In our book, *Pediatric Cardiovascular Medicine*, we have attempted to be concise and focused, and publish a single volume containing contemporary knowledge of pediatric cardiology. The book is available both as a text and online for the convenience of readers who may have different needs. For readers of the textbook there is supplemental material online, including videos of cardiac images. We have focused on the international aspects of pediatric cardiology, both in content and in the selection of authors from 16 countries to contribute chapters. In this edition we have included new chapters about pediatric cardiology in the tropics and developing countries, and about rheumatic heart disease in children (a major problem in many countries with limited health resources).

The chapters are grouped according to subject matter.

The first five chapters present basic scientific information that underlies pediatric cardiology and includes cardiac development and developmental physiology, basic cardiopulmonary physiology, pulmonary vascular physiology and pathology and genetics. The subsequent eight chapters discuss the various diagnostic methods to evaluate cardiovascular problems in childhood, particularly echocardiography, advanced radiologic imaging techniques and genetic testing. Two chapters follow which discuss bypass techniques and postoperative care and three about the fetus and neonates, including fetal treatment, neonatal diagnosis and circulatory issues of small neonates.

A major portion of the book covers congenital heart disease. After chapters on epidemiology and cardiac anatomy, descriptions of individual malformations are presented primarily in the following order: left-to-right shunts, outflow and inflow tract obstruction and regurgitation, anomalies associated with a right-to-left shunt, and then vascular and situs anomalies. In most of the 25 chapters about congenital heart disease, the organization and structure of the chapters are similar, making it easier for the reader.

The final 22 chapters concern various acquired conditions affecting the cardiovascular system during childhood. The issues of adults with CHD and the quality of life after cardiac treatment are discussed in separate chapters and where relevant within individual chapters.

As editors, we sought to emphasize pathophysiologic principles or understanding to help the reader comprehend and retain the information. Each chapter contains pertinent references to enable the reader to explore the subjects further.

Since the previous edition, echocardiographic techniques have advanced significantly; interventional methods have been developed to include a wider range of abnormalities and imaging techniques, particularly with magnetic resonance which has allowed more detailed information about cardiovascular structure and function. These are being widely applied to children.

Finally, we added three Associate Editors to assist in the preparation of this expanded edition and we appreciate their careful review of chapters and editorial comments.

1 Normal and Abnormal Cardiac Development

Adriana C. Gittenberger-de Groot, Monique R. M. Jongbloed & Robert E. Poelmann
Leiden University Medical Center, Leiden, The Netherlands

Introduction

In this chapter, the main events of cardiac morphogenesis are discussed. We focus on morphologic descriptions and insights based on the molecular biologic approaches in animal models that have enhanced and modified our understanding of normal and abnormal cardiac development, including relevance for adult disease with a developmental background.

Advances and limitations in studying human development

The normal cardiovascular development of the human embryo in its crucial stages from 2 to 8 weeks' gestation has to be deduced from postmortem morphologic studies of abortion material [1]. In this category we are mainly dealing with spontaneous abortions and do not know whether the material reflects normal morphogenesis. Descriptions in the literature referring to normal and abnormal human development do not emphasize this aspect. An addition to early detection of human embryonic malformations, mainly providing information on disturbed genes and chromosomes, is provided by amniocentesis, chorionic villus biopsies, and subsequent FISH (fluorescent *in situ* hybridization) analysis with genetic markers. However, these are not examined within the first crucial 8 weeks of development. Fetal diagnosis is a rapidly expanding area with increasing technical possibilities of ultrasound and echo-Doppler investigations *in utero*. The earliest observations indicating normal or abnormal heart development refer to 11–12 weeks' gestation [2]. Consequently, our knowledge of detailed cardiac morphogenesis relies on describing processes in animal species, the main embryonic models being avians (chick and quail) and rodents (mouse and rat) and more recently the zebrafish. With the development of transgenic techniques, the mouse embryo has become important, and we will regularly refer to mouse embryo models when discussing certain abnormalities of cardiac development.

Knowledge about an embryonic lethal phenotype after a gene knockout and the absence of a phenotype might contribute little to the understanding of human congenital cardiac malformations [3]; 85% of the diagnosed human cardiac malformations are described as having a multifactorial origin. Epigenetic, environmental, biomechanical, and hemodynamic factors have been underestimated in research on cardiogenic programming. Their role in the development of cardiac malformations has previously been acknowledged, however, and has led to the so-called mechanistic classification [4]. There are a few recent publications linking hemodynamics to cardiovascular developmental abnormalities [5–8], but their relation to gene expression and cardiogenic patterning is unclear. A multidisciplinary approach combining clinical knowledge with basic science will lead to new insights into developmental processes.

Formation of the cardiogenic plates and the cardiac tube

The cardiac developmental program starts with the formation within the splanchnic mesoderm of the bilateral cardiogenic plates, which give rise to the myocardium and probably to parts of the endocardium (Figure 1.1). The splanchnic mesoderm at the endoderm/mesoderm interface differentiates into the vascular endothelium [9] and part of the endocardium [10,11]. The evidence for a cardiogenic plate origin of the endocardium supports a dual origin for this layer of the heart [12].
Figure 1.1 (a) Whole mount of a quail embryo (stage HH 8) viewed from the ventral aspect, showing the bilateral cardiogenic plates (C) that have not yet fused across the midline. At this stage, the staining is done by a nonspecific neurofilament antibody. (b) Whole mount of the fused primary heart tube (PHT) of a quail embryo (stage HH 10) viewed from the ventral aspect. The staining is by an anti-smooth muscle actin antibody, showing the myocardial lining of the tube. H, head region; IP, intestinal portal; N, neural tube; O, omphalomesenteric vein; Ph, pharyngeal region; S, somite. (Copyright Leiden University Medical Center.)

The bilateral asymmetric cardiogenic plates can be delineated early in embryonic life because several transcription factors and proteins are expressed. These expression patterns distinguish a first or primary heart field (PHF) laterally flanking the second heart field (SHF) component of the cardiogenic plate (Figure 1.2a). Whereas the first heart field differentiates, the secondary component remains part of the body wall mesoderm before its cells are recruited and incorporated into the poles of the cardiac tube. With formation of the cardiac tube, the pericardial coelomic cavity becomes continuous across the midline and the ventral mesocardium disappears. The cardiac tube is thereafter solely connected to the dorsal body wall or splanchnic mesoderm by the dorsal mesocardium that runs from the developing pharyngeal arches (arterial pole) to the sinus venosus (venous pole) (Figure 1.3). At this stage, the tube consists of an inner endocardial and an outer myocardial layer separated by cardiac jelly (Figures 1.2b and 1.3a).

Initially, the primitive cardiac endothelial network is remodeled into a single endocardial tube that connects the omphalomesenteric veins to the pharyngeal arch vasculature (Figure 1.1). The asymmetric cardiac jelly surrounding the endocardial tube suggests bilateral endocardial tubes, giving the wrong impression that two endocardial tubes have to fuse. From the onset, however, the endocardial tubes are connected by endocardial cells that cross the midline [13]. Real cardia bifida can occur spontaneously and can also be produced

experimentally by retinoic acid overdose in the chicken embryo [14] or in a zebrafish mutational screen [15]. Therefore, each cardiogenic plate can potentially give rise to an independent cardiac tube, implying that fusion of the cardiogenic plates is unnecessary for the onset of cardiac formation. Nevertheless, cardia bifida is lethal to the embryo as further cardiac development is hampered and no connection with the endothelium of the pharyngeal vascular system is established.

Looping of the cardiac tube

The single cardiac tube is never completely straight as both cardiogenic plates have different dimensions [12]. Normally the cardiac tube loops to the right (D-loop) (Figure 1.2). Abnormalities in looping such as L-loop or anterior-loop formation are related to ventricular inversion, which differs from laterality problems as seen in abnormalities of the atrial situs.

The mechanisms underlying the looping direction are poorly understood, but several regulating genes have been described, such as sonic hedgehog, nodal and activin receptor IIa [16]. In mouse mutants iv/iv and inv, the laterality of the heart is also affected. The iv gene has been mapped to chromosome 12 in the mouse and is syntenic to chromosome 14q in the human. In the human, this abnormality is reflected in the heart by atrial isomerism and is discussed below when considering atrial development and septation.

During looping, the outflow tract becomes more ventrally positioned, moving in front of the atrioventricular (AV) canal. The arterial and venous poles remain fixed to the dorsal body wall (Figure 1.4 and Videoclip 1.1). Both remodeling of the inner curvature (site of the disruption of the dorsal mesocardium) and asymmetric addition of SHF-derived myocardium to the primary heart tube are essential for proper looping.

Contribution of first and second heart fields

Recent mouse studies, based on various transgenic mouse models with cell tracing [17–19], have shown that the primary heart tube does not contain all components necessary for the future mature heart [20]. The first heart field provides only for the AV canal and the future left ventricle (LV), implying that the primary heart tube already has additions of the second heart field (SHF) at both poles. The primary heart tube connects the omphalomesenteric veins at the venous pole via a small atrial component, the AV canal, and a primitive LV and small outflow tract component to the aortic sac and the first pair of pharyngeal arch arteries at the arterial pole (Figures 1.2 and 1.3).
Figure 1.2 Development of the heart from the first and second heart fields. (a) In the primitive plate, bilateral fields of cardiac mesoderm are present. Progenitor cells migrate from the primitive streak to the bilateral mesoderm (arrows). Cells depicted in yellow will contribute to the second heart field-derived parts of the heart, whereas cells depicted in brown depict the primary heart fields that will contribute the primary myocardial heart tube. (b) Schematic representation of the primary heart tube, consisting of endocardium and myocardium, with myocardial jelly between the two layers. Initially the primitive heart tube consists mainly of the AV canal and the LV. (c) After looping, several transitional zones can be distinguished in the tube, namely the sinoatrial transition (light blue, SAR) in between the sinus venosus and common atrium, the AV transition (dark blue, AVR) in between the common atrium and common ventricle, the primary fold (yellow, PF) in between the primitive right ventricle (RV) and LV, and a ventriculoarterial transitional (green, VAR) zone at the outflow tract (OT) of the heart. Second heart field-derived parts of the heart are depicted in yellow. (d) The heart after completion of atrial and ventricular septation. Due to outgrowth of the RV, a remodeling of the PF has occurred, and it has divided into a lateral septal part, the trabecula septomarginalis (TSM), that contains the right bundle branch [RBB, see (e)] and continues into the moderator band (MB). (e) Part of the transitional zones will contribute to definitive elements of the cardiac conduction system, depicted in red. Bright blue dots depict neural crest cells that contribute to the network of autonomic nerve fibers surrounding the sinoatrial node (SAN) and atrioventricular node (AVN). Shaded blue dots surrounding elements of the cardiac conduction system indicate neural crest cells with an inductive role in conduction system development. A, common atrium; AP, arterial pole; Ao, aorta; Ao sac, aortic sac; CV, cardinal vein; CS, coronary sinus; ICV, inferior caval vein; LA, left atrium; LAA, left atrial appendage; LBB, left bundle branch; LV, left ventricle; PT, pulmonary trunk; PV, pulmonary veins; RA, right atrium; RAA, right atrial appendage; SCV, superior caval vein; VP, venous pole. The cardiac splanchnic mesoderm consists of so-called SHF. This precardiac mesoderm is added at both the arterial and venous poles of the heart, mainly contributing myocardium but also smooth muscle cells of connecting vessels.

The mesodermal cell population grows in a caudocranial direction [21]. Recruitment starts at the arterial pole and almost the complete myocardium of the right ventricle (RV) including the outflow tract and the larger part of the ventricular septum is derived from the SHF. The smooth muscle cells of the aortic sac are derived from this source, although probably asymmetric with respect of contribution to the pulmonary and aortic aspects. More restricted studies of the outflow tract have led to a confusing nomenclature with respect to anterior heart field [22] and secondary heart field [23], the latter often being confused with SHF that contributes to both arterial and venous poles.

At the venous pole, the myocardium lining the sinus venosus derives from SHF mesoderm referred to as posterior heart field (PHF) [24]. Incorporation of the sinus venosus implies that the myocardium of the sinoatrial node, the venous valves, the atrial septum, and the cardinal and pulmonary veins also come from this source. A further mesenchymal derivative of the SHF is the proepicardial organ (PEO), which is crucial for many aspects of differentiation of the heart (see below).

Several transcription factors and morphogenetic genes and cascades are important in the precardiac mesoderm of both first heart field and SHF [25]. Specification of the precardiac cells is accompanied by early expression of TGFβ family members, including BMP4 (bone morphogenetic protein), followed by the earliest known marker for the cardiogenic lineage – the homeobox (Hox)-containing gene Nkx2.5 (homolog to tinman in *Drosophila*) [26] and the zinc finger-containing GATA 4/5/6 cluster of transcription factors [27]. Mesp1 [28] and Mef2c [29] are also early cardiac mesoderm markers. Recently, the platelet-derived growth factor receptor (PDGFRα) was added to this list [30]. Patterning of the heart field from arterial to venous pole is accompanied by the expression of T-box gene family members Tbx1, 5 and 20, Fgf 8 and 10, and Isl1. Finally, differentiation during heart tube formation involves, for example, MLC and MHC, alpha cardiac actin and troponin I, and RhoA [31]. Mouse models in which these genes are used for cell tracing and complete or conditional knockout provide essential data on their relevance for normal and abnormal cardiac development. In some instances, such as Nkx2.5, [32] human mutations are known.
Figure 1.4 Scanning electron micrographs of the developing heart. (a) The fused heart tube (also see Figure 1.1) has been opened to show the endocardial cells (EC) inside the myocardium (M) and the cardiac jelly (CJ). (b) The heart tube normally loops to the right showing a venous pole (VP) and an arterial pole (AP) and the inner curvature (asterisk). (c) As the inner curvature tightens, the outflow tract becomes positioned in front of the venous pole. (d) With completion of the looping process, the AP is wedged in between the atrioventricular orifices that connect the right atrium (RA) to the right ventricle (RV) and the left atrium (LA) to the left ventricle (LV). Segmentation of the heart tube

The primary heart tube consists of myocardium lined on the inside by cardiac jelly and endocardium. A number of genes are expressed along the anterior/posterior axis and there is from the onset a right–left designation. Chamber outgrowth or ballooning, intricately regulated by a balance

of Tbx2 and Tbx3 transcription factor expression [33], brings out more clearly the segments (atrial and ventricular chambers) and the transitional zones. These areas stand out against the myocardial trabeculated atrial and ventricular walls. Figure 1.2b–e depicts the cardiac segments and transitional zones. Starting at the inflow at the venous pole, we can distinguish the sinus venosus, the atrium, the atrioventricular canal, the primitive LV, the primary fold, and the primitive RV that develops into a trabeculated part and a part lined by endocardial outflow tract cushions. In general, the endocardial cushion-lined transitional zones form the atrioventricular and semilunar valves and function initially as temporary valves accompanying peristaltic contractions of the cardiac tube. The myocardium of the sinus venosus (considered as a transitional zone), the AV canal, the primary fold, and the endocardial cushion-lined outflow tract are important for the formation of the future cardiac conduction system. Furthermore, these transitional zones are involved in septation.

Neural crest and epicardium contributions

For many years, the neural crest and epicardial cells were described as extracardiac contributors essential for proper differentiation of the developing heart. With new insights into the contribution of the SHF, we need to adjust their relevance.

Neural crest cells are an extracardiac source of cells that migrate from the neural crest through the mesoderm of the SHF to the cardiac tube. The main entrance site into the heart is at the arterial pole, but they also reach the venous pole of the heart [34,35] (Figures 1.3b and 1.5). These neural crest cells differentiate into smooth muscle cells of the great arteries and into the cells of the autonomic nervous system that are needed to innervate the great arteries and the coronary arteries, and for the nodes of the cardiac conduction system (Figures 1.2e and 1.5). The neural crest cells that migrate into the heart do not differentiate into a particular cardiac cell but go into apoptosis. Through release or activation of growth factors such as TGFβ they may induce myocardialization of the outflow tract septum and, at the venous pole, differentiation of the cardiac conduction system [36,37]. They are also important in the interaction with the SHF cells, mainly in the pharyngeal region, so that genetic mutations of both cell types can lead to congenital heart disease. This is best exemplified in the Tbx1-related 22q11 deletion syndrome [38].

The epicardium develops from the proepicardial organ, an epithelial derivative of the PHF at the venous pole (depicted in Figure 1.3b). These cells differentiate into smooth muscle cells and cardiac fibroblasts and migrate to many cardiac structures where their function is less known [39]. Suggestions, based on cell tracing in transgenic mouse
Figure 1.5 (a) Whole mount staining of a chicken heart (stage HH 35) that shows the neural crest-derived cells after a retroviral transporter gene marker containing lac-Z. The neural crest cells are present at the arterial pole (AP) as smooth muscle cells in the vessel wall and over the heart as fine nerve fibers (N). The neural crest cells also reach the venous pole (VP) of the heart, where they enter the atrioventricular region through the dorsal mesocardium. (b) A section through the inflow and outflow tract of a chicken heart in which the neural crest cells are seen in the outflow tract septum (OTS) and also at the base of the atrial septum (AS) (arrows), where they have arrived through the dorsal mesocardium. The brown staining of the outflow tract septum (OTS) neural crest cells by the TUNEL [TdT-mediated dUTP (deoxyuridine triphosphate) nick end labeling] technique detected apoptosis of these cells. models, that epicardial cells can differentiate into myocardial [40] and endothelial cells [41] have been refuted.

Cardiac differentiation and development of cardiac malformations

Sinus venosus incorporation and atrial septation

The sinus venosus in the developing heart forms an intermediate transitional zone between the systemic cardiac veins and the developing atrium proper, and now receives much attention as the myocardium of the sinus venosus is derived from the PHF mesoderm, showing specific gene expression patterns. On the basis of endothelial vascular patterns, scanning electron microscopy data, and immunohistochemistry, we demonstrated that the sinus venosus is incorporated not only into the dorsal wall of the right atrium but also into the dorsal wall of the left atrium [42]. Here, it encircles the entrance of the future pulmonary veins. The sinus venosus also contributes to the posterior wall of the left atrium and pulmonary veins, as suggested for both the mouse and the human embryo [43,44], and earlier postulated by Van Praagh and Corsini [45]. Other groups, focusing on gene expression patterns, regard the pulmonary veins

(pulmonary pit lined by pulmonary ridges) as having their own origin independent of the sinus venosus [46]. All explanations have in common that the veins are connected to the cardiac tube by way of the dorsal mesocardium to the PHF mesoderm in the dorsal body wall. In the fully developed human heart, this area is demarcated by the epicardial/pericardial fold. The above morphogenesis of the sinus venosus also provides new data on the septation of the atria (Figure 1.6). The primary atrial septum is a structure that initially consists of atrial myocardium, but later becomes fibrous, and is derived from the PHF-derived myocardium. It forms an arch that runs from posterior to anterior and is lined on the inside by cushion-like tissue, called the mesenchymal cap. At this site, also PHF mesoderm, formerly referred to as spina vestibuli but now named the dorsal mesenchymal protrusion (DMP) [47], contributes to atrial and ventricular septation. The DMP provides cells to the inferior atrial septum and borders the mesenchymal cap on the right side. Fusion of the mesenchymal cap with the AV cushions is essential to close the primary atrial foramen.

The PHF mesoderm and also the derived myocardium have characteristic gene patterns that partly differ from the outflow tract. This refers to the transcription factors Tbx18, 20 [48], Shox2 [49], the functional marker HCN4 [50], and the growth factors RhoA [31] and PDGFRα [30,51]. The sinus venosus myocardium is Nkx2.5 negative before incorporation into the dorsal atrial wall and remains as such in the sinoatrial node. Transgenic mouse studies of these genes and some human mutations correlate with abnormalities in PHF-derived structures, including conduction system disturbances.

The primary atrial septum becomes perforated to form the ostium secundum that is never completely closed off by the septum secundum. The complex of the lower rim of the septum secundum and the ostium secundum is called the foramen ovale (Figure 1.6, arrow). The muscular secondary atrial septum is in its basal and dorsal part fused with the DMP. The major anterior and superior parts of the secondary atrial septum are merely a folding of the atrial wall forming the limbus fossa ovalis on the right side of the atrial septum.

Consequences for abnormal development
The above data provide new insights into abnormal pulmonary venous connections and also atrial septal defects (ASDs) and atrioventricular septal defects (AVSDs).

Abnormal pulmonary venous connection
As the plexus for forming the pulmonary veins has extensive connections to the cranial and caudal parts of the cardinal veins [52], persistent connections can lead to supracardiac and infracardiac pulmonary venous connection patterns. For cardiac abnormal pulmonary venous connection, the pulmonary veins do not grow out of the left atrial dorsal wall but
Figure 1.6 (a) Atrial septation starts out with formation of a septum primum (ASP) that grows out from the roof of the common atrium towards the AV canal (AVC). The AV cushions continue over the basal part of the primary atrial septum as the mesenchymal cap (MC). Initially, there is an opening at the basal part of the primary atrium septum, called the ostium primum (OP). Subsequently, probably by a process of apoptosis, several holes will form in the septum primum, that will eventually coalesce to form the ostium secundum [OS, see (b)]. The septum secundum (ASS) will grow out later in development from the roof of the common atrium. In between these structures, at the base, a protrusion of second heart field mesoderm called the dorsal mesenchymal protrusion (DMP) is present. (b) During further development, the ostium primum is closed by fusing the endocardial cushions with the dorsal mesenchymal protrusion. The septum secundum has grown out to form a wedge-shaped septum that during the embryologic and fetal phase will (owing to a higher pressure on the right side) allow the passage of blood towards the left side via the ostium secundum (arrow). The complex of the lower rim of the septum secundum and the ostium secundum is called the foramen ovale (FO) (arrow). After birth, the left atrial pressure rises and the FO will be functionally closed by the primary atrial septum that is being pressed to the septum secundum. The right atrium (RA) receives systemic blood via the superior caval vein (SCV), inferior caval vein (ICV), and coronary sinus (not shown). The left atrium (LA) receives pulmonary venous blood via the pulmonary veins (PV). DM, dorsal mesocardium; TO, tricuspid ostium; MO, mitral ostium. Second heart field-derived myocardium is depicted in yellow. (Copyright Leiden University Medical Center.)

are connected to the left atrial wall through incorporation of the sinus venosus. Disturbance of genes in the PHF can lead to abnormal formation of the wall of the pulmonary veins and the left atrium [53]. Familial total anomalous pulmonary venous connection (TAPVC) has been mapped to chromosome 4p13-q12 in the region near the PDGFRα gene. A knockout mouse of this gene shows TAPVC [51]. Interestingly, the DMP and mesenchymal cap are very hypoplastic in this model, leading to AVSD (see below). A recent review described the current clinical, genetic, and developmental data on pulmonary venous development and abnormalities [54]. Only pulmonary veins connected to the left atrium acquire a myocardial cuff [44]. This cuff is lacking in veins that connect to the right atrium or a spatium pulmonale.

Atrial septal defects

The most common defect is the septum secundum defect (ASD II), in which there is a discrepancy between the septum secundum (demarcated on the right side by the limbus) and the free edge of the fenestrated septum primum. In normal circumstances they overlap as two crescents (Figure 1.6) that fuse after birth. Defective development, including perforations, of the valve of the septum primum, the so-called valve of the foramen ovale, can also lead to an ASD. It is necessary to distinguish between retarded closure of the foramen ovale and a real secundum ASD.

Abnormalities in formation of the base of the atrial septum secundum can lead to so-called sinus venosus ASD, where both the inferior and superior caval veins are closely related to the defect and the pulmonary veins are often abnormally positioned [43].

Based on our new knowledge of addition of the PHF to both the atrial septal components and also the pulmonary veins, some genes are good candidates for study. We already know human mutations in Tbx5 (Holt–Oram syndrome) [55], Nkx2.5 [56], and the PDGFRα region [51] that explain the separate or combined abnormalities in atrial septation, pulmonary venous connection, and in

some patients conduction system problems particularly related to pace-making.

Atrioventricular septal defects

AVSDs are intriguing malformations with many postulated causes, including deficient differentiation of the AV valves and the endocardium lining these valves. This has been extensively studied [57] for the trisomy 21 (Down syndrome) and the syntenic trisomy 16 mouse model without resolution. In the human embryo with AVSD, however, studies of the disposition of the conduction system demonstrated a deficiency of the spina vestibuli (now DMP) and the mesenchymal cap [58], now confirmed in mouse models [47,59]. The primary ASD resulting from non-fusion with the AV cushions can now be explained by the hypoplasia of the mesenchymal cap lining the lower rim of the primary atrial septum. The deficiency of the ventricular inlet septum in humans still needs clarification [60]. The fact that the AV valve tissue in AVSD seems structurally normal confirms that abnormal AV endocardial cushion differentiation is not the primary problem.

Although the heart has two left- and two right-sided chambers, asymmetry is a dominant feature in both form and function. The ventricular asymmetry is determined during looping, whereas the atrial differences are determined by genetic regulation involving, for example, Pitx2 [61,62]. Pitx2 acts in breaking symmetry in early development, is present in the left-sided plate mesoderm only, and has subsequent roles in differentiation of the inflow and outflow segment of the heart. Pitx2 mutant mice present with right atrial isomerism, suggesting inhibition of the left program. Pitx2 mutants may present syndrome-like malformations also involving other organs, for instance the spleen, showing polysplenia in left isomerism and asplenia in right isomerism. Furthermore, DNA sequence variations close to Pitx2 have been described in patients with atrial fibrillation and atrial flutter [63]. Morphologists and clinicians are aware of the differences in the right and left atria, the most obvious being the appendage. Furthermore, the right posterior wall is trabeculated whereas the left is smooth. Usually, atrial situs correlates with bronchial anatomy (see Chapter 50). Lung lobulation, difficult to assess for the clinician, is less reliable.

Ventricular inflow tract septation and the formation of the RV inlet

The RV myocardium with all its components, including at least the right part of the ventricular septum, is derived from the anterior SHF [18]. At the border between the primitive LV and the developing RV, a myocardial ring called the primary ring or fold, previously referred to as bulboventricular fold, can be distinguished [64]. The primary fold is considered a transitional zone and attracts a great deal of attention because it forms the major part of the ventricular inlet and trabecular septum and contains precursors of the AV conduction system.

The primary fold borders on the inner curvature of the heart where it coalesces with the right side of the AV canal (Figure 1.2c). The lower part of the primary fold becomes a real septum by local condensation of the ventricular trabeculae combined with ballooning of the apices of both the LV and RV. Closure of the primary interventricular foramen between the RV and LV takes place by fusion of the inferior and superior atrioventricular cushions in combination with one of the outflow tract endocardial ridges that is connected to this superior cushion.

The role of the primary fold as progenitor of the main body of the ventricular septum deserves special attention. A proper septum is only established when a RV with the tricuspid valve and its orifice is formed. This has to be achieved during development and is important for forming the right ventricular inlet compartment. The right part of the AV canal with the adjoining part of the primary fold has to be transferred to the right side (for remodeling of the primary fold, see Figure 1.2c–e and Videoclip 1.2). Our opinion is that this is achieved by a widening in the dorsal wall of the ventricle adjacent to the primary fold. We have been able to support this developmental concept in a model for Mahaim conduction [65]. With growth of the initial minute inflow part of the RV, a new posterior wall of the right ventricle is formed. In this way, the RV consists eventually of three parts: the RV inlet, bordered by the remnants of the primary fold (trabecula septomarginalis and moderator band), the RV trabecular part (embryonic proximal ventricular outlet segment), and part of the distal ventricular outlet segment underneath the pulmonary orifice.

From an RV view, the ventricular septum is made up of three parts (Figure 1.7):

1 The inlet septum that is formed concurrently with expansion of the RV inflow.

2 This is separated from the trabecular part of the septum by the crista supraventricularis (composed of the continuum of the ventriculo-infundibular fold and the trabecula septomarginalis and also contains the outlet septum; see Figures 1.7 and 1.8), and the moderator band.

3 The muscular outflow tract "septum" or infundibulum derives its myocardium from the distal endocardial cushion-lined outflow tract or conotruncal region (see below).

Consequences for abnormal development

Isolated or multiple muscular VSDs can result from noncompaction of the myocardial trabeculae. Several mouse models present an extensive spongy myocardium that show both myocardial and epicardial differentiation problems as a basis (see below).

Tricuspid valve and orifice abnormalities

Abnormal looping of the heart tube can lead to the tricuspid valve not being optimally brought above the RV, causing a spectrum of tricuspid atresia and hypoplasia, to straddling
Figure 1.7 Schematic representation (a) and human specimen (b) demonstrating the elements of the ventricular septum after septation has been completed, as viewed from the right side. The ventricular inlet septum is below the tricuspid valve (TV) ostium, and separated from the primitive septum by the myocardial crista supraventricularis. The crista supraventricularis consists of the ventriculo-infundibular fold (VIF), the trabecula septomarginalis (TSM), and the outlet septum (asterisks) that in the normal heart cannot be distinguished as a separate structure. The TSM (that contains the right bundle branch) becomes continuous with the moderator band (MB). The membranous septum is part of the fibrous heart skeleton. Ao, aorta; PT, pulmonary trunk; RA, right atrium. (Copyright Leiden University Medical Center.)

tricuspid valve, and complete double inlet left ventricle. Severe deficient looping can also lead to double outlet right ventricle (DORV). In knockout mouse models with disturbed epicardial differentiation, the abnormalities result in abnormal looping, for example, the mutant RxRα [66], Sp3 [67], Ets1/2 [68], and TGFβ2 [69] mice. It is also possible that primary myocardial problems can cause these abnormalities.

Most perimembranous VSDs and also the outflow tract malalignment defects are the result of abnormal outflow tract septation (see below).

We consider the AVSD anomaly to result from abnormal fusion of the DMP, the mesenchymal cap, and the AV cushion mass [47,58].

Ventricular outflow tract septation

The myocardial contribution of the SHF, referred to as anterior [22] or secondary heart field [70], forms almost the complete RV. The relevance of neural crest cells [35] for outflow tract septation is still important but no longer unique, following studies of the 22q11 deletion syndrome in both patients and mouse models [38]. This complicated syndrome has a high incidence of outflow tract malformations, including aortic arch anomalies, persistent truncus arteriosus, and tetralogy of Fallot. Eventually, the transcription factor Tbx1 was found to be the crucial gene. This gene was not expressed in neural crest cells but in the mesoderm of the SHF. An intricate interaction between neural crest and SHF cells takes place and disturbed genes that are essential for either cell group can lead to outflow tract malformations.

We refer to the septation of the ventricular outflow tract as "separation" as in the normal heart the subpulmonary infundibular or muscular septum is mainly a free-standing sleeve of muscle in front of the vessel wall of the ascending aorta (Figure 1.8). Outflow tract separation has been described for the human embryo [71] and proved similar in animal species such as chick and mouse [64].

Outflow tract separation starts in the embryonic distal outflow tract that is lined by endocardial cushion tissue. This tissue consists of two opposing spiraling ridges. One ridge runs in a laterodorsal direction where it borders the myocardium of the primary fold at the future site of the ventriculo-infundibular fold in the full-grown heart. The other ridge runs ventroanterior to the myocardium of the primary fold as well as the superior atrioventricular cushion. This merging takes place in the bend of the inner curvature of the embryonic heart tube. The endocardial outflow tract ridges are the source of extensive nomenclature confusion. Some authors consider these ridges to consist of proximal or conal ridges (leading after septation to the conal septum) and distal or truncal ridges (leading to a truncal septum). Pexieder [72] clarified this nomenclature confusion. We indicated in a scanning electron micrograph both boundaries and ridges in their full length (Figure 1.8). It is practical to distinguish proximal and distal ridges, which are clearly visible as separate structures in the chicken embryo but are more continuous in humans and rodents (mouse and rat). The proximal ridges mainly form the muscular outflow tract septum whereas the distal ridge area is important for semilunar valve formation and the septation of the arterial orifice level.

Understanding outflow tract separation starts with acknowledging that the arterial orifice level indicated by the mesenchymal (vessel wall) joining the myocardial (outflow tract heart) boundary is not an oval or a circle in one plane but has a three-dimensional saddle shape (Figure 1.9). This
Figure 1.8 (a) Scanning electron micrograph of a preseptation chicken heart showing the proximal (P) and distal (D) outflow tract ridges. The borderline between myocardium (lined on the inside by endocardial cushions) and arterial wall is indicated by arrows. The distal cushions remodel into semilunar valves. (b) Septation of the outflow tract is achieved by fusion of the outflow tract ridges and an ingrowth of condensed mesenchyme (CM), also called the aortopulmonary septum (APS). The APS extends two prongs into the ridges. (c) After septation of the outflow tract, a muscular subpulmonary infundibulum (inf) is formed, which separates the right ventricular outflow tract (RVOT) from the outside world and the aorta (Ao). In a normal heart, the actual outflow tract septum separating the left ventricular outflow tract (LVOT) and RVOT is minimal. (d) Depiction of the difference in length of the RVOT and the relative tilted position of the aortic and pulmonary orifice. LA, left atrium; LV, left ventricle; MB, moderator band; MV, mitral valve; PT, pulmonary trunk; P, prong of CM; RA, right atrium; RV, right ventricle; TSM, trabecula septomarginalis; TV, tricuspid valve; VIF, ventriculoinfundibular fold; IV, VI, pharyngeal arch arteries. brings future aortic orifice more lateral and lower compared with the future pulmonary orifice. During normal looping, this orifice is brought even deeper into the heart, referred to as wedging of the aorta. We recently found (unpublished data) an asymmetric contribution of the SHF to the myocardium of the outflow tract. This Nkx2.5-expressing mesoderm differentiates into myocardium mainly confined to the subpulmonary region, explaining the relative growth of the subpulmonary outflow tract and the rotation to an anterior position with regard to the aortic orifice (see Videoclips 1.3 and 1.4). Molecular biologic experiments using retrospective clonal analysis [73] also showed a difference in subpulmonary and subaortic myocardium but did not link it to the asymmetric addition of SHF. This explains the known asymmetry in the outflow tract [74] for the human embryo. The final result is the well-known difference in position and plane of both arterial orifices.

The highest (most distal part) of the myocardium, always lined on the inside by endocardial cushion tissue, is positioned in the intersection between the sixth and fourth pharyngeal arch arteries. It is exactly at this site that the condensation of extracardiac mesenchyme takes place. The condensed mesenchyme extends two prongs that enter the endocardial cushions together differentiating into the aortopulmonary septum [64] that undergoes myocardialization. Our own chicken chimera studies and also the neural crest indicator
Figure 1.9 Concepts of outflow tract formation. (a) Early concept that assumed that the myocardium surrounding the aorta and pulmonary trunk was distributed symmetrically. Levels I–III indicate the supposed levels of separation, I being the great arteries, II the arterial orifices, and III the outflow tract. (b) In contrast, later work demonstrated that the myocardium in this area actually has a saddle shape, demonstrating the increase in length of the pulmonary trunk in respect to the aorta. The asterisk indicates the level of initiation of separation of the arterial pole. pulm aa, pulmonary arteries; V, ventricle. (Copyright Leiden University Medical Center.)
Figure 1.10 Section of the outflow tract of a chicken–quail cardiac neural crest chimera (stage HH 34). The quail cardiac neural crest cells (dark nuclei) fill almost completely the condensed mesenchyme of the aortopulmonary septum (APS). The semilunar valve leaflets (SEM) also show neural crest-derived cells. Ao, aorta; PT, pulmonary trunk. (Copyright Leiden University Medical Center.)

mouse show this condensed mesenchyme to be composed mainly of neural crest cells extending into the distal ridges and the semilunar valves and also the surrounding myocardium [75,76] (Figures 1.5 and 1.10). Staining for apoptosis reveals that most of the neural crest cells at this level have gone into apoptosis, which is particularly prominent during the stage of myocardialization of fused endocardial outflow tract ridges (Figure 1.5b). We postulate that this neural crest cell death program plays an active role in stimulating outflow tract myocardialization. This process

is much less obvious at the distal valve level, where a lump of condensed mesenchyme persists and turns into a fibrous structure (conus tendon).

In completing normal outflow tract separation, the myocardial outflow tract "septum" has merged seamlessly with the ventriculo-infundibular fold and the trabecula septomarginalis. The lower rim borders upon the anterior tricuspid orifice and is called in normal hearts the crista supraventricularis. The final result is an RV outflow tract that is long and surrounded by myocardium whereas the LV outflow tract is short and only partly surrounded by myocardium. In the normal heart, only a small stretch of musculature can really be called a septum between both outflow tracts (Figure 1.8). This situation differs markedly from specimens with disturbed outflow tract septation.

Consequences for malformations

Tetralogy of Fallot, double outlet right ventricle, malalignment defects

The main events in cardiac outflow tract septation are linked to addition of SHF and neural crest cells and their interaction. As a consequence, malformations in outflow tract septation, a major cause for CHD, are linked to disturbances of genes that are crucial for the development of both cell populations. Tbx1 is primarily expressed in the SHF mesenchyme and not in neural crest cells. Hence the phenotype of this malformation is based on a misdirection of neural crest cell contribution based on an abnormal interaction with SHF cells. Patients with solely a Tbx1 mutation have been reported to develop a 22q11 deletion phenotype [38].

van Mierop and Kutsche [77] suggested the possible impact of neural crest in outflow tract septation. Kirby *et al.* [78] were the first to show experimentally the link between outflow tract malformations and the neural crest. They ablated the neural crest in chicken embryos, ending up with a spectrum of outflow tract malformations ranging from a simple VSD to DORV and, in the extreme, a persistent truncus arteriosus (common arterial trunk).

Recent studies have refined this concept, adding specific SHF-expressed genes to the causes. Examples are semaphoring [79], TGFβ [69], and Pax3 [80] mutant mice. We recently showed a role for VEGF isoforms in development of tetralogy of Fallot in a VEGF120/120 mutant mouse [81]. There was selective apoptosis in the subpulmonary myocardium, which we know to have a distinct SHF-derived contribution that differs from the subaortic region.

Epigenetic or environmental factors also play a role, as we showed in embryos from maternal diabetic rats that presented with DORV and a too short outflow tract [82]. For the development of bicuspid aortic valve, some genes in patients have recently been described such as Notch1 [83] and Axin1 linked to endoglin [84]. This draws attention to a possible

role of hemodynamics and blood flow that has been neglected. Our studies of the chicken venous clip model showed the importance of alteration of blood flow for the development of a spectrum of outflow tract malformations, including semilunar valve abnormalities [85]. The eNOS (a shear stress responsive gene) mutant mouse showed development of a bicuspid aortic valve [86] after fusion of specific outflow tract endocardial cushions.

Transposition of the great arteries, including DORV with subpulmonary VSD (also termed the Taussig–Bing malformation), remains an enigma. Nakazawa and co-workers [87] showed that retinoic acid treatment of mouse embryos could lead to transposition of the great arteries. There seems to be a link to laterality problems during addition of SHF mesoderm at the outflow tract. In animal models with transposition, the proximal outflow tract ridges had a straighter position. This fits nicely with the morphology of the heart in human infants with transposition in which there is not simply a reverse of the great arteries but also a straighter outflow tract septum [88].

Outflow tract septation is a very vulnerable process. Abnormalities can be evoked by all key players in this area – myocardium, endocardial cushion tissue, and neural crest.

Atrioventricular and semilunar valve formation

Both valve types differentiate from the endocardial cushion tissue lining the AV canal for AV valve formation and the distal outflow tract for semilunar valve formation. The main morphologic difference is that the AV valves are connected to the ventricular wall by chordae and papillary muscles, whereas the semilunar valves do not have a tension apparatus.

The endocardial cushion tissue itself is remodeled into valve leaflets [89,90]. The chordae are also derived from the endocardial cushion tissue and are not differentiated from the papillary muscles (Figure 1.11). The endocardial cushions are formed by contributions of several cell types derived from the endocardium and myocardium in which the process of endothelial to mesenchymal transformation is very important [91]. More recent data show the addition of epicardium-derived cells (EPDCs) to the AV cushion tissue [92] (Figure 1.11). Periostin has been described as an important regulator in AV valve development [93]. Differentiation of the AV valve leaflets has not attracted much attention. Oosthoek *et al.* [89] showed for the chicken, mouse, and the human embryo expression of a number of layered differentiation markers that differ on the atrial and the ventricular side.

Semilunar valve development [94] takes place at the distal part of the outflow tract ridges on the borderline of mesenchyme and myocardium. Reconstructions of the human embryo [64] showed that the orifice level does not lie in one plane but has a saddle shape with the future aortic orifice already more dorsolateral and caudal than the
Figure 1.11 (a) The cardiac valves differentiate from the endocardial cushion tissue that is lining the AV canal for AV valve formation. AV valves are connected to the ventricular wall by chordae and papillary muscles. Both valve leaflets and the chordae are derived from endocardial cushion tissues that are remodeled from thick spongy structures into thin valve leaflets. The endocardial cushions are formed by contributions of several cell types derived from the endocardium (depicted as small circles) and myocardium. Epicardium-derived cells (EPDCs), depicted as star-shaped cells) also contribute to AV cushion formation. (b) These are derived from the epicardium and migrate towards the endocardium [arrows] once the myocardial continuity between atrium and ventricle has been disrupted by formation of the annulus fibrosis. Delamination of the valve occurs under the influence of the EPDCs, resulting in detachment of the endocardial cushion from the myocardial wall. A, atrium; AVS, AV sulcus; V, ventricle. (Copyright Leiden University Medical Center.)

pulmonary side. With septation of the outflow tract, the two main endocardial ridges are fused by the condensed mesenchyme of the aortopulmonary septum (Figure 1.8), so that four cushion masses can be distinguished, two in each orifice. To achieve three valve leaflets in each orifice, two intercalated cushion swellings are seen positioned on the far side of the facing valve cushions. In the aorta, the intercalated valve swelling develops into the noncoronary cusp. The two facing semilunar valve sinuses receive the main stems of the right and left coronary artery. For a proper attachment of the semilunar valve leaflets to the underlying myocardium and the above vessel wall, a collagen "ring" is formed [95].

Consequences for abnormal development

Atrioventricular valve abnormalities

Both in human CHD and in experimental animals, information is lacking on abnormal differentiation of the AV valve leaflets. There are reports of tricuspid valve insufficiency during fetal life which can lead to intrauterine death.

Furthermore, polyvalvar disease seems to have a genetic background [96]. As the valves are delaminated from the underlying myocardium, ventricular septation abnormalities can also lead to abnormal attachments and formation of the tricuspid and mitral valve; examples are AVSDs, straddling tricuspid and mitral valves. Studies on AV valve differentiation [97,98] provided new information on normal and abnormal papillary formation, especially with regard to the subject of parachute mitral valve in which there is usually asymmetric formation of the mitral valve rather than a real parachute. Abnormal atrioventricular valve leaflets such as seen in Ebstein's malformation are not easily explained from embryology but point towards incorrect undermining from the ventricular myocardium. The animal model using lithium treatment does not resolve the mechanism. Recently, the roles of EPDCs [99] and periostin [93] have been described. Transgenic mice (N-FATc [100] and Sox4 [101]) show specific expression in the endocardial cushion tissue. Knockouts show a spectrum ranging from absence to underdevelopment

of the mitral and tricuspid valves and also of the semilunar valve leaflets. These models are embryolethal and have not been evaluated. We postulate that absence of AV valve leaflets in the human embryo leads to early intrauterine death, as we have not seen that abnormality in humans.

Semilunar valve abnormalities

Several processes described for the AV cushions are also pertinent for the endocardial outflow tract cushions that develop into semilunar valve leaflets, with deficiencies leading to absent or very hypoplastic aortic and pulmonary valves [102]. Absence of aortic leaflets is lethal for the human fetus whereas absence of pulmonary valve leaflets is compatible with term delivery.

Extracardiac cells migrate into the developing valves, as proven for the neural crest cell population [75]. The mechanism underlying the formation of commissures and the sites of formation still need elucidation. A recent publication on the development of the bicuspid aortic valve shows beautifully the difference between a genetic Syrian hamster model and the eNos knockout [103]. Finally, hemodynamic factors [85] may play a role.

Cardiac conduction system (CCS) development

The impulse from the sinoatrial node (SAN) is propagated via Bachman's bundle to the left atrium, and via the internodal myocardium to the atrioventricular node (AVN). Although internodal tracts with specific histologic, immunohistochemical, and molecular characteristics [104–108] can be distinguished in the atria, their functionality is yet to be determined. The AVN is a compact cellular node, covered by transitional cells [109,110]. From this node, the common bundle or bundle of His supplies the ventricles (see Chapter 55).

During development of CCS, the sequence of activation changes from an immature base-to-apex activation pattern of the primary heart tube to a mature apex-to-base activation pattern, in accordance with the development of the His–Purkinje system. Pre-excitation of the ventricles can still occur after septation due to persisting myocardial AV bridges across the AV junction [111]. Insulation of the atrial myocardium from the ventricular myocardium occurs by development of the annulus fibrosis, which begins by fusion of epicardial sulcus tissue with endocardial cushion tissue at the ventricular site of the AV junctional myocardium and moves the original AV myocardium to an atrial position [90]. For this process, correct ingrowth of EPDCs is mandatory [112]. EPDCs produce in the AV annulus the extracellular matrix molecule periostin that is involved in fibrosis of the myocardium of the AV canal [112]. Fibrosis of the annulus however remains incomplete until late fetal stages [111].

In the developing and the adult heart, myocardium of the (putative) CCS can be distinguished from the surrounding working myocardium, based on histologic characteristics, and

also by the expression patterns of several immunohistologic and molecular markers [113]. Multiple genes, cells, and their interactions are involved. Furthermore, the developing CCS seems to be much more extensive than in the adult CCS. After looping of the heart has started, several *transitional zones* (Figure 1.2b–e) can be distinguished from the surrounding working myocardium [104,106,107,114]. These transitional zones are the sinoatrial transition comprising the sinus venosus segment connecting to the primitive atrium, the atrioventricular transition or primitive AV canal between the primitive atrium and primitive left ventricle, the primary fold that separates the primitive left ventricle from the primitive right ventricle, and the ventriculoarterial transition at the junction of the primitive right ventricle with the truncus arteriosus or putative outflow tract of the heart (Figure 1.2). The so-called "ring theory" hypothesizes that these transitional zones contribute to elements of the CCS [114].

Due to further looping of the primitive heart tube, the zones meet in the inner curvature of the heart where they contribute to AVN formation. During development, part of this embryonic myocardium differentiates into working myocardium. The transcription factors Tbx2/3 function as transcriptional repressors of this chamber formation process [108,115], whereas Tbx5 is required for maturation and differentiation of the CCS [116]. The latter transcription factor is also involved in molecular pathways for CCS specification, which includes the inhibitor of DNA-binding Id2 [117]. Parts of the zones that do not differentiate into working myocardium form elements of the mature cardiac conduction system (Figure 1.2).

As explained above, the first heart field contributes to the primary heart tube that includes the primitive AV canal. The myocardium at the venous pole of the heart, the sinus venosus, that includes the SAN, is incorporated later to the heart from the PHF [17,24]. This venous myocardium is characterized by the expression of several markers, including podoplanin [24] linked to RhoA [31], Shox2 [49,118], Tbx18 [119], and the functional marker HCN4 [50], and by a lack of expression of the transcription factor Nkx2.5 [24,48].

A transient left-sided SAN precedes the formation of the definitive right-sided SAN [31], making the complete embryonic sinus venosus myocardium a potential pacemaking area.

Whether the SHF also contributes to the elements of the AVN is debatable. Although a contribution from the SHF has been suggested [120], the compact part of the AVN appears to come from the primitive AV canal (first heart field derived), except from the lower part that is derived from the primary fold [121]. However, the origin of the atrial septal component of the AV conduction axis and of the transitional cells still needs to be elucidated. In addition to a direct contribution, an interaction between the tissues from the different transitional zones may also contribute to CCS formation as a

result of induction. Generally, based on histologic studies, the transitional cells are regarded as an atrial or sinus venosus contribution to the AVN [109,110]. The His bundle and bundle branches are most likely derived from the myocardium of the primary fold that undergoes extensive remodeling during development (see Videoclip 1.2). The newly incorporated SHF-derived myocardium forms the right ventricular inflow tract with expansion of the primary fold tissue, after which the medial part of the ventricular septum consists of the trabecula marginalis, containing the right bundle branch, which remains continuous with the moderator band that runs to the lateral right ventricular wall. The peripheral Purkinje fibers develop from differentiating ventricular cardiomyocytes [122] in close association with both the coronary arteries and EPDCs [92,122,123]. In the chick, EPDCs are important for inducing Purkinje fiber formation [124].

Neural crest cells also reach the venous pole of the heart, where they probably play an inducing role in CCS formation and maturation [34,37].

Consequences of abnormal development in relation to arrhythmias

Clinical arrhythmias are related to anatomic predilection sites and many of these ectopic pacemaker foci are preferentially encountered in specific parts of the right and left atrium that are related to the sinus venosus. These include the crista terminalis [125,126], the adult counterpart of the embryonic right venous valve, being related to initiating/perpetuating atrial flutter. The myocardium of the caval veins [127] and coronary sinus [128] are clinically known to initiate arrhythmias. In the left atrium, atrial fibrillation has been attributed to arrhythmogenic foci that originate from the pulmonary veins [129]. The sinus venosus myocardium, which includes the myocardium surrounding the caval and pulmonary veins, is derived from the SHF, and is characterized by specific gene expression patterns including absence of Nkx2.5 expression [24,48]. During development, the sinus venosus myocardium largely differentiates towards a chamber phenotype and acquires expression of Nkx2.5, but loses some of the characteristic early conduction system markers such as Tbx18, CCSLacZ, and Shox2 [113]. Failure of this chamber differentiation, and also re-expression of the embryonic phenotype, may explain the occurrence of clinical arrhythmias originating specifically in these areas.

AV re-entrant tachycardias are based on accessory myocardial bundles connecting atrial and ventricular tissue, thus bypassing the insulating function of the AV groove. The best known is the bundle of Kent, present in Wolff–Parkinson–White (WPW) syndrome [130]. As described above, accessory AV myocardial continuities may persist in the embryo until late stages [111]. Insulation of the annulus fibrosis requires EPDCs. In animal models in which the epicardial outgrowth is inhibited, accessory connections causing ventricular pre-

excitation, as in WPW syndrome, are observed. Valvar anomalies such as Ebstein-like malformations due to non-delamination of valves are also part of the phenotype of epicardial deficiency in avian models [99], perhaps explaining the frequent association of Ebstein's anomaly of the tricuspid valve and WPW syndrome [131]. A special form of re-entrant tachycardia is Mahaim tachycardia, during which antidromic re-entrant tachycardia occurs over an accessory bundle with AV node-like conduction properties [65]. Arrhythmias originating in the right ventricular outflow tract can be related to the ventriculoarterial transition and studies on the role of Tbx2 mutations are ongoing [115].

Whether disturbed migration and subsequent apoptosis of neural crest can be linked to human rhythm problems is uncertain. After neural crest ablation in chick embryos, there is a lack of differentiation of a compact lamellar organization by the His bundle and of (electrical) isolation from the working myocardium, and also failure of the conduction system to convert to a mature apex-to-base activation pattern [36]. Genes with differentiation abnormalities of the SHF-derived cardiac conduction system have been described but a link to human malformations has not been made with the exception of Nkx2.5 [56] and Tbx5 [117] mutations. Mutations in both genes cause ASDs and conduction disorders, explained by deficient contributions from the SHF, since both the atrial septum and elements of the CCS are SHF derived.

Development of the epicardium and the coronary vasculature

The epicardial epithelium growing out from the proepicardial organ serves as a covering layer of the myocardium. This epithelium differentiates into epicardium-derived cells (EPDCs) entering the subepicardial space and migrating into the myocardial wall where they differentiate further into the cardiac fibroblasts (also forming the annulus fibrosis) and the smooth muscle cells of the coronary vessels [39,132].

The coronary vasculature is the last part in the developing embryonic heart that is essential for its survival as a beating pump. It provides nutrients to the cardiac wall which cannot survive solely on diffusion from the cardiac lumen. In a normal human embryo at about 6 weeks of development, the coronary arteries contact the two facing semilunar sinuses of the aorta (the right and left sinus of Valsalva) [133,134].

The development of the coronary endothelial network takes place within the confinement of the subepicardial covering of the heart (see Figure 1.12) adjacent to the liver primordium. The microvasculature originates from the sinus venosus endothelial lining where it runs through the liver and enters the subepicardial space [135,136]. Patterning of the main branches of the coronary arteries is largely guided by the underlying AV sulcus (derived from EPDCs) and the position of the interventricular septum, even when abnormally positioned. Development of a peri-truncal microvascular network that remodels into arteries and veins

precedes the differentiation of these main branches [137]. The variation in the main branching pattern at the orifice level seems related to the shortest distance to the area that has to be perfused and might, therefore, depend on hypoxia-dependent gene expression.

The coronary venous drainage is through the large veins accompanying the major coronary arteries and ending in the coronary sinus. A number of small anterior veins enter the anterior part of the right atrium. The development of this system has been followed in both chicken–quail chimeras and transgenic mice. In studying the human embryo, we have been unable to find an extensive Thebesian network connecting the ventricular lumen to the coronary veins. There is evidence, however, of an extensive arteriovenous collateral network. The coronary veins have a myocardial media at their connection to the atria and only more distally is this replaced by a vascular wall containing smooth muscle cells [138].

Consequences for malformations

Cardiomyopathies

The EPDCs that enter the myocardium are essential for the development of the compact myocardial layer. Inhibition of epicardial outgrowth [139] or disturbance of the differentiation of the PHF and epicardium results in a very thin myocardium. This lack of myocardial differentiation could be the origin of cardiomyopathies such as noncompaction cardiomyopathy [39]. The important role of the epicardium for myocardial differentiation has also resulted in the use of EPDCs as cell therapy to ameliorate cardiac function after myocardial infarction [140].

Coronary vascular abnormalities

The coronary arteries grow into the aortic wall, and do not sprout from it (Figure 1.12). Why normally the two facing sinuses of the aorta harbor a coronary artery, leaving the nonfacing (noncoronary cusp) and the pulmonary sinuses empty, remains elusive. We postulate that the unequal contributions of the SHF to the aortic and pulmonary segments of the early aortic sac designates this pattern and depends in part on Tbx1. The interaction with the neural crest is shown after its ablation in the chick embryo. In persistent truncus arteriosus, the coronary arteries enter only the aortic side of the orifice [141]. For humans, this was confirmed in a pathomorphologic study [142].

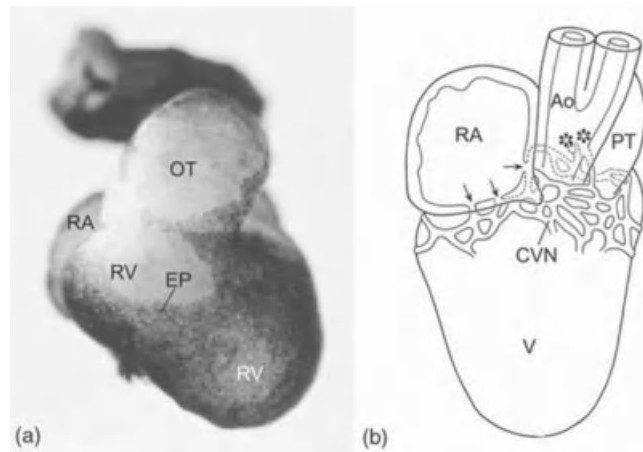
An explanation for coronary fistulas, more common in the right ventricular wall, combined with diseased coronary arteries is incompletely understood. EPDCs are necessary for correct ingrowth of the coronary arteries into the aorta [68,143] and studies demonstrate transient connections between endocardium and coronary microvasculature through lacunas in the ventricular myocardium. If these connections persist, fistulas could develop. In fetal life, large fistulas are a


Figure 1.12 (a) Cytokeratin whole mount staining of the epicardium (EP) of a quail heart (stage HH 24). The epicardium grows out from the epicardial organ at the sinus venosus and covers the outer part of the outflow tract (OT) and the right ventricle (RV). (b) Schematic view of the coronary vascular network (CVN) at the peritruncal area underlying the epicardium. This network grows at a quail stage HH 32 into the aorta (two lumenized sprouts, asterisks) and into the anterior part (arrows) of the right atrium (RA). Ao, aorta; PT, pulmonary trunk; V, ventricle. (Copyright Leiden University Medical Center.)

primary abnormality, leading secondarily to atresia of the pulmonary orifice [144,145]. Hypoplasia of the coronary artery wall and the plasticity of coronary vessels is influenced by growth factors such as VEGF [146] and PDGF [147].

Development of the aortic arch system and pulmonary arteries

The aortic arch and its branches develop from an essentially bilaterally symmetric pharyngeal arch artery system. In the human embryo this is remodeled into a left aortic arch and prenatally a left ductus arteriosus (Figure 1.13). The first and second pairs of arch arteries are transformed into craniofacial arteries whereas the third pair provides the common stem of the carotid arteries. The fourth and sixth pairs (the fifth pair does not appear in most mammals) develop asymmetrically. The left fourth pharyngeal arch artery persists as the aortic arch, whereas the right fourth forms a small segment of the subclavian artery. The sixth pair forms a transient connection on both sides between the pulmonary trunk and the descending aorta. On the right side, the distal part of the sixth pair disappears early, leaving the left one to persist as the ductus arteriosus until birth. In human embryos, the pulmonary arteries might contact the aortic sac directly and are never inserted into the sixth arch artery. The right and left subclavian arteries have to move cranially from the seventh intersegmental level to the aortic arch. During normal development, the early left
Figure 1.13 (a) Schematic view of the remodeling thoracic arterial vasculature, from an almost symmetric system with a number of pharyngeal arch arteries (depicted are III, IV, and VI) to a left aortic arch. Dashed lines represent regressing vessels. α and β indicate the aortic segments proximal and distal to the left subclavian artery. (b and c) After the left subclavian artery (LSA) has migrated into its proper position the aortic arch has an isthmus (IST) and a segment B (vulnerable in the 22q11 deletion syndrome). (Copyright Leiden University Medical Center).

subclavian artery crosses over the ductus arteriosus entrance, thereby creating the isthmus.

The study of the pharyngeal system in the chicken and mouse shows the significance of several tissues in this region, including the neural crest, the anterior heart field, and even the foregut endoderm. The latter is involved in molecular signaling but not in cellular contributions. The significance of the cardiac neural crest, positioned between the otic placode and the third somite level, is evident as ablations of this rhombencephalic crest in chicken embryos result in abnormalities of the third, fourth, and sixth pharyngeal arch arteries and also the outflow tract of the heart. The neural crest migrates through the circumpharyngeal region and is influenced by signals from the foregut, including the sonic hedgehog and Tbx1 pathways. Next, the neural crest joins the anterior SHF area ventrally to the foregut and makes differentiation of the pharyngeal arches and the enclosed arteries even more complicated. The smooth muscle cells of the root of the ascending aorta and the pulmonary trunk derive from the anterior SHF [23], whereas the medial smooth muscle cells of the arteries come from the cardiac neural crest [148], as is true for the fibroblasts of the adventitia and for the surrounding ganglia. Vessels not populated by neural crest cells include the subclavian arteries,

the distal and intrapulmonary arteries, and the coronary arteries. The data from chicken and mouse studies cannot be simply transferred to the human embryo as reliable markers for the various vessels and the outflow tract are lacking. Note that the mouse embryo lacks the human isthmus section located between the left subclavian artery and the entrance of the ductus arteriosus (in later life a ligament).

Consequences for abnormalities

Aortic arch abnormalities

Abnormalities of the aortic arch system, including those encompassed in the 22q11 deletion syndrome (DiGeorge syndrome), show a phenotype that is paramount in certain parts of the fourth arch derived segment and also the ductus arteriosus/left pulmonary artery connection, which is sixth arch derived. The problem is mainly right sided and is probably related to the right-sided dominance of the anterior heart field-related expansion of the pulmonary trunk compared with the aortic root. The disappearance of vessel segments is accompanied by increased local apoptosis programs [149] that are at least partly governed by sonic hedgehog signaling. The postulation that hemodynamics [5,7,8] influence normal arch artery development is gaining

importance, particularly for hypoplasia and coarctation [150]. Shear stress-induced genes include Kruppel-like factor (KLF2), TGFβ and endothelin-1 [151]. The downstream mechanism is complicated, as shown by malformations including DORV, VSD, aortic arch malformations, and abnormal semilunar valves caused by rerouting the venous return in chicken embryos.

The relatively common coarctation of the aorta, localized on the border of the ductus arteriosus and the aortic arch, cannot be explained from a mouse model as this segment is missing. Interruption, hypoplasia, and local coarctation of the isthmus seem best explained by hemodynamic factors related to left ventricular outflow tract obstruction.

2 Genetics of Cardiovascular Disease in the Young

Lisa J. Martin, Robert B. Hinton & D. Woodrow Benson
Cincinnati Children's Hospital Medical Center and University of Cincinnati School of Medicine, Cincinnati, OH, USA

Introduction

Cardiovascular disease in the young comprises varied phenotypes, including cardiovascular malformations (CVMs), cardiac arrhythmias, cardiomyopathies, and vasculopathies. In the past two decades, there has been an explosion of relevant genomic/genetic information. In this edition, progress in understanding the genetic origins of specific cardiac disease phenotypes is provided in each chapter. Although cardiovascular genetics is still in an early phase of gene discovery, genetic testing of embryos, fetuses, children, and adults is expanding rapidly in both research and clinical settings, and Chapter 13 addresses the challenge and current utility of genetic testing. However, despite progress in the genetics of cardiovascular disease in the young, cause is still unknown in most anomalies. Because the genetic origins of cardiac arrhythmias (Chapter 55), cardiomyopathies (Chapter 58), and vasculopathies (Chapter 67) are dealt with in other chapters, the emphasis here will be on genetic etiology of CVMs.

CVMs are the most common birth defects, with an estimated incidence of 5–10 per 100 live births [1] and 20 per 100 abortuses [2]. Although there have been tremendous advances in the medical and surgical care of infants and children with CVMs [3], CVMs remain a major cause of fetal loss, infant death, and childhood morbidity [4,5]. Healthcare providers have long had an interest in elucidating the cause of CVMs, and for many families with an affected child, the cause of their child's heart disease remains an important question. Based on the increased availability of genomic/genetic information in the past decade (Table 2.1), an increasing role of genetics in the diagnostic approaches, therapeutic strategies, and outcomes of assessments of cardiovascular disease in the young can be expected.

What is the incidence of CVMs?

An estimate of 4–10 liveborn infants per 1000, 40% being diagnosed in the first year of life, is often cited as the prevalence of CVMs [2,5]. The true prevalence, however, may be much higher. For example, bicuspid aortic valve (BAV), the most common CVM, occurring in 10–20 per 1000 in the general population, is usually excluded from this estimate. When isolated aneurysms of the atrial septum and persistent left superior vena cava, each occurring in 5–10 per 1000 live births, are considered, the incidence of CVMs approaches 50 per 1000 live births. The incidence of ventricular septal defect (VSD) has also been demonstrated to be as high as 5% in two independent Israeli cohorts of 5000 serial newborns and 5000 serially studied premature infants [1]. In the light of these considerations, an incidence of CVMs of 50 per 1000 live births is a conservative estimate.

Cause of CVMs: understanding in the pregenomic era

Although early epidemiologic studies recognized environmental teratogens, such as rubella and thalidomide, as risk factors for CVMs, in the Baltimore-Washington Infant Study [6], the risk factor identified most often was a positive family history, suggesting a significant genetic component. Numerous examples of increased CVM risk in family members of affected individuals support a genetic cause of CVMs [7], as does the association of CVMs and other birth defects with chromosomal abnormalities [1]. At present, the cause of most CVMs remains unknown, however. Although only ~15% of all CVMs can currently be attributed to genetic causes [8], increasing evidence suggests that most if not all CVMs have a genetic component [9,10].

Cause of CVMs: understanding in the postgenomic era

The primary challenge in identifying additional genetic causes of CVMs may be the approach to discovery. Despite the relative rarity of CVMs that exhibit Mendelian inheritance patterns (single gene), molecular and cytogenetic studies have used family-based linkage analysis to identify a handful of CVM-causing genes (reviewed in [1]). These studies have demonstrated variable expressivity, reduced penetrance, and genetic heterogeneity (Figure 2.1), confirming that most CVMs are the result of complex inheritance. Complex inheritance occurs when multiple genes contribute to the phenotype, and different combinations of genetic variants may result in variable expressivity based on gene–gene interactions or gene–environment interactions. From developmental biology (Chapter 1), it is clear that cardiogenesis results from multiple tightly regulated processes, and dysregulation of any of these processes can result in CVMs [11]. Taken together, a mixture of genetic and environmental or epigenetic insults may result in CVMs, and identifying these combinations is challenging.

The presence of multiple genes and interactions between genes and the environment does not preclude the ability to identify genes associated with CVMs; however, complex inheritance must be considered if researchers are to continue to define the genetic underpinnings of CVMs and other forms of cardiovascular disease in the young. This approach requires careful phenotype definition, estimation of genetic effects, recruiting strategy, and integrated statistical methods. In the sections that follow, our goal is to provide an overview of these study design considerations.

Definition of the phenotype

Genetic studies have shown that the clinical taxonomy (the clinical phenotypes used by anatomists, cardiologists, and surgeons) does not precisely align with the emerging genetic taxonomy. For example, there is not a tetralogy of Fallot gene or an atrial septal defect gene, as both conditions exhibit

Table 2.2 Single gene and cytogenetic abnormalities for ASD and TOF.

Defect	Secundum atrial septal defect	Tetralogy of Fallot
Single gene defects	EVC/EVC2	FOG2
	GATA4	JAG1

	PTPN11	TBX5
	TBX5	
	ZIC3	
Cytogenetic defects	Trisomy 21	Trisomy 21
	Del22q11	Del22q11

considerable genetic heterogeneity (Table 2.2). Further, individuals within a family harboring the same mutation may exhibit distinct phenotypes (i.e., variable expressivity) that cross the clinical taxonomy boundaries. Therefore, the first step of any human genetic research study is to define the phenotype precisely. Studies using too broad or too narrow a phenotype definition may fail either to find association with an existing genetic variant or to identify a pathologic variant. Hence definition of the phenotype most aligned with the underlying genetic etiology is essential for successfully identifying causative genetic variants.

Clinically, CVMs have clearly defined phenotypes and individual lesions are classified based on anatomy (e.g., atrial septal defect), physiology (e.g., left to right shunt defects), and embryology (e.g., endocardial cushion defects), with echocardiography being the gold standard for diagnosis. Although these approaches to classification have been useful, there is substantial phenotypic heterogeneity in clinically defined CVMs. For example, ventricular septal defect (VSD) is further classified into four types: conoseptal, conoventricular, muscular, and inlet (Figure 2.2). Evidence is accumulating that each VSD type has a distinct genetic basis and different developmental origins. Specifically, some conoventricular VSDs are associated with 22q11 deletion syndrome, whereas inlet VSDs are often associated with trisomy 21. Further, the second heart field and neural crest programs are expected to contribute to conoseptal and conoventricular septation but not inlet or muscular septation. In addition, in complex CVMs such as tetralogy of Fallot, defined by pulmonary stenosis, overriding aorta, and VSD, specific phenotypic details distinguish subtypes. For example, tetralogy of Fallot phenotype heterogeneity may be subclassified into variants involving aortic arch specification, pulmonary valve anatomy, and noncardiac malformations (Figure 2.2).

Recent advances in cardiac developmental biology have revealed new complexity in the genetic regulation of heart morphogenesis and may help explain CVM phenotypic heterogeneity. The cardiovascular system is the first to function in the embryo, and viability depends on the successful establishment of this organ system (Chapter 1). The cardiac crescent including the lateral plate mesoderm is a major source of cardiac progenitor cells; however, there are other extracardiac precursors derived from the second heart field,
Figure 2.2 Phenotype variability. The clinical taxonomy names lesions implying specificity; however, there is significant variability in phenotypic detail. For example, ventricular septal defects may be classified as conoseptal, conoventricular, muscular, or inlet (a). In addition, complex lesions such as tetralogy of Fallot may have anatomic features that distinguish them from the group at large, for example, right aortic arch (b). These distinctions have significant implications when considering genetic etiology and the contribution of specific molecular cardiac developmental pathways. (Modified from Geva T, Powell A. Pediatric Heart Disease. In: Edelman R, ed. In Clinical Magnetic Resonance Imaging, 3rd edition. Elsevier, 2005: 1050–1059. With permission.)

cardiac neural crest, and pro-epicardium which migrate into the heart and contribute to its development. Differentiation of the progenitor cells results in spatially and temporally organized lineages, including muscle, conduction system, coronary vessels, and cardiac valves. The linear heart tube then loops, develops endocardial cushions, which ultimately contribute to valve structures, and forms chambers. Further, epigenetic factors, such as blood flow perturbations, that occur after primary cardiac morphogenesis but before birth may significantly affect and modify the ultimate phenotype [12]. Thus, CVMs result from complex interaction between multiple developmental factors, which may not be captured by the clinical nomenclature of CVMs.

Phenotypic heterogeneity may also affect the ability to detect genes and the underlying etiology of CVMs. Thus, although there are clinical definitions of specific phenotypes that are essential for establishing a diagnosis and designing a surgical treatment strategy, these definitions do not address etiology and may not be sufficient for genetic discovery. The insights gained by human genetic and molecular biology studies must be reconciled with the established clinical taxonomy to provide the most precise classification scheme for CVM. Elucidating the genetic basis of CVMs will result in a meaningful classification system that integrates the molecular basis of cardiac development with the clinical phenotype.

Evidence of genetic origins

Before conducting any gene discovery study, it is important to establish that there is a genetic basis. Researchers have long noted that CVM risk is increased in family members of affected individuals, suggesting a genetic basis [10,13]. However, given the variation in phenotype determination and the phenotypic variability of CVM, it is not surprising that there are also many reports of anomalies with no known family history [14,15]. Thus, statistical evidence of an increased occurrence of a specific CVM in family members of affected individuals compared with the general population is needed. There are two main quantitative measures of familial risk, recurrence risk and heritability.

Recurrence risk of a specific phenotype (e.g., atrial septal defect) or group of phenotypes (e.g., CVM) measures the proportion of the proband's relatives (usually defined as degree or relationship type) who are affected. CVM recurrence risk in siblings varies greatly, ranging from 0.5 to 22% [10,14,16–18]. One possible reason for the marked differences is that these estimates are specific to the study cohort and are influenced by study design (phenotype definition, ascertainment bias). Nonetheless, these studies demonstrate several interesting findings. First, there is approximately a doubling of recurrence risk on expanding the phenotype to include siblings with any type of CVM as compared with complete concordance [14,18]. This demonstrates significant

phenotypic heterogeneity with risk of one type of CVM increasing relatives' risk of a different CVM. Second, the method of evaluating relatives is important; recurrence risk estimates are higher when individuals are phenotyped with echocardiography as compared with interview [14,16,17]. Third, the definition of CVMs can influence the estimates. For example, the definition of a CVM often excludes subclinical or nonpediatric diagnoses, such as BAV, mitral valve prolapse, and left superior vena cava. Exclusion of these common CVMs results in lower recurrence estimates [14]. Recurrence risk studies support phenotypic heterogeneity and demonstrate a strong genetic component to CVMs.

Heritability estimates the proportion of a trait attributable to genetics. CVM heritability estimates are high, ranging from 49 to 95% [19,20]. Like recurrence risk, heritability is population specific and dependent on phenotyping. Importantly, some of the lower heritability estimates were based on self-reported phenotypes [18], compared with studies clinically examining all relatives [20]. Heritability was also lower when probands were defined broadly (e.g., ascertained groups of CVMs) [19,21] as compared with a specific CVM phenotype [14,15,22]. Taken together, these studies support the recurrence risk finding that there is a strong genetic basis to CVMs.

Study design for CVM gene discovery

Once the phenotype has been defined and a genetic component established, the next decision is which study design to use. Human genetic discovery research is challenging given the long lifespan, complex genetic background, and variable environmental exposures. Appropriate study design, however, helps minimize confounding. Factors that should be considered include prevalence and the timing of milestone events.

Prevalence is an estimate of how common a condition is within a population (the number of diseased individuals/ population size) and is a critical variable in genetic studies. Rare traits (prevalence <5%) have specific implications for study design. Although CVMs are the most common congenital malformation, it is a rare trait as only 5% of live births have CVMs [1]. Further, specific CVM phenotypes are even more rare and occur in <1% of live births [5]. Phenotypes that have a relatively high prevalence, such as obesity (occurring in >30% of the adult population), allow random selection of individuals from the population resulting in a large number of affected individuals. In contrast, for rare traits such as CVMs, large samples are necessary to obtain a modest number of patients. As a result, researchers often use nonrandom sampling, such as the case–control strategy.

Another factor to consider when designing a study is the timing of events. *Age of disease onset* influences potential misclassification of phenotype. Diseases with a late age of onset, such as mitral valve prolapse [23], potentially describe

individuals as "normal" or "unaffected" when they are actually affected. Additionally, diseases with late age of onset may be difficult to study using family-based data because few evaluated individuals may be affected. Conversely, CVMs unequivocally determined *in utero* should have minimal classification error. *Age of death* may bias the sample because only those who survive until sampled are included. Given the substantial mortality with some forms of CVMs, researchers must recognize this potential bias. Indeed, CVMs are responsible for a significant proportion of pre- and postnatal loss, with 20% of abortuses having a CVM [2]. For example, hypoplastic left heart syndrome (HLHS) is uniformly fatal without intervention in the newborn period. Because surgical palliation for HLHS has only been used for the past 25–30 years and interstage mortality continues to be significant (Chapter 38), identifying multiplex families may be difficult because individuals with HLHS might not have been recognized and have only survived to childbearing recently.

The next step is to determine the appropriate sampling strategy, family or population based, as sampling design affects the hypotheses that can be tested. There are two main questions in gene discovery: (1) are there genetic differences between affected and unaffected individuals, and (2) do genetic variants segregate with disease in families? The first question can be answered using *family-* or *population*-based data; however, the second question can only be tested using family-based information.

Family sampling may include trios (proband and parents), nuclear families (first-degree relatives, i.e., parents and siblings), or extended families (multiple generations). For rare traits such as CVMs, families are ascertained by a proband. Familial sampling depends on the inheritance pattern. A low recurrence risk means that a large number of family members must be sampled to find affected individuals. For CVMs with a modest to high recurrence risk, sequential sampling is effective [15]. In this approach, phenotypic information is collected on all first-degree relatives. If another affected individual is identified within the family, then all of that person's first-degree relatives are phenotyped. Sequential sampling is superior to traditional extended family sampling because it focuses on informative arms of the family.

Because CVMs are rare traits, the classic population-based sampling strategy is *case–control*. In this approach, the researcher recruits individuals with disease (cases) and unrelated individuals without disease (controls). Although this approach appears simple, the challenge is to ensure that the controls come from the same population as the cases and that controls are definitively unaffected. Differences between cases and controls can result in spurious associations. For example, in BAV, the male to female ratio is ~3:1. Thus, in a sample of BAV cases there would be more males than in a random sampling of the general population (male to female ratio ~1:1). For a case–control study of BAV, researchers should ensure that the case and control populations have similar proportions of males to minimize false associations. Further, ensuring that the controls do not have BAV requires echocardiographic assessment.

Methods for genotyping

Completion of the Human Genome Project made it clear that genetic variation is common and occurs on many different scales, ranging from gross karyotype alterations to single nucleotide changes [24,25]. The most common markers for population- and family-based studies are simple sequence tandem repeats (SSTRs, microsatellites) and point changes in nucleotides (single nucleotide polymorphisms, SNPs) (Figure 2.3). SSTRs are useful genetic markers because they tend to be highly polymorphic and therefore segregation of alleles can be traced in families. Current SSTR linkage maps contain approximately 400 markers. Limitations with SSTRs include a relatively high error rate compared with SNPs and lower density. On the other hand, there are over 3 million SNPs in the genome [26], creating data management and computational challenges. Current SNP linkage panels utilize only a fraction of those available (approximately 5000). Although less polymorphic than SSTRs, the number of SNPs available means that the information content can surpass that of SSTRs [27]. Further, the genotyping error rate is much lower in SNPs [28]. Cost and ease of automation have made SNPs the current preference [27].

Statistical approaches to gene discovery

There are two main statistical approaches to gene discovery, *linkage* and *association*. Linkage analysis tests to determine whether a variant segregates with disease in families, whereas association analysis determines whether a genetic variant occurs more often in individuals with disease than without disease. Linkage studies can be performed only in family-based studies, but association testing can be performed in population- or family-based studies. These two approaches may appear to ask the same question, but statistically they are independent tests.

Linkage
Linkage analysis is based on the assumption that the genetic marker and the disease variant are in close proximity and transmitted intact across generations [29]. Thus, markers in close proximity to the disease-causing gene segregate with disease. Evidence of linkage is determined either by consistent transmission of both the disease and the marker from parent to offspring (parametric) or by an increased proportion of alleles shared between affected relative pairs (nonparametric). Parametric linkage analyses are most powerful (e.g., a relatively small sample size can be informative) when the
Figure 2.3 Strategy for continued CVM genetic discovery. Various markers of genetic variation (frameshift, SNP, STR, methylation, CNV) will be used to combine evidence from linkage and association. The genetic and molecular elucidation of CVMs will require complementary statistical approaches to realize discovery.

correct underlying disease inheritance model (e.g., autosomal dominant, X-linked) is specified. Specifying the appropriate model can be challenging as small pedigrees, incomplete penetrance, and complex inheritance may result in the incorrect inference. Non-parametric linkage analyses do not require a genetic model to be specified but are less powerful than a correctly specified parametric model. If the underlying model is complex or unknown, nonparametric methodology is appropriate. Linkage identifies genomic regions (i.e., loci, not genes), which often encompass hundreds of genes. Hence linkage analysis is traditionally coupled with fine mapping to identify individual variants at a particular locus.

Linkage analysis identifies genetic cause of CVMs

In this section, we provide three examples of the successful use of linkage analysis to identify genomic regions harboring rare variants with large effect. In each example, statistical analysis of the linkage data was based on the assumption of simple inheritance. However, mutations identified in all three examples exhibit reduced penetrance and variable expressivity, features typically associated with complex inheritance.

First, use of linkage analysis led to the identification of mutations in TBX5 as the cause of Holt–Oram syndrome (MIM #142900). Holt–Oram syndrome is one of the "heart–hand" syndromes, so called because of the association of skeletal abnormalities in the hand and fore limbs with varied CVMs, typically atrial septal defects. Holt–Oram syndrome is inherited as an autosomal dominant trait; to date, numerous genetic variants in *TBX5*, resulting in loss of function of this T-box transcription factor, have been identified in patients with Holt–Oram syndrome (reviewed in [30]).

Linkage analysis also led to the identification of *PTPN11* as a gene causing Noonan syndrome (MIM #163950), a constellation of findings characterized by cardiac and noncardiac abnormalities. The most common cardiac defects are pulmonary stenosis with a dysplastic valve, secundum atrial septal and atrioventricular septal defects, and/or hypertrophic cardiomyopathy. Noncardiac defects include hypertelorism and short stature. Noonan syndrome is primarily inherited as an autosomal dominant condition; however, inheritance may be heterogeneous. Mutations in *PTPN11* account for approximately 50% of Noonan syndrome patients. Studies of the related Noonan, Costello, and cardio-facio-cutaneous (CFC) syndromes led to a new concept that these clinically related disorders are caused by dysregulation of the RAS/mitogens-activated protein kinase (MAPK) pathway [31].

Linkage analysis was also successful in patients with nonsyndromic CVMs and led to the identification of mutations in the homeobox transcription factor, *NKX2.5* (MIM #600584). Heterozygous *NKX2.5* mutations are fully penetrant but exhibit variable expressivity. Progressive atrioventricular block is common. A variety of CVMs have been observed, and *NKX2.5* mutations account for 2% of all nonsyndromic CVMs. Atrial septal defects are common (~80%), but ventricular septal defects including tetralogy of Fallot and double outlet right ventricles (~30%) are also observed (reviewed in [32]).

In each example, linkage was used to identify a region that contained promising candidate genes. Successful linkage required careful broad definitions of phenotype to determine affected status. For example, identifying Noonan syndrome, rather than a specific CVM, determined affected status, and for *NKX2.5* affected status was determined by finding any

CVM or being the parent and sibling of someone with any CVM. Candidate genes were selected based on biologic insight into their function; mutational analyses of the candidate genes identified rare genetic variants predicted to alter protein function, thus supporting causation. In retrospect, even though the associated traits exhibit characteristics of complex inheritance (variable expressivity, reduced penetrance), the assumption of simple inheritance worked adequately to determine linkage, possibly due to the large size of the genetic effect.

Association

Association studies measure the statistical dependence between two or more variables. For genetic studies, association tests the hypothesis that a genetic variant occurs more or less frequently in individuals with a particular phenotype than without, and can use population- or family-based samples. A challenge for genetic association is the selection of the type of genetic variant to test [26]. The human genome organization facilitates gene localization. Instead of each variant being independent, variants close together are more likely to be inherited together. This nonrandom segregation is known as linkage disequilibrium (LD). There are blocks of high LD conserved within populations [33]. The important implication of LD blocks is that researchers can test a subset of variants for association (known as a tagging approach) and capture nearly full information about untyped common variants [34] but not rare variants [35]. Hence, if a disease is caused by a rare variant, the power to detect association using a tagging SNP approach is low. Taken together, although genetic association studies are well positioned to find common variants for common (high prevalence) traits with small effect, they are not well suited for rare variants that cause rare (low prevalence) diseases [36]. As such, the suitability of association for gene discovery in CVMs is questionable.

Association does not equal causation. Significant associations can be due to one of several misleading factors, including LD, population stratification, or random chance. Although LD can reduce the number of variants tested, it makes identifying the causal variant difficult because the causal variant will be in LD with other variants in the region. Another possible cause of spurious association is population stratification, where cases and controls are not drawn from the same population [37] To account for population stratification, researchers can test whether cases and controls differ over a large number of variants not expected to be associated with disease. If differences exist, adjustments can be made to minimize this effect. Family-based association affords protection against stratification, which is a decided advantage of family-based designs [38]. Random associations may also occur by chance. In traditional statistical testing, biomedical researchers require a p-value of 0.05. For a genome-wide chip, significance thresholds of 10^{-8} are required to control for multiple comparisons [39]. Given this level of significance, the number of samples required to obtain adequate power in a genome-wide association study (GWAS) is in the thousands for a gene with modest effect. Once significance is achieved, replication is required to ensure the validity of the results [39].

To date, a GWAS has not been published for CVMs, perhaps in part because of their rarity. A GWAS has, however, identified genes for QT interval [40] and atrial fibrillation [41]. A common feature of these traits is moderate prevalence. These successes were characterized by variants accounting for a modest proportion of variation and therefore required very large sample sizes to identify these effects. Extrapolating from GWASs performed in other disciplines, rare traits will require large sample sizes, which means that consortia with many participating centers will be required to have sufficient power to identify associations [42]. Even then, the characteristics of previously identified variants and genes for CVM (locus heterogeneity, genetic heterogeneity, rare variants) suggest that GWAS findings will be limited.

Prioritizing statistical approaches

When deciding whether to use linkage or association as a first step, researchers should consider several factors (Table 2.3). First, they need to determine the characteristics of causal genes/variants. Specifically, is the CVM expected to be due to common or rare variants? Although association is a powerful

Table 2.3 Comparison of linkage analysis and association studies.

	Linkage	Association
Sampling	Family based	Families or unrelateds (case–control)
Population stratification adjustment	Matching ethnicity unimportant	Matching ethnicity crucial
Markers required for coverage	Few: 300–400 STRs or 5000 SNPs	Many: 10^5–10^6 SNPs
Localization of region	Good for initial detection	Poor for initial detection
	Poor for fine mapping	Good for fine-mapping
Identification of common variants	Low power	High power
Identification of rare variants	High power	Very low power

method to identify common variants, association studies have low power to detect rare variants. Further, if the researcher expects multiple causal variants within a gene, linkage will be more powerful as it is designed to identify regions and not specific variants. Second, researchers need to determine what types of sampling are available for the disease of interest. For example, when multiple affected family members are not available, linkage is not feasible.

Strategies for finding genes given complex inheritance

Combined linkage-association

Because linkage and association use different information and each method has distinct strengths for gene discovery, combined linkage–association is an excellent approach for discovering CVM genes. A major benefit of linkage analysis is that it can identify regions that harbor susceptibility variants. By performing association in select regions of interest, as opposed to scanning the whole genome, researchers can minimize false positives as fewer variants must be screened. Given the same false-positive rate, the traditional case–control design is more efficient than the family-based design for detecting association. However, the family-based combined linkage–association approach is more powerful because a lower false-positive threshold can be utilized for association analysis as fewer tests are being performed [43]. With combined linkage–association, families responsible for the linkage can be identified and association analyses can be restricted to those individuals most likely affected by that locus.

Gene–gene interactions

Gene–gene interactions have been a common theme for gene discovery of CVMs. For example, the cardiac phenotype of *Nkx2.5* knockout mice differed when placed in different strains, and suggested interaction with other loci to determine phenotype [44].Although a combined linkage–association approach is useful in identifying variants with significant main effects, it will not identify interactions between loci. As secondary loci modify genetic effects [45], interactions should be considered when searching for genes. Both linkage and association analyses can incorporate statistical interactions; however, researchers must recognize that the power to detect these interactions may be low, especially when at least one of the risk variants is of low frequency.

Novel genotyping technology – moving beyond SNPs

In recent years, it has become clear that genetic variation occurs on different scales. Indeed, Mendelian inheritance of CVMs has been attributed to structural variation, such as microdeletion and microduplication, copy number variation (CNV), and also traditional mutations (nonsynonymous, frameshift, and missense). In addition, the genome may be modified by patterns of methylation. Methylation can alter gene transcription without changes to the underlying DNA sequence bed and may explain inconsistent patterns of disease segregation (Figure 2.3). Unfortunately, usually gene discovery projects are limited to genetic variants of a specific type, for example, SNPs, CNV, methylation; analytical methods to evaluate multiple genotyping techniques have been used infrequently. Increasingly, it will be useful to combine evidence from linkage, GWAS associations, and candidate gene associations (Figure 2.3). In addition, approaches such as meta-analyses may be used across multiple domains to reinforce evidence for trait loci qualitatively [46]. Novel analytical methods of this type may be required to dissect the genetics of CVMs.

Causality

Once a statistically significant association has been demonstrated, the next logical question is what the nature of this association is with respect to etiology, that is, causal or probabilistic. Determination of causality is essential in interpreting results of genetic testing. For Mendelian traits, variants are considered causal if they are sufficient (when the variant is present disease occurs). Given the phenomenon of reduced penetrance, a more inclusive definition is that the variant is probabilistic (variant increases the probability of the disease occurring) [47]. Further, determining definitively whether the variant is associated with disease can be a challenge. To demonstrate causality, statistical association should be consistent, specific, and unbiased. Further, evidence of association should be coupled with basic biologic research, for example, *in vitro* biologic (functional) effect. Sometimes the functional effect can be anticipated based on the predicted effect of the genetic variant on protein structure, for example, a nonsense mutation predicted to truncate the protein prematurely. More subtle alterations, however, may require specific assays of protein function, such as enzyme assay or patch clamp study in a heterologous expression system. In addition, with complex inheritance, this biologic evidence may be hard to obtain, as this would require concurrent functional assessment of two or more gene products. In the absence of biologic evidence, data supporting causality include biologic plausibility, coherence with previous knowledge, and experimental evidence [47]. In the postgenomic era, there are many public sources that may provide insight into biologic plausibility, including SNP/gene expression databases, categorization of putative functionality of SNPs, and gene pathway analysis (Table 2.1) [48].

Conclusion

Cardiovascular disease in the young comprises varied phenotypes, including CVMs, cardiomyopathies, vasculopathies, and cardiac arrhythmias. CVMs are a common and clinically important form of pediatric heart disease. Despite advances in diagnosis and therapy, morbidity and mortality of CVM remain significant, and there is considerable interest in understanding the causes of these clinically important birth defects. Although some progress has been made in identifying the genetic origins of CVMs, in most anomalies the cause remains unknown. The frequent observation of genetic heterogeneity, reduced penetrance, and variable expressivity indicates that a single gene does not fully explain inheritance and the occurrence of sporadic anomalies suggests that inheritance is complex. Advances in methodology to determine individual human genetic variations provide an opportunity to revolutionize discovery in individuals with CVMs. Continued genetic discovery of CVM-causing genetic variants poses challenging study design questions and suggests that complementary approaches may be required to realize discovery. Strategies to identify genetic causes of CVMs will require precise phenotype assessment and an emphasis on statistical considerations (study design).

Developmental Physiology of the Circulation

Abraham M. Rudolph

University of California San Francisco, San Francisco, CA, USA

The adult circulation is characterized by series blood flow. Blood is oxygenated in the lungs, returns through the pulmonary veins to the left atrium and ventricle, and is ejected into the arterial system to be distributed to the tissues. At the tissue site, oxygen is extracted for metabolism, and carbon dioxide is taken up by blood, which then returns through the venous system to the right atrium and ventricle, which ejects it into the pulmonary arteries.

In the fetus, oxygen uptake and carbon dioxide elimination occur in the placenta. Oxygenated blood flows to the fetus through the umbilical veins, which connect with the hepatic portal venous system and distribute blood to the liver. The ductus venosus, a connection between the umbilical vein and the inferior vena cava, allows some umbilical venous blood to bypass the hepatic vasculature and enter the central circulation directly. This well-oxygenated blood mixes with poorly oxygenated blood from the gastrointestinal tract in the portal veins or with venous blood from the lower body in the inferior vena cava. Unlike the adult, in whom there is a complete separation of oxygenated blood returning to the left side of the heart from the lungs and poorly oxygenated blood returning to the right side of the heart, there is some admixture in the fetus, and the blood distributed to the tissues is a mixture of well-oxygenated and poorly oxygenated blood.

In the fetus, the lungs do not serve the function of gas exchange as in the adult. Blood flow to the lung is limited by passage of some blood ejected by the right ventricle through the ductus arteriosus, which connects the pulmonary trunk to the descending aorta. A third connection present in the fetus is the foramen ovale, which allows blood to enter the left atrium from the inferior vena cava and right atrium without having to be ejected by the right ventricle through the pulmonary circulation. The importance of these three fetal communications is discussed below.

Course of the fetal circulation

Patterns of flow have been studied in fetal lambs *in utero*, several days after recovery from surgery to insert catheters into limb vessels. Radionuclide-labeled microspheres with different isotopic labels were injected into fetal vessels, and the specific isotopes and also their quantity could be measured in various tissues [1]. From these data, it was possible to calculate not only the patterns but also the magnitude of blood flows in cardiac chambers and major vessels.

Maternal arterial blood entering the uterine circulation has a P_{O_2} of about 100 mmHg and an oxygen saturation close to 100%. Oxygen diffuses across the placental membrane into fetal arterial blood; in the sheep, blood entering the placenta from the umbilical artery has a P_{O_2} of ~20–23 mmHg and an oxygen saturation of ~45–50%. Umbilical venous blood has a P_{O_2} of ~32–36 mmHg and an oxygen saturation of ~80–90%. This high oxygen saturation at a relatively low P_{O_2} is due to the greater affinity of fetal hemoglobin for oxygen compared with that of adult hemoglobin; the P_{50} for fetal hemoglobin is ~25–28 mmHg, compared with 35–38 mmHg in the adult. Umbilical venous blood returns to the fetus through the umbilical vein, which enters the fetal abdomen and courses to the porta hepatis. It provides several branches to supply the left lobe of the liver, after which the ductus venosus arises and passes dorsally and cephalad to connect with the left side of the inferior vena cava just below the diaphragm. The umbilical vein then arches to the right side of the porta hepatis to connect with the portal vein. The portal veins to the right lobe of the liver arise beyond this junction (Figure 3.1a).

Umbilical blood flow averages ~200 ml min⁻¹ kg⁻¹ of fetal weight in the sheep; this represents ~40% of the combined ventricular output (see below). About 50% of the
Figure 3.1 (a) Pattern of blood flow in major fetal veins. The umbilical vein provides branches to the left lobe of the liver; it then gives rise to the ductus venosus and arches to the right to join the portal vein. The ductus venosus blood is joined by left hepatic venous blood and is preferentially distributed through the foramen ovale. Portal venous blood is distributed mainly to the right liver lobe. Distal inferior vena cava blood is joined by right hepatic venous blood and passes preferentially through the tricuspid valve. Almost all superior vena cava blood is directed through the tricuspid valve. IVC, inferior vena cava; LHV, left hepatic vein; RHV, right hepatic vein; SVC, superior vena cava. (b) Blood oxygen saturations in vessels entering and leaving the liver in the fetal lamb. DAo, descending aorta; DV, ductus venosus; IVC, inferior vena cava; LHV, left hepatic vein; P, placenta; PS, portal sinus; PV, portal vein; RHV, right hepatic vein; UV, umbilical vein. umbilical venous blood is distributed to the left and right lobes of the liver, and the other half bypasses the liver through the ductus venosus [2]. Portal venous blood is almost completely distributed to the right lobe of the liver; only 5–10% passes through the ductus venosus, and none enters the left lobe of the liver. Thus, the left lobe of the liver receives almost exclusively well-oxygenated umbilical venous blood, whereas the right lobe receives umbilical venous blood and also most portal venous blood, which has a P_{O_2} of 12–14 mmHg and an oxygen saturation of 20–25%. Because of these flow patterns, left hepatic venous blood has an oxygen saturation of 70–75%, whereas right hepatic venous blood oxygen saturation is 55–65% (Figure 3.1b).

The inferior vena cava just below the diaphragm receives blood from four sources, all with different oxygen saturations, namely umbilical vein, distal inferior vena cava, and left and right hepatic veins. Distal inferior vena cava blood has a P_{O_2} of 12–15 mmHg with an oxygen saturation of 20–28%. The blood flowing from these four veins does not mix completely but shows differential streaming. The ductus venosus and left hepatic vein enter the inferior vena cava through a single orifice, which in the sheep fetus is partly covered by a thin valve-like membrane. The blood from these two veins is well oxygenated, and it streams in the posterior and left portion of the inferior vena cava in the direction of the foramen ovale to enter the left atrium

(Figure 3.1a and b). This valve-like membrane has not been identified in the human fetus. The preferential distribution of ductus venosus blood through the foramen ovale is probably related to the high velocity of blood in the ductus venosus. Color Doppler flow studied in both lamb and human fetuses indicate that the velocity of flow in the distal inferior vena cava is ~15 cm s^{-1}, whereas flow velocity in the ductus venosus is ~55 cm s^{-1}. The poorly oxygenated blood from the right hepatic vein joins blood returning from the distal inferior vena cava, and these flows stream along the anterior and right portions of the inferior vena cava towards the tricuspid valve to enter the right ventricle. Although these are the preferential patterns of flow, some of the blood derived from the ductus venosus does enter the tricuspid valve, and some blood from the distal inferior vena cava crosses the foramen ovale into the left atrium.

Blood returning to the heart through the superior vena cava has a P_{O_2} of 12–15 mmHg and an oxygen saturation of 20–30%. It is deflected by the tubercle of Lower in the right atrium in the direction of the tricuspid valve, and ~95% enters the right ventricle, whereas only ≤5% of superior vena caval blood passes across the foramen ovale into the left atrium.

The preferential streaming of the venous blood returning to the heart results in blood of higher oxygen saturation in the left atrium than in the right ventricle and pulmonary artery. The blood entering the left atrium through the
Figure 3.2 (a) Percentages of the combined ventricular output flowing through the major veins and arteries, and the proportions of blood ejected by each ventricle, are shown for the fetal lamb. (b) Volumes of blood (ml min^{-1} per kg fetal body weight) flowing through the great vessels and cardiac chambers are shown for the fetal lamb heart. (Reproduced with permission from Rudolph AM. *Congenital Diseases of the Heart*. Oxford: Wiley-Blackwell, 2009.)

foramen ovale is joined by pulmonary venous blood. In the fetus, because there is no gas exchange in the lung, the oxygen saturation of pulmonary venous blood (~50%) is slightly lower than that in the pulmonary artery. However, because pulmonary blood flow is low in the fetus and is considerably less than the volume of blood traversing the foramen ovale, the oxygen saturation of mixed blood in the left atrium and left ventricle is only moderately lower than that of ductus venosus blood (left ventricular oxygen saturation of 65–70% versus ductus venosus blood oxygen saturation of 80–90%).

Distribution of cardiac output

In the adult with a series circulation, the cardiac output is defined as the volume of blood ejected by each ventricle. These volumes are essentially similar, although small differences in left and right ventricular output may occur during short periods. The term *cardiac output* represents the volume of blood flow per unit time, through the series circulation.

In the fetus, the blood from umbilical and systemic veins mixes to some extent and enters both the left and right sides of the heart. Blood ejected by each ventricle consists of a mixture of poorly oxygenated and well-oxygenated blood.

The concept of cardiac output used for the adult circulation cannot be applied to the fetus. It has become customary to use the term *combined ventricular output* for the total volume of blood ejected by the fetal heart [3]. Combined ventricular output has been measured most definitively in fetal lambs by use of radionuclide-labeled microspheres or electromagnetic flow transducers placed around the ascending aorta and pulmonary trunk [4]. Measurements in human fetuses have been more limited, but left and right ventricular output measurements have been reported with the use of ultrasound techniques and application of the Doppler principle [5,6].

Figure 3.2a shows the proportions of the combined ventricular output returning to the heart through various veins and the proportions of blood ejected by each ventricle into the central arteries in the fetal lamb. Figure 3.2b presents the volumes of blood flowing through the cardiac chambers and great vessels. Unlike in the adult, the volumes ejected by each ventricle are different. In the fetal lamb, the right ventricle ejects ~65% of combined ventricular output, almost twice as much as the 35% of combined output ejected by the left ventricle. Combined ventricular output is fairly constant in relation to fetal body weight in the last trimester of gestation in the sheep at 450–500 ml kg^{-1} fetal body weight per minute. Hence right ventricular output is ~300–325 ml kg^{-1} min^{-1} and left ventricular output is ~150–175 ml kg^{-1} min^{-1}.

Because pulmonary vascular resistance is high in the fetus, only ~12% of blood ejected into the pulmonary trunk is distributed to the lungs; this represents ~8% of combined ventricular output or ~40 ml kg^{-1} min^{-1}. The remaining 88% of blood ejected by the right ventricle passes through the ductus arteriosus to the descending aorta. Thus, ~57% of combined ventricular output or ~265–285 ml kg^{-1} min^{-1} traverses the ductus arteriosus.

About 70% of the blood ejected by the left ventricle into the ascending aorta is distributed to the coronary circulation, the brain, the tissues of the head and neck, and the forelimbs, whereas only ~30% crosses the aortic isthmus to the descending aorta to join the blood traversing the ductus arteriosus from the pulmonary trunk. Of the 35% of combined ventricular output ejected by the left ventricle, ~22% is distributed to the forelimbs, heart, head, and brain, and only ~10% of combined ventricular output traverses the aortic isthmus to the descending aorta. This represents only ~50 ml/kg body weight per minute. This low flow explains why the aortic isthmus is the narrowest part of the aorta in the term infant and why lesions that alter ascending aortic flow in utero affect the diameter of the aortic isthmus and transverse aortic arch. The left ventricle is filled by blood returning to the left atrium from the pulmonary veins (~8% of the combined ventricular output) and through the foramen ovale (~27% of combined ventricular output).

The descending aortic flow is ~67% of combined ventricular output, or 335 ml min^{-1} kg^{-1}. The umbilical-placental circulation receives ~40% of combined ventricular output, or ~200 ml min^{-1} kg^{-1}. The lower trunk, hind limbs, and abdominal organs receive ~27% of combined ventricular output, or 135 ml min^{-1} kg^{-1}.

Human fetus

The body configuration of the human fetus differs greatly from that of the lamb; the most striking difference is in brain size. Because brain blood supply is derived from branches of the ascending aorta, left ventricular output might be expected be higher in the human.

Measurements of blood flows in various vessels and of left and right ventricular output have been made in human fetuses by ultrasound and the Doppler technique. A wide range of outputs has been reported, but in most studies right ventricular output was only 1.2–1.4 times the left ventricular output, compared with a ratio of 2:1 in the sheep. The combined ventricular output in the human fetus has been reported to be 450–500 ml kg^{-1} min^{-1}, similar to that in the fetal lamb. The greater volume of blood ejected from the left ventricle could be derived either from a higher pulmonary blood flow or by a larger flow across the foramen ovale. Although wide variations in the magnitude of pulmonary blood flows have been reported, several studies have

recorded pulmonary blood flow of 85 –100 ml min^{-1} kg^{-1} of estimated fetal weight [7,8]. This is about twice the pulmonary blood flow in fetal lambs, and it could account for most of the higher left ventricular output in human compared with lamb fetuses.

The higher pulmonary blood flow and left ventricular output in the human fetus are also associated with considerable differences in the proportions of combined ventricular output and in actual blood flows through various vessels and to various organs of the fetus. These differences are summarized in Table 3.1. Of note is the considerably smaller flow from the pulmonary trunk to the descending aorta through the ductus arteriosus and the smaller umbilical blood flow relative to fetal size.

Determinants of cardiac output

Cardiac ventricular output is the product of heart rate and stroke volume. Stroke volume is determined by the force of contraction of the ventricle, which is influenced by preload, afterload, and myocardial contractility. In the intact heart, ventricular volume at end-diastole determines the degree to which the ventricular muscle is stretched and thus the length of the cardiac myocytes and the sarcomeres immediately prior to contraction. This represents preload. The greater the length of the sarcomere, up to an optimal level, immediately before contraction occurs, the greater is the force generated during contraction. An increase in end-diastolic volume enhances the force of ventricular contraction and, in the intact heart, increases the stroke volume in the absence of other changes. Afterload, or load on the heart muscle during development of active force, determines the degree of shortening of the sarcomeres and thus the volume ejected during systole. If the ventricular contractile force is the same, a greater volume will be ejected if afterload is low and stroke volume will be lower if afterload is high. In the intact circulation, afterload is influenced by several factors, such as arterial pressure, compliance of the arterial system, and peripheral vascular resistance. Contractility is the intrinsic force of contraction of the muscle; with isolated muscle, increased contractility increases the force developed and, in the intact heart, increases the stroke volume, or developed pressure (see Chapter 4). In the intact circulation, heart rate, preload, afterload, and contractility are interrelated, and a change in one factor may modify other parameters. Therefore, changes in all factors regulating ejection must be considered when assessing the effects of alteration of one regulatory factor.

Effects of heart rate

In the adult, cardiac output is relatively constant over a wide range of heart rates. The resting heart rate is 70–80 beats min^{-1} (bpm); increasing the heart rate to 150 bpm or

Table 3.1 Comparison of the distribution of blood flows in the sheep and human fetus as percent combined ventricular output (% CVO) and as actual blood flows (ml min^{-1} kg^{-1} fetal weight)[a].

	Sheep		Human	
	% CVO	ml min^{-1} kg^{-1} fetal weight	% CVO	ml min^{-1} kg^{-1} fetal weight
Combined ventricular output	100	450	100	450
Left ventricular output	34.0	150	45.0	202
Aortic isthmus	10.0	45	8.0	36
Brain	3.5	16	24.0	107
Upper trunk, forelimbs	20.5	90	13.0	59
Right ventricular output	66.0	300	55.0	248
Ductus arteriosus	58.0	260	30.0	135
Pulmonary circulation	8.0	36	25.0	113
Descending aorta	68.0	305	38.0	171
Umbilical–placental circulation	40.0	180	26.0	112
Hepatic circulation	18.0	80	14.0	68
Ductus venosus	22.0	100	11.0	44
Lower body organs, hindlimbs	28.0	125	12.0	60
Superior vena cava	24.0	108	37.0	165
Inferior vena cava + umbilical flow	68.0	305	38.0	172
Foramen ovale	25.0	115	20.0	90

[a]The values for sheep were obtained in chronically instrumented fetuses in the latter part of gestation. The values for human fetuses were obtained by ultrasound in the third trimester; in view of the considerable variations in reported measurements, those considered most appropriate have been selected. CVO-combined ventricular output

decreasing it to 50 bpm does not significantly affect cardiac output, because the stroke volume changes appropriately. Cardiac output falls progressively with further increases in heart rate, because the duration of diastole is decreased and there is inadequate filling of the ventricle. As the heart rate falls, the stroke volume is increased to maintain cardiac output, but when maximum diastolic filling has been achieved, further slowing results in a decrease in ventricular output.

In studies in fetal sheep, spontaneous increases in heart rate above the resting level were associated with increases of ventricular output of up to 15–20%, and spontaneous decreases in heart rate resulted in a fall in output. It is not possible to assess whether these changes were directly related to the heart rate changes or whether the factors inducing changes in heart rate could also have altered myocardial contractility or afterload [4]. Increases in heart rate were induced in fetal lambs by electrical pacing of the left or right atrium. Pacing the right atrium at rates of 240–300 bpm induced a small increase in left ventricular output of up to 15%, with no significant change in right ventricular output. At rates above 300–320 bpm, the output of both ventricles fell progressively with increasing rate, probably as a result of inadequate filling time in diastole. Pacing the left atrium resulted in a small increase in right ventricular output, but a

decrease in left ventricular output. This deleterious effect on left ventricular output was shown to result from alteration of left atrial pressure contour, which resulted in interference in filling of the left atrium through the foramen ovale.

Effects of preload and afterload

In the intact circulation, preload and afterload are closely related, because a change in one is likely to affect the other; thus, if the stroke volume of the ventricle during systole is decreased, the residual volume will increase and, if ventricular filling is maintained, preload will be greater with the next beat. The effects of preload on cardiac output have been studied in fetal lambs. In several reports, ventricular end-diastolic or atrial pressures have been used as an index of preload; this may not be a reliable indicator of volume, because ventricular compliance may change. Studies in both isolated myocardium and intact hearts have shown that fetal myocardium is less compliant than that of the adult [9]. In newborn lambs, rapid intravenous infusions of 0.9% NaCl solution elevated atrial pressures and this was associated with a progressive increase in cardiac output as the mean atrial pressures rose to ~15 mmHg [10].

In fetal lambs, atrial pressures were decreased by reducing the blood volume by bleeding, or increased by rapid

intravenous infusion of electrolyte solution [11]. A fall in right atrial pressure resulted in a marked decrease in cardiac output. Output rose when the atrial pressure increased by 2–4 mmHg above resting levels, but further increases in pressure did not result in a greater output by the ventricles. This response is distinctly different from that in postnatal lambs. Based on these studies, it was proposed that the fetal heart is normally operating near the top of its ventricular function curve; the elevation of cardiac output associated with an increase in preload is limited because myocardial performance, or contractility, is relatively poor in the fetus. However, a decrease in atrial pressure reduces preload, resulting in a fall in cardiac output.

In these studies, the effects of rapid infusion of electrolytes on arterial pressure were not taken into consideration. Associated with the infusion, fetal arterial pressure also increased and therefore the afterload on the ventricles changed. We examined the effects of changing preload when the arterial pressure was maintained constant at various levels [12]. An increase in arterial pressure dramatically reduced the left ventricular stroke volume at all levels of mean atrial pressure. At constant arterial pressure levels, progressive elevation of the left atrial pressure increased the left ventricular stroke volume even with atrial pressures of 10–12 mmHg. This study demonstrated that the fetal heart responds to increases in preload by increasing its output. It did not, however, resolve whether the performances of the fetal and adult myocardium are comparable.

Myocardial performance

Studies of isolated myocardium from fetal and adult sheep have demonstrated that fetal myocardium develops less active tension than adult myocardium at similar muscle lengths [9]. Also, the maximum force that can be generated is considerably lower for fetal than for adult myocardium.

Several differences in morphologic and biochemical features of myocardium have been described that could account for the lesser contractility of fetal myocardium. Fetal myocardium contains fewer sarcomeres, or contractile units, in each myocyte. Another factor that may be important is the development of the sarcoplasmic reticulum, which regulates the movement of calcium ions, essential for myocardial contraction. The fetal myocardial sarcoplasmic reticulum is well developed, but the T-tubular system, representing the extension of the sarcoplasmic reticulum to provide closer relations with the contractile elements, is either poorly developed or absent in the immature myocardium. Not only are there structural differences in the sarcoplasmic reticulum, but also in studies with isolated sarcoplasmic reticulum vesicles, calcium uptake was found to be impaired in fetal myocardium [13].

Local release of norepinephrine (noradrenaline) at sympathetic nerve endings is an important mechanism for increasing myocardial contractility. Sympathetic nerve endings are sparse or even absent in fetal myocardium. The abundance of sympathetic nerve endings varies greatly during development in different species. In the guinea pig, myocardial sympathetic innervation is almost fully developed at birth [14], whereas in the rabbit and the rat there is almost no innervation at birth, but it develops within 14–21 days after birth [15]. The sheep fetus has no detectable sympathetic innervation at 75 days (mid-gestation), but innervation begins to appear at 90–100 days, and is abundant but not yet fully developed just before birth [16]. In addition to the difference in sympathetic innervation, β-adrenergic receptor concentration is lower in fetal than in adult myocardium [17]. Although these differences in sympathetic innervation and β-adrenoreceptor concentration may not be important in the resting fetal heart, they could influence the ability to respond to stress.

Regulation of the circulation in the fetus

In the adult, the systemic and pulmonary circulations are separate. The preload and afterload of the right and left ventricles are different, and their stroke volumes could differ. The Frank–Starling mechanism adjusts the outputs of the two ventricles so that over a short period the ventricles eject similar volumes. A reduction in venous return to the right atrium decreases the filling pressure and end-diastolic volume of the right ventricle, resulting in a decrease in stroke volume. Pulmonary blood flow and venous return to the left atrium and ventricle are also reduced and the stroke volume decreases. An increase in systemic arterial pressure decreases left ventricular stroke volume; the end-diastolic volume increases so that, with the next beat, greater force is generated to increase the stroke volume. In the fetus, the large foramen ovale tends to equalize right and left atrial pressures throughout the cardiac cycle. The ductus arteriosus provides a large communication between the aorta and the pulmonary artery, resulting in almost identical pressures in the two vessels. In view of the similar atrial pressures and similar aortic and pulmonary arterial pressures, differences in stroke volumes of the left and right ventricles in the fetal lamb are the result of differences in afterload. The aortic isthmus, which is narrower than the ascending and descending aorta, to some extent functionally separates the upper and lower body circulations. The left ventricle ejects into the ascending aorta and the vessels of the head and neck, a circulation that in the lamb fetus is poorly compliant and has a relatively high vascular resistance. The right ventricle ejects into the pulmonary trunk and directly through the large ductus arteriosus into the descending aorta and its branches. This circulation has a higher compliance and a lower resistance because it includes the umbilical–placental circulation.

Reflex regulation

Chemoreflexes

Previous studies have suggested that aortic and carotid chemoreceptors are relatively inactive in the fetus, but they were performed in anesthetized exteriorized fetal lambs [18]. Aortic chemoreceptors are important in the bradycardic response of the fetus to hypoxia [19]. More recent studies in fetal lambs have shown that chemoreceptors are active, at least in the last third of gestation [20]. Responses to hypoxemia are much greater to carotid than aortic chemoreceptor stimulation [21]. The chemoreceptors are stimulated by hypoxemia, and experimentally can be activated by intravascular injection of small doses of sodium cyanide [22]. The cardiovascular response dominates, with bradycardia and immediate hypotension, but respiratory gasps are noted. The bradycardia can be abolished if the lambs are pretreated with atropine, indicating that the bradycardia is induced by vagus nerve stimulation. Confirmation of the fact that the cyanide response is the result of chemoreceptor stimulation was obtained by demonstrating the loss of the cardiovascular and respiratory responses in fetal lambs after sinoaortic denervation.

In the adult, chemoreceptor stimulation results in reflex peripheral vasoconstriction. It is likely that the peripheral vasoconstriction induced by fetal hypoxemia is largely mediated by chemoreceptor stimulation. From the studies in fetal lambs, it is apparent that their chemoreflex responses are different from those in the adult. The respiratory response in the adult animal dominates, whereas chemoreceptor stimulation in the fetus causes only a minor respiratory response. There is as yet no explanation for this difference in response.

Baroreflexes

In the adult, arterial pressure is maintained over a fairly narrow range through the control of baroreceptors. An increase in arterial pressure stimulates the aortic and carotid baroreceptors, resulting in bradycardia, depression of myocardial contractility, and peripheral vasodilatation. Ablation of aortic and carotid baroreceptors, by bilateral section of the aortic and carotid afferent nerves, results in an initial increase in resting heart rate and arterial pressure, but these soon return to normal levels. However, wide swings of arterial pressure and heart rate occur around the average pressure and rate, in response to stimuli that produce only small changes in the normal animal [23].

Arterial baroreceptors are functional in the fetus relatively early in gestation, but their importance in regulating fetal arterial pressure has been questioned. In fetal lambs, baroreflex sensitivity increases with gestational age from about 80 days' gestation; near term, the bradycardia induced by increased arterial pressure is equal to that observed postnatally. In fetal lambs, sinoaortic denervation results in the same wide variations in heart rate and blood pressure as observed in adult animals [24]. It is therefore apparent that baroreflexes are also important in stabilizing arterial blood pressure in the fetus.

Changes in circulation at birth

Conversion of the fetal to the adult circulation requires eliminating the umbilical–placental circulation, an increase of pulmonary blood flow to a level necessary for adequate gas exchange, and separation of the left and right sides of the heart by closure of fetal channels. The major events occurring at the time of birth include separation of the placental circulation and establishment of rhythmic ventilation. Ventilation comprises two components: physical expansion of the lungs with gas and elimination of fluid in the alveoli, and increase in alveolar oxygen concentration associated with breathing air.

Changes in patterns of blood flow

The changes in circulation at the time of birth normally occur almost simultaneously. It has been difficult to establish the role of individual events in inducing postnatal circulatory adjustments. To examine the contribution of ventilation and elimination of the placental circulation, we chronically instrumented fetal lambs *in utero* with a tracheal tube to ventilate the fetus, a balloon occluder around the umbilical cord, and various intravascular catheters to measure blood flows with radionuclide-labeled microspheres [25,26]. The lungs were ventilated with a gas mixture of 3% oxygen, 5% carbon dioxide, and 92% nitrogen. This did not change the fetal arterial blood P_{O_2} of ~21 mmHg and P_{CO_2} of ~40 mmHg. Rhythmic ventilation resulted in a marked reduction in pulmonary vascular resistance and an increase in pulmonary blood flow (Figure 3.3). Subsequent ventilation with air or oxygen markedly increased systemic arterial P_{O_2}, and the pulmonary blood flow increased further. Individual fetuses showed considerable differences in the increase in pulmonary blood flow resulting from lung expansion alone and ventilation with oxygenation.

During ventilation with 3% oxygen, the proportion of blood ejected by the right ventricle that entered the pulmonary circulation increased, whereas the volume traversing the ductus arteriosus from the pulmonary trunk to the descending aorta fell (Figure 3.4). Although pulmonary vascular resistance fell, there was no significant fall in pulmonary arterial pressure, probably because the ductus arteriosus remained widely patent. The blood flow through the foramen ovale into the left atrium also decreased. Left ventricular output increased and right ventricular output decreased.

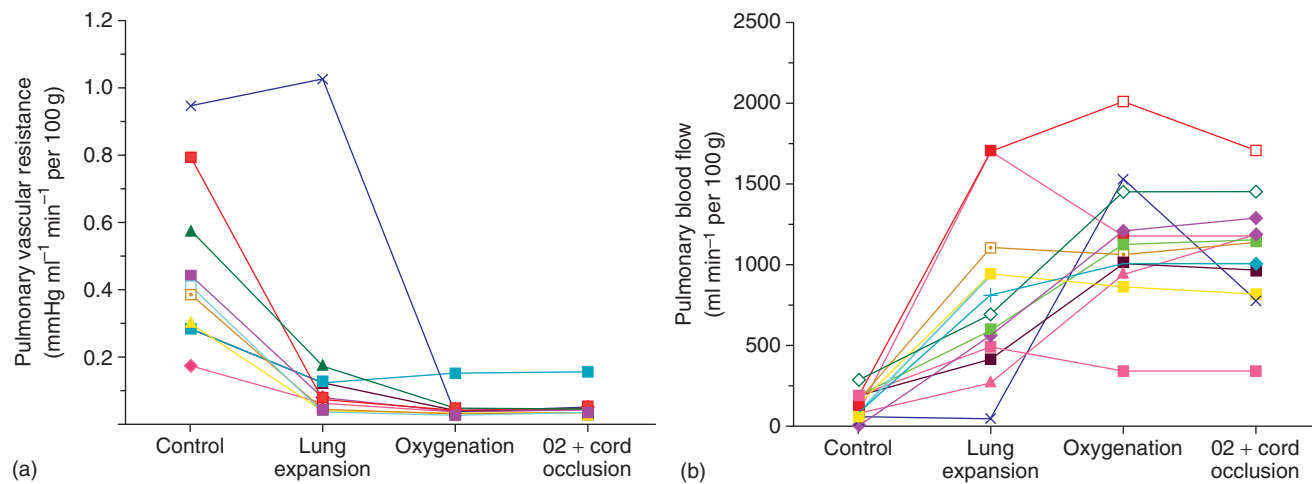
Ventilation with 100% oxygen produced a further fall in pulmonary vascular resistance and, with the greater rise in pulmonary blood flow, flow from the pulmonary trunk through the ductus arteriosus was negligible and there


Figure 3.3 Changes in (a) pulmonary vascular resistance and (b) pulmonary blood flow are shown following physical expansion of the lung, ventilation with oxygen, and umbilical cord occlusion in fetal lambs *in utero*. (Reproduced from Rudolph AM. *Congenital Diseases of the Heart*. Oxford: Wiley-Blackwell, 2009. Original figure reproduced with permission from Teitel *et al.*, *Pediatr Res* 1987;**22**(5):557–66.)

was a small left-to-right shunt from the aorta to the pulmonary artery. Also, flow through the foramen ovale into the left atrium was abolished. The left ventricular output increased and was slightly higher than that of the right ventricle. This was the result of a small left-to-right shunt through the ductus arteriosus. In association with these changes, the left atrial mean pressure increased to levels 2–3 mmHg higher than that in the right atrium. The pulmonary arterial pressure fell slightly in the first few minutes after ventilation with oxygen and subsequently fell slowly. This was probably related to gradual constriction of the ductus arteriosus, leading to separation of the two sides of the heart.

Occlusion of the umbilical cord after ventilation with oxygen produced little further change. The systemic arterial pressure increased slightly and the left-to-right shunt through the ductus arteriosus increased slightly, but no further changes in pulmonary blood flow occurred.

Hence the changes in the circulation after birth can be accounted for largely by the onset of rhythmic ventilation with air. Even without eliminating the placental circulation, ventilation increases pulmonary flow and results in foramen ovale closure, and even though the ductus arteriosus does not close completely immediately after birth, flow from the pulmonary trunk to the aorta is almost completely eliminated.

Removal of the placental circulation abolishes umbilical venous return. Hepatic blood flow is reduced within the first few hours after birth but increases after the portal blood flow is increased in association with feeding. The elimination of umbilical venous blood flow reduces inferior vena caval return by 200 ml min^{-1} kg^{-1}. This facilitates closure of the foramen ovale and causes a small decrease in right atrial pressure.

Changes in pulmonary circulation

During fetal life, pulmonary blood flow is low owing to the high pulmonary vascular resistance. This high resistance is related to both morphologic and functional features of pulmonary vessels. Small pulmonary arteries have a thick medial layer composed predominantly of smooth muscle cells. These vessels are extremely reactive; they constrict markedly with hypoxia and dilate with an increase in P_{O_2}. Endothelial factors, such as endothelium-derived relaxing factor and nitric oxide, have an important role in regulating pulmonary vascular resistance.

The reduction in pulmonary vascular resistance after birth is associated with rhythmic ventilation and oxygenation. The mechanisms by which these events affect the pulmonary vessels have not been fully delineated. Studies in fetal lambs indicate that gaseous expansion of the lungs results in liberation of prostacyclin (prostaglandin I$_2$), a pulmonary vasodilator [27]. A rise in P_{O_2} is thought to increase endothelial release of nitric oxide, which is also a potent vasodilator. Other vasoactive agents, such as endothelin, bradykinin, and angiotensin, possibly also have a role in affecting pulmonary vascular responses after birth. Oxygen-sensitive potassium channels have recently been considered to play an important role in these changes [28]. Physiologic responses of the fetal pulmonary circulation and the mechanisms involved in the postnatal fall in pulmonary vascular resistance are discussed in Chapter 5.

After the immediate fall in pulmonary vascular resistance that follows birth, morphologic changes in the pulmonary vessels result in a permanent fall in pulmonary vascular resistance. The most striking change is a decrease in the thickness of the smooth muscle layer in the small arteries. This results in a gradual further decrease in pulmonary vascular resistance and pulmonary arterial pressure within
Figure 3.4 Effects of simulated birth events on the percentages of combined ventricular output flowing through great vessels and cardiac chambers are shown in late gestation fetal lambs. (a) Control fetal circulation; (b) ventilation (physical expansion of lung with no change of blood gases); (c) ventilation with oxygen; (d) occlusion of umbilical cord. 2–3 weeks after birth. The perinatal changes in morphology of the pulmonary vessels are discussed in Chapter 5.

Closure of the ductus arteriosus

The ductus arteriosus, normally widely patent in the fetus, constricts after birth. The current concept is that two factors are largely responsible for maintaining ductus patency *in utero* – the low oxygen tension of pulmonary arterial blood to which it is exposed, and the effect of circulating prostaglandin (prostaglandin E_2), which relaxes ductus arteriosus smooth muscle. Closure of the ductus after birth occurs at variable times in different species. In the lamb, it is usually closed within 1 h of birth, but in the human, complete closure may be delayed for 10–15 h. Constriction of the ductus arteriosus occurs with increase in arterial P_{O_2} associated with ventilation. After birth, there is a decrease in plasma prostaglandin E_2 concentrations. These two factors are thought to be the important mechanisms responsible for ductus constriction. Recently, oxygen-sensitive potassium channels have been demonstrated to play an important role in the contraction of ductus arteriosus smooth muscle in response to increased oxygen levels [29]. Subsequently, permanent closure of the ductus is achieved by fibrosis. The initial process is thought to be dissolution of normal smooth muscle cells by hypoxia of the muscle associated with constriction. Recently, however, the importance of platelets in effecting permanent closure of the ductus has been considered [30]. The ductus arteriosus is discussed in Chapter 24.

Congenital cardiovascular malformations and the fetal circulation

It has long been recognized that congenital cardiovascular malformations may influence the development of the fetal circulation. In recent years, ultrasound examination has provided the opportunity to assess the changes in circulatory development associated with advancing gestation. It has also become apparent that gestational changes in development and responses of the fetal circulation may affect the influence of various cardiovascular anomalies. The principal mechanisms by which congenital cardiovascular anomalies may affect fetal circulatory development are discussed in this section.
Cardiovascular malformations may

- change the volume or direction of blood flow
- obstruct blood flow
- alter the oxygen saturation of blood delivered to various organs
- cause hydrops fetalis by increasing venous pressure.

Changes in blood flow

Ventricular Development

Interference with blood flow into or out of the left or right ventricle may affect the development of chamber size. It had been suggested that restriction of the foramen ovale or mitral orifice reduces blood flow into the left ventricle and results in hypoplasia as a result of the decreased volume in the chamber [31]. Experimental reduction of inflow of blood into the left ventricle of the fetal lamb for at least several days interferes with growth of the chamber [32].

Postnatally, outflow obstruction of a ventricle reduces the stroke volume, resulting in an increased end-systolic volume, with ventricular enlargement. An increase in atrial and ventricular end-diastolic pressures enhances ventricular contractility; this helps to maintain stroke volume. If obstruction is maintained, hypertrophy ensues but ventricular volume is not significantly different from normal.

In the fetus, obstruction to the outflow of either the left or right ventricle also reduces stroke volume. However, there is no significant increase in either atrial pressure because of the large communication created by the large foramen ovale. Ventricular filling is thus not augmented and the volume ejected by the ventricle is reduced. Ventricular muscle mass increases in response to the increased pressure, but ventricular volume is reduced. The total combined ventricular output may be maintained at normal levels because the volume ejected by the unobstructed ventricle can be increased to compensate for the lower volume ejected by the obstructed chamber. Outflow obstruction of the left ventricle was induced in fetal lambs by placing a constriction around the ascending aorta; this resulted in increased left ventricular muscle mass but a substantial reduction in the size of the left ventricle within just a few days [32]. Ultrasound studies in human fetuses with aortic stenosis show that the left ventricular volume becomes progressively smaller during gestation and may result in hypoplasia of the left heart [33,34].

We produced pulmonary stenosis in fetal lambs at about 60 days' gestation by placing a band around the pulmonary trunk. The lambs were allowed to develop *in utero* and studied at about 120 days' gestation. Right ventricular muscle mass was greatly increased but, in the majority of fetuses, the size of the cavity of the ventricle, and also the diameter of the tricuspid valve, were markedly reduced. These studies confirm that reducing the volume of blood flowing into and out of a ventricle in the fetus resulted in hypoplasia of the chamber.

Ascending aorta and aortic arch development

In fetal lambs, the left ventricle ejects ~33% of combined ventricular output (CVO), and about two-thirds of blood entering the ascending aorta is distributed to the head and upper body. Thus only ~10% of CVO passes through the aortic isthmus. The relatively low blood flow through this segment is reflected by the fact that the isthmus diameter is only half that of the ascending aorta. In the human fetus, the left ventricle ejects ~45% of CVO. The volume passing through the aortic isthmus is not known, but it appears to be similar to that in the lamb and thus accounts for the fact that the isthmus diameter is ~75% of that of the ascending aorta.

The diameter of the ascending aorta is also affected by the volume of blood flowing though it. Thus in the fetus with aortic atresia, no blood enters the aorta from the left ventricle, but flow occurs retrograde from the ductus arteriosus across the arch to the ascending aorta. The flow into the ascending aorta is very low, only that passing to the coronary circulation, hence the marked hypoplasia.

In the fetus with pulmonary atresia, the right ventricle ejects no blood into the pulmonary artery. All blood returning to the right side is directed through the foramen ovale and joins pulmonary venous return to the left atrium. Thus the total CVO is ejected into the ascending aorta. In the lamb, this would represent a flow about three times normal and in the human fetus a flow about twice normal. This high flow is associated with an aortic diameter considerably greater than normal.

Ductus arteriosus size and orientation
In fetal lambs, the ductus arteriosus transports ~60% of CVO from the pulmonary trunk to the descending aorta in the fetal lamb. In the human fetus, ~30% of CVO is estimated to pass through the ductus from the pulmonary trunk to the descending aorta. Because the ductus conducts such a large volume, the diameter is large, being similar to or somewhat greater than the aortic diameter. Also, because all ductus flow is from the pulmonary artery to the descending aorta, the inferior angle between the ductus and the descending aorta is oblique.

When right ventricular output is completely or severely obstructed, as with pulmonary atresia, all blood flow in the pulmonary arteries is derived from the aorta through the ductus arteriosus. The direction of flow in the ductus induces an acute inferior angle between the aorta and the ductus. Also, because the magnitude of flow through the ductus is reduced, it may be smaller in diameter than normal.

With severe reduction of output by the left ventricle, as in fetuses with aortic atresia, the total combined ventricular output passes through the ductus arteriosus to supply the whole body. In this condition, the ascending aorta is considerably smaller than normal, whereas the ductus arteriosus diameter is increased.

Effect of obstruction
The effect of obstruction of left or right ventricular output on blood flow into and out of the ventricle and on the development of chamber size has been discussed above. Two other sites of obstruction that may affect fetal development are in the ductus arteriosus and in the aortic arch proximal to the ductus.

Ductus arteriosus obstruction and the pulmonary circulation
Pulmonary arterial and aortic pressures are similar in the fetus. Studies in fetal lambs have shown that constriction of the ductus arteriosus elevates pulmonary arterial pressure.

This may result from constriction by mechanical means; prolonged compression of the ductus arteriosus in fetal lambs induces an increase in the medial smooth muscle layer of small pulmonary arteries, resulting in increased pulmonary vascular resistance [35]. The increased smooth muscle development may interfere with the normal fall in pulmonary vascular resistance after birth and result in the clinical presentation of persistent pulmonary hypertension of the newborn.

Aortic arch obstruction and cerebral blood flow
In fetuses with aortic atresia, no blood is ejected from the left ventricle into the ascending aorta. Blood flow to the head is derived from blood traversing the ductus arteriosus and then passing retrogradely across the aortic arch to the carotid arteries. Aortic atresia is frequently associated with coarctation of the aorta adjacent to the ductus arteriosus. Infants with aortic atresia have been reported to show a high incidence of neurodevelopmental problems [36] and also cerebral lesions on imaging [37], and reduced cerebral blood flow during fetal life may be responsible [38].

Effects of changes in blood oxygen content
Oxygen saturation of blood in various fetal vessels may be modified by alterations in blood flow patterns resulting from congenital cardiovascular malformations.

Increased oxygen saturation of pulmonary arterial blood
In the normal fetus, well-oxygenated umbilical venous blood passing through the ductus venosus is preferentially directed through the foramen ovale to the left atrium and ventricle, which ejects it into the ascending aorta. However, in the fetus with aortopulmonary transposition, this well-oxygenated blood will be directed into the pulmonary artery, which arises from the left ventricle. The fetal pulmonary circulation is very reactive to changes in oxygen content of perfusing blood; thus, pulmonary vascular resistance may be lowered in fetuses with transposition. This could induce an increase in pulmonary blood flow with a greater than normal pulmonary venous return to the left atrium, resulting in a higher left atrial pressure and a reduction in the size of the foramen ovale. A restricted foramen ovale has been reported in some fetuses with transposition; they are very likely to show rapid clinical deterioration after birth, with severe cyanosis and cardiopulmonary distress [39].

A narrowed ductus arteriosus has also been reported in some fetuses with transposition. This could be related to the increase in pulmonary blood flow, so that only a small proportion of flow from the pulmonary trunk is directed through the ductus. Perhaps more important is that the ductus could be constricted by the high oxygen content of pulmonary arterial blood passing through the ductus to the descending aorta. Constriction of the ductus may result in

elevation of pulmonary arterial pressure that could induce the persistent pulmonary hypertension encountered in some neonates with transposition [40]. These concepts are presented in more detail in Rudolph AM [41].

Decreased oxygen saturation of ascending aortic blood

In the normal fetus, ascending aortic blood is derived from the left ventricle and has an oxygen saturation of ~65%. However, with aortopulmonary transposition, the aorta arises from the right ventricle and ascending aortic blood oxygen saturation will be considerably lower, probably ~45–50%. Whether this lower oxygen saturation will affect the cerebral circulation is open to speculation. Studies in fetal lambs indicated that cerebral vasodilation was able to compensate for arterial hypoxemia, thus increasing cerebral blood flow and maintaining cerebral oxygen consumption [42]. It is possible, however, that if the fetus is subjected to intrauterine stress, oxygen supply to the brain would be more readily compromised than in the normal fetus.

Hydrops fetalis and cardiac failure

The occurrence of fetal hydrops with cardiovascular malformations had been noted, but the frequency with which hydrops resulted from cardiovascular anomalies was emphasized following the introduction of ultrasound examination. The hemodynamic feature common to all instances of hydrops associated with circulatory disturbances is an increase in systemic venous pressure. The congenital cardiac lesions most likely to be associated with hydrops are those resulting in valvar insufficiency, such as Ebstein malformation and atrioventricular septal defect. Myocardial disease is also an important cause of hydrops. Factors favoring the development of edema in the fetus with elevated venous pressure are the greater permeability of the vascular system, the low plasma albumin concentration, with lower plasma colloid osmotic pressure and reduction of lymph flow from tissues. These features are discussed in Rudolph AM [38].

Basic Anatomy and Physiology of the Heart, and Coronary and Peripheral Circulations

Julien I. E. Hoffman

University of California San Francisco, San Francisco, CA, USA

This chapter summarizes the structure, actions, and interactions of components of the cardiovascular system.

Gross anatomy

Aspects of cardiac anatomy are presented in Chapters 20 through 48, but the architecture of ventricular muscle is summarized here. The left ventricle and septum of all mammalian hearts essentially have three layers (Figure 4.1) [1].

The outer subepicardial layer of the free wall and the right side of the septum (light blue) are spirals with an average angle of –60° to the equatorial axis, the middle layer (purple) is approximately in the plane of the equator (0°), and the inner subendocardial layer (red) forms a spiral with an average angle of +60° to the equator. The subendocardial spiral layer forms a right-handed helix and the subepicardial layer a left handed helix [2] (Figure 4.2).

The subendocardial helix of the free LV wall, sometimes called the descending loop, forms a vortex at the apex and continues into the subepicardial helix of the apex and septum, sometimes called the ascending loop (Figure 4.3) [3].

These spiral fibers are shown well in studies using diffusion tensor magnetic resonance imaging (Figure 4.4) [4]

These spirals develop the torsion that is essential for effective ventricular ejection and filling (see below). The 60° angulation is essential for optimal function, and when the ventricle dilates and becomes more globular, the angulation becomes 40–50° and function becomes abnormal. This is the basis of the RESTORE procedure after a myocardial infarction; the infarcted area is excised and the ventricle is changed from a globular to a more elongated form [5]. This remodeling procedure has been extended to hearts dilated from other causes. Details of the anatomy are still debated, but the main features are accepted.

Physiology and pathophysiology

Cardiovascular function is a complex interaction between the heart, an efferent arterial system, and an afferent venous system. The heart is a pump, designed to accept various amounts of venous blood (venous return) and eject a required amount of blood (cardiac output) at a desired pressure. This pump interacts with the arterial system that has compliance, resistance, and inertance. Once the blood passes through the capillaries, it is contained in a capacious venous system whose pressure, as exemplified by central venous or right atrial pressure, is one of the driving forces of the heart pump.

Cardiac function curves

The heart is a pump that responds to increased venous return by dilating and stretching its fibers (increased preload), and this by the Frank–Starling effect produces a greater output. The relationship between preload and output (Figure 4.5) is complicated by the fact that output is affected by the arterial systolic blood pressure, and also by the intrinsic contractility of the heart muscle. The input–output relation shown is therefore an overall description of cardiac function but does not distinguish between its various components.

Attempts made to separate intrinsic contractility, a function of calcium entry into the myofiber or the sensitivity of the myofibrillar apparatus to calcium, from the associated mechanical events are based on the isovolumic period of the cardiac cycle or on ejection indices. Most of them are unsatisfactory [6,7].
Figure 4.1 Cross-section of left ventricle (septum on left) to show three major layers of the wall defined by their fiber angles, as measured by diffusion tensor MRI. Arrow indicates papillary muscle. (Reproduced from Wu *et al.*, *Circulation* 2006;**114**:1036–45, with permission from the American Heart Association.)

Figure 4.2 Right- and left-handed spirals. The right-handed spiral is subendocardial and the left-handed spiral is subepicardial in the free wall and continues on to the right side of the septum. (Reproduced from Sengupta PP, Krishnamoorthy VK, Korinek J, *et al. J Am Soc Echocardiogr.* 2007; **20**:539–51, with permission from the American Society of Echocardiography.)

The isovolumic indices are typified by the V_{max} concept that examined the initial velocity of muscle contracting against zero load [8,9]. Unfortunately, even in isolated muscle strips it was not possible to assess the true index, that of the contractile element alone [10], and its application to the intact heart was even more tenuous. As an alternative, investigators used dP/dt_{max} (the maximal rate of change of ventricular pressure) or dP/dt at a developed ventricular pressure of 40 mmHg. These values, usually measured before the aortic valve opens, are relatively unaffected by changes in preload but are affected by changes in afterload.

Ejection indices, for example, ventricular function, examine the relationship of left ventricular diastolic pressure and stroke work such as the curve shown in Figure 4.5 except that the *y*-axis represents stroke work and not just cardiac output [11]. The curve becomes steeper with increased contractility and less steep if contractility decreases. Because stroke work is the product of flow and pressure, these curves
Figure 4.3 Diagrams of formation of the apical loop. did allow for aortic pressure, but because pressure work uses more energy than volume work, a given product might have different effects on cardiac function depending on the actual pressures and stroke volumes. In addition, end-diastolic pressure is not a good measure of end-diastolic fiber length because fibrosis or altered pericardial or pleural pressures changes their relationship.

A more satisfactory model is the time-varying elastance model of Sagawa [12,13] to explain how the ventricles adjust beat by beat to changes in preload and afterload; elastance = $\Delta P/\Delta V$, that is, the inverse of capacitance. The elastance approach requires simultaneous measurement of ventricular pressure and volume to produce a pressure–volume (PV) loop. Figure 4.6 shows changes in PV loops (a) when venous return increases at constant aortic pressure and (b) when aortic pressure changes at constant venous return.

In Figure 4.6a, each loop shows the phases of pre-ejection pressure increase, ejection with decreased volume, decreased pressure at a constant volume, and then filling. When venous return increases at constant aortic pressure, the ventricle dilates, and the ventricle ejects more blood (Frank–Starling law). The end-systolic pressure–volume point does not change, and the ejection fraction increases. In Figure 4.6b, if aortic pressure increases with constant venous return, the ventricle also dilates, and by virtue of the Frank–Starling law ejects the same amount of blood at a higher pressure. The
Figure 4.5 Function curve relating preload (*CVP*) to cardiac output (Q_c). The solid line is a control state, and the dashed line shows decreased function due to increased aortic pressure, decreased contractility, or reduced distensibility.

different end-systolic pressure–volume points lie on a straight line termed E_{max}. This line intersects the volume axis at V_0, the unstressed volume.

The slope E_{max} is an index of contractility, and it becomes less steep when contractility decreases (Figure 4.7a) and steeper when contractility increases (Figure 4.7b).

In Figure 4.7a, if contractility decreases from disease or decreased β-adrenergic stimulation, the loops are shifted to the right. The increased preload (end-diastolic fiber length) allows the ventricle to eject a normal stroke volume, but now the end-systolic pressure–volume points lie on a less steep E_{max} line. If preload did not increase, (absence of preload reserve [14,15]) then the ventricle would be unable to eject a normal stroke volume. Because of the elasticity of relaxed ventricular muscle, an increased preload produces a raised end-diastolic pressure that rises higher and higher as the ventricle dilates more; in addition, the ejection fraction decreases. In Figure 4.7a, because the E_{max} slope of the diseased heart is relatively flat, a slight reduction in afterload causes a relatively large decrease in end-diastolic pressure. If the stroke volume had been abnormally low because of absence of preload reserve, then reducing afterload would also have increased stroke volume. In Figure 4.7b, the

increased contractility allows the ventricle to eject a normal stroke volume in the face of increasing aortic pressures without such large increases in end-diastolic volume. The E_{max} slope is steeper.

These PV loops are not measured routinely because they are time consuming. They avoid many of the problems of sensitivity to changes in afterload and preload that makes other indexes of contractility unreliable. Glower and colleagues described a similar concept termed preload recruitable stroke work [16,17].

The maximal elastance line is often alinear and can give a negative intercept on the pressure axis [18,19]. To avoid these problems, some investigators use the values of E_{max} in the mid-range of pressures [19].

Ejection fraction and velocity of shortening also help to evaluate ventricular function, but changes in afterload must be accounted for. This can be done in adults and children [20–25] by providing normal data for the relationship between end-systolic wall stress and either velocity of shortening or ejection fraction (Figure 4.8). Because the relationship is not linear, single-point determinations are difficult to interpret [26].

Vascular hydraulics

Peripheral vascular function is characterized by flow acceleration and velocity (fastest in larger vessels), and also by vascular resistance and compliance. Vascular resistance (R) is defined as pressure drop across a vascular bed ($P_1 - P_2$) divided by flow (Q) through the bed. This relation can be further examined by the modified Poiseuille equation:

$$R = \frac{P_1 - P_2}{Q} = \left(\frac{8}{\pi}\right)\left(\frac{l}{kr^4}\right)\eta$$

where η is viscosity, l is the vessel length, r is the vessel radius, and k is the number of vessels. Because the first component $8/\pi$ is constant, and because in the second component length and vessel number are usually constant in any vascular bed at a given age and body size, the main factors

$$V_{cf_c} = -0.0044\ \sigma_{es} + 1.23$$
$$r = -0.84$$
$$n = 118$$

affecting resistance are viscosity (increased by polycythemia, decreased by anemia), and vessel radius. Because of the fourth power function, a small decrease in radius produces a disproportional increase in resistance.

Vascular compliance (C) is given by $C = \Delta V/\Delta P$, where ΔV is the change in volume and ΔP is the change in pressure.

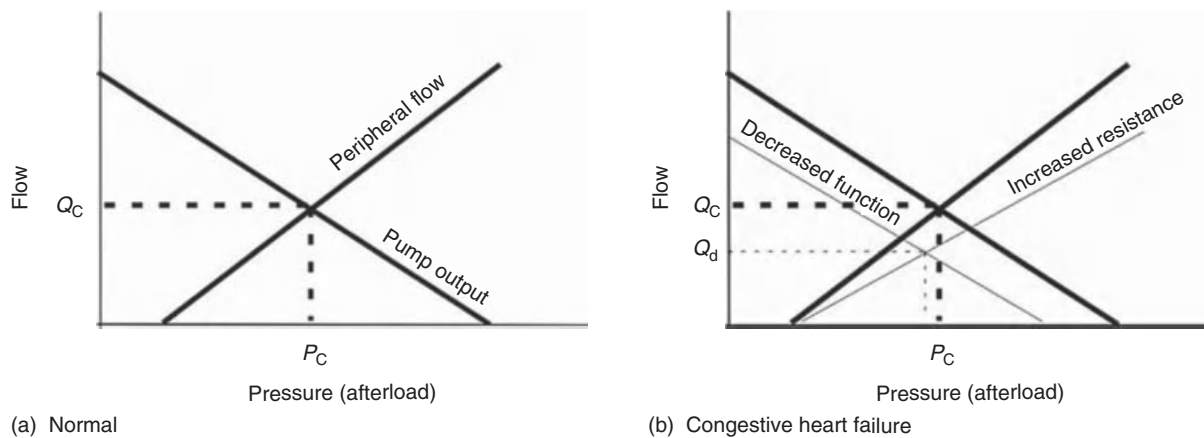
Because an absolute volume change does not have the same meaning for a small than a large structure, specific compliance is calculated by dividing by the baseline volume. Therefore, specific compliance is $C = \Delta V/V\Delta P$. Because veins have thinner walls and are about 20-fold more distensible than arteries, most of the blood volume is in the venous system.
Figure 4.9 Effective arterial elastance (E_a) shown by diagonal dashed lines passing from end-diastolic to end-systolic points. The slope of this line is $\Delta P/\Delta V$, that is, the inverse of capacitance. (a) Change in PV loop at constant E_{max} does not change E_a. (b) Increased elastance – or decreased compliance – (thin dashed line) reduces stroke volume at a given pressure.


Figure 4.10 Cardiac and arterial response to aortic pressure loading. Q_c, control output; P_c, control arterial pressure; Q_d, disease output. The line showing peripheral flow is equivalent to the line showing effective arterial elastance as described above. Thick lines, control lines; thin lines, effect of disease.

Sunagawa *et al.* [27] showed that an effective arterial elastance ($\Delta P/\Delta V$) could be calculated from the pressure–volume loop as end-systolic pressure/stroke volume, as shown in the pressure–volume diagram in Figure 4.9. They showed that arterial peripheral resistance was more important than arterial compliance in changing effective elastance.

Cardiovascular coupling

The heart pumps blood into the arteries and receives blood from the veins, and all three components interact. If we disconnected (uncoupled) the heart from the rest of the circulation we could consider each component separately. Increasing the load against which the left ventricle pumps causes the output to decrease, and eventually the heart cannot eject. If we connect a mechanical pump to the aorta and change perfusing pressure, the higher the pressure, the greater is the flow through the system. For simplicity, both relationships are shown in Figure 4.10 as linear.

In the intact circulation, aortic pressure is an afterload for the ventricle and a pressure that pushes blood around the body; cardiac output and peripheral flow will be equal and

occur where the two pressure-flow lines intersect (Figure 4.10a). In disease, the heart can pump less blood at any given pressure, and peripheral resistance is usually elevated, so that the two function lines cross at a markedly reduced stroke volume, even though the arterial pressure may be fairly normal (Figure 4.10b). Therefore, treatment to reduce afterload or increase inotropy, or both, will raise the crossover point and increase stroke volume.

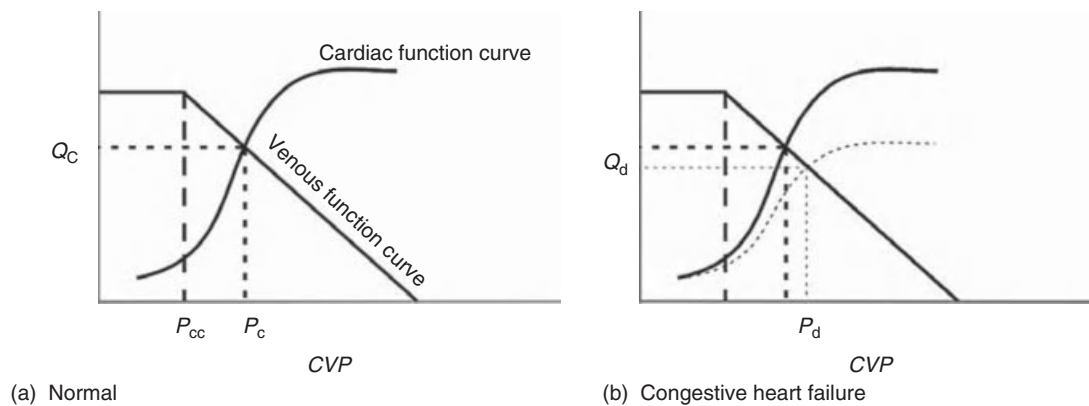
Now consider replacing the heart by a pump to move blood from the venous to the arterial systems (equivalent to the cardiac output); as the pump speed increases, blood is moved from the venous to the arterial side and venous pressure decreases. Eventually so much blood is transferred out of the veins that they collapse and no more blood can be moved. The pressure at which this occurs is termed the critical closing pressure. If the pump slows, more blood remains in the veins, and venous pressure increases. However, with the heart in place, an increased venous pressure causes an increase in cardiac output (Frank–Starling law). These two curves, the vascular and cardiac function curves, are shown in Figure 4.11.


Figure 4.11 Cardiac function curve and vascular function curve relating central venous pressure (*CVP*) to cardiac output (*Q*). P_c, control venous pressure; Q_c, control, cardiac output; P_{cc}, critical closing pressure; P_d, venous pressure with congestive heart failure. (a) Normal (all thick lines) and (b) decreased cardiac function (light dashed lines).
Figure 4.12 Effects of increased or decreased blood volume.

To study venous coupling in more detail, note that increases in atrial or cardiovascular pressure cause a large increase in output at first (preload effect), and then subsequently output rises less markedly because preload reserve is used up; sarcomeres have reached or passed their optimal lengths (Figure 4.11). For small increases in atrial pressure, the venous return does not change, because the atrial pressure is below critical closing pressure, but after atrial pressures of about 10–12 mmHg the venous return decreases more or less linearly as atrial pressures increase. The point at which these two curves cross is the operating point for the normal circulation; this is normally near the plateau of the venous return curve (Figure 4.11a). In the normal heart, decreasing venous return decreases cardiac output, as occurs in the brief hypotension when a person suddenly stands up. In other words, cardiac output is normally limited by venous return and not by cardiac performance. In congestive heart failure, however, the venous system is overfilled and at high pressure. The cross-over point occurs on the sloping portion of the venous

return curve because cardiac output is now determined by the depressed cardiac function and is low, and because venous pressure is high, cardiac function is not limited by venous return (Figure 4.11b).

These function curves may also be altered by changes in blood volume (Figure 4.12). In Figure 4.12a, an increased blood volume (upper thin line) moves the crossing point up and to the right, so that cardiac output and *CVP* increase even though contractility is constant (thin long dashed lines). A decreased blood volume (lower thin line) lowers cardiac output and *CVP* at constant contractility. Figure 4.12b shows what occurs commonly in congestive heart failure, namely blood volume is increased, as is *CVP*, but the cardiac output is reduced. Then reducing blood volume (by diuretics, for example) shifts the crossing point to a higher cardiac output and a lower *CVP* without any change in contractility.

Pericardial function

The parietal pericardium is a stiff membrane that surrounds the heart loosely, separated from it by a small amount of
Figure 4.13 Effect of positive airway pressure on cardiac output in humans. Paw-mean airway pressure (mmHg). Percentage change compared with normal breathing. Three airway pressure curves are shown, differing in peak airway pressure and relative durations of inspiration and expiration. The effects on cardiac output are shown to the right of each curve. (Reproduced from Cournand *et al. Am J Physiol* 1947;**152**:162–74, with permission from the American Physiological Society.)

lubricating pericardial fluid. Normally, it does not affect ventricular filling and emptying. Intrapericardial fluid pressure is negative if measured by a catheter, reflecting the negative intrapleural pressure. On the other hand, the pericardium exerts a surface pressure on the heart; if the pericardium had holes in it, fluid would leak out and there would be no fluid pressure, but the heart could still be compressed, just like a fish caught in a net. This surface pressure is different in various regions, but in general is similar to right atrial pressure [28–30]. Therefore, transmural diastolic pressure across the wall of the left ventricle is not the same as left ventricular diastolic ventricular pressure, and can be estimated by subtracting right atrial from left ventricular pressure. The pericardium can tense and restrict left ventricular dilatation if there is a tense pericardial effusion (tamponade) [31] or if the ventricles enlarge because of a sudden volume load or sudden myocardial depression [32,33]. In some patients with acute myocardial ischemia, left ventricular diastolic pressure can be greatly increased without much change in ventricular volume because of tension in the pericardium. This mechanism makes it difficult to interpret changes in diastolic pressure–volume relations only in terms of myocardial stiffness [29,32,34–36].

Interaction between the ventricles

Ventricular interaction occurs in two ways. If right ventricular output decreases, filling of the left ventricle that is in series with the right ventricle is reduced so that left ventricular output decreases. Second, the left and right ventricles interact because they share the ventricular septum and are both contained by a relatively rigid pericardium. Consequently, right

ventricular distention, as in acute pulmonary embolism or congestive heart failure, pushes the septum to the left, thereby decreasing left ventricular volume and preload [37,38]. Sudden volume infusion may produce similar changes [39]. The resulting decrease in cardiac output should not be taken to indicate left ventricular dysfunction [28,38,40–42]. Volume unloading of the right ventricle under these circumstances will paradoxically increase left ventricular volume and function [43].

Cardiopulmonary interaction

The effects of pericardial restraint and ventricular interaction are important during positive pressure ventilation [44–46]. With a normal circulation, increased intrathoracic pressure with positive pressure inspiration (PPV or PEEP) reduces venous return to the right atrium, and by raising pulmonary vascular resistance may also increase right ventricular afterload [47]. Both of these actions decrease right ventricular output and therefore also reduce left ventricular output. PPV or PEEP therefore decreases transmural pressures, end-diastolic volumes, and stroke work of both ventricles. This was well shown in humans by Jellinek *et al.* [48], who noted that cardiac output was decreased by ~30% for a 10 mmHg increase in right atrial pressure secondary to positive pressure ventilation.

The reverse occurs when PPV or PPEP is lowered ("expiration"), and the net effect on the circulation depends on the ratio of inspiration to expiration [49] (Figure 4.13).

The degree to which increased airway pressure affects cardiac output depends greatly on lung compliance [48], because a stiffer lung allows less transmission of airway

(a)

(b)

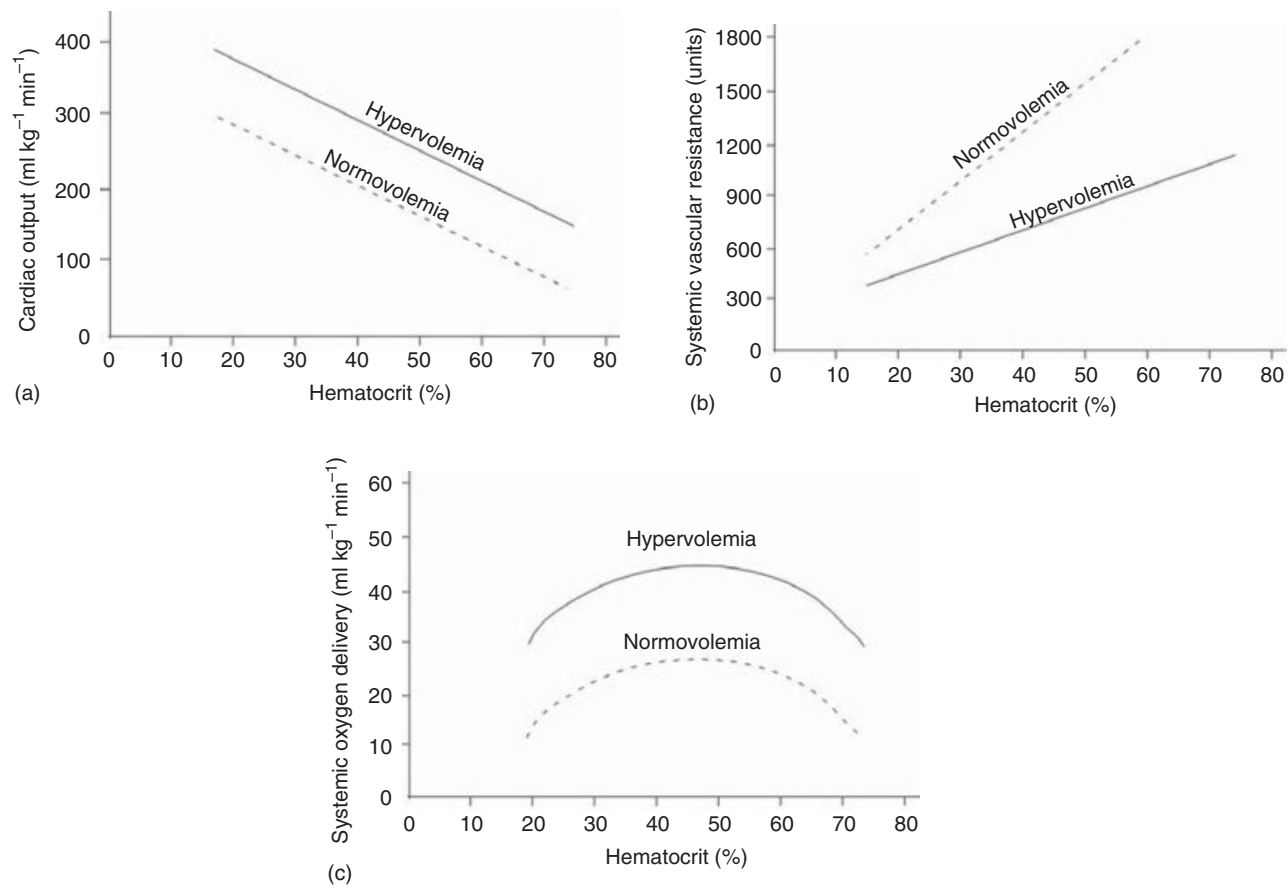
(c)


Figure 4.14 Relationships between hematocrit, cardiac output, blood volume, systemic vascular resistance, and systemic oxygen delivery. (a) As hematocrit increases, cardiac output decreases at any blood volume, but at a given hematocrit cardiac output is higher at higher blood volumes. (b) As hematocrit increases, so does systemic vascular resistance, but the resistance is lower with hypervolemia because the vessels are more dilated. Both of these panels show lines that are approximately linear, although linearity in the original data was less in (b) than in (a). (c) Systemic oxygen delivery as the product of two roughly linear relationships shows a second-order, that is, parabolic relationship to hematocrit at any blood volume. (Based on figures of Murray *et al. J Clin Invest* 1963;**42**:1150–9.)

pressure to the pericardiac region. Fuhrman [50] described the relationship of positive airway pressure to cardiovascular function as preload dependence and emphasized that the effects were exaggerated by hypovolemia.

In congestive heart failure, however, where pericardial restraint regulates total cardiac volume, increased intrathoracic pressure decreases right ventricular transmural pressure, filling, and volume, resulting in an increased left ventricular transmural pressure, end-diastolic volume, and stroke work via the Frank–Starling relationship.

Systemic oxygen delivery

Delivery of oxygen to tissues is measured by calculating systemic oxygen delivery (or transport), the product of arterial oxygen content and cardiac output. Systemic oxygen delivery is greatly influenced by hemoglobin concentration and blood volume. Patients who have heart disease frequently have anemia or polycythemia, and may have altered blood volumes. In an elegant series of experiments,

Murray and colleagues [51–55] examined factors that influence systemic oxygen delivery. Their results are summarized in Figure 4.14.

The peak of the inverted U is broad, but centered approximately at the normal hematocrit. (This centering occurs in species that have different normal hematocrits.) The curved relationship means that at low hematocrits cardiac output is increased, but not enough to compensate for the reduced amount of arterial oxygen per milliliter, and at high hematocrits the increased amount of arterial oxygen per milliliter does not compensate for the effect of increased blood viscosity in decreasing cardiac output.

To determine if systemic oxygen delivery is sufficient for tissue metabolism, we can measure mixed venous oxygen saturation to find out if oxygen extraction has increased beyond normal values, a technique often used in the intensive care unit, or can measure the lactate:pyruvate ratio that rises once systemic oxygen delivery decreases below a critical value [56]. Note that global measurements of mixed venous
Figure 4.15 Traditional diagram of events during the cardiac cycle. (Reproduced with permission from Buckberg *et al.*, *Circulation*. 2008; **118**:2571–87.)

oxygen saturation and lactate:pyruvate ratio may be normal in the face of localized ischemia of one organ system.

Ventricular mechanics

The pressure–volume loops described above have the disadvantage that they lump all ventricular muscle into a single amorphous structure. In fact, the ventricle has a complex architecture, and this is beginning to be incorporated into physiologic understanding. The spiral muscle bands are involved in torsion of the ventricle that is essential for normal contraction. Details of ventricular contraction and relaxation are still being worked out (for reviews, see [2,57–59]), but basically the following sequence occurs (Figure 4.15).

At the onset of systole, during the isovolumic (pre-ejection period), the left ventricle narrows and lengthens, and then during ejection it continues to narrow and becomes shorter. When the aortic valve closes, in the isovolumic (pre-filling period), the ventricle lengthens, and then widens as blood fills it in later diastole. To this accepted description we now have to add information about torsion. If we look up at the heart from the patient's feet, we will notice that the left ventricle rotates around an axis passing from the apex to the middle of the aortic valve (Figure 4.16).

As shown in Figure 4.16, at the onset of the QRS complex the whole heart rotates slightly clockwise for a few milliseconds, then counter-clockwise for a few more milliseconds, after which the apex and base rotate in opposite directions; rotation in opposite directions is the definition of torsion. Note that there is more rotation of the free apex than the tethered base. During systolic torsion, the apex continues to rotate counter-clockwise but the base rotates clockwise,
Figure 4.16 Torsion during the cardiac cycle. Clockwise rotation below the zero line, counter-clockwise rotation above it. (Reproduced with permission from Buckberg *et al.*, *Circulation*. 2008;**118**:2571–87.)

produces an action just like wringing water out of a wet towel; if there were no torsion, ejection would be inadequate. Then, once the aortic valve has closed, there is a rapid untwisting, most marked at the apex, and it is this rapid untwisting that generates a negative pressure within the ventricular cavity and enables rapid filling of the ventricle once the mitral valve opens.

The degree and velocity of torsion increase with age [60]. Torsion increases strikingly in rate and magnitude with exercise or adrenergic stimulation, and this helps rapid filling during the shortened systolic interval that accompanies tachycardia. Torsion decreases with adrenergic blockade [59,61]. Abnormal torsion may be the earliest sign of diastolic dysfunction, as shown by Stuber *et al.* [62], who compared normal subjects, athletes with left ventricular

hypertrophy, and patients with aortic stenosis. The normal subjects and athletes had almost identical torsion. The patients with aortic stenosis, however, had torsion that although greater in magnitude was unduly prolonged, so that it delayed untwisting during early diastole.

Coronary pathophysiology

Myocardial energetics

The heart requires an enormous amount of oxygen per gram per minute. At rest it uses 8–10 ml of oxygen per 100 g of tissue per minute, and 60–80 ml per 100 g min^{-1} at maximal exercise [63]. The oxygen is used to fuel the ATP cycle, the main substrates being fatty acids and glucose that are moved into the mitochondria [64–66]. Preferentially the heart gets its energy by β-oxidation of long-chain fatty acids that require carnitine to cross the mitochondrial outer and inner membranes and also to transport potentially toxic acylcarnitine esters of CoA out of the mitochondria. In infants, who have low quantities of carntine palmitoyl transferase, short-chain fatty acids are preferred [67,68]. During oxygen deprivation, the heart can turn to glycolysis, but the metabolic products that accumulate soon inhibit function and decrease contractility. Carnitine deficiency is most often inherited [69], but can occur in preterm infants [70], chronic congestive heart failure [71,72], end-stage renal failure [73], and a variety of diseases and drug exposures [74–76].

Determinants of myocardial oxygen consumption

The main determinant of myocardial oxygen consumption is peak wall stress [77–80]. An earlier index, the tension–time index (TTI) that measured the area under the left ventricular pressure curve [81], is less satisfactory because the true afterload of the left ventricle is not aortic pressure but wall stress. In an isolated muscle strip, the afterload is the force that the strip exerts in lifting a weight during contraction, but in the intact heart the best equivalent is wall stress and not arterial pressure. Based on the LaPlace law (wall stress = $Pr/2h$, where P is pressure, r is radius, and h is wall thickness), wall stress in an irregularly shaped left ventricle can be approximated by an equation derived developed by Grossman *et al.* [82]:

$$Wall\ stress = \frac{Pr}{2h}\left[\frac{1.35}{1+\frac{h}{r}}\right]$$

Therefore, if the ventricle dilates, the radius increases, the wall thins, and stress rises markedly.

Other factors that also affect myocardial oxygen consumption are stroke volume [83–87], which involves shortening of fibers, and also contractility. The best way of incorporating all of these factors is to use the pressure–volume diagram of Suga [88,89] (Figure 4.17). These components of oxygen

usage are a function of ATP breakdown and re-formation, and also calcium cycling, and were discussed in detail by Suga [88,89].

Myocardial blood flow

Definitions, units of measurement

Coronary blood flow (flow passing through the coronary arteries) and *myocardial flow* (flow entering the myocardium) are normally similar, except for a small amount of myocardial flow that comes from pericardial and mediastinal vessels. In coronary–cameral or coronary–pulmonary arterial fistulas, not all the flow entering the coronary arteries goes into the myocardium.

Myocardial oxygen consumption or uptake is the amount of oxygen used by the myocardium. It may be measured in units of milliliters or micromoles of oxygen per beat or per minute for the whole heart, the left ventricle, or per unit mass of tissue (per gram or 100 g). *Myocardial oxygen demand* is the amount of oxygen that the heart needs. Normally, myocardial oxygen consumption and demand are equal as long as myocardial oxygen supply is unrestricted, but if supply falls below demand, there will be *myocardial ischemia*. The definition of ischemia has been defined in many ways [90]. In general, ischemia represents an imbalance between oxygen supply and demand that leads to impaired myocardial oxidative metabolism and function. The impairment may be transient, causing stunning or hibernation, or permanent. If ischemia lasts more than several hours, cells die and are replaced by scar tissue.

Basic flow mechanisms

The heart has an enormous demand for oxygen at rest and on exercise (Figure 4.18).

Heart data are for the left ventricle based on sampling blood from the coronary sinus, and we know little about regional myocardial oxygen consumption in ventricles or atria, or different layers of the left ventricle. Because of its lower systolic pressure, the right ventricle normally has less oxygen consumption than the left ventricle, but the two ventricles are more alike when there is right ventricular hypertension and hypertrophy. One study [91] observed slightly greater oxygen extraction and oxygen consumption in the left ventricular subendocardial muscle than in the midwall or the subepicardial muscle. This may reflect the greater shortening and intramyocardial systolic pressure generated by the subendocardial layer during systole [92].

Flow per 100 g to the normal right ventricular myocardium is about 50–67% of that of the left ventricle [93]. The ventricular septum, although usually contracting as part of the left ventricle, has flow characteristics of both ventricles. The left side of the septum behaves like the left ventricular free wall, particularly its subendocardial region, whereas the right part of the septum has flows similar to those in the right ventricular free wall [94].

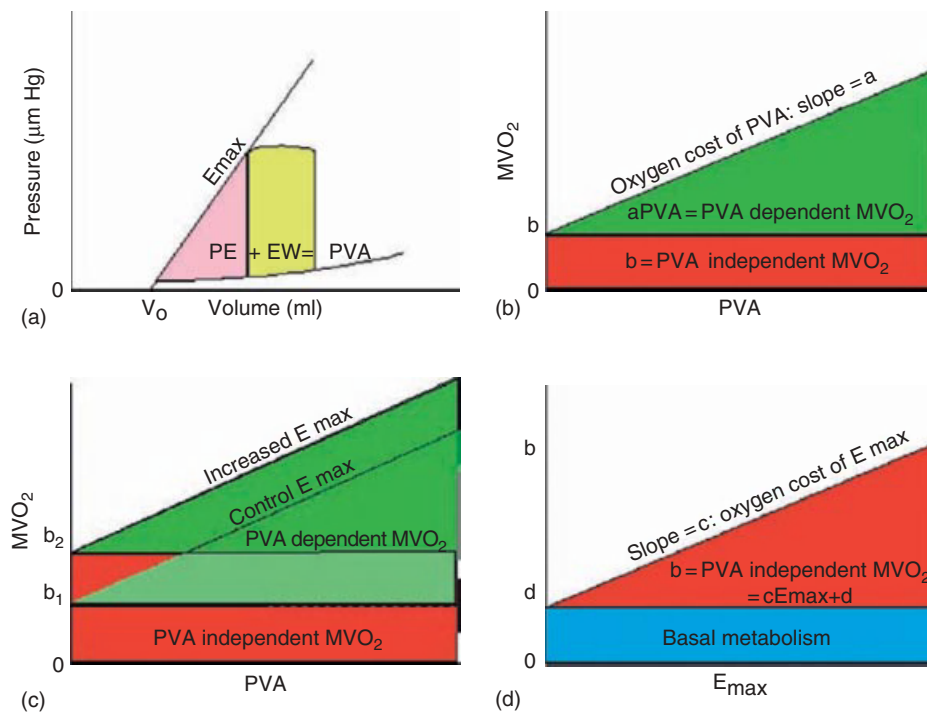
55


Figure 4.17 (a) The *PV* loop (*EW*) represents external work. The shaded triangular area (*PE*) represents elastic potential energy. The two areas combined make up *PVA* (pressure–volume area) that represents the total mechanical energy. (b) If *PVA* is changed and MVO_2 is measured, the relationship is a straight line with the equation $MVO_2 = aPVA + b$; *b* is the intercept on the *y*-axis, and the area between *b* and the zero baseline is independent of changes in E_{max}. The triangular shaded area above line *b* is the *PVA*-dependent MVO_2. Therefore, with increased *PVA* (equivalent to increased stroke work), MVO_2 also increases, with part of the increase proportional to the increase in *PVA* and another part that is independent of it. Panel (c) shows what happens if contractility and therefore E_{max} increase. The *PVA*-dependent portion of MVO_2 does not change (see triangle between dashed lines), but the independent part that represents basal metabolism has increased, thus accounting for the increased MVO_2. Panel (d) shows a different relationship, that between E_{max} and the value of *b*, the *PVA*-independent MVO_2. This quantity is composed of two parts. One is the basal metabolism (the hatched area below *d*) and is constant. (About 15% of total MVO_2 is used for basal metabolism – protein synthesis, transport of sodium and potassium – and about 10% in activation, related to Na⁺,K⁺-ATPase and Ca^{2+}-ATPase.) The other part that varies is the shaded triangular area above line *d*. This area represents the MVO_2 that is independent of PVA but dependent on E_{max} or, in other words, contractility. Therefore, MVO_2 is a function of basal metabolism (fixed), contractility (variable), and *PVA* that can also vary with the workload.

Flows in ventricular walls are inhomogeneous. If the left ventricular free wall is cut into concentric layers, flows tend to be less in the outermost third or quarter (subepicardial muscle) than the innermost third or quarter (subendocardial muscle), particularly in conscious animals [93]. Therefore, the LV inner:outer (or subendocardial:subepicardial) ratio of flows per gram may normally be 1.2–1.4. In addition to this regional layer inhomogeneity, there is considerable small-scale inhomogeneity within each layer [95,96]. In the right ventricle, the inner:outer flow ratio per gram is usually close to 1 [93].

What determines the regional distribution of myocardial blood flow? For a given coronary arterial pressure, flow depends upon the vascular resistance; the lower the resistance, the higher is the flow. In any region of the ventricle, there are three resistances to consider [95,97]. The first is the minimal resistance (R_{min}) of the vascular bed when it is maximally dilated and the heart is not contracting (long diastole, cardioplegia). The second is the added resistance ($R_{beating}$)

imposed when the heart beats and compresses the vessels. Finally, when the vessels have tone, this superimposes another resistance, R_{tone}.

R_{min} is lower in left ventricular subendocardium than subepicardium, so that in the arrested heart with maximally dilated vessels subendocardial flow is much greater than subepicardial flow [93,98]; the inner:outer flow ratio may be 2 or more. Within any layer, however, there is great variability of flow [95,96], presumably due to differences in the resistances of the vascular pathways to small regions of the ventricular wall. The flow patterns are not completely random. Regions with high or low flows surround other regions with high or low flows, respectively; the diameters of regions with similar flows are about 5–9 mm in the canine left ventricle.

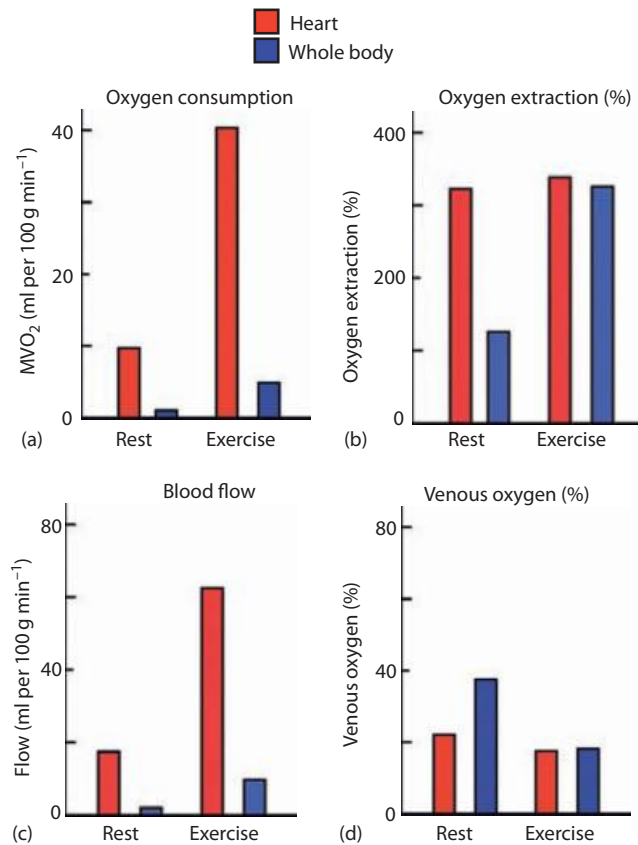
$R_{beating}$: with increasing heart rate, subendocardial flow per minute per gram decreases roughly linearly [99]. Because of the high intramyocardial pressures in the subendocardium in systole, there is probably no systolic perfusion of the


Figure 4.18 Oxygen consumption and flow at rest and severe exercise. Comparison of heart and whole body made with the same units for each. Drawn from data in humans studied by Kitamura *et al.* [12]. (a) Although the whole body's oxygen consumption increases with severe exercise, the usage per 100 g is still only about 10% of the heart's usage. (b) The high left ventricular MVO_2 is associated with a high oxygen extraction at rest, and although a little more oxygen can be extracted to meet increased oxygen demands, as with severe exercise, this amount is limited by the hemoglobin oxygen dissociation curve if tissue hypoxia is to be avoided. Therefore, the only way for the myocardium to obtain more oxygen is to increase flow. (c) The increased flow needed for maximal MVO_2 is shown. (d) During maximal exercise, the venous oxygen saturation of the body decreases to that seen normally in the coronary sinus.

subendocardial muscle. As heart rate increases, the duration of diastole per minute decreases, and therefore so does subendocardial blood flow. On the other hand, when the heart beats, subepicardial flow exceeds the flow in the arrested heart [100], for complex reasons. There are no high systolic intramyocardial pressures in the subepicardium, so that no obstruction to forward flow occurs in this region in systole or diastole. Studies performed with tiny flow transducers placed on small coronary arteries just before they enter the myocardium [100,101] have shown little, if any, forward flow in systole, particularly if contractility is increased. Therefore, although 20–25% of the coronary flow enters the origins of the left coronary arteries in systole, most or all of this merely

distends the extramural arteries and is stored there. On the other hand, microscopy of the superficial subepicardial vessels in the beating heart has shown continuous forward flow throughout the cardiac cycle [102]. The conclusion is that almost no flow enters the myocardium from the extramural vessels in systole, and that systolic subepicardial forward flow comes from blood squeezed retrograde from the subepicardial vessels [100]. These conclusions have been confirmed by direct observation of the intramyocardial vessels [103–105].

R_{tone}: when tone is added to the vessels, the flows are lower than when the vessels are maximally dilated. There is still great heterogeneity of flow, even within a layer, but no correlation exists between flows in the beating heart with and without vascular tone. The inner:outer flow ratio per gram remains about 1–1.4, but in small regions flows are determined primarily by local metabolic demands rather than by intramyocardial pressures or static minimal vascular resistances.

Autoregulation

Normally each region of the heart regulates flow to match its metabolic needs. This can be studied by cannulating the left coronary artery so that its perfusing pressure can be raised or lowered without altering left ventricular pressure or heart rate, and thus without altering myocardial oxygen consumption. When pressure is raised, flow immediately rises but then over 20–30 s returns to near its control value because the vessels constrict. When pressure is lowered, flow immediately decreases but then gradually returns to near normal because the vessels dilate. At high pressures (over about 120 mmHg mean perfusing pressure in acute studies), the flows increase persistently, presumably because high pressure has overcome vasoconstriction. Below a pressure of about 60–70 mmHg in anesthetized dogs and about 40 mmHg in conscious dogs [106], flow begins to decrease, because some vessels cannot dilate further and so can no longer compensate for a reduced perfusion pressure. These vessels are then pressure dependent, and in them any fall in pressure decreases flow, or any increase in myocardial oxygen demand at a constant pressure cannot be met by an increased flow. In either event, ischemia will occur in the territory supplied by those vessels.

The mechanisms underlying autoregulation are not fully understood, and probably involve both myogenic and chemical regulation [107].

Metabolic regulation

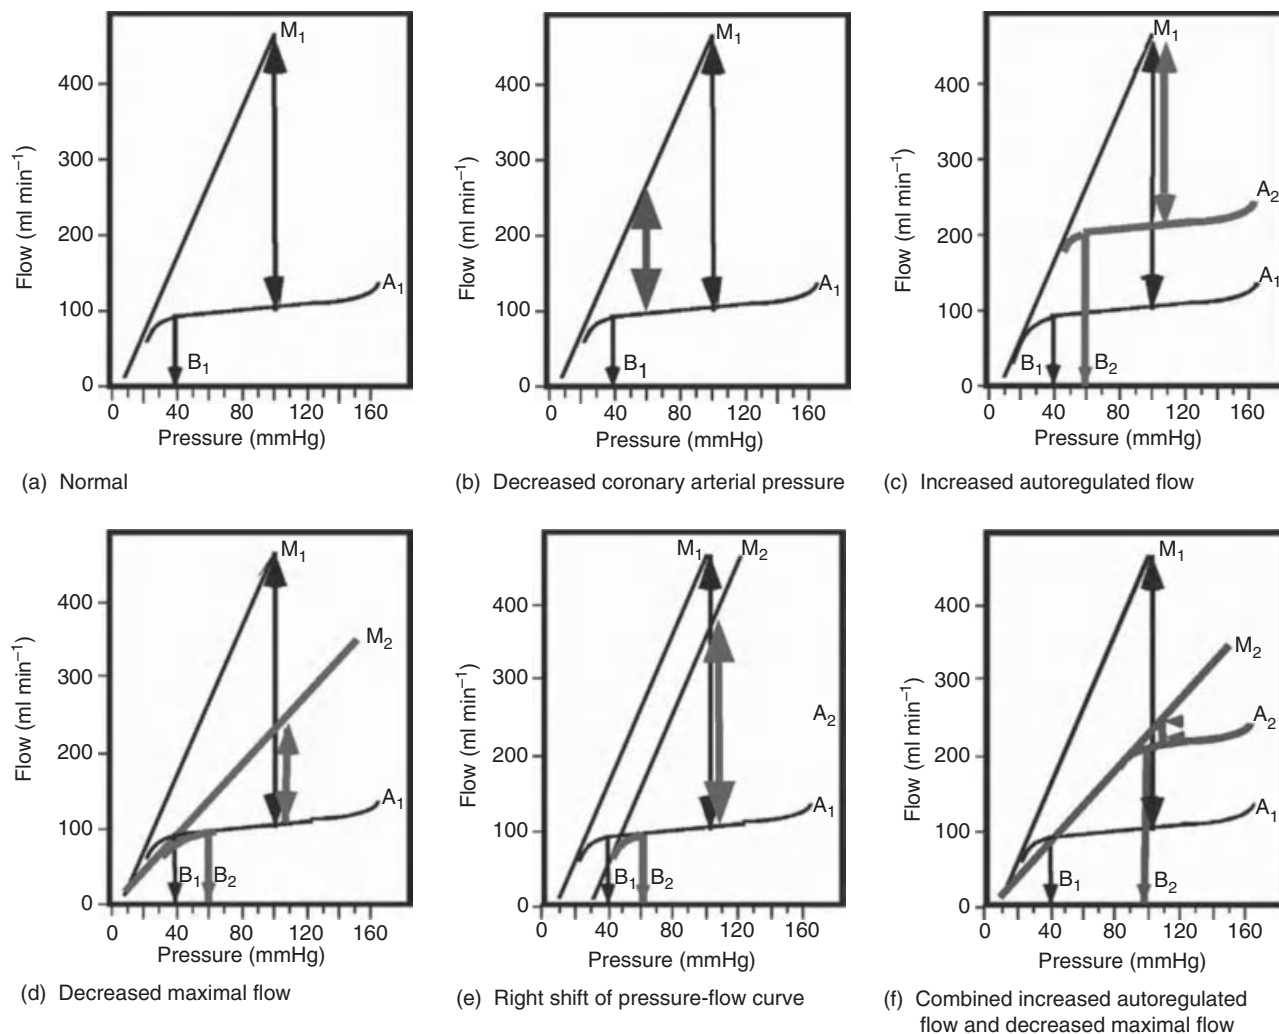
Myocardial oxygen demands are increased by tachycardia, increased pressure, and, to a lesser extent, volume work, and an increase in contractility. Normal hearts can tolerate very high heart rates, for example, 200–250 beats per minute, for short periods [108,109]. The tachycardia decreases the total diastolic time per minute and the proportion of diastole per cycle [110]. It also decreases stroke volume, ventricular volume, and wall stress, but increases contractility. Therefore, tachycardia increases myocardial oxygen consumption [111].


Figure 4.19 Coronary conductograms under various circumstances (see text). Abnormal CFR in thick gray lines and arrows shown by vertical lines slightly offset for clarity.

Increased wall stress due to higher pressure or volume work also increases myocardial oxygen demand, as does an increase in contractility. Even when myocardial oxygen demands are increased, however, autoregulation still occurs at the higher flow.

Coronary flow reserve [112–114]

At any given pressure, the flow when the vessels have tone is determined by the myocardial oxygen needs at that moment. When the vessels are maximally dilated, flow depends only on vascular resistance and myocardial contraction, independent of metabolism. If flow is measured at different perfusing pressures when the vessels have tone and then when they are maximally dilated, a typical coronary conductance diagram results (Figure 4.19). (Conductance is the reciprocal of resistance; the higher the conductance, the greater is the flow at any perfusion pressure.) The normal conductogram (Figure 4.19a) shows a relatively horizontal

line of autoregulated flow (A_1) between perfusing pressures of 40 and 120 mmHg; autoregulation fails outside those limits.

When the coronary vessels are maximally dilated, there is a steep pressure–flow line (M_1). The vertical difference between the two lines indicates the extra flow that can be attained at any given pressure by dilating the vessels, and is termed the coronary flow reserve (CFR) that is also measured in milliliters per minute. A dimensionless coronary flow reserve ratio is obtained by dividing maximal flow by autoregulated flow; this is particularly useful if flows or velocities cannot be related to a particular tissue mass. Note that flow reserve becomes smaller as the perfusing pressure decreases (Figure 4.19b); this occurs, for instance, with stenosis in a coronary artery.

What happens to flow reserve when, in the uncannulated preparation, aortic pressure rises? The increased pressure work increases the autoregulated flow, but the increased

   Thrombosis
   Embolism
   Loss of cardiac muscle to scar tissue

[a]May increase zero flow pressure.
[b]May also increase basal flow.

coronary perfusing pressure increases maximal flow. McGinn *et al.* [115] observed in humans that increases in mean arterial pressure of ~20 mmHg increased autoregulated and maximal flows proportionally, so that the coronary flow reserve ratio was unaltered. What happens at greater pressure elevations is unknown.

Three types of changes can reduce coronary flow reserve. The first is if maximal flow remains unchanged but autoregulated flow increases (Figure 4.19c); the second is if autoregulated flow remains the same but maximal flows are reduced (Figure 4.19d); and the third is if the pressure–flow curve is shifted to the right (Figure 4.1e). The causes of these changes in flows are given in Tables 4.1, 4.2, and 4.3, respectively.

Some factors, such as tachycardia, may both increase autoregulated flow and decrease maximal flow, and some diseases such as cyanotic heart disease may elevate autoregulated flow (from hypoxemia) and decrease maximal flow (from polycythemia). Such combinations may decrease coronary flow reserve (between two horizontal arrow points) profoundly (Figure 4.19f).

Note that when coronary flow reserve is reduced, because of either an increase in autoregulated flow, a decrease in maximal flow, or a shift of the pressure–flow curve to the right, then the pressure at which autoregulation fails and pressure dependence starts shifts to the right, that is, towards higher pressures. This is a consequence of the slope of the line of maximal pressure–flow relations. As a result, autoregulation can fail at normal perfusing pressures (Figure 4.19f).

Regional coronary flow reserve

Failure of autoregulation and therefore pressure dependence occurs first in the subendocardial muscle, no matter what the cause. The loss of reserve is heterogeneous, even within a layer [116].

Table 4.3 Causes of increased zero flow pressure.

Increased left ventricular diastolic pressure[a]
Increased right ventricular diastolic pressure >12 mmHg
Pericardial tamponade[a]
Increased coronary venous pressure >12 mmHg but normal right ventricular diastolic pressure, e.g., after Fontan procedure

Tachycardia[a]
Some anesthetic agents, e.g., nitrous oxide

[a]May also reduce maximal flow.

Pressure–flow relations

When the coronary perfusing pressure is progressively reduced, flow ceases at a pressure of about 45 mmHg during autoregulation and at about 10–18 mmHg when the vessels are maximally dilated. The mechanism is not fully resolved [117]. Some investigators believe that there is vascular closure within the myocardium that causes this back-pressure, whereas others believe that the zero flow pressure is a mixture
Figure 4.20 Mechanisms of small vessel vasomotion. Details of the endothelial compartment are omitted for clarity (see Figure 4.21). Ca^{2+}, calcium ion; H_2O_2, hydrogen peroxide; H_2S, hydrogen sulfide; $H_2S_2O_3$, thiosulfuric acid; SOD, superoxide dismutase; I and III, components of mitochondria

of a vascular waterfall in the epicardial coronary veins and a time factor related to intramyocardial blood volume. (In a waterfall, raising the level of the water in the river below the fall does not change flow over the lip of the fall; similarly, in a vascular waterfall, there is a discontinuity between pressure in the "waterfall" segment and more distal venous pressure, and increasing venous pressure will not alter flow in the vascular bed until it exceeds the waterfall pressure [117].)

Under some circumstances, the zero flow pressure rises and reduces the coronary driving pressure (the difference between inflow perfusion pressure and outflow or back-pressure). This can certainly occur with pericardial tamponade, and with very high right or left ventricular diastolic pressures. A rise in back-pressure, for whatever reason and mechanism, has the same effect in reducing coronary flow reserve as a decrease in perfusing pressure (Figure 4.19e).

Regulation of myocardial vascular tone

When myocardial work increases with tachycardia or exercise, coronary blood flow must increase to supply the added oxygen needed. This response is so important that many redundant systems have evolved [118,119]. Increasing myocardial blood flow involves first the dilatation of the resistance arterioles that are about 100–150 μm in diameter and then subsequent dilatation of the upstream conduit arteries and arterioles to help provide the added flow. The major mechanism of muscle relaxation is reduced calcium influx, and this follows hyperpolarization of the muscle cell when potassium leakage out of the cell through potassium channels is increased [107,120]. Other mechanisms also exist.

One mechanism for dilating resistance vessels could be autonomic nerve activity, but myocardial flow in exercise can still increase after denervation, and Duncker and Bache [119] concluded that the autonomic nervous system modulates but does not necessarily initiate the increased flow. The primary mechanisms are biochemical changes in the myocardial cells, attributed to a decrease in tissue oxygen or to products produced by increased breakdown of ATP as it generates the energy for contraction. Possible mechanisms are shown in Figure 4.20.

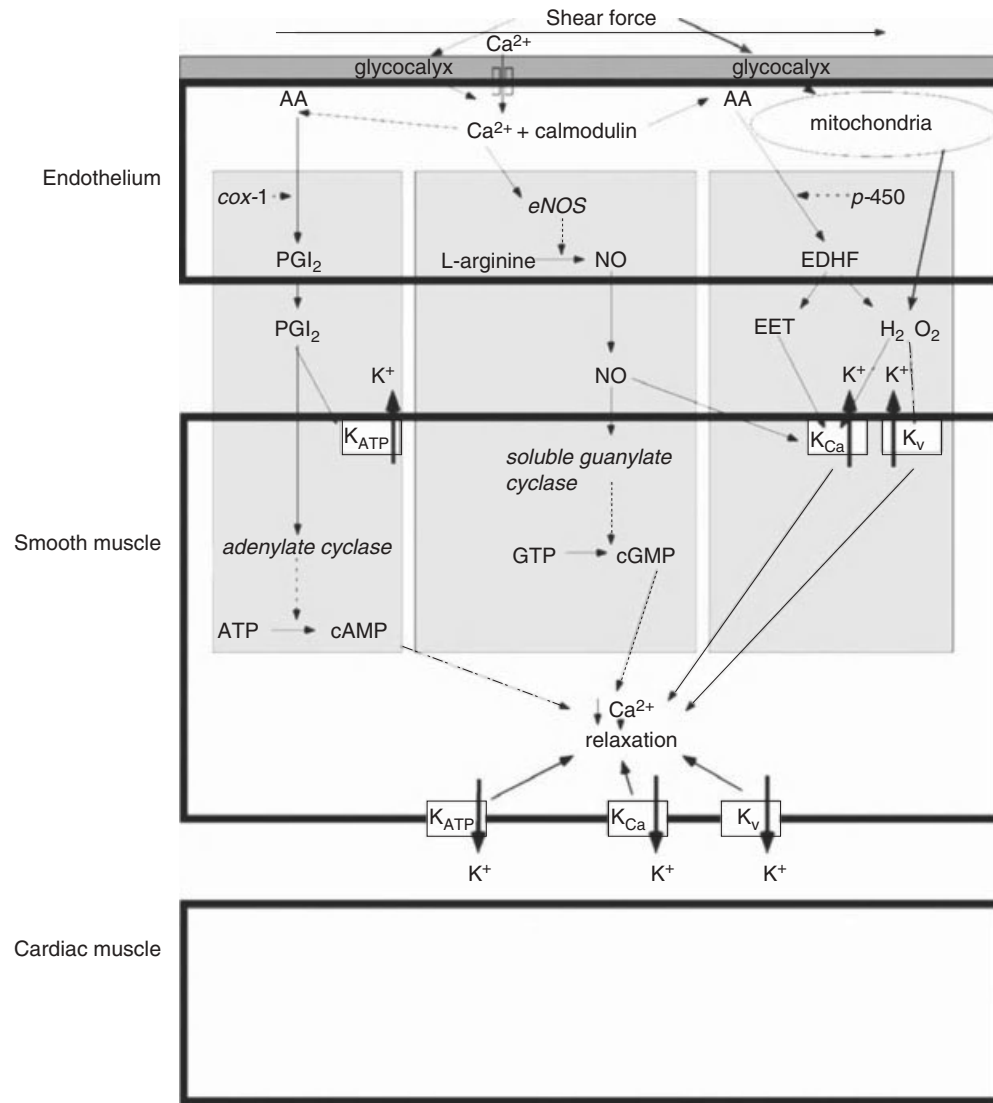
The first major mechanism proposed (not shown in the diagram) involved adenosine as the by-product of ATP metabolism [121]. When muscle contraction breaks down ATP, some of the adenosine monophosphate produced is degraded by 5'-nucleotidase to adenosine, a powerful coronary vasodilator. The more the muscle works, the larger is the amount of adenosine produced and the greater is the coronary vasodilatation. The increased myocardial oxygen supply therefore increases to match the demand. When muscle work increases, so does the amount of adenosine produced, and the vessels dilate to increase flow and oxygen supply appropriately. Although this mechanism has all the ingredients needed for a control system, there are some major arguments against it being the only or even the most important system. Eliminating almost all of the interstitial adenosine by infusing low molecular weight adenosine deaminase does not alter autoregulation. Even with definite ischemia, as in reactive hyperemia, infusing adenosine deaminase reduces but does not abolish the hyperemic response [122]. Furthermore, intracellular adenosine concentrations in the absence of profound ischemia are probably too low to affect vascular tone [123,124]. Finally, Saitoh *et al.* [125] pointed out that once tissue oxygen levels had been restored, the error signal responsible for the changes would disappear.


Figure 4.21 Simplified diagram of some vasomotor control mechanisms, based on studies from the laboratories of Gutterman [107,129,130], Chilian [125,131,132], and others [126,133–136]. The cardiac muscle compartment is left blank for clarity (see Figure 4.20). AA, arachidonic acid; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; EDHF, endothelial-derived hyperpolarizing factor; EET, epoxyeicosatrienoic acid; eNOS, nitric oxide synthase; GTP, guanine triphosphate; cGMP, cyclic guanine monophosphate; H_2O_2, hydrogen peroxide; K, potassium; K_{ATP}, ATP-dependent potassium channel; K_{Ca}, calcium-dependent potassium channel; K_v, voltage-dependent potassium channel; NO, nitric oxide; PGI_2, prostacyclin.

The alternative mechanism associated with increased ATP metabolism is that when oxygen provides energy for the Krebs cycle, complexes I and III of the mitochondria produce superoxide anions as a by-product. These anions are converted by superoxide dismutase into hydrogen peroxide that also acts on potassium channels to hyperpolarize the smooth muscle cell and relax it.

Another possibility involves oxygen that diffuses into the muscle cell and is consumed. Hydrogen sulfide (H_2S) is constitutively produced in the cardiac muscle cell and the endothelium by the action of cystathionine-γ-lyase (CSE) or cystathionine-β-synthase (CBE) on L-cysteine [126], and via mitochondrial action H_2S is oxidized to a compound with no

vasomotor action. Calcium–calmodulin acts as a regulator for the action of CSE, just as it does for the enzymes that produce NO and CO [127]. Lack of tissue oxygen leads to excess free H_2S, a potent vasodilator that acts on potassium channels to hyperpolarize the smooth muscle cell and decrease calcium influx [128]. In support of the role of H_2S is the fact that mice with CSE knockout are hypertensive, with blood pressure decreasing in response to exogenous H_2S [127]. These mice also show reduced endothelial-stimulated vasodilatation.

The increase in flow at the level of the resistance vessels then causes a flow-mediated increase of flow in the upstream conduit vessels, with major proposed mechanisms delineated in Figure 4.21. Although the conduit vessels are also exposed

to products of myocardial cell metabolism, the thicker vessel walls limit the effects of diffusion from myocytes.

Shear forces acting on glycoproteins (integrins and others) in the glycocalyx transmit changes to the intracellular domains of these proteins, and via complex interactions affect mitochondria in the endothelial cells in addition to activating arachidonic acids in the cell membranes. The result is stimulation of the production and co-release of nitric oxide and prostacyclin, and also the generation of two important components of endothelial-derived hyperpolarizing factor (EDHF), epoxyeicosatrienoic acids (EETs), and hydrogen peroxide. These agonists act to inhibit calcium influx both by hyperpolarizing the smooth muscle cell via a variety of potassium channels and also by activating adenylate and guanylate cyclase. These same factors may play a secondary role at the small arteriolar level, with EETs predominating. With vascular disease, not only coronary artery disease but also diabetes mellitus and hypercholesterolemia, reactive oxygen species increase and inhibit the production of prostacyclin, nitric oxide, and epoxyeicosatrienoic acids (EETs), leaving hydrogen peroxide as the main dilator. Not shown in the diagram are interactions among these various agonists.

There are many other potential modulating factors, including potent vasodilators such as substance P, prostacyclin, vasoactive intestinal peptide, bradykinin, atrial natriuretic peptides, and calcitonin gene-related product (CGRP), and also vasoconstrictors such as neuropeptide Y and endothelin, the adrenergic nerves with their transmitters, and cellular PKC and MAPK. A role for carbon monoxide has been suggested [129–144]. The pathways featured in Figures 4.20 and 4.21 are currently regarded as those of greatest importance.

General considerations of causes of ischemia

When perfusing pressure decreases below the lower limit of autoregulation, the fall in flow occurs first in the subendocardium [145,146]. The changes in flow are not uniform within each layer; some pieces of muscle retain reasonable flows whereas others decrease their flow markedly [116]. Nevertheless, most low-flow regions are in the subendocardium, some are in the mid-wall, and a few are in the subepicardium. A similar pattern of selective subendocardial ischemia was shown in experiments in non-cannulated dogs in which severe supravalvar aortic stenosis, an arteriovenous fistula, or rapid ventricular pacing all reduced the inner:outer ratio per gram to very low values, even though the absolute subendocardial flow might not have been reduced. In these studies, some of the maneuvers increased myocardial oxygen demand throughout the heart, but the pathophysiologic changes prevented the appropriate increase in subendocardial blood flow [147]. Common to all these experiments is the notion that once the vessels become maximally dilated, and this always occurs first in the subendocardium, subendocardial flow becomes pressure dependent. Therefore, an inadequate perfusion pressure or a reduced diastolic perfusion time for myocardial needs either decreases subendocardial flow or leads to failure to increase flow appropriately, and leads to a lowered inner:outer flow ratio per gram and also functional and biochemical manifestations of subendocardial ischemia.

Specific cardiac lesions or abnormalities

Tachycardia

Heart rates above 250 beats per minute for extended periods may decrease the inner:outer flow ratio, due to a shorter diastolic perfusion time, lowered aortic diastolic perfusing pressure, and perhaps a rise in left ventricular diastolic pressure. Although the absolute flows rise in all layers, coronary flow reserve becomes reduced in the inner half and, at very high rates, may be absent. The subendocardial vessels become pressure dependent and ischemia may result. The absolute subendocardial flow might be above normal, but is not high enough to supply the oxygen needed to the muscle. The inner:outer flow ratio per gram in these instances is a better guide to subendocardial ischemia than the actual subendocardial flow [148]. If the ventricle is hypertrophied, then tachycardia causes subendocardial ischemia much more readily, in fact, above heart rates of 200 beats per minute [108,109]. Modest tachycardia at a rate of 200 beats per minute causes subendocardial ischemia in dogs with coronary stenosis. The tighter the stenosis, the smaller is the heart rate increase required to cause subendocardial ischemia. In infants during recovery after prolonged paroxysmal supraventricular tachycardia, the T waves may be generally inverted for several hours, and this has been attributed to subendocardial ischemia.

Ventricular hypertrophy

With ventricular hypertrophy in adult animals, muscle mass increases without a corresponding increase in arteries and larger arterioles [145,149,150]. In general, increased wall thickening tends to keep wall tension normal, so that myocardial oxygen consumption per unit mass remains at control values. However, because of a greater muscle mass, myocardial oxygen consumption per ventricle is increased in proportion to the increase in muscle mass. Flow increases to supply this increased amount of oxygen, and does so by dilating the normal-sized myocardial vascular bed. On the other hand, maximal flow per ventricle is not increased (or may even be decreased if there is associated small-vessel medial hypertrophy or intimal disease). Therefore, coronary flow reserve is reduced [151–153]. Similar results have been found in humans [151,152]. When hypertrophy is due to hypertension, the increased perfusion pressure may result in a normal coronary flow reserve, with both resting and maximal flows being increased in proportion.

Young animals, however, can increase the cross-sectional area of the right ventricular myocardial vascular bed to keep pace with the increase in ventricular muscle mass [154,155].

There is one study that suggested that this can also occur for the left ventricle [156].

Aortic stenosis

In this lesion, subendocardial ischemia and fibrosis are prominent, both in children and in adults [145,157–159]. The pressure load causes ventricular hypertrophy that normalizes the wall stress. Therefore, flow per unit mass is relatively normal but total flow is increased in proportion to the increased muscle mass. Because conducting intramyocardial coronary vessels do not increase in number or size, or do not increase enough to compensate for the increased muscle mass, coronary flow reserve is reduced, and may even be absent in the subendocardium. Because the subendocardial vessels are the first to be affected, the effort angina that these patients get is accompanied by ST depression in the left precordial leads, and often there will be substantial subendocardial fibrosis and necrosis. If there are added obstructive changes in intramural arteries, the tendency to subendocardial ischemia is more marked. With significant aortic stenosis, subendocardial ischemia occurs earlier with added stresses such as anemia, tachycardia, extramural coronary arterial disease, or anything that causes the ventricle to dilate and increase the wall stress. Injudicious use of catecholamines in treating non-cardiac disease in these patients may also be detrimental.

Aortic regurgitation

With severe aortic regurgitation, left ventricular systolic pressure is elevated and there is ventricular hypertrophy, but with the associated increase in ventricular volume the wall stress is elevated. Furthermore, the mean diastolic aortic perfusing pressure is reduced. These patients therefore have a reduced coronary flow reserve, so that angina pectoris and subendocardial ischemic damage may occur. One notable difference from aortic stenosis is that with regurgitation, tachycardia can improve cardiac function and subendocardial blood flow for at least two reasons. First, a faster heart rate reduces the time available for regurgitation and so reduces the degree of regurgitation and ventricular volume. Second, the shorter diastole raises the mean diastolic perfusing pressure. This may explain why clinically pacing about 15–20 beats per minute above the resting heart rate has produced major clinical improvements in patients with aortic regurgitation and intractable cardiac failure [160,161].

Anemia

Anemia increases cardiac output and thus myocardial oxygen consumption, and at the same time decreases the oxygen carrying capacity of the blood. This is compensated for by an increased coronary blood flow, but at the expense of reducing coronary flow reserve.

Polycythemia

Polycythemia reduces resting blood flow because of its increased oxygen-carrying capacity and viscosity. Because increased blood viscosity decreases maximal flows, coronary flow reserve is reduced. As for anemia, resting blood flow can be supplied (to a normal heart) at any hematocrit and perfusing pressure, and arterial oxygen saturation, but the demands of exercise cannot be met.

Hypoxemia

Hypoxemia increases coronary blood flow and reduces coronary flow reserve.

Coronary Arterial Stenosis

With a localized atheromatous lesion of a major branch of the left coronary artery, there is a pressure drop at rest across the obstruction because of the increased resistance that it offers to flow. This pressure drop is greater in diastole, when flow is highest, than in systole. Autoregulation causes the small intramural vessels to dilate and lower their resistance, so that myocardial oxygen demands can be met. Coronary flow reserve is, however, decreased in this distal bed. If the stenosis becomes more severe, whether acutely by spasm or hemorrhage into the plaque, or chronically by growth in volume of the plaque, then distal pressures may fall below the level at which autoregulation can compensate; coronary flow reserve will be absent. Consequently, flow decreases below the amount needed to supply myocardial oxygen needs, particularly in the subendocardium, and the patient has rest pain. Because rest pain indicates severely impaired coronary flow to a region that does not have an increased oxygen demand, it is a precursor of necrosis if it persists.

If a mild obstruction gradually increases, resting flow remains at its previous value but coronary flow reserve becomes progressively reduced. Exercise that raises myocardial oxygen needs may then exhaust flow reserve and lead to subendocardial ischemia. These features are the basis for various types of exercise tests, with or without radionuclide scans to delineate ischemic regions.

Cardiopulmonary bypass

Acute subendocardial necrosis in patients with normal coronary arteries was all too frequent in the early days of bypass surgery [162–166]. Necrosis was seen most often during prolonged normothermic ventricular fibrillation, the mechanism being the difficulty of perfusing the subendocardium in the absence of a prolonged period of relaxation equivalent to diastole [167–169]. With improved myocardial protection, this lesion is seen less often, but still occurs.

Direct and indirect measurement of coronary blood flow

Although these measurements are easy and relatively accurate in animals, they are is more difficult in humans, especially
Figure 4.22 The systolic:diastolic pressure-time index.

small children. Ideally, non-invasive or minimally invasive methods should be used. Transthoracic Doppler echocardiography of the major coronary arteries has been done, and yielded results that are comparable to those found in animals [170–176]. The method can usually make repeatable measurements of flows in the left anterior descending, left circumflex, or right coronary arteries, and gives values for flow and flow reserve that match those in animal studies. Only large regions can be studied, and flow variations within a region are not obtainable. Nuclear medicine techniques with technetium or thallium can show localized deficits, but do not measure absolute flow. Positron emission tomography (PET) scanning with rubidium has better spatial resolution but is complex and expensive [177]. Inserting a Doppler flow wire (Cardiometrics, Mountain View, CA, USA) through a small catheter provides the most accurate measurements for specific coronary arteries. Just as with the echo-Doppler method, however, this does not give information about small regions.

Because none of these methods currently give information about ischemia of the subendocardium, which is the earliest region affected, an indirect index has been proposed. Based on acute animal studies, Buckberg *et al.* [147] examined the ratio of two pressure–time areas (Figures 4.22).

The rationale for the ratio is that the area under the left ventricular pressure curve in systole (SPTI) represents myocardial oxygen demand (with the caveats mentioned above about pressure and wall stress not being the same), whereas the area between the aortic and left ventricular curves in diastole (DPTI) represents the time and pressure head for perfusion of the subendocardium that, as described above, is perfused only in diastole. DPTI is directly related to flow as flow = Pressure difference/resistance. With maximal vasodilatation, subendocardial flow becomes pressure dependent, and subendocardial flow is proportional to the pressure difference per minute, which, for subendocardial muscle, is DPTI.

The DPTI:SPTI ratio thus represents a supply:demand ratio. Buckberg *et al.* [147] produced various models of heart disease in dogs, and found a good linear correlation between the DPTI:SPTI ratio and the subendocardial:subepicardial flow ratio. If the DPTI:SPTI ratio decreased to <0.8, the flow ratio decreased below its normal value of about 1. Note that these ratios do not predict absolute flows, but instead use the subepicardial flow (which is almost never jeopardized) as a normalizing value.

The concept is straightforward, and it fits many lesions in which subendocardial ischemia is known to occur [178,179]. The difficulty in using this concept is determining the critical values for the ratio. Some guidance is available. Studies done on healthy athletes immediately after the onset of a 100 m sprint showed 4 mm ST depression of classical ischemic pattern [180]. To investigate this finding, normal healthy firemen were exercised on a treadmill either with gradual increase to maximal speed or with maximal speed started immediately. The first group showed merely the expected tachycardia, whereas the second group showed initial ST depression. A rough estimate of DPTI:SPTI ratio was obtained from a brachial arterial pressure. The investigators found that ischemic changes in the electrocardiogram occurred if the DPTI:SPTI ratio decreased below 0.45. It is essential to correct the DPTI:SPTI ratio for the hemoglobin concentration [181]. This is done simply by multiplying the DPTI area by arterial oxygen content in milliliters per 100 ml of blood (normal value about 20). The critical oxygen content adjusted ratio would then be about 8–9.

It is therefore reasonable to use this cut off value for normal hearts. What happens if hearts are hypertrophied or dilated? Then the SPTI underestimates myocardial oxygen demand because either wall stress is increased or the wall is hypertrophied, and the critical value is <0.45 by some unknown amount. In a study of patients known to have aortic stenosis, lactate production detected in the coronary sinus (and by inference subendocardial ischemia) was associated with a DPTI:SPTI ratio <0.3 [182]. It is safe to state that any DPTI:SPTI ratio >0.45 (or if corrected for arterial oxygen content >9) suggests that the subendocardium is not ischemic.

Coronary flow patterns

In the left coronary artery, about 75–80% of the flow is diastolic, for reasons discussed above. A reduction of the proportion of diastolic blood flow probably reflects underperfusion of the subendocardium of the left ventricle [146].

On the other hand, systolic flow in a large branch of the left coronary artery may be reduced if excess systolic backflow from the myocardium opposes normal systolic inflow, as may occur when ventricular pressure exceeds aortic pressure in systole, as occurs with aortic stenosis. It has also been described with acute hemorrhage, a large coronary cameral fistula, and pericardial tamponade [146]. Now that it is possible to use Doppler-tipped flow wires in children, assessment of flow patterns may provide indirect information about subendocardial flow.

The flow wire has been used also to determine whether a child with some degree of coronary artery stenosis after Kawasaki disease will benefit from coronary bypass surgery [183]. This has been done by using the concept of myocardial fractional flow reserve, in which measurements are made during maximal vasodilatation of the coronary arteries of pressures in the artery proximal to the stenosis (P_a), distal to the stenosis (P_d), and a wedge as a measure of coronary venous pressure (P_v). Then myocardial fractional flow reserve (FFR_{myo}) is calculated [162–164] as

$$FFR_{myo} = \frac{P_d - P_v}{P_a - P_v}$$

A value of <0.75 suggests that there is significant stenosis. In the study by Ogawa et al. [183], there was a good relationship between the coronary flow reserve (determined by the same Doppler flow wire) and FFR_{myo}. The method has value, although questions have been raised about its value in practice [184] and even about the validity of the method [185].

Right ventricular myocardial blood flow

Right ventricular myocardial blood flow follows the general principles regarding coronary blood flow, but has differences related to the low right ventricular systolic pressure and to the fact that alterations in aortic pressure change coronary perfusing pressure without altering right ventricular pressure work. If the normal right ventricle is acutely distended, for example, by pulmonary embolism, there will eventually be right ventricular failure; the increased wall stress increases its oxygen consumption but the raised systolic pressure reduces the coronary flow, so that when supply cannot match demand there will be right ventricular myocardial ischemia [186]. Raising aortic perfusing pressure mechanically or with α-adrenergic agonists increases right ventricular myocardial blood flow, relieves ischemia, and restores right ventricular function to normal despite continued right ventricular systolic hypertension. Improved coronary flow is not the only mechanism of this improvement; the increased left ventricular afterload moves the ventricular septum towards the right ventricle and improves left ventricular performance [187]. As shown by Sonnenblick and colleagues [188] in earlier experiments, ischemia is likely to be the predominant mechanism.

If right ventricular systolic pressure is chronically elevated so that there is right ventricular hypertrophy, as in pulmonic stenosis, many forms of cyanotic congenital heart disease, and some chronic lung diseases, then right ventricular myocardial blood flow behaves in the same way as left ventricular blood flow [189–191], with one exception. If aortic pressure is lowered, left ventricular pressure also decreases, as does left ventricular work and oxygen consumption. In the right ventricle, however, the workload may not be reduced (if there is no ventricular septal defect), so that an imbalance between myocardial oxygen supply and demand may occur. The worst imbalance occurs when aortic systolic pressure is maintained but coronary perfusing pressure decreases, and this can occur in a child with tetralogy of Fallot who has too large an aortopulmonary anastomosis. The high aortic and left ventricular systolic pressures mandate an equally high right ventricular systolic pressure, but the low diastolic aortic pressure reduces coronary perfusion pressure in diastole and can cause both left and right ventricular ischemia and failure [192].

In the right coronary artery, because some of the flow perfuses the low-pressure right ventricle, about 40–60% of the flow is in systole. With increased right ventricular pressures, as in congenital pulmonic stenosis, the flow pattern resembles that of the left coronary artery [193].

Pulmonary Vascular Pathophysiology

Marlene Rabinovitch

Stanford University School of Medicine, Stanford CA, USA

Development of the pulmonary vasculature in embryonic and fetal life

Severe pathological changes of pulmonary hypertension (PAH) are observed in the arteries accompanying the terminal respiratory unit or the acinus. The acinus is composed of the terminal bronchiole, respiratory bronchioli, alveolar ducts, and alveoli. Normally in the newborn, arteries at the level of the terminal bronchiolus are muscular, whereas those accompanying respiratory bronchioli are mostly partially muscular (surrounded by a spiral of muscle). Arteries at alveolar duct and wall levels are generally nonmuscular. The immediate postnatal period is characterized by rapid recruitment of small alveolar duct and wall arteries, which appear to be functionally and structurally closed in the prenatal period [1].

Progressive dilatation of muscular arteries also occurs postnatally – that is, the smallest muscular arteries (<250 μm) dilate, and their walls thin to adult levels within a few days; by the age of 4 months, this process has included the largest pulmonary arteries (PAs) at the hilum. With age, more distal arteries become muscularized. Although most alveolar duct arteries become partially muscularized, most alveolar wall arteries remain nonmuscular even in the adult [2]. The process of distal muscularization appears to be related to the differentiation of pericytes and recruitment of fibroblasts that also differentiate into muscle cells.

Precapillary (alveolar duct and alveolar wall) arteries proliferate through the neonatal period and early infancy, accompanying the proliferation of alveoli; the ratio of alveoli to arteries can therefore be used as a measure of numerical arterial growth. The ratio of alveoli to arteries decreases from the newborn value of 20:1 to 6:1–8:1, which is achieved first in early childhood and persists.

Experimental studies indicate that the normal adaptation to postnatal life is regulated by remodeling of the smooth muscle cell actin cytoskeleton through the Rho-kinase pathway and by changes in the production of connective tissue, especially elastin and collagen. Several groups relate lung vascular development to alterations in growth factors and extracellular matrix molecules that regulate migration, proliferation, and differentiation of endothelial, smooth muscle cells, and fibroblasts and direct the process of branching morphogenesis. Cells sense changes in extracellular matrix proteins, such tenascin-C [3],that influence the activity of growth actors, including vascular endothelial growth factor (VEGF), fibroblast growth factors (FGF-1 and FGF-2), and angiopoietins and their interaction with receptors. The balance between proteases and antiproteinases regulate the constant turnover of matrix and the cell surface expression of growth factor receptors that direct vascular cell behavior.

Recent studies have shown that VEGF coordinates alveolar and vascular development [4] and is regulated by transcription factors, such as the hypoxia inducible transcription factor [5]. The Wnt signaling pathway also plays an important role in lung vascular development [6], as do specific transcription factors [7]. Vasoactive peptides, such as endothelin, induce smooth muscle cell proliferation. This effect is balanced by nitric oxide (NO) [4], produced by NO synthase [8]. The availability of NO is also controlled by nitrites [9].

Congenital heart defects with pulmonary hypertension

Lung biopsy studies from patients with a congenital heart defect first suggested how structural alterations in the PAs lead to progressive hemodynamic changes in the pulmonary circulation [10] (Figure 5.1). The first PA abnormality detected in a patient with a congenital heart defect and high pulmonary blood flow and pressure is extension of muscle into peripheral normally non-muscular arteries (morphometric grade A) [11] (Figure 5.1). This appears to be an acceleration and exaggeration of the normal process of growth associated with differentiation
Figure 5.1 Pathobiology of PH. Schema illustrating the different vascular abnormalities compared with normal pulmonary circulation, associated with PH. This schema depicts the abnormalities throughout the pulmonary circulation, including (i) abnormal muscularization of distal precapillary arteries, (ii) medial hypertrophy (thickening) of large pulmonary muscular arteries, (iii) loss of precapillary arteries, (iv) neointimal formation that is particularly occlusive in vessels 100–500 μM, and (v) formation of plexiform lesions in these vessels. EC, endothelial cell; SMC, smooth muscle cell. (Reproduced from Rabinovitch, *J Clin Invest* 2008;**118**:2372–9, with permission.)

of pericytes into smooth muscle cells (SMCs) that subsequently proliferate and also recruitment of fibroblasts. The initial response to high flow induced experimentally from the time of birth appears to be angiogenic with high levels of VEGF and its receptors.

The second change is medial hypertrophy of muscular arteries (grade B). It always accompanies abnormal muscularization of distal arteries and is associated with high mean PA pressure. This change represents an increase in the number and size of smooth muscle cells in the muscular media of the arterial wall.

The third change, reduced arterial number (grade C), is always accompanied by muscularization of peripheral arteries and medial hypertrophy of muscular arteries, and is associated with elevated pulmonary vascular resistance. The basis for grade C is likely the failure of new vessels to develop and also "injury"-mediated loss of arteries through apoptosis of endothelial cells and pericytes. Grades A and B are refinements of Heath–Edwards grade I (medial hypertrophy). Grade C may be found with Heath–Edwards grade I, is common with grade II (cellular neointimal formation), and is invariable with grade III (occlusive neointimal formation with fibrosis). In fact, when grade III is seen, the arterial concentration is generally half of normal or less.

Progressive neointimal obliterative and plexiform lesions are associated with a progressive rise in resistance to flow that culminates in right to left shunting in the presence of a congenital heart defect. The extensive neointimal obliterative changes (Heath–Edwards grade III) are related to an expansive proliferation and migration of cells considered to be SMCs because they express α-SM actin. These cells may represent a specialized subpopulation of SMCs or they may have originated as stem cells or fibrocytes (cells that have properties of fibroblasts and leukocytes), or they may even be transformed endothelial cells (ECs).

The development of the dilatation complex and plexiform lesion (Heath–Edwards grade IV and V, respectively) is characterized by the formation of aberrant channels in the otherwise obliterated lumen of the vessel and in the adventitia. These channels may reflect clonal expansion of apoptosis-resistant ECs or they may originate from circulating endothelial progenitor cells that accumulate at sites of endothelial denudation or injury and expand locally.

In general, features of grade IIIC or more severe abnormalities, such as Heath–Edwards grade IV (dilatation complexes) or grade V (angiomata formation), that together comprise plexiform lesions, or grade VI (fibrinoid necrosis), are observed with severe elevation in pulmonary vascular resistance >8 U m^{-2} that is frequently refractory to acute vasodilation in response to oxygen, prostacyclin, or NO. A pulmonary wedge angiogram performed at the time of a catheter study can help relate the extent of pulmonary vascular disease to the calculations of pulmonary vascular resistance. A frozen section is a valuable addition to the hemodynamic data and angiogram in helping make a clinical decision with regard to operability.

Age at cardiac repair is critical in the potential for hemodynamic improvement and (presumably) resolution of the vascular pathology. For example, infants repaired under

6 months of age had normal hemodynamics as assessed at cardiac catheter study 1 year later, whereas those repaired over 2 years of age characteristically had some impairment or even progressive disease, except if the pathology was limited to muscularized arteries and medial hypertrophy (grade B) [12–14]. This is consistent with early studies showing that in a congenital heart defect, such as a ventricular septal defect with PAH, banding the PA band in infancy could substantially reverse the PA vascular pathology [15]. Regression of medial hypertrophy and muscularization of distal vessels has been shown in experimental studies following pressure off-loading. We showed that transplantation into a normal rat of a lung from a rat in which a toxin, monocrotaline, had induced severe pulmonary vascular disease resulted in regression of those abnormalities. Regression of severe pulmonary vascular disease occurred in the original lung from a PAH patient that remained after single lung transplant [16]. However, there is the possibility that the regression might have been induced by immunosuppressive agents rather than by the reduction in PA pressure. Experimentally, immunosuppressive agents can attenuate PAH. As we learn more about the genetic basis of congenital heart disease, we may uncover genes that contribute to the PA pathology independent of the hemodynamic changes.

Endothelial biology and pathobiology of PA hypertension

EC dysfunction appears to play a central role in the development of pulmonary vascular disease. Scanning and transmission electron microscopic analyses [17] revealed structural alterations in the PA ECs from patients with PAH. These were related functionally to defective von Willebrand factor, a blood glycoprotein involved in coagulation and fibrinolysis, and also to abnormal production of vasodilators and repressors of SMC proliferation.

Endothelial alterations precede the development of muscularization of PAs. Cultured PA ECs release factors, such as FGF-2, that stimulate the proliferation of PA SMCs [18]. In PA ECs from patients with idiopathic PAH (IPAH), there is an increased release of serotonin from ECs and serotonin-mediated SMC proliferation. In recent studies, we have shown that reduced production of apelin by PAH PA ECs impairs endothelial recovery from injury (survival) and derepresses PA SMC proliferation.

PA ECs from patients with IPAH produce decreased amounts of NO, a vasodilator and suppressor of SMC proliferation. The reduction in NO is thought to be related to reduced endothelial nitric oxide synthase or high arginase levels [19], because L-arginine is the substrate of NO synthase required to produce NO. The ECs from patients with PAH are highly proliferative in response to growth factors and represent expansion of apoptosis-resistant clones that exhibit high rates of glycolysis attributed to induction of hypoxia inducible factor [20]. These cells, however, appear poorly differentiated and show impaired formation of endothelial tubes in culture. This is consistent with the observation that PAH ECs fail to restore the precapillary vessels that have been occluded or lost.

There is also considerable thickening of the pulmonary adventitia and venous hypertrophy in patients with PAH. Immunohistochemical studies have revealed increased expression of transforming growth factor (TGF)-β, matrix glyoproteins and glycosaminoglycans, in addition to macrophages, and T cells, and also inflammatory mediators such as fractalkine. Our immunohistochemical studies carried out on lung biopsy tissue from patients with congenital heart defects showed that the deposition of the glycoproteins tenascin-C and fibronectin in the media and neointima increases progressively with the severity of the lesion. We related increased expression of tenascin-C to vascular smooth muscle cell proliferation and deposition of fibronectin to smooth muscle cell migration associated with neointimal formation [21]. Studies by other investigators found evidence that the neointimal lesions in PAH are accompanied by increased expression of TGF-β and procollagen. More recently, we described an increase in the expression of the calcium binding protein S100A4/Mts1 in advanced lesions from patients with congenital heart defects causing PAH or with IPAH (Figure 5.2) [22]. S100A4/Mts1 stimulates vascular smooth muscle cell migration and proliferation, is produced in response to serotonin stimulation [23], and is enhanced with increased activity of the serotonin transporter. This is in keeping with studies indicating that a polymorphism causing heightened activity of the serotonin transporter is increased in patients with PAH [24].

Counteracting the pathology of PAH with "vasodilator" therapy

The idea that the advanced pathology associated with PAH could be attenuated or reversed by vasodilator therapy originated in studies of patients with IPAH in which there was evidence of reduced circulating levels of the vasodilator prostacyclin relative to the vasoconstrictor thromboxane. This observation led to the institution of continuous intravenous prostacyclin as a therapy for PAH patients, a treatment that, despite not always reducing the pulmonary vascular resistance, has appreciably improved the quality of life and the survival of PAH patients (see Chapter 51). A recent meta-analysis, however, has questioned the survival benefit of this and other therapies for PAH in adults. A compelling need exists to find oral and improved alternatives to intravenous prostacyclin. Experimental studies in rats with hypoxia-induced pulmonary hypertension documented elevated levels of endothelin (ET), a powerful vasoconstrictor that promotes SMC proliferation and inflammation [25]. In clinical studies, an increase in ET was
Figure 5.2 Representative photomicrographs of human lung biopsy tissue after immunoperoxidase staining for S100A4/Mts1. (a) Vessel from patient graded 0–IB showing normal pulmonary artery with no immunodetectable S100A4/Mts1. (b) Vessel showing a typical grade IB lesion with severe medial hypertrophy but without immunoreactivity for S100A4/Mts1. (c) An artery from a patient with grade IVC disease with occlusive neointimal proliferation and strong positive staining for S100A4/Mts1 particularly in the intima compared with the media of the vessel. S100A4/Mts1 was not detected in all cells and appears to be localized in a subpopulation of intimal cells. (d) A plexogenic lesion from a patient with grade IVC disease with staining of the smooth muscle cells and sparing of the endothelial cells (arrows). Immunoreactivity for S100A4/Mts1 was present in the lung parenchyma at a similar level in all grades of pulmonary vascular disease. Original magnification, ×40. (Reproduced from Greenway *et al*. *Am J Pathol* 2004;**164**:253–62, with permission.)

detected in the lungs of patients with IPAH [26]. Hence ET receptor blockade was proposed as a potential treatment for PAH. The two endothelin receptor subtypes ET_A and ET_B are found in smooth muscle cells of blood vessels and both can mediate vasoconstriction. However, ET_B receptors on ECs may mediate vasodilatation and ET clearance, particularly in microvessels. Recent results using either the dual ET receptor antagonist or a selective ET_A receptor antagonist demonstrate a reduction in symptoms and slowing of PAH progression in some patients. Studies documenting reduced expression of NO synthase, the enzyme that generates NO, suggested that phosphodiesterase V inhibitors, such as sildenafil, could prolong the NO-mediated increase in cGMP to dilate PAs effectively. Phosphodiesterase inhibitors also improve cardiac function. Recent studies showed that nitrites, molecules that produce NO in the lung, may also be of therapeutic benefit as they reverse experimental pulmonary vascular disease.

Experimental studies have also shown success in reversing PAH with other vasodilators that include adrenomedullin. Vasoactive intestinal peptide (VIP), a vasodilator and inhibitor of SMC proliferation, is a very promising agent. Transgenic mice that are null for VIP develop PAH with remodeled distal arteries. Studies in rodents showing vasodilatation and reversal of PAH by Rho-kinase inhibitors such as fasudil that disassemble the cytoskeleton suggest that these agents should be developed for clinical use. Fasudil has shown some benefit in acute testing of PAH patients. The systemic hypotensive side effects of fasudil may be reduced when it is administered via inhalation. Table 5.1 lists novel agents currently in use or in trial for treatment of pulmonary hypertension.

Table 5.1 Summary schema outlining current and future therapeutic strategies. Those with asterisks are in trial for PAH, those in bold are in trial for other indications and that in italics is in clinical use for other indications.

Elastin inhibition
Kv channel openers (DCA)
Malonyl coenzyme decarboxylase inhibitor
TRP channel suppressor
Dominant negative survivin
*Statins
VIP
*PPARγ agonists
*Growth factor inhibitors (anti-PDGF, EGF)
Adrenomedullin
*Rho-kinase inhibition
*Endothelial progenitor cells engineered with eNOS
Cyclosporine and rapamycin
Apelin
γ-Secretase inhibitors

Modified from Rabinovitch, *J Clin Invest* 2008;**118**:2372–9.

Chronic hypoxia-induced pulmonary hypertension

Chronic hypoxia induces PAH and vascular changes that, based upon experimental studies, consist of muscularization of distal vessels, medial hypertrophy of muscular arteries, and a reduced number of peripheral arteries despite the increase in capillaries from an increase in hypoxia-inducible transcription factors. These features are largely reversible with restoration of a normoxic environment. However, we have learned about the pathobiology of PAH by studying mechanisms by which chronic hypoxia causes remodeling of the PAs.

Stenmark *et al*. [27] took newborn calves to a simulated high altitude of 4300 m and observed severe PAH with right-to-left shunting from the rapid development of suprasystemic levels of pulmonary artery pressure. There was striking medial hypertrophy and remarkable proliferation of a dense adventitial sheath that, in large vessels, was sometimes seen to exhibit neovascularization. A striking increase in elastin synthesis in the pulmonary arteries of these neonatal calves [28,29] was observed but, based on studies in rats, this is likely stimulated by ongoing elastin degradation. Fibrocytes, cells having characteristics of both fibroblasts and leukocytes, appear to be key contributors to the remodeling of the pulmonary vasculature. They migrate into the vessel wall through openings in the expanding adventitia [30].

There are both direct cellular effects of hypoxia and indirect effects that are the consequence of the hemodynamic changes, that is, vasoconstriction. For example, pulmonary artery smooth muscle cells of neonatal lambs and bovine endothelial cells in culture show decreased production of prostacyclin in response to acute hypoxic exposure. Endothelin receptor blockade appears to be most selective in reversing acute hypoxia-induced pulmonary vasoconstriction and also the remodeling associated with chronic exposure. However, even without vasoconstriction, hypoxia inhibits endothelin receptor B-mediated NO synthesis and cyclic guanosine monophosphate (cGMP)-dependent activation of NO is impaired. Agents useful in treating chronic hypoxic pulmonary hypertension, at least based on experimental studies in rodents, include inhibitors of 5-lipoxygenase activating protein and also phosphodiesterase inhibitors and continuous inhalation of NO. Because potassium channels are down-regulated during hypoxia in association with an influx of calcium that promotes vasoconstriction and smooth muscle cell proliferation, activation of voltage-gated K channels (Kv 2.1) by gene transfer or a metabolic activator inhibits chronic hypoxic pulmonary hypertension. Activating metabolic pathways that positively influence mitochondrial metabolism and prevent K channel activation and SMC proliferation can also be achieved by Nfatc inhibition and by malonyl coenzyme carboxylase.

Recent studies of transgenic mice have extended our knowledge about important mechanisms in regulating both hypoxia-induced vasoconstriction and vascular remodeling. For example, in the absence of hemoxygenase 1, there is reduced production of CO and its associated vasodilatory effects [31]. Prostacyclin synthetase overexpression can protect against the hemodynamic and vascular changes in pulmonary hypertension. In the fawn-hooded rat, abnormal release of serotonin is implicated in the pulmonary hypertension observed with mild hypoxia. There are also abnormalities in mitochondrial metabolism that activate hypoxia-inducible genes [20]. Consistent with this observation, the severity of pulmonary vascular disease induced by chronic hypoxia is enhanced in mice lacking the serotonin transporter gene. Recently, Rho-kinase inhibitors and PPARγ agonists have proven effective in preventing and reversing pulmonary hypertension and structural changes associated with chronic hypoxia. Mice lacking PPARγ in either endothelial cells [32] or smooth muscle cells [33] have PAH.

Over-expression of the serotonin transporter worsens hypoxia-induced pulmonary hypertension, as does loss of function of bone morphogenetic protein receptor II (BMP-RII) (the gene that is mutant in familial and sporadic IPAH). Reduced BMP-RII in cultured smooth muscle cells and in transgenic mice makes them more sensitive to the pro-proliferative effects of serotonin or of inflammatory stimuli. Experimental studies in hypoxic rodents first suggested that vascular smooth muscle growth inhibitors may be useful in preventing PAH. Heparin infusion decreases the severity of hypoxia-induced vascular changes, presumably by binding growth factors. Calcitonin gene-related peptide administered

by gene transfer not only attenuates hypoxia-induced vasoconstriction and remodeling but also enhances the effects of phosphodiesterase inhibitors. We also showed that serine elastase inhibitors reduce chronic hypoxia-induced pulmonary hypertension.

Collagen vascular disease, inflammation, and pulmonary hypertension

Pulmonary hypertension is a frequent complication of certain collagen vascular diseases (e.g., commonly scleroderma), the CREST syndrome (calcinosis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasias), and, more rarely, systemic lupus erythematosus, rheumatoid arthritis, Takayasu's arteritis, polymyositis, and dermatomyositis. Although the pathological features of PAH include thromboemboli, particularly associated with the antiphospholipid syndrome, an immune/inflammatory vasculitis appears to be the initiating event. The prevailing hypothesis is that endothelial injury coupled to an immune defect leads to a peri- and intravascular inflammatory response causing vascular lesions leading to progressive PAH. In addition to high circulating levels of endothelin-1 (indicating an endothelial injury), there is increased production of autoantibodies that reflect the immune compromise. Activating antibodies to platelet-derived growth factor (PDGF) receptor could explain the proliferative response of smooth muscle cells causing vascular lesions. In an allergic model of PAH, an IL-13-mediated increase in an α-resistin-like molecule was observed and this protein can induce SMC proliferation. An increase in a similar molecule was observed in patients with scleroderma and pulmonary hypertension.

The results of therapy, including intravenous prostacyclin, have not appreciably improved long-term survival in the subset of patients with PAH associated with systemic sclerosis. These patients appear to deteriorate with lower levels of PA pressure and resistance, perhaps because of intrinsic abnormalities in the right ventricle or increased stiffness of the conduit PAs.

Severe PAH has been associated with acquired immunodeficiency syndrome, even in the absence of lung parenchymal disease, and has been reproduced experimentally [34]. Here too there is a combination of endothelial injury and immune compromise that could explain the observed pathology. The development of PAH in the subset of patients with human immunodeficiency virus infection appears to be linked to the immunogenetic background (i.e., human leukocyte antigen class II alleles) and to the injurious effect of a virus. Here the human herpesvirus 8 (HHV-8) is associated with Kaposi sarcoma virus, which is prevalent in HIV, and some patient groups with idiopathic PAH. The Kaposi sarcoma virus appears to stimulate lysosomal-mediated degradation of BMP-RII, the gene that is mutant in patients with idiopathic pulmonary hypertension that protects the vasculature, as will be discussed later in the chapter. The HIV-nef gene has been implicated in plexogenic pulmonary vascular lesions associated with PAH in HIV-infected patients and SIV-infected non-human primates.

Recently, we reported that the mouse that overexpresses S100A4/Mts1 develops extensive and severe neointimal lesions following injection of the gamma murine herpes virus-68 (the murine homolog of HHV-8). This is associated with an elevated elastase activity that we have now identified as neutrophil elastase produced by PA SMC. Overexpression of S100A4 also appears to be linked to an immune defect.

Neointimal formation associated with inflammatory processes in systemic arteries is also accompanied by an increase in serine elastase activity [35] and fibronectin production. Inflammation has been linked to the development of PAH, and both the chemokine receptor CX3CR1 and the chemokine fractalkine appear to be elevated [36]. An interesting recent study showed that loss of function of BMP-RII leads to up-regulation of IL-6, the pro-inflammatory cytokine, and we have delineated a post-transcriptional mechanism associated with up-regulation of the cytokine GM-CSF (unpublished). We have also shown that GMCSF co-distributes in PAH lesions with TNF-α and that GMCSF can aggravate hypoxia-induced PAH. Other experimental models of chronic inflammation, such as repeated injections of endotoxin and TNF-α, produce pulmonary vascular changes.

The high incidence of PAH in areas of the world endemic for schistosomiasis has resulted in several experimental studies addressing pathogenesis and pathobiology of this complication. About 10% of patients with schistosomiasis develop portal hypertension and 10% of those (1% of the total) have PAH. Chronic infection with high-dose cercariae resulted in extensive lung vascular remodeling [37]. Allergic responses to ovalbumin or to aspergillus can result in extensive vascular remodeling, although in this model of disease, as in the S100A4 over-expressing mice inoculated with virus, right ventricular systolic pressure is not elevated. A Th2 immune response characterizes both the ovalbumin and the cercariae models but not the viral model of pulmonary vascular remodeling. Here an autoimmune Th17 response may be relevant. In mice lacking prostaglandin synthase, inducing allergic inflammation with the house dust mite induces intense pulmonary vascular remodeling, changes that are reversed by administration of PGE2.

In the model of PAH in which loss of arteries is induced by combining injection of an inhibitor of vascular endothelial growth factor (VEGF) and hypoxia, depletion of T cell subsets actually worsens the pathology [38]. This adverse response has been attributed to unbalanced B cell activity resulting from impaired Treg production.

Even in patients with IPAH, with no documented immunodeficiency, there are heightened circulating levels of cytokines

and their receptors, stromal-derived factor (SDF)-1 and monocyte chemoattractant protein (MCP)-1, in addition to fractalkine [36] and its cognate receptor, which are associated with heightened SMC proliferation. Also intriguing are recent studies suggesting that heightened expression of the transcription factor NFATc2 that is associated with inflammatory cells may underlie PAH. Increased nuclear NFATc2 is observed in T cells from IPAH patients and in pulmonary vascular lesions, and this can lead to repression of Kv 1.5 channel expression. NFATc2 can be inhibited by VIVT and its nuclear translocation can be suppressed by cyclosporine. These agents can also attenuate experimentally induced PAH [39].

Toxins and pulmonary hypertension

Ingested substances associated with PAH include aminorex, which resembles epinephrine in its chemical structure, suppresses appetite, and causes symptoms of right-sided heart failure in 10% of patients within 6–12 months of initial administration, as do fenfluramine compounds, for example, dexfenfluramine, a serotonin antagonist [40]. Pathophysiologic studies have also suggested that there are similarities to IPAH. Toxic oils, such as rapeseed oil, have been implicated in the development of malignant PAH. Ingesting pyrrolizidine alkaloids, such as bush tea, causes hepatic veno-occlusive disease, and a similar compound, monocrotaline, when ingested by animals, causes severe pulmonary vascular disease. Rats that ingest the toxin monocrotaline develop pulmonary arterial changes that can be correlated with increased elastase activity. Furthermore, we demonstrated that elastase inhibitors are effective not only in reducing the pulmonary hypertension and vascular changes but also in reversing them.

Based on subsequent knowledge that the effect of elastase was critical in maintaining survival signals through the epidermal growth factor receptor (EGFR), other studies were carried out to block these receptors [41]. Reversal of progressive PAH was sustained even 1 month after cessation of treatment, but the extent of regression was not as great as with elastase inhibition. The use of a PDGF receptor blocker to reverse PAH in this experimental model [42] has prompted a report showing the successful use of a tyrosine kinase inhibitor imatinib (Gleevec) in a patient with advanced pulmonary vascular disease. Subsequent clinical trials using Gleevec in patients with PAH have shown some efficacy but perhaps only in the patients with the most severe disease.

Simvastatin has been used to reverse PAH in a monocrotaline–pneumonectomy model. In the monocrotaline model of PAH, endothelial nitric oxide synthase (eNOS) gene therapy in association with endothelial progenitor cell administration (Figure 5.3) [4,43], gene therapy with survivin, angiopoietin-1, inhibiting the serotonin transporter (SERT), adrenomedullin and the Rho-kinase inhibitor fasudil,

and gene therapy restoring K channel function or BMP-RII have all been used effectively to suppress or reverse pulmonary vascular disease in this model [44].

Unexplained pulmonary hypertension: novel insights through genetics

After all known causes of PAH have been ruled out, the diagnosis becomes that of idiopathic IPAH. This unexplained disease, in which a structural abnormality is always found either in the arteries or in the veins, occurs in both children and adults, sometimes with a familial tendency [45–47]. A mutation in the gene for BMP-RII is associated with >70% of familial PAH [45–47], but the penetrance is only ~20%, that is, 80% of family members who carry the mutation never develop PAH. Moreover, mutations in BMP-RII have been described in 20% of sporadic instances of PAH. In addition, other BMP–TGF-β receptor family members such as ALK1 and endoglin, that were first identified as mutated in hemorrhagic telangiectasia, are also occasionally mutated in patients with PAH.

Although the penetrance is low, the functional link between mutations in BMP-RII and PAH is reinforced by the fact that independent of a mutation in BMP-RII, IPAH patients have reduced BMP-RII protein expression, as do, to some extent, patients with secondary PAH. The functional consequence of reduced or absent BMP-RII in endothelial or smooth muscle cells is related to the pathological features observed in PAH. Impaired downstream signaling has been described in association with a variety of BMP-RII mutations [48,49] and there is also a newly described mutation in pSmad 8 in a patient with IPAH. Signaling through a Smad-independent, p38-mediated pathway may be abnormal when there are alterations in BMP-RII. A few studies have specifically addressed the transcription factors and genes that are subsequently up-regulated or suppressed as a result of impaired BMP-RII signaling. We have shown in smooth muscle cells that BMPs can induce PPARγ transcriptional activity to induce apoE, a suppressor of smooth muscle cell proliferation. These studies showed that the main function of BMP-RII signaling is suppression of the proliferative response of SMC when stimulated by growth factors that are induced under conditions of vascular injury. In EC, in contrast to SMCs, BMPs induce a complex between PPARγ and β-catenin to regulate genes such as apelin that have important protective paracrine and autocrine effects. BMPs suppress apoptosis of endothelial cells in response to injury and are pro-angiogenic, indicating that they may play an important role in repairing damaged microvessels. Apelin, in addition to being a factor that improves endothelial survival, can also suppress smooth muscle cell proliferation.

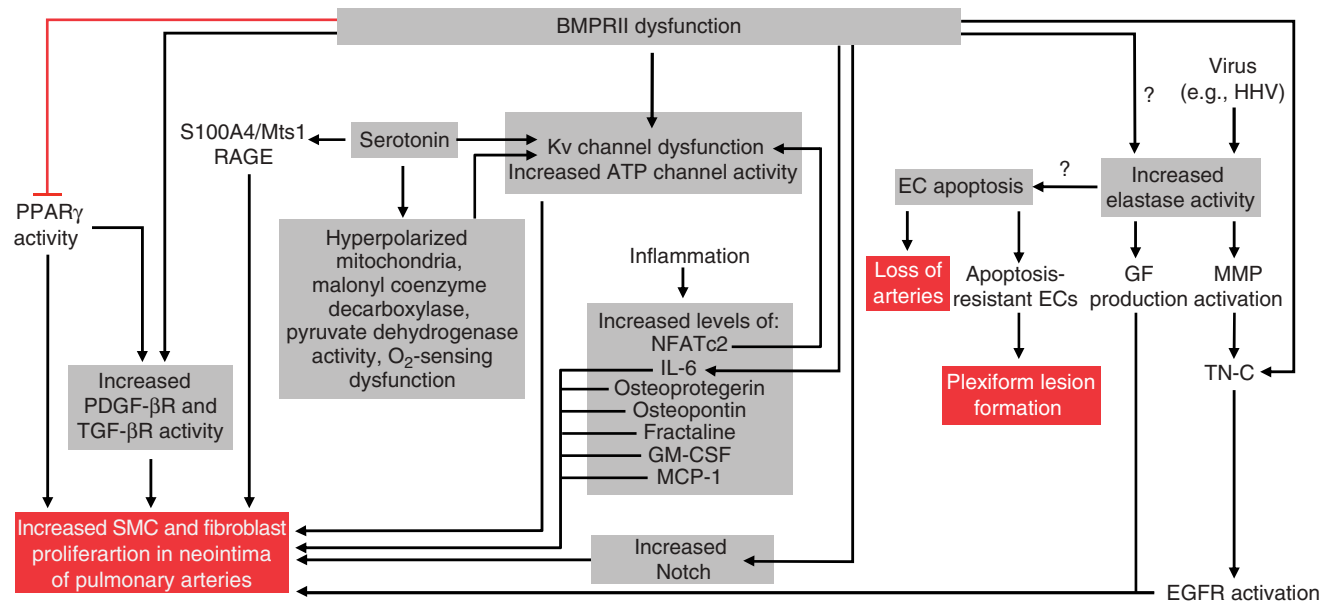
Interactions between the BMP-RII signaling pathway and the Notch signaling pathway led investigators to determine


Figure 5.3 Schema outlining factors that converge in the molecular pathogenesis of PAH and how these may interact with BMP-RII dysfunction, a known genetic defect associated with PAH. This schema focuses on factors causing increased SMC and fibroblast proliferation and also apoptosis of ECs, causing an initial reduction in vessel number, followed by proliferation of apoptosis-resistant ECs in plexiform lesions. It shows multiple levels of interaction, with numerous factors related as described in the text. For example, serotonin stimulates both PDGF-mediated and S100A4/Mts1-mediated SMC and fibroblast proliferation and it also reduces Kv channel function, as does hyperpolarized mitochondria. BMP-RII dysfunction causes Kv channel dysfunction and enhances TRP channel activity, which increases intracellular calcium levels, and may (as reflected by the question marks) induce elastase activity. Viruses of the herpes family can induce elastase activity. Elastase, via activation of MMPs and tenascin C (TN-C), up-regulates growth factor (GF) receptors such as EGF receptors (EGFRs) and also triggers release of growth factors such as EGF from the extracellular matrix, all of which leads to SMC proliferation. BMP-RII dysfunction can also increase PDGF activity, increase SMC proliferation by suppressing PPARγ, and increase TGF-β activity. BMP-RII dysfunction can enhance inflammation via osteoprotegrin and IL-6. NFATc2 can suppress Kv channel function. Other inflammatory mediators such as fractalkine and MCP-1 can, in addition to osteoprotegrin and IL-6, increase SMC proliferation. BMP-RII dysfunction can lead to EC apoptosis, as can elastase activity. EC apoptosis may predispose to the development of apoptosis-resistant ECs in plexiform lesions. MCP-1, mast cell proteinase 1; TRP, transient receptor potential Ca^{2+} channels. Loss of BMP-RII also activates Notch signaling that induces smooth muscle cell proliferation. ATP, adenosine triphosphate; BMPII, bone morphogenetic protein II; EC, endothelial cell; GF, growth factor; GM-CSF, granulocyte macrophage colony stimulating factor; HHV, human herpes virus; IL6, interleukin 6; Kv, voltage gated potassium; MCP-1, mast cell proteinase 1; MMP, matrix metalloproteinase; NFATc2, nuclear factor of activated T cells c2; PDGF, platelet derived growth factor; SMC, smooth muscle cell; TGF, transforming growth factor; TN-C, tenascin C; TRP, transient receptor potential. (Modified from Rabinovitch, *J Clin Invest* 2008;**118**:2372–9.)

that in PAH there is an increase in activity of Notch. The cleavage of Notch following its interaction with a receptor on the SMC surface leads to the internalization of the Notch intracellular domain that serves as a transcription factor to induce genes that cause smooth muscle cell proliferation [50]. Blockade of γ-secretase, the enzyme that cleaves Notch, resulted in prevention and regression of experimental PAH.

Future directions

Further insights into the pathophysiology of PAH will come from genomic studies in which extensive sequencing will likely reveal additional genetic variants associated with this disease. Epigenetic studies are currently being undertaken to address whether changes in chromatin remodeling will help explain why the lung is a target organ and how environmental factors perturb the genome and can lead to further alterations in expression of a rare variant or in the genes that interact with this rare variant. High-throughput gene expression and proteomic studies are also revealing changes that reflect specific pathways that are perturbed and how environmental exposures and immune defects can interact with a vulnerable vasculature. Intense focus on aberrations in immune mechanisms ranging from disturbances in T cell subsets and autoantibody production will be important in understanding all forms of PAH. The more we learn about specific pathways, the better equipped we will be to develop new treatments for pulmonary hypertension.

6 Clinical History and Physical Examination

James H. Moller
University of Minnesota, Minneapolis, MN, USA

In infants and children, the clinical history and physical examination are key in the diagnostic process. After completing these two initial steps, the physician should usually have a major diagnosis or a narrow differential diagnosis and a focused approach to further diagnostic studies. For example, in requesting an echocardiogram after the history and physical examination, the physician requesting the study should indicate a tentative diagnosis and the particular anatomic and hemodynamic information being sought. In neonates, the physical examination changes with the transition from fetal to neonatal life and is often unclear so that the diagnosis often relies primarily on the echocardiographic findings.

History

The history provides four categories of information: (1) diagnostic, (2) severity assessment, (3) etiologic, and (4) effect on the child and family. In addition, while obtaining the history from the parents and the child (when it is age appropriate), the physician can allow the parents to express their concerns and questions, and can assess the level of understanding about the child's condition. The medical interview is an excellent time to provide information and allay anxiety.

Diagnostic information
The medical history, although generally not specific for a particular diagnosis, can often lead to specific diagnostic categories.

The age at onset of congestive heart failure can suggest a diagnosis. Heart failure present at birth or in a fetus is rare and caused by paroxysmal tachycardia, myocardial abnormality, or a volume load that is independent of pulmonary vascular resistance, for example, a severely regurgitant valve or a large arteriovenous fistula. Failure within the first 10 days of life is usually secondary to closure of the ductus arteriosus that unmasks a serious left-sided obstructive condition, such as hypoplastic left ventricle, aortic stenosis, coarctation of the aorta, or interruption of the aortic arch.

Cardiac failure presenting between 6 weeks and 3 months of age occurs with a shunt at either the ventricular or great vessel level. Examples are a large ventricular septal defect, patent ductus arteriosus, and truncus arteriosus. In each of these, the volume of blood shunted is inversely related to the pulmonary vascular resistance. As the pulmonary vascular resistance declines postnatally, the volume of pulmonary blood flow increases. The left ventricle is incapable of handling this excessive volume load, and failure ensues. Heart failure occurring at an older age is likely related to an acquired cardiac problem (see Chapter 70).

The age at which a murmur is first heard is important. A loud systolic murmur heard at or immediately after birth reflects either semilunar valve stenosis, atrioventricular valve insufficiency, or a small ventricular septal defect. Classically, the murmur of a large ventricular septal defect or patent ductus arteriosus is heard initially on the first examination after discharge from the nursery. Murmurs heard for the first time on preschool or school examinations are usually functional, but mild valvar stenosis, atrial septal defect, mitral valve prolapse, and hypertrophic cardiomyopathy may be recognized initially at this time.

Cyanosis, blueness, or duskiness must be carefully assessed by history, physical examination, and oximetry to distinguish central (serious) from peripheral cyanosis (see Chapter 17). The age at onset of the cyanosis is also helpful diagnostically. Complete transposition is the most common cause of cyanosis appearing during the first day of life; more severe forms of tetralogy of Fallot, pulmonary atresia, and tricuspid atresia are others. Ebstein's malformation can also result in severe neonatal cyanosis, but becomes milder as pulmonary

vascular resistance declines, allowing improved pulmonary blood flow (see Chapter 36).

Stridor or noisy breathing and dysphagia can point to a vascular ring or sling (see Chapters 47 and 49). These symptoms appear in infancy and may improve with extension of the neck. Dysphagia can develop with the introduction of solid foods.

Chest pain

In children, chest pain, a common complaint both in emergency rooms [1] and in cardiology clinics [2], is usually of musculoskeletal origin. Chest pain accounts for about 0.25% of clinic visits for children [3,4]. One study [5] reported that 0.6% of encounters in a pediatric emergency room was for chest pain with a 1:1 male to female ratio. In one study [6], the most common causes were chest wall pain (28%), pulmonary causes (19%), minor trauma (15%), idiopathic (12%), psychogenic (5%), and miscellaneous (21%), most often from referred abdominal or respiratory tract. There were no instances with myocardial ischemia. Sik and colleagues [7] wrote of the problem of atypical chest pain in athletes and indicated that it is common and, although almost always unrelated to myocardial ischemia, careful evaluation is indicated. A report by Gregory et al. [8] discusses the common occurrence of musculoskeletal problems of the chest wall in athletes.

Because chest pain in adults is often associated with cardiac disease, its occurrence in a child causes parental anxiety. Careful history of the features of the pain can usually identify its cause. Most chest pain in children and adolescents [9] originates in the chest wall and occurs from costochondritis, trauma, myositis, and precordial catch syndrome. It may be related to a chest wall deformity [10]. Such pain starts abruptly and may last for 15 min, but it usually lasts only a few seconds and is sharp and focal [11]. When asked to indicate its location, the child usually points with a finger to a small area usually lateral to the sternum. In my experience, it is usually on the left side.

Selbst [12], in a prospective study, found that pain of acute onset, abnormal physical findings, pain that awakens the child, and fever indicate an organic cause, but that chest pain in children is usually benign.

Anginal chest pain occurs rarely in children with a cardiac abnormality and is usually associated with severe valvar aortic stenosis or supravalvar aortic stenosis (in the latter, coronary arterial abnormalities may coexist), cardiomyopathy, or pulmonary hypertension. The characteristics of angina in children are similar to those in adults. The chest pain is typically substernal, pressing or constricting, of some duration, and may follow exertion. The child indicates the location by placing the palm of the hand over the midsternum. In an 11-year period, Lane and Ben-Shachar [13] found nine children and adolescents with myocardial infarction presenting to their emergency room. Each had elevation of myocardial enzymes and eight showed an electrocardiographic abnor-

mality. None had an abnormal coronary arterial abnormality, but several had left ventricular hypokinesis.

Other uncommon causes of chest pain in children include the typical pain complexes of dissecting aortic aneurysm of Marfan's syndrome, pericarditis, pulmonary embolism, spontaneous pneumothorax, pleurisy, and peptic ulcer disease.

Pneumonia and pleuritis cause chest pain by irritation of the pleura. The pain is sharp, accentuated by respiration or cough, and may be referred to the shoulder. Pneumonia, bronchitis, and other conditions associated with excessive coughing can irritate the chest wall. Gastritis and esophagitis may cause chest pain, but the history of relation to meals helps to identify these conditions.

Apley [14] has written a great deal about pain in children which is helpful, even though his focus was abdominal pain. In general, if the pain has been present for more than 6 months and there are no abnormal findings, then the pain can be considered as having no organic cause. In this regard, Driscoll et al. [4] found that the average duration from onset of symptom to presentation was 244 days, but with trauma or bronchitis it was 1–18 days.

Syncope is discussed in Chapter 56.

Information about severity of cardiac condition

Details about growth patterns, cyanosis, or congestive heart failure may provide information about severity.

Growth

Growth is often slowed by a serious cardiac malformation. Weight is more affected than is length, and head circumference is seldom affected by the severity of the cardiac anomaly [15]. An abnormally small head circumference can point to a potential cause of the cardiac malformation (e.g., a syndrome, or intrauterine growth retardation secondary to maternal viral infection).

Perhaps 20% of neonates with a cardiac malformation have a birth weight below 2500 g [16]. The frequency of low birth weight varies with the type of anomaly, being higher in ventricular septal defect and atrioventricular septal defect but rare in those with complete transposition. In fact, in complete transposition, the weight frequently exceeds 4.0 kg.

The explanation for delayed growth in utero is uncertain but could include hemodynamic effects of the anomaly on the developing fetus, the generalized effect of an etiologic agent (e.g., rubella), or the presence of an associated syndrome. Postnatal slow growth may be related to a combination of poor feeding and increased metabolic demands related to increased respiratory effort.

Congestive heart failure

The physiologic mechanisms associated with congestive heart failure are discussed in Chapter 70. The cardinal symptoms in infants are slow feeding, rapid respiration, excessive perspiration, growth failure, and frequent respiratory

infections. An infant with congestive heart failure is a "poor feeder." Although eager to eat, the infant soon tires from the fatigue of sucking (sucking is exercise to a infant). Heart failure indicates a severe cardiac malformation.

Cyanosis

Central cyanosis indicates a right-to-left shunt. The intensity of cyanosis reflects the magnitude of shunting and, when combined with knowledge of the anatomy of the malformation, allows estimation of the severity of factors influencing pulmonary blood flow or intracardiac mixing (see Chapter 17).

Etiologic factors

Although the etiology of the cardiac condition cannot be discovered in many instances of congenital or acquired heart disease, the history and physical examination may provide clues to etiology, the underlying diagnosis, and, at times, prognosis.

A careful history seeking information about siblings or other relatives with cardiac problems, neonatal deaths, sudden unexpected deaths, "blue babies," and cardiac operations during childhood may provide clues. The recurrence rate of congenital heart disease is about 3% between siblings or between parent and child, and the concurrence rate for the type of defect is about 50%. Certain conditions, such as complete transposition, seem to have a low rate of recurrence. Others, such as hypoplastic left ventricle, coarctation of the aorta, and aortic stenosis, have perhaps a 10% recurrence rate if careful screening is done to identify bicuspid aortic valves in relatives.

Many acquired conditions afflicting the heart follow Mendelian patterns of inheritance. These are discussed in Chapter 2 (genetics), Chapter 58 (myocardial disease), Chapter 67 (connective tissue disorders), Chapter 30 (aortic stenosis relative to Williams' syndrome), and Chapter 33 (pulmonary stenosis relative to Noonan syndrome).

As many as 50% of children with Down syndrome (trisomy 21) have a cardiac malformation, most commonly atrioventricular septal defect and ventricular septal defect. Less common, but occurring in equal proportions, are tetralogy of Fallot, patent ductus arteriosus, and atrial septal defect. Pulmonary vascular obstructive disease tends to develop early. Aortic stenosis and coarctation are rare. The frequency of Down syndrome increases with maternal age, being 1 per 1925 women at age 20 years and 1 per 100 women at age 40 years, and trisomy is found in age-related Down syndrome. Chromosome analysis should be performed to identify familial translocation involving chromosome 21 or mosaicism. Half of the translocations arise *de novo*, and the other half are inherited from a carrier parent.

Maternal history

A history of acute illness during pregnancy, especially within the first trimester, or a chronic condition in the mother may provide important etiologic information.

A viral infection during the first trimester may be an etiologic factor. Only rubella, which can cause the classic triad of cataracts, neurosensory deafness, and congenital heart disease (patent ductus arteriosus and peripheral pulmonary artery stenosis) [17], has been clearly identified.

Maternal diabetes mellitus has been associated with a higher (about three times) occurrence rate of cardiac malformation [18]. Diabetes mellitus during pregnancy, even of gestational origin, has been associated with asymmetric septal hypertrophy that resolves in the months after delivery. About 30% of such infants of diabetic mothers have cardiomegaly, and cardiac failure occurs in 5–10%.

Maternal systemic lupus erythematosus and other collagen vascular disease cause complete heart block from the transplacental transfer of antibodies that attack this developing conduction system (see Chapter 68).

Excessive maternal alcohol ingestion is associated with fetal alcohol syndrome, in which ventricular septal defect is common [19]. The level of alcohol intake during the first trimester of pregnancy correlates with teratogenic risk.

Maternal medications may also have a teratogenic effect. Phenytoin, trimethadione, and paramethadione have been associated with a higher rate of cardiac malformation, including congenital heart disease, although it remains controversial. Lithium use in mothers has been associated with Ebstein malformation of the tricuspid valve. Thalidomide was found 40 years ago to cause truncus arteriosus and limb abnormalities in infants born of mothers who took this agent as a sedative. Major fetal abnormalities are related to isotretinoin, including cardiovascular anomalies, and this drug must not be used in pregnant women.[20]

The American Heart Association has published two important scientific statements that review the current data about genetic and about other etiologic factors associated with cardiac malformations [21,22].

Physical examination

The patient's age and the setting of the examination determine the way in which the physical examination is performed. Most physicians who care for infants and children have developed particular techniques and sequences of the examination, so that all the necessary information is gathered and key data are not overlooked. Examination of neonates and infants receiving ventilatory assistance may be difficult because access to the patient may be limited and the ventilator noise interferes with auscultation. Often in these situations, it may be difficult to listen to the back, but this should be done if possible because cardiac murmurs may be louder or heard only over the back.

Children aged 1–3 years fear strangers. Having the child sit on the parent's lap for the examination is helpful. Begin by inspecting a child of this age and palpating the peripheral

pulses, before progressing to palpating the thorax. Auscultation should be performed last. In older children, the examination can proceed in the usual manner. Examine from the patient's right side if you are right-handed, from the left side if you are left-handed.

In all patients, length and height must be measured and plotted on a growth chart. For those younger than 3 years, the occipital–frontal circumference should be measured and plotted. In infants and children, cyanosis or cardiac failure affects growth. Weight may be severely affected, but height is affected to a lesser extent. Head circumference is usually unaffected. When head circumference, height, and weight are each low or the severity of the cardiac condition is mild, the retarded growth should be attributed to another factor, such as familial factors or a chromosome anomaly.

The body mass index (BMI) should be calculated and the resultant value compared with normal values to determine if the child is overweight or obese: BMI = weight (kg)/[height (m)]^2. The normal values are available from the Centers for Disease Control; these graphs are similar to standard growth charts showing mean and percentiles for males and for females (http://apps.nccd.cdc.gov/dnpabmi/; http://kidshealth. org/misc/body_mass_index/P_bmi_chart.html).

General appearance

Take a moment to assess the general appearance of the infant or child. Is there distress or appearance of acute or chronic illness? Is the infant or child responsive? Most infants respond to people and are happy. Infants with cyanosis or congestive cardiac failure are frequently irritable.

Skin color

Particularly in neonates and infants, the skin color can provide a clue about the cardiovascular status. Is it pale, red, blue, or mottled?

Cyanosis may be difficult to note, particularly in neonates, especially if the degree of hypoxemia is mild. The amount of ambient light, the examiner's experience, pigmentation, and other factors influence ability to detect cyanosis. Nurses or parents often use the term "dusky" to describe mild cyanosis. With the widespread availability of oxygen saturation monitors, milder degrees of hypoxemia can be detected and quantified.

Cyanosis can be detected when approximately $5\,g\,dl^{-1}$ of reduced hemoglobin is present in capillary beds. Therefore, in a patient with a normal hemoglobin concentration, cyanosis can be detected when oxygen saturation is less than 88% [23]. With polycythemia, it should be possible to detect cyanosis at a higher oxygen saturation. Conversely, anemia makes it difficult to detect even more marked desaturation.

Cyanosis has been divided into peripheral and central. In peripheral cyanosis, also called acrocyanosis, the arterial oxygen saturation is normal, but because of sluggish peripheral circulation, cyanosis appears peripherally. The classic examples are the hands and feet of neonates or infants that

appear blue when exposed to ambient temperature and the circumoral cyanosis that occurs in children who live in a cold climate or have a fair complexion. This form of cyanosis disappears with passive or active motion of the extremity or exposure to warmth. The trunk, abdomen, lips, and mucous membranes are not cyanotic. On occasion, generalized cyanosis occurs in a cardiac condition with normal arterial oxygen saturation, but a severe reduction in cardiac output that causes inadequate and slow tissue perfusion.

In central cyanosis, generalized cyanosis is present, including mucous membranes. In contrast to peripheral cyanosis, aortic oxygen saturation is reduced. Pulmonary, cardiac, and hematologic abnormalities may be associated with central cyanosis. Any condition that interferes with the transport of oxygen from the air to the pulmonary capillary bed can reduce the oxygen saturation of blood returning to the left atrium. In neonates, the respiratory conditions include choanal atresia, respiratory distress syndrome, pneumothorax, severe pneumonia, and pulmonary edema.

Methemoglobinemia can cause cyanosis [24]. Whether it is inherited or acquired, as from infant formula made with contaminated well water (with nitrates), the ferrous ion of hemoglobin is being replaced with the ferric ion. The resultant methemoglobin with the ferric ion cannot combine with oxygen, and cyanosis results. Methemoglobinemia can be suspected by finding a normal arterial P_{O_2} but reduced oxygen saturation value. Another cause of methemoglobinemia is from local anesthetic agents used during transesophageal echocardiography.

Malformations with a right-to-left shunt cause cyanosis, because some of the blood reaching the aorta has not passed through the pulmonary capillary bed. In one group, there is coexistent obstruction to pulmonary blood flow and an intracardiac shunt (e.g., tetralogy of Fallot and tricuspid atresia). In the second group, systemic and pulmonary venous returns mix within the heart (e.g., complete transposition, truncus arteriosus, and total anomalous pulmonary venous connections). A rare cause of cyanosis is pulmonary arteriovenous fistula.

In older infants and children, it is usually easy to determine from history and physical examination the organ system causing the cyanosis. In neonates, it may be difficult to identify cyanosis and determine the underlying condition by physical examination alone. In neonates, the hemoglobin is elevated, which may give a ruddy appearance. The ductus arteriosus and foramen ovale may be patent and allow an intermittent right-to-left shunt if the neonate cries or there is pulmonary disease. Finally, a serious cardiac condition may be present without a murmur to point to the heart as being an issue. With oximetry and echocardiography, the diagnosis can usually be determined

In neonates, cyanosis requires careful assessment (discussed fully in Chapter 17). Oxygen saturation should be

measured in the right arm and a lower extremity in neonates to detect differential cyanosis [25], indicating different levels of oxygen saturation in the upper and lower portions of the body. If the ductus is patent and blood flows from the pulmonary trunk to the descending aorta, the oxygen saturation is lower in the legs than the arms. This difference in oxygen saturation may be found during the first 24 h of life in a neonate without a cardiac anomaly, but is abnormal if found later. This pattern of differential cyanosis is the result of either increased pulmonary vascular resistance, due to causes ranging from pulmonary parenchymal disease to pulmonary venous obstruction (as from obstructed total anomalous pulmonary venous connection), or severe obstruction in the distal aortic arch (as from interruption of the aortic arch or coarctation of aorta). The pattern of differential cyanosis is reversed in a neonate with complete transposition and a patent ductus arteriosus, with flow of oxygenated blood from the pulmonary trunk to the descending aorta. Cyanosis in a single extremity is usually from interference to venous return, as may be associated with a vascular catheter.

Neonates may appear ruddy if hemoglobin or hematocrit is elevated, as from maternal–fetal transfusion or stripping of the umbilical cord [26]. In this situation, the arterial oxygen saturation is usually normal. Because of hypervolemia, there are tachypnea and tachycardia and the chest radiograph shows cardiomegaly and increased pulmonary vascular markings. Distinction from a cardiac malformation may be difficult without echocardiography.

Pallor or mottling of the skin indicates reduced cardiac output or cardiogenic shock. Sepsis, aortic atresia, and critical aortic stenosis or coarctation of the aorta are typical causes in neonates.

Respiration

The respiratory pattern and effort should be assessed. In neonates and infants with elevated pulmonary venous pressure and congestion, edema develops in alveoli and bronchial and interstitial tissues. This leads to increased work of breathing manifested initially by tachypnea; but as the condition progresses, it becomes associated with flaring of the alae nasi and suprasternal and intercostal retractions. Wheezing and rales may appear.

Hyperpnea is found in neonates and infants with reduced pulmonary blood flow and hypoxemia.

Tachypnea is present in infants with left heart failure because of reduced pulmonary compliance from increased pulmonary blood flow or pulmonary edema.

Features of syndromes

The more common syndromes associated with cardiac malformation are given in Table 6.1. The diagnosis of a specific syndrome often pinpoints a cardiac diagnosis or a limited set of conditions.

Thorax

Inspect the thorax for symmetry and precordial abnormalities. Usually the left side of the chest is slightly more prominent than the right. This is accentuated with cardiac enlargement. The posterior thorax is inspected throughout the respiratory cycle for size and symmetric movement with breathing. In patients with a hypoplastic lung, as in scimitar syndrome, the involved hemithorax is smaller. Scoliosis can also cause thoracic asymmetry. Scoliosis should be sought, particularly in adolescents, and it can be brought out by having the patient stand and touch their toes. Although scoliosis may be more common in children with a cardiac malformation, all adolescents should be screened for it. Other causes of thoracic asymmetry and scoliosis include a classic Blalock–Taussig shunt, Marfan's syndrome, and muscular dystrophy.

A precordial bulge signifies cardiac enlargement or right ventricular hypertrophy. In some patients, particularly with Marfan's syndrome, there may be pectus carinatum or pectus excavatum. The latter is also common in prematurely born neonates. Even if severe, it rarely causes cardiac problems. The apex impulse, however, is displaced to the left; on chest radiography, the transverse diameter of the cardiac silhouette is increased, but it is narrow on a lateral film.

Palpate the precordium for the apex impulse, heaves, or thrills. The apex impulse is the most lateral spot on the thorax where cardiac activity can be felt. Percussion may also help identify the location of the cardiac apex. The apex should be within the midclavicular line and in the fourth interspace through age 4 years and in the fifth interspace thereafter. Displacement lateral to the site indicates cardiac enlargement or mediastinal shift. Dextrocardia can be identified by palpating or percussing the heart in the right hemithorax. On palpating the precordium with the palm of the hand, an outward movement along the left sternal border reflects right ventricular hypertrophy, and at the apex, left ventricular hypertrophy.

It was Auenbrugger in 1776 who described the use of percussion to identity the position and size of organs, including the heart. His father was an innkeeper who sent his son to determine the level of wine in the casks. He did this by tapping on the barrel head, finding the point where the tap became dull, thus marking the level of the fluid [27].

Thrills should also be sought with the palm of the hand since it is more sensitive to vibration than fingertips. Thrills indicate a loud murmur, and help to identify the location of its maximal intensity. The suprasternal notch should also be palpated (with the finger tips). Murmurs originating from the base of the heart, particularly from aortic stenosis, result in a thrill in this area. Pulmonary stenosis, coarctation of the aorta, and patent ductus arteriosus are sometimes associated with a thrill at this site, but ventricular septal defect is not. Aortic notch pulsations are prominent in patients with "aortic runoff," as in significant aortic or truncal regurgitation or a large systemic arteriovenous fistula or patent ductus arteriosus.

Table 6.1 Major syndromes associated with cardiac anomalies.

Disorder	Major feature	Cardiovascular abnormality[a]	Etiology
Craniofacial syndrome			
Goldenhar syndrome (oculoauriculovertebral dysplasia, hemifacial microsomia)	Facial asymmetry and hypoplasia, microtia, eartag, cleft lip/palate, hypoplastic vertebrae	(35%) VSD, T of F	?
DiGeorge syndrome (velocardiofacial syndrome, Shprintzen syndrome, familial conotruncal disease, CATCH-22)	Hypertelorism, short philtrum, down-slanting eyes, cleft palate, hypoplastic/absent thymus and parathyroid	IAA, type B; T of F ± pulmonary atresia, right aortic arch	Chromosome 22q11 deletion
Alagille syndrome (arteriohepatic dysplasia)	Long, thin face, intrahepatic bile duct paucity, butterfly vertebrae	Peripheral pulmonary arterial stenosis	Chromosome 20p11.2
Laurence–Moon–Biedl syndrome	Obesity, retinitis pigmentosa, syndactyly, polydactyly, hypoplastic genitalia, mental retardation, diabetes mellitus	Common atrium	Autosomal recessive
Syndromes with limb defects			
Holt–Oram syndrome (see also Chapter 2)	Upper limb deficiency – absent or triphalangeal thumb	ASD	Autosomal dominant
Aase syndrome	Triphalangeal thumb, radial hypoplasia, hypoplastic anemia	CHD	?Autosomal recessive
Thrombocytopenia-absent radius (TAR) syndrome	Thrombocytopenia, absent radii	VSD	Autosomal recessive
Associations			
VATER	Vertebral defects, anal atresia, tracheoesophageal fistula, radial dysplasia, renal dysplasia	VSD	
Charge	Coloboma, congenital heart defect, choanal atresia, growth and mental retardation, genitourinary anomalies, ear anomalies	CHD	8q12 deletion
Cardiofacial syndromes			
Noonan syndrome (see also Chapters 2 and 13)	Abnormal facies, hypertelorism, low-set ears, small stature, lymphedema, mental retardation	Pulmonary stenosis (often dysplasia), peripheral pulmonary artery stenosis, ASD, hypertrophic cardiomyopathy	Autosomal dominant
Williams syndrome	Small stature, mental retardation, characteristic facies (epicanthal folds, anteverted nares, periorbital fullness), infantile hypocalcemia, stellate iris	Supravalvar aortic stenosis, peripheral pulmonary artery stenosis	Sporadic 7q23
Rubenstein–Taybi syndrome	Short stature, mental retardation, broad thumbs and toes, beaked nose, hypoplastic mandible	VSD	Microdeletion of 16p13.3
de Lange syndrome	Prenatal growth retardation, microcephaly, limb reduction anomalies, hirsutism, synophrys, anteverted nares, down-turned lips	CHD	Some partial deletion of chromosome 3
Major chromosome abnormalities			
Down syndrome (trisomy 21)	Characteristic facies, hypotonia, mental retardation, Brushfield's spots, simian crease, intestinal obstruction	40–50% AVSD, VSD; PDA, ASD, T of F, often PVOD; aortic stenosis, coarctation – rare	Trisomy 21, balanced translocation
Turner syndrome	Short stature, webbed neck, lymphedema, gonadal dysgenesis	(20%) Coarctation of aorta–bicuspid aortic valve	Monosomy 45,X (50%); other abnormalities of sex chromosomes (50%)

Table 6.1 (cont'd).

Disorder	Major feature	Cardiovascular abnormality[a]	Etliology
Edward syndrome (trisomy 18)	Low birth weight, microcephaly, micrognathia, rocker-bottom feet, closed fist with overlapping fingers	80% VSD with pulmonary hypertension	Trisomy 18
Patau syndrome (trisomy 13)	Low birth weight, central facial anomalies, polydactyly, chronic hemangiomas, low-set ears, visceral and genital anomalies	80% VSD with pulmonary hypertension, dextrocardia	Trisomy 13
Other syndromes discussed elsewhere			
Tuberous sclerosis	See Chapter 66 (cardiac tumors)		
Marfan syndrome	See Chapter 67 (connective tissue disease) and Chapter 2 (genetic disease)		
Ehlers–Danlos syndrome	See Chapter 67 (connective tissue disease)		

[a]ASD, atrial septal defect; AVSD, atrioventricular septal defect; CHD, congenital heart disease; IAA, interruption of aortic arch; PDA, patent ductus arteriosus; PVOD, pulmonary vascular obstructive disease; T of F, tetralogy of Fallot; VSD, ventricular septal defect.

Cardiac auscultation

With the attention directed to learning and applying a variety of diagnostic techniques, such as echocardiography, to evaluate the heart of children, the skills of auscultation are frequently considered to be less important. The important skills of auscultation must be learned by supervised listening to a variety of heart sounds and murmurs and maintained by frequent practice. Studies of the auscultatory skills of residents showed a disappointing ability to recognize commonly encountered findings [28]. Furthermore, studies have shown that the auscultatory ability did not improve following the third year of medical school through further training including cardiac fellowship [29]. Repetition is very important in developing the ability to identify properly murmurs and heart sounds [30,31]. The Internet can be searched for recordings of heart sounds and murmurs which are on-line. Individuals who play a musical instrument have a greater ability for auscultation [32]. It is ironic that Laennec, who is considered to have discovered the use of stethoscope, was a superb flautist [33,34].

Physical examination is a highly sensitive and specific method of screening asymptomatic subjects for valvar heart disease [35,36]. Newburger *et al.* [37] evaluated the ability of pediatric cardiologists to detect accurately a cardiac condition or a functional murmur by history and physical examination. They further determined the frequency that the initial categorization rate of abnormal or normal status was altered by subsequent investigative studies. Among 142 children considered to have a normal heart, 134 were still considered normal after further testing with electrocardiography and chest X-ray, five had a possible anomaly, and only three had a cardiac anomaly, and these were considered minor anomalies. Among the 104 initially diagnosed with a cardiac anomaly, after investigation all 104 did have an abnormality. The study concluded that an experienced pediatric cardiologist could accurately distinguish between normal and abnormal murmurs. Through training, experience, confidence in one's abilities, and a conviction that auscultation is a valuable diagnostic technique, physicians can correctly identify cardiac murmurs and avoid unnecessary costs and parental anxieties.

To gather the maximal amount of information from cardiac auscultation, particularly in neonates and infants, concerted effort, patience, and experience are required. Repeated examination may be necessary, particularly in neonates or critically ill infants and children, because of changes in cardiac rate or physiologic state. It is preferable to listen to neonates and infants when they are asleep, because the cardiac rate is slower and respirations are quieter. In the young, it is wise to listen through the clothing initially, before disturbing the infant by removal of the clothing, causing the infant to cry or have a faster cardiac rate. In 1–3 year olds, it is best to examine them while they sit on the parent's lap. Because of the natural fear of strangers in this age group, the child should be approached slowly and in a nonthreatening way. Distraction with a toy, a flash-light, blowing bubbles, or having the child view his (her) self in a mirror facilitates auscultation. In older children and adolescents, the anxiety from being examined may cause tachycardia and make auscultation more difficult.

Physicians should use their own stethoscopes rather than one available at the bedside or in the clinic. Stethoscopes can dampen and distort heart sounds and murmurs. Various types have differences in transmission of sound. The ideal stethoscope should have short (about 10 in), thick, fairly stiff tubing and snugly fitting earpieces. Even a tiny leak around

the ear pieces about five times the diameter of a human hair can reduce the sound transmission [38]. The bore of the tubing should be 1/8 in as this is the most efficient for sounds with a frequency of 40–115 cps, the range of most heart sounds [39]. The metal tubing adjacent to the earpieces can be bent to create a firm fit with the external auditory canal. The stethoscope should have both a bell and a diaphragm. I use a 1 in wide diaphragm and 3/4 in bell. It is not necessary to use a smaller sized diaphragm even when examining premature infants; a smaller diaphragm may mask some high-pitched sounds. The chest pieces should fit snugly to the thorax to avoid loss of sound.

High-pitched murmurs, clicks, and cardiac sounds are heard best with a diaphragm. Low-frequency sounds and murmurs are heard better with the bell. Do not press the bell tightly against the skin, as this stretches the underlying skin, creating a diaphragm and diminishing low-frequency sounds. The interested reader is directed to a number of articles on the stethoscope in the digital age [40–46]. A wonderful poem by Oliver Wendell Holmes describes the perils of using a new stethoscope [47]. It might amuse you.

The examination should be performed in a setting with minimal ambient noise. Auscultate both the anterior and posterior thorax for murmurs with the patient in the upright and supine positions. The back can be examined for both respiratory sounds and murmurs when the child sits, when an infant is held against the parent's chest, or when a neonate is prone. The murmurs of coarctation of aorta and peripheral pulmonary artery stenosis are heard over the back, as are murmurs from pulmonary stenosis. Frequently, I sit to the right side of the recumbent patient to perform auscultation. My head is positioned slightly above the level of the patient's head. Often I close my eyes to improve my concentration and open my mouth slightly because this improves hearing.

The examiner should develop a standard sequence to listen to the heart. Each of the four standard auscultatory areas, cardiac apex (mitral area), lower left sternal border (tricuspid area), upper left sternal border (pulmonary area), and upper right sternal border (aortic area), should be systematically listened to with both diaphragm and bell. The right anterior chest and both axillae should also be auscultated, particularly in neonates and infants in whom peripheral pulmonary artery stenosis is common. Both sides of the back should also be auscultated for transmissions of murmurs, such as pulmonary stenosis or coarctation of the aorta, which is heard well in the fourth left intercostal space between the spine and scapula. If abnormalities are noted at a particular site, further exploration should extend outwards from that site. In neonates with severe cardiac failure, auscultation over the head, liver, or other sites may identify an arteriovenous malformation. Attention must be directed to both the characteristic of the heart sounds and the features of murmurs.

The cardiac apex is a logical place to begin because at this location the first heart sound is loudest. In the pulmonary area, the second heart sound is the loudest. Identification of these two sounds allows one to identify more easily the location of murmurs and other heart sounds within the cardiac cycle.

The human ear can select desired sounds from many frequency patterns. With experience, two sounds separated by 20 ms can be distinguished. On the other hand, if a soft sound follows a very loud sound, it may not be heard. The examiner should try to develop the skill of selective auscultation by focusing only on high-pitched sounds or particular aspects of a murmur without interference from the other sounds. It is similar to the ability to listen to a symphony orchestra and pick out the music from a particular instrument to the exclusion of others. One way to help develop this skill is by making a simple line drawing of the sounds and murmurs showing their sequence, location, and loudness.

The human ear has a range of perception from 20 to 16 000 Hz (cps). The normal speech range is from 1000 to 2000 Hz. In comparison, most heart sounds and murmurs are of lower frequency. Most significant murmurs are from 600 to 1000 Hz and functional murmurs are usually below 200 Hz, as are the heart sounds. Below 200 Hz, the human threshold for audibility increases dramatically so that only a portion of the heart sounds may be heard. To be heard, a sound at 30 Hz must have an energy level thousands of times that at 1000 Hz.

Cardiac sounds

The classic work of Wiggers [48] describes the relationship between electrical events, intracardiac pressure, and flow changes during the cardiac cycle. An understanding of these relationships is invaluable in understanding cardiac sounds and in interpreting murmurs on the basis of their location within the cardiac cycle (Figure 6.1). The origin of heart sounds is uncertain, having been ascribed to valvar events, acceleration or deceleration of columns of blood, myocardial contractions, or a combination of these [49].

Although a number of mechanisms for heart sound production have been proposed, the one discussed most widely involves the generation of vibrations which are transmitted to the thoracic wall. These vibrations in the cardiovascular system are caused by (1) acceleration or deceleration of blood and (2) turbulence during rapid blood flow.

In this proposed theory, the relationship between the combined mass of the heart and its blood–volume–cardiohemic system is compared with the elasticity of the cardiac walls. As blood moves within the heart and great vessels, the momentum of the moving blood causes overstretch of the wall, which then recoils. In diastole, when the combined mass is large in comparison with the elasticity of the relaxed ventricle, low-frequency vibrations are produced. During systole, with the heart contracting, the frequency of the
Figure 6.1 Modifications of Wigger's diagram [48]. (a) Pressure curves from right and left sides of heart and superimposed heart sounds and murmurs. Pressure curves: Ao, aorta, LA, left atrium, LV, left ventricle, PA, pulmonary artery, RA, right atrium, RV, right ventricle. Heart sounds: A_2, aortic component of second sound, ESC, ejection systolic click, OS, opening snap, P_2, pulmonic component of second sound. S_1, first sound, S_3, third heart sound, S_4, fourth heart sound. (b) Events on left side of heart. Systolic ejection murmur (SM) begins when left ventricular pressure exceeds that in aorta and extends to point where aortic pressure falls below LV pressure (A_2) Regurgitant murmur (RM) begins when left ventricular pressure exceeds left atrial pressure and extends to closure of aortic valve (A_2). (c) Events on right side of heart. Systolic ejection murmur (SM) extends to closure of pulmonary valve (P_2). Regurgitant murmur (RM) extends to point where right ventricular pressure falls below that of right atrium.

vibrations is increased. These vibrations are transmitted to the thoracic wall with sufficient intensity and high enough frequency to be audible. The sound waves are not reflected. The energy from the heart sounds is lost in the compressible lungs and dampened by fat tissue. Transmission is best through solid tissues.

First heart sound. At the onset of systole, blood is accelerated towards the AV valves before they are sealed, causing the low-pitched vibrations of the first component of the first heart sound. Once the valve has closed and the ventricular pressure is rising during systolic contraction, the movement of blood towards the valve is suddenly stopped and there is recoil towards the ventricle, causing the higher pitched second component of the first heart sound. The intensity of this component depends on the velocity and abruptness with

which it is decelerated. The sound is loudest when the valve has been widely open at the beginning of systole. A third component is heard following the opening of the semilunar valves. The inertia of the columns of blood in the great vessels opposes the acceleration of blood flow from the ventricles. This may lead to some rebound towards the ventricle. There may be a fourth component from blood flowing through the arterial trunks.

Second heart sound. At the end of systolic ejection, ventricular pressure falls rapidly and the ventricle relaxes. The column of blood in the arterial trunks rushes back towards the semilunar valves and its movement is stopped by the closed valves and recoils, causing vibrations. The difference in time between the closure of the valve and the dicrotic notch on the arterial pressure tracing and the second heart sound is

called the "hang out" interval. This interval for the aortic valve ranges from 5 to 13 ms It is longer for the pulmonary valve because of the much more compliant or distensible pulmonary circuit. This is a major factor in the splitting of the second heart sound.

Third heart sound. When the atrioventricular valves open, blood rushes into the relaxed ventricles. Its forward motion is arrested and recoil occurs, causing low-frequency vibrations because the ventricular walls are relaxed.

Murmurs. Murmurs often result from some form of obstruction to flow. Several hypotheses have been made for their production. These were outlined by Rushmer [49] as follows:

1 Eddies occurring around a jet through a restricted orifice.

2 A jet impacting a wall, which would produce vibrations from that wall.

3 Vortex shedding causing vibrations.

4 Periodic wake as sounds travel alternately around either side of an obstruction. This is unlikely.

5 Flutter. This would be produced by a Bernoulli effect. Although this phenomenon can produce sound, it is unlikely in the vascular system.

6 Cavitation. Although cavitation can be produced with high-speed jets and sound, it is unlikely to be found in the cardiovascular system.

Because both normal and abnormal heart sounds occur at approximately the same time as closure or opening of cardiac valves, it has been convenient to ascribe a causal relationship between the two, particularly in discussing cardiac auscultation as in this chapter. In 1958, Leatham [50] wrote an excellent article about cardiac auscultation. It is an extremely helpful review for understanding heart sounds and murmurs, even though it is six decades old. The information included in his paper is used extensively in the sections on heart sounds and murmurs below. This article is one of the most important publications that I read as a fellow and I have used its information throughout my career as a foundation to build upon; it can be highly recommended. Another excellent source was published by Chizner [44].

Heart sounds mark the transition of phases of the cardiac cycle (Figure 6.1). In infants and children, four distinct heart sounds may normally be heard. These include a first heart sound, the aortic component of the second heart sound, the pulmonic component of the second heart sound, and a third heart sound (about 50% of children). Below these are described first, followed by abnormal heart sounds including systolic ejection click, mid to late systolic click, opening snap, and fourth heart sound. The normal characteristics and the alterations from normal are discussed.

First heart sound (S₁)

The first heart sound occurs near the time of closure of the mitral and tricuspid valves [51,52]. Although consisting of several components, the first heart sound appears single in most infants and children. It may be split, with the initial component reflecting the earlier closure of the mitral valve. Rarely is the first heart sound split in infancy. When it is, Ebstein's malformation of the tricuspid valve must be considered strongly. Some adolescents have a split first heart sound.

The first heart sound is heard best at the cardiac apex, where it is louder than the second heart sound. If the first heart sound is heard better along the lower left sternal border, an abnormality on the right side of the heart must be suspected.

The first heart sound may be either accentuated or diminished. The first heart sound may be accentuated in four conditions:

1 *Increased blood flow across an atrioventricular valve.* In patients with either increased pulmonary blood flow from a left-to-right shunt or regurgitation of an atrioventricular valve, the first heart sound may be accentuated. The first heart sound is accentuated at the cardiac apex in patients with increased anterograde flow across the mitral valve, as in ventricular septal defect, or patent ductus arteriosus. The first heart sound is accentuated along the lower left sternal border (tricuspid area) in patients with increased anterograde flow across the tricuspid valve, as in atrial septal defect or tricuspid regurgitation.

2 *Atrioventricular valvar stenosis.* Both mitral stenosis and tricuspid stenosis are rare in children in the developed world. In areas with a high prevalence of rheumatic heart disease, however, mitral stenosis may be found in late childhood and adolescence. In such patients, a high-pressure differential exists across the mitral valve at the end of the diastole. Thus, a higher than normal ventricular systolic pressure must develop before valve closure occurs. Because of the higher closure pressure, the first heart sound is accentuated. I have heard accentuation of S1 in older children with congenital mitral stenosis but have not appreciated it in infants or young children with this condition.

3 *Short PR interval.* If the PR interval is short, as in Wolff–Parkinson–White syndrome, the interval between atrial contraction and onset of ventricular systole is also shortened. Thus, the atrioventricular valves are maximally open, so the length of excursion of leaflets to closure is great. Therefore, the first heart sound is loud.

4 *Conditions with increased cardiac output.* Increased cardiac output from conditions such as anemia and arteriovenous fistula is associated with increased anterograde flow across the atrioventricular valves, shortened diastole, and increased ventricular contractility. These factors combine to increase loudness of the first heart sound.

The loudness of the first heart sound may be diminished from three general conditions:

1 *Prolonged atrioventricular conduction.* When the interval between atrial contraction and onset of ventricular systole is prolonged, the atrioventricular valve leaflets have returned from their maximally opened position. Hence the length of

valvar excursion to closure is presumably decreased, and the first heart sound is soft. The loudness varies with atrial fibrillation [53] and with heart block.

2 *Depressed myocardial function.* In patients with depressed myocardial contractility, as in myocarditis, the first heart sound may be diminished.

3 *Moderate to severe mitral regurgitation.*

Second heart sound (S₂)

The normal second heart sound is composed of two sounds; the first, A_2, represents the earlier closure of the aortic valve, and the second, P_2, the later closure of the pulmonary valve. The second heart sounds occur at the time of the incisura of aortic and pulmonary arterial pressure tracings and are generally coincidental with the transition between the end of ejection and the onset of isovolumetric relaxation. The two components of the second heart sound are heard best in the second and third left intercostal spaces because the pulmonary valve, the most anteriorly located valve, lies immediately below this area and the aortic valve slightly lower along the left sternal border.

The term *splitting of the second heart sound* is applied to the phenomenon of hearing two components of the second heart sound. Our studies have indicated that an interval of at least 20–25 ms must be present between the two components before they can be heard as separate sounds by an experienced pediatric cardiologist. The degree of splitting normally varies with respiration, increasing with inspiration and decreasing with expiration, reflecting the variable volume of blood returning to the right ventricle with the phases of respiration. This phenomenon is termed *variable splitting.* In patients with tachycardia, particularly neonates and infants, it may be difficult to appreciate splitting or variability. Repeated auscultation when the heart rate is slower may allow clearer characterization of the second heart sound components. Considerable diagnostic information can be obtained by careful attention to details of the second heart sound. Three aspects of the second heart sound must be assessed: loudness of individual components, degree of splitting, and variations in patterns of splitting.

Loudness of the components of the second heart sound depends on the level of pressure in the great arteries, position of the aortic and pulmonary valves within the thorax, and thickness of the anterior chest wall. In infants and children, P_2 is louder than A_2 because the pulmonary valve lies immediately below the chest wall, whereas the aortic valve is located centrally within the thorax and is surrounded by cardiac structures. The difference occurs even though pulmonary arterial pressure is considerably lower than aortic pressure. In patients with transposition of the great arteries, the second heart sound is loud and single because the aortic valve, located beneath the chest wall, is closed with a high pressure and the more distant pulmonary valve being closed at a lower pressure is masked.

The loudness of a component of the second heart sound depends on the pressure level at the time of the incisura of the arterial pressure wave It reflects neither peak systolic nor diastolic arterial pressure. Because many forms of cardiac malformation are associated with pulmonary hypertension, care must be directed towards increased loudness of P_2, which reflects an elevated pulmonary arterial pressure.

The aortic valve is centrally placed in the thorax, approximately behind the sternum at the level of the fourth space and midway in the chest. The ascending aorta comes closest to the chest wall to the right of the upper sternum. Therefore, A_2 is normally heard loudest at the upper right sternal border or equally loud at the upper right and left sternal borders. If A_2 is loudest at the left sternal border, an abnormal aortic position is indicated. Thus, in tetralogy of Fallot, with a dextroposed and dilated ascending aorta, A_2 is loudest to the left of the sternum in the fourth intercostal space. In both complete and corrected transposition, A_2 is loudest to the left of the sternum in the second intercostal space, and the same may be true in a truncus arteriosus. Other forms of malposition, including dextrocardia, may also give an A_2 that is loudest at the upper left sternal border.

During the first 2 days of life, the second heart sound appears single because of the elevated pulmonary vascular resistance normally present at this stage of life and the nearly identical aortic and pulmonary arterial pressure curves. Subsequently, the second heart sound becomes split as the pulmonary vascular resistance falls. A single second heart sound beyond the immediate neonatal period indicates a serious cardiac anomaly with a single functioning semilunar valve. There may be only one semilunar valve, as in truncus arteriosus, or two valves in which one is either atretic or severely stenosic. The second heart sound is single (aortic component) in patients with pulmonary atresia, severe pulmonary stenosis, or tetralogy of Fallot. It may be single (pulmonary component) in aortic atresia or severe aortic stenosis. Unfortunately, these anomalies cause severe symptoms in the neonatal period, when S_2 normally appears single, so auscultation cannot allow their identification.

If the second heart sound is split but does not vary with respiration, the phenomenon is called *fixed splitting.* This usually coexists with wide splitting and indicates a large atrial communication, as typically occurs in patients with an atrial septal defect in which wide, fixed splitting is characteristic. Wide splitting reflects an increased volume of blood being ejected from the right ventricle and being fixed reflects an atrial communication that allows adjustment of flow distribution in the atria with phases of respiration.

In evaluating the second heart sound, attention should be directed to the degree of splitting. With experience, it is possible to identify wide splitting, indicating that this interval between the components of the second heart sound exceeds 60 ms. If the second heart sound can easily heard as split in a tachycardic neonate or infant, it should be considered widely split.

The second heart sound is widely split in patients with prolonged right ventricular ejection due to:

1 *Increased volume of right ventricular ejection.* If the volume of blood ejected by the right ventricle across the pulmonary valve is increased, P_2 is delayed. This may result from pulmonary regurgitation or an atrial level shunt, such as atrial septal defect or anomalous pulmonary venous connection.

2 *Obstruction to right ventricular outflow.* In severe pulmonary stenosis or tetralogy of Fallot, right ventricular ejection is prolonged and P_2 delayed.

3 *Complete right bundle branch block in which right ventricular depolarization is prolonged abnormally, as is right ventricular systole.* Thus, P_2 is delayed.

Delayed closure of the aortic valve can be identified by paradoxical splitting of the second heart sound. Because A_2 is delayed and may occur after P_2, the degree of splitting narrows on inspiration and widens on expiration, a pattern opposite of normal. In my experience, paradoxical splitting is rare during childhood and adolescence. Three types of conditions associated with paradoxical splitting are (1) increase in left ventricular ejection volume, as in severe aortic regurgitation or patent ductus arteriosus; (2) obstruction to left ventricular outflow, as found in patients with severe aortic stenosis; and (3) complete left bundle branch block.

Third heart sound (S₃)

A third heart sound may be heard in childhood. This low-frequency, broad sound occurs at the peak velocity of ventricular inflow and the transition between rapid and slow filling phases of diastole. This sound has been considered to arise in a ventricle from sudden deceleration of flow during rapid filling [54–59]. The normal third heart sound disappears in adulthood by the age of 40 years because the increased left ventricular wall thickness with age causes a decrease in the velocity of ventricular filling [60].

Third heart sounds may originate from either the left or right ventricle, being heard better at the cardiac apex (mitral area) or lower left sternal border (tricuspid area), respectively. This sound is prominent in patients with increased volume of ventricular filling [61–63]: increased pulmonary blood flow, valvar regurgitation, and anemia. In a patient with tachycardia from any cause, a third heart sound may become prominent and be interpreted as a gallop, a sound suggesting cardiac failure and myocardial dysfunction. In this situation, proceed carefully and reserve the term *gallop* when other findings support a diagnosis of cardiac failure.

Early systolic ejection click

An early systolic ejection click occurs shortly after the first heart sound and at the transition between isovolumetric contraction and the onset of ejection. It is recorded at or shortly after the opening of a semilunar valve. During the first 24 h of life, a click may be heard normally; but after that age, an ejection click is always abnormal and indicates dilatation of either the ascending aorta or pulmonary trunk. Dilatation may occur from either aortic or pulmonary valvar stenosis (poststenotic dilatation) or from conditions associated with an enlarged major arterial trunk, such as truncus arteriosus, Marfan's syndrome or pulmonary hypertension.

The mechanism for production of a click is unknown. It occurs at the time of maximal opening of a stenotic valve, suggesting that it may be valvar in origin. On the other hand, it may result from sudden tensing of the wall of a dilated great vessel in which elastic fibers are known to have degenerated so that the wall is supported mainly by indistensible collagen.

The characteristics of a systolic ejection click reflect the vessel of origin – pulmonary artery or ascending aorta. Pulmonary clicks are heard best with the diaphragm of the stethoscope in the pulmonary area with the patient sitting. They become louder in expiration. Aortic ejection clicks are heard best at the cardiac apex and left lower back with the patient reclining. They do not vary with the phase of respiration. They are lower pitched and may be difficult to distinguish from the second component of a split first heart sound.

Mid to late systolic click

Mid to late systolic clicks occur with mitral valve prolapse, and are sharp, high-pitched sounds heard best at the cardiac apex. They vary considerably in loudness with maneuvers that alter left ventricular volume. They are louder when the patient is standing or sitting because of the smaller left ventricle volume and become softer and later when the patient reclines or squats, resulting in a larger left ventricular volume. This click may also be heard along the left sternal border when a ventricular septal defect is being closed by a pseudoaneurysm, but it does not vary during the respiratory cycle.

Opening snap

An opening snap is a rare auscultatory finding in children and adolescents in most parts of the world. It is heard in mitral valve stenosis, which is most commonly caused internationally by rheumatic heart disease. This sound, heard better with a diaphragm at the cardiac apex or lower left sternal border, occurs shortly after the end of isovolumetric relaxation, at the time of maximum opening excursion of the anterior leaflet of the mitral valve. The mechanism for the sound production is unknown.

Fourth heart sound (S₄)

A fourth heart sound is low pitched, occurs during atrial contraction, and precedes peak atrial inflow velocity. It is associated with lesions that limit ventricular distensibility. It is a frequent finding in patients with coronary artery disease, cardiomyopathy, severe semilunar valve stenosis (either aortic or pulmonic), and hypertension (systemic or pulmonary) [64]. A fourth heart sound may be found in patients with

increased cardiac output, as in anemia or arteriovenous fistula. It can also be heard in patients with second- or third-degree heart block. Fourth heart sounds originating from the left ventricle are heard at the apex, those from the right ventricle along the lower left sternal border. These are common in adults but infrequent in children.

Cardiac murmurs

Cardiac murmurs result from turbulence of blood flow through the heart or major arteries. Reynolds' number has been used to understand the factors that cause turbulence in a system of laminar flow. Although blood flow is not necessarily laminar and homogeneous, the equation helps understand factors leading to turbulence. Reynold's number (Re) [65] indicates that turbulence arises in a Newtonian fluid of viscosity η and density ρ, flowing with a velocity V through a tube with diameter D according to the relationship $Re = DV\rho/\eta$. Reynolds' number is dimensionless, but when it exceeds a critical value, about 2000 for a viscous fluid, turbulence occurs. Turbulence could occur with a high flow velocity or low blood viscosity.

Six characteristics of a murmur should be identified and described. Each provides a specific type of information about hemodynamic and anatomic associations. These characteristics are

- loudness: reflecting severity of the anomaly
- location within the cardiac cycle: relating the murmur to hemodynamic events
- location on the thorax: relating the murmur to an anatomic site
- radiation: indicates direction of turbulent blood flow
- pitch: reflecting the pressure difference
- other characteristics meaningful to the examiner, such as "musical," "blowing."

By identifying and describing these characteristics, the examiner can gain much understanding of the underlying condition causing the murmur.

Loudness

The loudness of a murmur is described by a system of grades. These are

- grade 1/6: soft and heard after an extended period of listening
- grade 2/6: soft but immediately heard
- grade 3/6: moderately loud, unassociated with a thrill
- grade 4/6: loud, usually associated with a thrill
- grade 5/6: loud, heard with stethoscope barely off the thoracic wall
- grade 6/6: loud, heard with stethoscope off the thoracic wall.

This system is most useful to an individual examiner who has developed an internal sense of grading so that, with experience, murmurs of similar loudness receive the same grade. Even with experience, this is not always possible to achieve. I find it particularly difficult to apply grades 3/6

and 4/6 to systolic murmurs and grades 1/6 and 2/6 to diastolic murmurs.

The loudness of a murmur reflects the severity of a lesion and the amount of blood passing through the abnormal area, as in the following examples.

1 In aortic or pulmonic regurgitation, the more severe the lesion, the greater is the regurgitant volume and the louder the regurgitant murmur. If the regurgitant orifice is small, there is a pressure gradient from the artery to the ventricle throughout the whole of diastole, and the murmur is long. If the regurgitant orifice is large, pressures tend to equalize in the artery and the ventricle so that the murmur tends to end earlier during diastole.

2 When the entire cardiac output passes through an abnormal structure, as in aortic, pulmonic, or mitral valve stenosis, the more severe the stenosis, the greater is the pressure drop across the valve, the flow is more turbulent, and the murmur is louder. If the obstruction is severe enough to reduce the cardiac output, the murmur becomes softer. Furthermore, with significant aortic or pulmonic stenosis, the velocity of flow across the valve is greater and the resulting murmur is higher pitched (see below).

3 In a small ventricular septal defect, the pressure difference between the ventricles is large, and the murmur is often loud. If the defect is larger and associated with a huge left-to-right shunt through it, the murmur is also loud, even though the pressures are similar in the two ventricles. If a ventricular septal defect is associated with increased pulmonary vascular resistance (neonatal period, or after pulmonary vascular disease develops), only a small flow crosses the defect. This results in little turbulence and only a soft murmur. Similarly, when the ventricular septal defect is small, perhaps less than 2 mm in diameter, little blood crosses and the murmur is high pitched and soft.

Location in the cardiac cycle

Murmurs should be described according to when they occur in the cardiac cycle. Timing of murmurs has been described as systolic, diastolic, or continuous, each being further subdivided into more specific intervals of the cardiac cycle. In neonates, infants, and others with tachycardia, it may be difficult to categorize beyond systolic, diastolic, or continuous. Other features, such as location on the thorax or pitch, may be helpful.

Systolic murmurs

There are three types of systolic murmurs: pan(holo)systolic, ejection systolic, and late systolic.

Pansystolic murmurs

Although the prefix *pan-* suggests all of systole, these murmurs do not necessarily extend to the second heart sound, but they do begin with the first heart sound. Therefore, pansystolic murmurs include the period of isovolumetric

contraction, and make it difficult to identify the first heart sound. During isovolumetric contraction, because all cardiac valves are closed, blood should not be moving within the heart. Only three conditions allow blood to flow during isovolumetric contraction: ventricular septal defect, because the ventricles are in full communication throughout systole; mitral insufficiency; and tricuspid insufficiency. In the last two, the higher ventricular systolic pressure compared with lower atrial pressure allows blood to regurgitate from a ventricle to an atrium during isovolumetric contraction. Pansystolic murmurs are also called regurgitant murmurs, indicating regurgitation across an atrioventricular valve.

The murmur of mitral insufficiency is heard best at the cardiac apex, is high pitched, and has been described as "blowing." Tricuspid insufficiency is low pitched and heard along the lower left sternal border. In this same area, the much more frequently occurring ventricular septal defect murmur is heard and is generally high pitched.

The systolic murmur of a ventricular septal defect, located over the precordium and associated with a thrill, has been called a Roger murmur. Roger described it as "long and loud" and that "it entirely occupies the period of the normal tic-tac of the normal heart sounds" [66]. Henri Louis Roger (1809–1891) was a French pediatrician who was very interested in auscultation. He presented his observations to the French Academy of Medicine and concluded that the only explanation for such a prominent murmur was a defect in the interventricular septum. Subsequent to his initial presentation, he observed a 26-month-old child with such a murmur who died of "pulmonary mishap." The autopsy of the child showed a ventricular septal defect in the "upper portion of the interventricular septum" [67].

Ejection systolic murmurs

Ejection murmurs are limited to the ejection phase of systole. Therefore, they begin after the isovolumetric contraction phase. This point is a key distinction between the two major types of systolic murmurs. In an ejection murmur, a short period exists between the first heart sound and the onset of the murmur.

Ejection murmurs result from turbulence either into or within the aorta or pulmonary trunk. These can be caused by outflow tract obstruction, by stenosis in large central arterial vessels, or from increased volume of blood across a normal outflow tract. Respective examples are pulmonary or aortic stenosis (valvar, subvalvar, supravalvar), coarctation of the aorta or peripheral pulmonary artery stenosis, and atrial septal defect. Because there are only two outflow tracts by which blood exits the heart, the maximal location of the murmur allows identification of whether obstruction lies in the right (pulmonary area) or left (aortic area) outflow tracts.

Late systolic murmurs

Late systolic murmurs occur with mitral valve prolapse. As the left ventricular volume becomes progressively smaller during systole, the volume becomes small enough so that the posterior leaflet prolapses into the left atrium. This permits regurgitation that increases as the ventricle continues to contract to the end of systole. Hence the murmur is crescendo to the second heart sound. As discussed previously in this chapter, the murmur is introduced by a mid to late systolic click (see also Chapter 28) and its duration varies with body position as discussed above.

Diastolic murmurs

There are three types of diastolic murmurs, early, mid, and late. The first follows S_2, the second represents a widening of the S_3, and the last reaches a peak in the cardiac cycle where an S_4 would be heard.

Early diastolic murmurs

Early diastolic murmurs immediately follow the second heart sound, occupy the period of isovolumetric relaxation, and may extend beyond that period. They result from insufficiency of either the aortic or the pulmonary valve. Regurgitation occurs from flow from the higher pressure great artery to the lower pressure ventricle. They have been called regurgitant murmurs. Note that all regurgitant murmurs, whether in systole or diastole, occupy isovolumetric periods.

Mid-diastolic murmurs

Mid-diastolic murmurs occupy the period of time at the transition from rapid to slow filling phases of the cardiac cycle. They occur from increased volume of blood flow across anatomically normal atrioventricular valves. Usually, the anterograde flow must be about twice normal before a mid-diastolic murmur is heard. Mitral mid-diastolic murmurs are heard in conditions such as mitral insufficiency and shunts at the ventricular or great vessel level (ventricular septal defect, patent ductus arteriosus, truncus arteriosus). Tricuspid mid-diastolic murmurs occur in tricuspid regurgitation (as in the Ebstein's malformation) and atrial level shunts (atrial septal defect, total anomalous pulmonary venous connection). Mid-diastolic murmurs occur with mitral and tricuspid stenosis with presystolic accentuation. Because there is little diastolic pressure difference across the atrioventricular valves in these conditions, mid-diastolic murmurs are low pitched. In 1862, Austin Flint described in patients with aortic insufficiency a mid-diastolic murmur that was distinct from the high-pitched early diastolic murmur from the regurgitation [68]. Called an Austin Flint murmur, he considered it to be related to fluttering of the anterior leaflet of the mitral valve being struck by the regurgitant jet.

Late diastolic murmurs

Murmurs occurring late in diastole are also called protodiastolic or presystolic. They result from atrioventricular valve stenosis, which is usually of the mitral valve. They increase in loudness (crescendo) to the first heart sound as the gradient between the atrium and its respective ventricle increases and is accentuated by atrial contraction.

Continuous murmurs

A continuous murmur begins in systole and continues into diastole, but does not necessarily continue throughout the cardiac cycle. The murmur has the same characteristics in both phases of the cardiac cycle. It is not a separate systolic and a diastolic murmur. Continuous murmurs can be divided into two categories, depending on whether the murmur is louder in systole or in diastole.

Louder in systole

A continuous murmur, louder in systole, indicates a communication between the arterial and venous systems, usually large vessels. The classic example is patent ductus arteriosus, but others include bronchial collaterals in cyanotic patients and a peripheral arteriovenous malformation. In a neonate, a continuous murmur over the upper chest often indicates pulmonary valvar atresia, with a patent ductus arteriosus being the major or sole source of pulmonary blood flow. In a neonate, continuous murmurs are also heard from arteriovenous malformations or fistulas and are heard best over their anatomic location. In a patent ductus arteriosus, the murmur is often crescendo in late systole because of the time taken for the pulse wave to reach the ductus. The original description of the murmur by Gibson in 1900 remains as true today as it was over a century ago [69].

Louder in diastole

Continuous murmurs louder in diastole point to an abnormality of blood flow in major veins. The volume of blood returning to the right atrium is greater during diastole because of right ventricular filling. The most frequent cause is a benign venous hum, but it can occur if there is increased blood flow in the superior caval system, as in total anomalous pulmonary venous connection to a supracardiac vein or cerebral arteriovenous fistula.

Location on the thorax

A murmur is loudest closest to its anatomic origin. Murmurs should be described by their anatomic location, such as upper right sternal border, upper left sternal border, lower left sternal border, or cardiac apex, rather than by the respective terms commonly used: aortic area, pulmonary area, tricuspid area, mitral area. Because of the array of cardiac malformations, for instance the pulmonary artery and valve may not be located in the "pulmonary area," as in transposition of the great arteries, and a murmur in the "mitral area" may arise from an inverted tricuspid valve as in congenitally corrected transposition of the great arteries.

In addition to the four traditional auscultatory sites, both axillae should be auscultated (peripheral pulmonary artery stenosis), as should the back, particularly the left paraspinal area (coarctation of the aorta). In patients with normally related great arteries, murmurs heard best along the upper left sternal border and beneath the left clavicle originate from the right ventricular outflow tract, and those extending from the midsternum to the area beneath the right clavicle originate from the left ventricular outflow tract. Murmurs along the lower left sternal border commonly result from a ventricular septal defect, and less frequently from obstructive cardiomyopathy or tricuspid regurgitation.

Radiation

Other locations where the murmur is heard should be described. These secondary sites indicate radiation of the murmur and reflect the direction of turbulent blood flow. Murmurs from the right ventricular outflow tract radiate to the left upper back. The left pulmonary artery is a direct extension of the pulmonary trunk and is directed posteriorly and to the left. In tetralogy of Fallot, wherein the right ventricular outflow tract is oriented typically towards the right, the murmur is heard best over the right side of the back. Murmurs from the left ventricular outflow tract area are directed into the carotid arteries, particularly the right. In patients with a moderate or large ventricular septal defect or significant tricuspid regurgitation, radiation is towards the right sternal border and right anterior chest, reflecting the direction of turbulent flow. The murmur of mitral regurgitation classically extends to the left axilla and left lower back.

Pitch

The pitch or frequency of a murmur reflects the pressure difference creating the turbulent flow and murmur. High-pitched murmurs result when there is a large pressure difference, as in mitral regurgitation or aortic regurgitation. In contrast, the murmurs of tricuspid and pulmonary regurgitation are lower pitched because of lower right-sided cardiac pressures in normal individuals. Diastolic murmurs from anterograde flow across an atrioventricular valve, as in a left-to-right shunt, are low pitched.

The murmur of pulmonary regurgitation can be higher pitched with pulmonary hypertension. This murmur has been named Graham Steell murmur [70], after the English physician who described it. Steell lived from 1851 to 1942 and was an Assistant Physician to the Manchester Royal Infirmary when he described it. In his paper, he indicated how it could be distinguished from the murmur of aortic regurgitation which was also high pitched.

Other features

A variety of other terms are used commonly on rounds or in clinics to describe murmurs. These terms, such as harsh, blowing, musical, and to-and-fro, are less precise and perhaps are of greatest use to the individual examiner who has his or her own auditory concept of harsh, blowing, or musical.

Functional murmurs

During childhood, half of children have a murmur. These are often transient, appearing when the child has a fever or only on one examination, and occur in a structurally normal heart. Although these have been called functional or innocent murmurs, I prefer to call them "normal murmurs" when describing them to parents, to indicate that the heart is structurally and functionally normal and that these murmurs are normal phenomena.

The clinical diagnosis of a functional (normal) murmur is a two-step process. The first is to distinguish whether the patient's murmur reflects a major cardiac condition or could represent a normal murmur. This step depends on whether the murmur is associated with five features common to all children with a functional murmur:

1 There are no meaningful cardiovascular symptoms.

2 The murmur is less than grade 3/6.

3 The heart sounds are normal. Particular attention must be directed to the second heart sound.

4 The heart size is normal. This can be assessed by palpation of the cardiac apex.

5 The murmur is usually short, ending by the first half of systole.

In a study of children with an innocent vibratory or a pulmonary flow murmur and a group of children with an easily confusable mildly pathologic murmur, phono-spectrographic analysis was performed. The functional murmurs were usually below 200 Hz and with a frequency spectrum with more harmonic structure. In contrast, pathologic murmurs had both lower and higher frequencies [71].

Rosenthal, in an article about distinguishing innocent from pathologic murmurs, listed six criteria for identifying a pathologic murmur [72]:

1 all diastolic murmurs

2 all pansystolic murmurs

3 late systolic murmurs

4 very loud murmurs

5 continuous murmurs

6 associated cardiac abnormalities.

Eight distinct normal murmurs have been identified, and each must be distinguished from murmurs resulting from cardiac abnormalities that may have some similar features. One early study of children showed that 85% were Still's murmurs, 14% pulmonary flow murmurs, and 1% cardiopulmonary murmurs [73].

Pulmonary flow murmurs

This soft, short systolic ejection murmur, believed to result from turbulence in the right ventricular outflow tract and pulmonary trunk, is heard along the upper left sternal border. It is more common in adolescents and in females by a ratio of 3:1 [71]. It can appear with fever and anemia. It must be distinguished from atrial septal defect, which has a similar murmur, but the wide, fixed splitting of the second heart sound is diagnostic. Also in atrial septal defect, in contrast to a functional pulmonary flow murmur, the tricuspid valve closure is loud, and a mid-diastolic murmur is common in the tricuspid area. Mild valvar pulmonary stenosis may have a similar murmur, but it is longer, higher pitched, and preceded by an ejection click.

Vibratory, "twangy string," or still's murmur

This short, early midsystolic murmur is heard best between the lower left sternal border and the cardiac apex. Like the pulmonary flow murmur, it seldom persists beyond midsystole. It is uniform in frequency, hence its name vibratory. The origin of the murmur is uncertain. Many believe it to be related to turbulent flow in the left ventricular outflow tract and related to higher aortic flow volume and velocity [74–76]. Harris *et al.* [77], using cathode-ray oscilloscopy, found relatively dense spectrographs below 250 cps for both Still's and murmurs from other high-output states. They considered that the murmur was caused by vibrations of its natural period of some structures of the cardiac walls or great vessels. In some children, an anomalous band has been found in the left or right ventricle [78]. In one study [79], 76% of patients with this murmur had a band in the left ventricular outflow tract, compared with 14% of those without a murmur. Joffe, however, could not detect turbulence around the anomalous bands by echocardiography [80]. Others [81–85] suggested that the murmur is from the combination of a small aortic diameter and high aortic velocity. A report [86] and accompanying commentary [87] provide insight into this type of murmur as possibly originating from increased intraventricular velocities. Klewer *et al.* [88] used dopamine stress echocardiographic studies in normal subjects without a murmur to produce a Still's-like murmur when the cardiac output was increased. They found that a lower body surface area correlated with the presence of the murmur, explaining why Still's murmur is most often seen in younger ages. Subsequently, Donnerstein and Thomsen [89], using spectral analysis of Still's murmurs, found characteristic time-varying spectra related to a patient's age and cardiac dimensions rather than flow velocity. The spectral frequency decreased with age. They suggested that the disappearance of the murmur as the child grows may be related to a murmur having such a low frequency that is below the auditory threshold. The murmur is usually heard in preschool-aged children [90].

The major differentiation is from ventricular septal defect. Because most ventricular septal defects are membranous, they are heard best along the left sternal border in the third and fourth interspace. The murmur of a muscular ventricular septal defect may be heard in the same area, but it is harsher.

It was the British pediatrician, Sir George Frederick Still (1868–1941), who first described this functional murmur in an era before echocardiography. Still also described a variety of chronic polyarthritis associated with lymphadenopathy, splenomegaly, and irregular fever. Still's description of the murmur which bears his name is as follows [91]: "It is heard usually just below the level of the nipple and about half way between the left margin of the sternum and the vertical nipple line; it is not heard in the axilla nor behind, it is systolic and is often so small that only a careful observer would detect it; moreover it is variable in audibility; its characteristic is a twangy sound very like that made by twanging a piece of tense string."

Venous hum

This continuous murmur is louder in diastole and heard best along the upper right sternal border. It results from turbulent flow in the jugular venous system. Thus, there may be a thrill posterior to the sternocleidomastoid muscle over the jugular vein. The murmur is heard better when the patient is sitting and disappears or softens on reclining. The murmur varies as the patient turns the head back and forth or when gentle pressure is applied over the base of the neck.

A similar murmur can be heard in an occasional patient with total anomalous pulmonary venous connection to the left superior vena cava. It may also be heard with a cerebral arteriovenous malformation.

Carotid bruit

In virtually all children, an early systolic murmur may be heard over the bifurcation of the carotid arteries. It should not be confused with radiation of a murmur of aortic stenosis to the carotid arteries. Palpation of the suprasternal notch helps to distinguish these because with aortic stenosis, a thrill is palpated in this area.

Cardiopulmonary murmur

This noise is believed to result from compression of the lingula of the lung between the heart and anterior chest wall. I have heard a similar noise along the right sternal border. This noise is louder during mid-inspiration and mid-expiration, becoming soft or absent on full inspiration or full expiration. It is heard better when the patient is sitting.

Peripheral pulmonary artery stenosis

In some neonates, particularly those born prematurely, a midsystolic ejection murmur may be heard over both lung fields, including on the back, in the axillae, and beneath both clavicles, but not over the precordium. Present in the neonatal period, it usually disappears by 3 months of age

and is always gone by 1 year of age. In fetal life, because little flow occurs through the lungs, there is a discrepancy of size between the large main pulmonary artery and smaller branch pulmonary arteries. Postnatally the murmur disappears as the branch pulmonary arteries increase in size.

Mammary souffle

In lactating women, a low-frequency background hum due to a large increase in blood flow to the breasts through superficial blood vessels may be heard immediately over the breast. Gentle pressure over the area may diminish the loudness. Its importance is in distinguishing it from a patent ductus arteriosus or an arteriovenous fistula.

Cephalic bruit

Cephaic bruits are heard much more commonly in early school-aged children than adults, perhaps because of the higher cerebral blood flow in the young than adults. (100 ml per 100 g min^{-1} in a 5-year old versus 50 ml per 100 g min^{-1} in a 30-year-old) They are more common in those with decreased blood viscosity (anemia), increased blood flow (hyperthyroidism, cerebral arteriovenous fistula), or local narrowing of an artery.

Variant auscultatory findings

In two groups of pediatric patients, neonates and athletes, the auscultatory findings are unique.

Neonates

The first heart sound is loud at birth and decreases in intensity during the first 48 h of life. It may be split, with the second component being loud in the tricuspid area. A systolic ejection click along the left sternal border has been reported to occur in many neonates. The second heart sound is single at birth, presumably due to elevated pulmonary vascular resistance [92]. By 2 days of age, it becomes split in normal neonates.

Several studies of normal neonates have described the frequency and types of murmurs in neonates [93–102]. On careful auscultation, one-third to three-quarters of neonates have been described as having a murmur.

1 A continuous murmur in the pulmonary area heard best with the bell. In one series, this occurred in 37% of normal neonates [95], was transient, and usually disappeared by 12 h of age. Its frequency is higher in premature infants and those with asphyxia, in whom it may not disappear for several months, indicating delayed closure of the ductus arteriosus.

2 Crescendo systolic murmur in the pulmonary area. This grade 1 to 2/6 murmur is believed to be related to flow through the ductus, because in some neonates this murmur represents a transition towards closure.

3 Pulmonary systolic ejection murmur. This grade 1 to 2/6 murmur may develop during the first day of life and last up to 6 days.

A high occurrence of functional murmurs has been found in infants and, in one study, in 80% of prematurely born infants [97], most frequently at 3 months of age. Many of these have characteristics of a vibratory murmur. Other authors have described a low incidence of functional murmurs in neonates and infants [99–101].

In neonates, a significant murmur present at birth or during the first hours of life usually indicates either aortic stenosis or pulmonary stenosis (with either intact ventricular septum or a ventricular communication). Mitral and tricuspid insufficiencies, both rare conditions in a neonate, also result in a systolic murmur. A small ventricular septal defect may be heard within days of birth. Large shunts at either the ventricular or great vessel level may not be evident in the neonatal period because elevated pulmonary arterial pressure and resistance limit blood flow through the communication.

Athletes

In trained athletes, the resting cardiac rate is often low. Therefore, the stroke volume and end-diastolic volume are increased as a result of these physiologic adaptations. The peripheral pulses are strong. The pulse pressure is increased, reflecting an increase in systolic pressure from increased stroke volume and lowered diastolic pressure from prolonged diastole. The apex impulse may be slightly beyond the midclavicular line. An ejection systolic murmur is heard along the upper left sternal borders, and a third heart sound may be prominent.

Evaluation of murmurs

In a 1996 article entitled "The demise of the physical examination," Janhar [102] commented that physicians are busier and have less time for physical examination and that their examinations are often inaccurate. He also posited that doctors are uncomfortable with uncertainty and rely on technology. But technology also can be inaccurate and the results be irreproducible and filtered through the eyes and mind of the interpreter. Thus, they may be contaminated by subjectivity. There have been a number of articles about the evaluation of murmurs in children particularly because of the incidence of functional murmurs. McCrindle *et al.* [103] found that referring physicians are reasonably accurate in determining the presence of a cardiac abnormality and that a noncardiac factor often was a major factor in referral to a cardiologist. One study showed that the decision for referral to a cardiologist is based on the presumed diagnosis, confidence of the referring physician, and the level of parental anxiety [104].

In the evaluation of a child referred for evaluation of a cardiac murmur, are diagnostic studies necessary? An early study by Newberger *et al.* [37] showed that diagnostic tests of electrocardiography and chest X-rays were unlikely to change a diagnosis of either the presence of a functional murmur or a murmur of a cardiac anomaly, when evaluated by a qualified pediatric cardiologist. As echocardiography became available, the issue has become whether this relatively more expensive test should be performed. Many authors have indicated that careful clinical examination allowed the diagnosis of functional murmurs and that echocardiography was unnecessary [104–109].

The discovery of a murmur causes parental anxiety, which is lessened by parental understanding of murmurs. Consultation relieves the anxiety in most parents [110]. High parental anxiety, however, is associated with lower pediatrician reassurance and greater pediatrician practice years [111]. In one study [112], on referral only 3% of parents felt their child could have a serious cardiac condition, 19% felt there was a non-serious cardiac problem, 76% felt their child had a normal heart, and 2% felt confused. After consultation, the perception that their child had a non-serious problem increased by 30%, those who felt that their child's heart was normal decreased to 68%, and 3% were confused. None felt that there was a serious heart problem.

Pericardial friction rubs

Pericardial friction rubs are characteristic of pericarditis, but are not always present. Sometimes the rub disappears if there is coexisting effusion, but the fluid in the pericardial sac does not necessarily obliterate the rub. Friction occurs as the heart moves, and so can be present during atrial systole, ventricular systole, and ventricular diastole. Although separate rubs may occur during each cardiac phase, they often blend into a single rub. Rubs are scratchy noises that sound close to the ear and become louder as pressure is placed on the stethoscope. Usually they are heard better over the lower left sternal border and may be loudest in either phase of respiration.

Abdomen

Hepatic location and size are key components to be determined in examining an infant or child with a cardiac abnormality. Hepatic location helps identify visceral situs, which is important in understanding the nature of a cardiac malposition. Assessment of hepatic size aids in recognizing congestive cardiac failure, for in this hemodynamic state hepatomegaly is present and may change rapidly. The lower margin of the liver should be palpated and its distance from the rib margin measured in the midclavicular line. The upper margin of the liver should be assessed by percussion over the lower thorax. Therefore, the total height of the liver can be determined. Studies have shown no correlation between palpability of the lower border and the total height of the liver. This finding shows that both parameters of the size of the liver depend on the position of the organ apart from size. Thus, a child could have an enlarged liver even with a liver edge in the normal range. The upper extent of the liver is normally located in the fifth

intercostal space in the mid-clavicular line. The hepatic span is 6 cm in neonates [113]; it may be palpated as far as 3 cm below the right costal margin, and it is usually no longer palpable by 4 years. Remember that the liver edge may be easily palpable in patients with hyperexpanded lungs as it is displaced into the abdomen by the flattened diaphragms. The normal (average) liver span is 7–8 cm in the first 6 months of life, 9–10 cm until 24 months, 12 cm for preschoolers, 14 cm for 5–9 year olds and 16 cm for 10–16 year olds [114,115].

The spleen tip may be palpable in infants and is rarely enlarged in pediatric patients with cardiac failure. It may be enlarged in those with infective endocarditis.

In children with hypertension, stenosis of a renal artery can be suspected by finding a bruit over the upper or mid-abdomen.

Peripheral edema

Peripheral edema is present in many normal neonates during the first 2 days of life. It may persist longer in premature infants.

Abnormal degrees of edema are found at birth from fetal hydrops and nonpitting lymphedema, often associated with Turner's syndrome. Cardiac causes are uncommon (supraventricular tachycardia being the most common); urinary tract obstruction and hepatic cirrhosis are other causes. Observing puffy eyelids or edema over the back of a neonate may identify the edema.

Edema from cardiac causes is also uncommon after the neonatal period and is usually related to renal disease or exudative enteropathy. An unusual but important cause to recognize is constrictive pericarditis.

Skin

Hypoxemia, even mild, may be associated with digital clubbing after 6 months of age. Early in the process, there is a decrease in the angle between the base of the nail and the mantle. At this stage, there is redness or shininess of the terminal phalanx. There are often hangnails. Subsequently, widening and thickening of the distal phalanx of the toes and fingers occur, and the nails become convex like the back of a spoon. In some infants and small children with a large left-to-right shunt, the fingertips and at times the palms are unusually erythematous. Nail beds should be inspected for splinter hemorrhages in patients with suspected infective endocarditis. In cyanotic patients, the scalp veins are often dilated. The skin should be inspected for hemangiomas, particularly of the strawberry type, in patients with a clinical picture that could represent multinodular hemangiomatosis [116]. In infants with cyanosis or cardiac failure, the hair is thin and fine and the fingernails require clipping infrequently. Following relief of their condition, the hair becomes thicker and the nails need clipping much more frequently.

7 Electrocardiography

Anne M. Dubin

Stanford University, Palo Alto, CA, USA

The electrocardiogram (ECG) is useful in diagnosing a variety of functional and pathological changes from arrhythmias to electrolyte disturbances or atrial and ventricular hypertrophy, in addition to their progression or regression. It aids in diagnosing several specific anomalies, such as tricuspid atresia and anomalous left coronary artery from the pulmonary artery.

Principle and technical considerations

Basic vector principles

Contracting heart muscle generates an electric current that flows in specific pathways through the heart. It is convenient to regard the current as coming from a single source in the heart, although this oversimplifies the problem. If we could place electrodes on the heart to detect the current or its associated voltage, it would be relatively simple to deduce where the current came from and where it was going. Because the electromagnetic forces are altered as they spread through the various body compartments and tissues to reach the surface, the voltages detected there are not the same as the voltages in the heart.

As in all electromagnetic phenomena, the voltage detected at the skin surface follows the inverse square law, so that for a given vector, voltages are diminished if the ventricular wall is far from the surface and exaggerated if it is very close. This explains why in some premature infants the mid-precordial leads show abnormally large voltages. Furthermore, the media through which the voltage is transmitted to the skin (blood in the chamber, pericardial fluid, air in the lung, and skeletal muscle) affect the surface voltages. Because air is a poor conductor of electricity, lung hyperinflation (airway disease, cystic fibrosis, emphysema) often decreases voltage transmission anterior and laterally but increases posterior

transmission, rotating the vector posteriorly. This may make diagnosing right ventricular hypertrophy difficult. As another example, in Pompe disease (glycogen storage disease type II), the ECG voltages are out of proportion to the degree of hypertrophy because of altered conductivity of the muscles of the chest.

Because an electric current has a voltage and a direction of flow, it can be represented by a vector, an arrow pointing in that direction with a length proportional to the voltage. Two vectors moving simultaneously in different directions produce a single resultant vector (Figure 7.1). In the heart, electrical currents may travel in different directions simultaneously, and at each moment we see the resultant vector. Thus, although the impulse spreads out from the sino-atrial node in all directions, because the sino-atrial node is at the upper right portion of the atria, the resultant vector – the P wave – passes down and to the left. In the ventricles, the initial vector normally is negative in aVF and positive in lead I, as shown by a q wave in lead aVF and no q wave in lead I, and so passes to the left and superiorly. At the apex, some impulses pass to the right in the right ventricular wall and some pass to the left in the left ventricular wall. In the neonate, the right and left ventricles are equally thick, but the right ventricular wall is closer to the anterior chest leads so that the QRS complex has a predominant R wave in V1. In the left chest leads, the left ventricular wall is closer to the leads, so that there is usually a dominant R wave in V6, although not as large as the R in V1. Because mean right vectors are greater than mean left vectors, the main frontal plane QRS axis is to the right.

With age, the right ventricular wall thins, the R wave in V1 becomes smaller and the R wave in V6 becomes larger; the main frontal plane vector moves to the left (Figure 7.2). At the end of ventricular depolarization, the vector points to

(a) (b)

(c) (d)
Figure 7.1 Two pairs of vectors with different directions are shown in (a) and (b), and (c) and (d) show how the resultant vectors would look (heavy arrows). It is shown in (d) that the negatively directed vector reduces the size of the resultant positive right-directed vector. The final vectors cannot indicate what the initial vectors were.

Neonate Older child
Figure 7.2 Diagram to show how right ventricular wall thickness influences main frontal plane QRS axis.

the right and superiorly, generating small negative waves in leads I and aVF. The tips of the mean vectors at each moment can be joined to form a loop (Figure 7.3). At times, analyzing the initial and terminal vectors helps in evaluating complex depolarization patterns. Although vector recordings are not used much clinically today, projection of vectors on the various leads produces the typical scalar ECG.

Vector loops can also be constructed in the horizontal plane, and can be applied to all the waves on the ECG.

Scalar ECG

The standard ECG has 12 leads recorded from 12 standard body surface positions (Figure 7.4). Electrodes must be placed accurately, and the skin cleaned with alcohol to decrease skin resistance. The patient should be quiet to eliminate motion artifact, but this may be difficult to achieve, especially in infants and small children.
Figure 7.3 Diagram of five sequential vectors labeled 1–5. A thicker line shows the main vector 3. The tips of the vectors are joined to form a loop that here is counterclockwise.

In children, the ECG often includes three additional leads, V3R, V4R, and V7, to add right- and left-sided chest leads to determine ventricular hypertrophy.

ECGs are routinely recorded at a paper speed of $25\,mm\,s^{-1}$, but can provide speeds up to $50\,mm\,s^{-1}$ that help determine rhythm disturbances. The machine has a standard voltage gain of $1\,mV$ per $10\,mm$ in vertical deflection that can be decreased to reduce large voltages and so avoid overlap between leads.

Reading the pediatric ECG

An organized approach to reading a pediatric ECG is essential. Rate and rhythm are assessed, as are intervals: RR, PR, QRS, and QT (Figure 7.5). The P, QRS, and T wave axes are determined. Atrial and ventricular hypertrophy and also abnormalities of ventricular repolarization are sought. For each major wave, three features should be assessed: axis, amplitude, and duration. Normal intervals and voltages are age dependent. Davignon *et al.* published normal ECG measures by age in 1979 [1], standards commonly used when interpreting pediatric ECGs (Table 7.1). Any interpretation of the tracings must consider the clinical setting.

Rate and rhythm

The RR interval is commonly reported as cycle length (measured in milliseconds), and the heart rate measured by dividing the cycle length into $60\,000\,ms\,min^{-1}$. Heart rate depends on many factors, including age, autonomic nervous tone, and physical activity.

The first step in assessing the cardiac rhythm is to confirm normal AV conduction with P waves preceding each QRS. Sinus P waves have an ECG pattern indicating atrial depolarization from top to bottom and right to left (positive in leads I, II, and aVF). The normal P wave axis is 15–75° in both the frontal and horizontal (precordial lead) planes. P waves are often biphasic in lead V1, with an initial upright
Figure 7.4 Electrode placement for standard ECG. (a) At any moment during ventricular depolarization there is a net voltage moving in a given direction. This voltage can be depicted as an arrow pointing in that direction with a length proportional to the voltage, that is, a vector. The main frontal plane vector is indicated by the thick solid line and arrowhead inside the loop. Around the vector is the Einthoven triangle, derived from the three limb leads (I, II, and III). The long, thin lines parallel to the Einthoven triangle indicate the convention for each lead, with a wave passing from negative to positive being upright. If perpendiculars are drawn from the end of the major frontal plane axis to the three edges of the triangle (dotted lines), they show how much of the voltage of the frontal plane axis will appear in each lead. These voltages are shown by the heavy lines and arrows superimposed on the triangle. The greatest voltage appears in the lead most nearly parallel to the frontal plane axis (lead II), and the smallest voltage appears in the lead most nearly perpendicular to the frontal plane axis. (b) The conventional sites for placing the unipolar V leads. V1 and V2 are in the fourth intercostal space at the right and left sternal edges, respectively. V4 is in the fifth space in the midclavicular line (MCL), and V3 is half way between V2 and V4. V5 and V6 are in the fifth interspace in the anterior and mid-axillary lines, respectively. V3R and V4R are the equivalent of V3 and V4, but in the right thorax. Sometimes V7 is placed in the fifth space in the posterior axillary line, especially if no Q wave is seen in V6.
Figure 7.5 Scalar ECG showing P, Q, R, S, T, and U waves. The J point and also standard intervals including the PR interval, QRS duration, ST segment, and QT interval are shown.

deflection followed by a brief downward deflection and are upright in the left precordial leads. If the P wave does not meet these criteria, there is an ectopic atrial rhythm or cardiac malposition. The P wave vector can be used to predict the origin of the atrial pacemaker: an inverted P wave in leads I and aVL suggests a left atrial rhythm, a P wave inverted in leads I, II, and aVF suggests a low right atrial rhythm, and a P axis positive in lead aVF and negative in lead I suggests situs inversus, other cardiac malposition, or an artifact of reversal of right and left arm leads.

Conduction of the impulse slows as it passes through the atrioventricular node, producing the PR interval and allowing time for complete ventricular filling. The PR interval increases with age, and varies with activity and heart rate. Abnormally prolonged AV conduction can indicate impaired AV nodal or infranodal disease, and is classified as first- (long PR interval), second-, or third-degree AV block. A short PR interval can be seen with glycogen storage disease, tricuspid atresia, Wolff–Parkinson–White (WPW) syndrome, or a low atrial pacemaker near the AV node.

Axis

The electrical axis is the direction of the predominant vector of a waveform. In the frontal plane, it is presented on a Cartesian system with lead I as 0° (left) to 180° (right) and lead aVF as 90° (inferior) to 270° (superior), with the other limb leads corresponding to other angles in the frontal plane (Figure 7.4). The frontal plane axis should be calculated for the P, QRS, and T waves. Initially the quadrant is determined by looking at leads I and aVF. Once the quadrant is established, the most isoelectric frontal lead is identified. The axis is perpendicular to this lead in the previously identified quadrant (Figure 7.6). Frontal plane QRS axis deviation depends on the child's age and generally moves from right to left as the heart develops (see Table 7.1 for changes in axis with age).

The precordial leads essentially map a transverse plane, with right–left and anterior–posterior coordinates. In this plane, the QRS axis also shifts from right anterior in neonates to leftward in older children.

Table 7.1 Normal ECG standards for children by age. All values are 2nd to 98th percentiles (and mean, in parentheses). All amplitudes of waves are given in millimeters at full standardization [1].

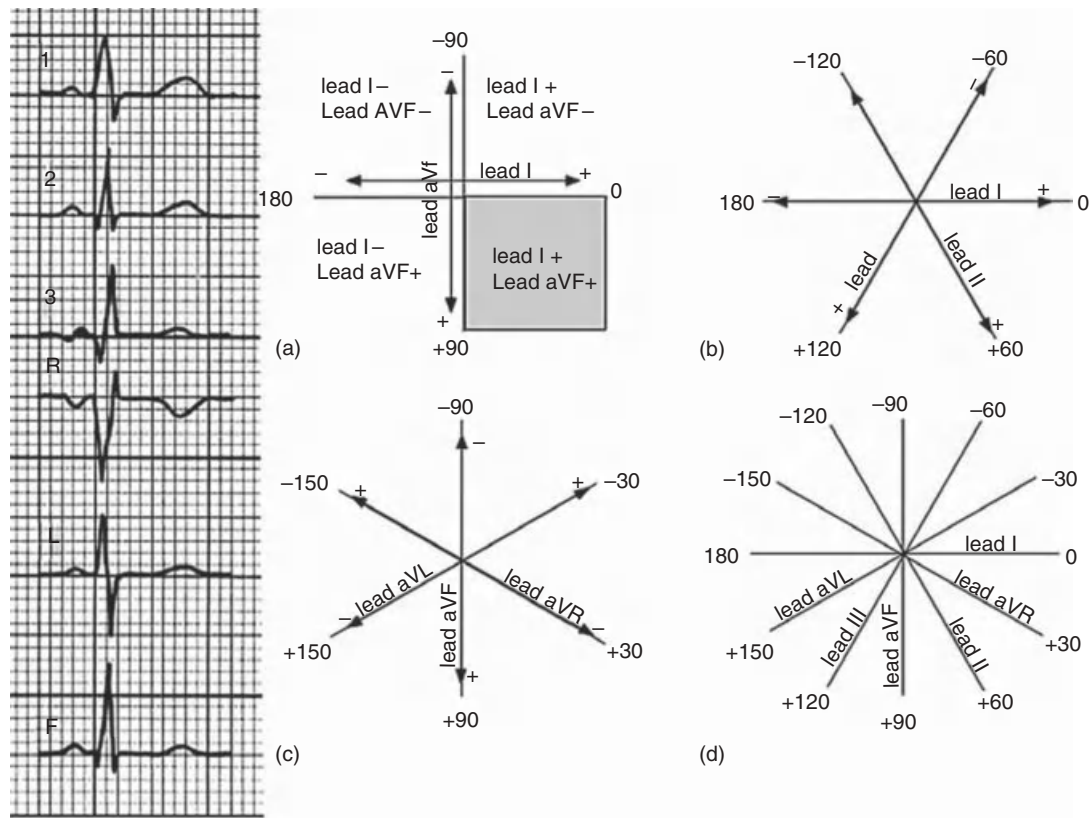

Figure 7.6 A normal electrocardiogram in an older child is shown. To calculate a frontal plane QRS axis: (a) first assign a quadrant, based on the area under the QRS deflection (positive or negative) in leads I and aVF. In the tracing shown, the left lower quadrant (shaded) is selected. (b) The three limb leads I, II, and III are inclined at 60° to each other. The + and – symbols on the arrowheads indicate the direction of each major deflection. (c) The three unipolar limb leads aVF, aVL, and aVR are also inclined at 60° to each other but at 30° to the bipolar limb leads. Because they are unipolar leads, an impulse directed towards either shoulder or the foot will give a positive deflection, as shown by the symbols over the arrowheads. (d) The two triaxial sets of lines in panels (b) and (c) can be superimposed in a hexaxial figure. This can be used to refine the calculated axis. In the accompanying example, the axis lies in the left lower quadrant, so we examine leads aVR and II. The S wave in lead aVR is similar in height to the R wave in lead II, so that the axis is between +30 and +60°. Alternatively, look for the lead with nearly equiphasic RS waves and take the perpendicular to this lead. The lead with almost equiphasic RS waves in the example is aVL, and the perpendicular to this which passes through the lower left quadrant is ~60°. Because it is actually area under the QRS rather than maximal voltage, there may be slight differences in the axis calculation made by eye. In most modern ECG machines, the axis is calculated automatically. Occasionally, some or all of the leads show almost equiphasic R and S waves so that a frontal plane axis cannot be calculated. This has no clinical significance.

Atrial enlargement

Because the normal spread of activation in the atria is from right to left, the first part of the P wave is right atrial, the last part is left atrial, and the middle has an overlap. Therefore, right atrial enlargement increases the P wave voltage but does not make the P wave wider, and left atrial enlargement makes the wave wider.

In assessing P wave amplitude, right atrial enlargement can be diagnosed by a peaked tall P wave in lead II, usually accompanied by a biphasic or tall P wave in lead V1. Left atrial enlargement shows a broad notched P wave in lead II, or a deep slurred biphasic P wave in V1 with a prominent terminal negative component and the P wave duration is 100 ms or longer. Biatrial enlargement is diagnosed when signs of both right and left atrial enlargement are seen.

Ventricular depolarization

Ventricular depolarization produces the QRS duration on the surface ECG. The QRS duration is age dependent, with a normal upper limit of 80 ms at <8 years of age, and 90 ms through childhood and adolescence. By assessing QRS duration, an abnormality of ventricular depolarization can be identified. Fairly specific conditions prolong the QRS, including bundle branch block (left or right), pre-excitation, or a ventricular pacemaker. The term intraventricular conduction delay refers to QRS prolongation that does not fit the above categories.

Bundle branch block

The distal conduction system is divided into the left and right bundle branches that depolarize the right and left ventricles, respectively. The right bundle is narrow and long, and passes

Figure 7.7 Typical right bundle branch block pattern.

Figure 7.8 Typical left bundle branch block pattern.

across the apex of the right ventricular body in the moderator band. The left bundle divides into two fan-like sheets of specialized conduction tissue, the anterior and posterior fascicles. Because of the wide distribution of the left fascicles, damage must be extensive before conduction to the left ventricle is affected. Conduction delay or block of one of these bundles, or in one of the fascicles, whether secondary to CHD surgery, medication, or ischemia, delays activation of the corresponding ventricle with a characteristic appearance on ECG.

Right bundle branch block (RBBB)
In RBBB, the QRS complex is characterized by abnormalities of its terminal portion. There is rapid initial depolarization of the left ventricle followed by a slower depolarization of the right ventricle. Complete RBBB is diagnosed when QRS exceeds upper limits of normal for age, and a terminal QRS complex is delayed and directed anteriorly, to the right, and superiorly. Characteristically there is a broad R′ wave in leads aVR, V1 and V 2 and a broad S wave in leads I, II, V5 and V6 (Figure 7.7). RBBB is common following surgical closure of ventricular septal defects. Occasionally it is familial. With RBBB, it is not possible to diagnose right ventricular hypertrophy (RVH) because criteria for ventricular hyper-

trophy are based on normal depolarization. The secondary ST and T wave abnormalities cannot be used to diagnose ischemia reliably.

Left bundle branch block (LBBB)
In LBBB, the initial portion of the QRS complex is affected. The QRS in LBBB is prolonged, slurred, and directed towards the left, posteriorly and inferiorly. LBBB is diagnosed by prolonged QRS duration because of delayed initial portions, indicated by notched slurred QRS complexes directed leftward and posteriorly (QS or rS in lead V1 and tall notched R wave in lead V6). The initial part of the QRS complex is directed towards the right rather in the normal pattern of a Q wave in leads I and V6 (Figure 7.8). LBBB is uncommon in children and results from surgery on the left ventricular outflow tract and hypertrophic cardiomyopathy. It is difficult to assess hypertrophy and ischemic changes with LBBB.
Figure 7.9 Left anterior hemiblock.

Left anterior hemiblock

The left anterior fascicle activates the anterior and superior portion of the left ventricle, and when blocked the posterio-inferior region activates first, followed by the anterior–superior aspect. This produces a marked superior left axis deviation (−30 to −90°) with an rS in the inferior limb leads (II, III and aVF) and a qR complex in leads I and aVL. The QRS is minimally prolonged (Figure 7.9). This abnormality, relatively rare, can occur after left ventricular outflow tract surgery. This diagnosis should not be made simply on the appearance of left superior axis deviation, because a similar ECG pattern is found regularly in endocardial cushion defects.

Left posterior hemiblock

The left posterior fascicle activates the posterior and inferior portion of the left ventricle, and when blocked causes antero-superior activation followed by postero-inferior activation. This produces a rightward and inferior axis (>120°). Q waves in leads II, III, and aVF are found because initial forces are directed superiorly. Isolated left posterior hemiblock is extremely rare in children but can follow a cardiac operation or myocarditis.

Bifascicular block

Bifascicular block usually refers to a left anterior hemiblock plus RBBB, as often seen after repair of tetralogy of Fallot. The ECG shows an RBBB with initial forces directed right and superiorly. When associated with PR interval prolongation, it suggests more significant conduction system disease. It may presage complete atrioventricular block, because normal conduction then depends on the one remaining fascicle.

Pre-excitation

Pre-excitation, the most common form being WPW syndrome, refers to an accessory pathway that connects atria directly to ventricular muscle, bypassing the AV node. Because of early abnormal activation of local ventricular myocardium secondary to bypassing the AV node and His–Purkinje system, in the WPW syndrome there is a short PR duration and wide QRS duration as the impulse spreads slowly through ventricular muscle. This slowly conducted wave produces a characteristic slurred upstroke of the QRS, the delta wave, which fuses with the remainder of the QRS complex resulting from normal conduction thorough the AV node. Children with this finding may have episodes of atrioventricular re-entrant tachycardia. Ventricular hypertrophy is difficult to diagnose with WPW.

Hypertrophy

Ventricular hypertrophy criteria primarily depend on QRS voltages in specific leads, compared with ECG findings of normal infants and children. Interpreting these criteria assumes that both the cardiac–torso geometry and the ventricular depolarization sequence (i.e., no bundle branch block or WPW) are normal. Think anatomically when assessing ventricular hypertrophy. The right ventricle is positioned to the right, anterior, and superior, hence increased QRS forces directed towards the right, anterior, and superior suggest right ventricular hypertrophy (RVH). The left ventricle is located to the left, inferior, and posterior, and therefore increased forces directed to the left, inferior, and posterior suggest left ventricular hypertrophy (LVH). There are many sets of criteria for diagnosing ventricular hypertrophy, each considered by the author to distinguish best abnormal from normal, because there will be overlap between the two.

Right ventricular hypertrophy

Criteria for RVH are more specific than those for LVH and include QRS voltage and repolarization criteria. These include:

1 R wave >98%tile in lead V1. This is a very specific finding for RVH outside the neonatal period.

2 S wave >98%tile in lead V6. An abnormally deep S wave in V6 is a very sensitive indicator of RVH, but is less specific than the R wave in V1. It is often seen with increased RV pressure secondary to chronic lung disease.

3 The R/S ratio is well established for different ages. If it is abnormally high in V1 or low in V6, this suggests RVH.

4 The T wave orientation changes with age. It is upright in lead V1 until 5–7 days of age, and then becomes negative until adolescence, when it reverts to upright again. An upright T wave in lead V1 after 7 days of age is a sensitive indicator of increased right ventricular systolic pressure.

5 A qR pattern in lead V1 can indicate RVH when seen, especially with a large R wave. It can also occur with l-looping of the ventricles (ventricular inversion), where it is due to reversed initial septal depolarization.

6 An RSR′ in lead V1 can be normal in children. It is also associated with right ventricular volume overload, such as in atrial septal defects, when the R′ amplitude is large and broadened.

7 Right axis deviation alone is not a criterion for RVH, but may support other findings.

8 A pattern of tall R waves and small S waves in the right precordium progressing to small R waves and deep S waves in the left lateral precordium in the child or adolescent suggests severe RVH.

Left ventricular hypertrophy

LVH criteria are based on QRS voltage and repolarization criteria (T wave axis). These include:

1 R wave >98%tile in lead V6, S wave >98%tile in lead V1. The large S wave in lead V1 is a relatively good predictor of LVH. However, LVH may have normal left-sided QRS forces and normal children may present with R waves >98%tile in lead V6.

2 A tall R wave in lead aVF can support LVH, especially with large mid-precordial voltages.

3 An adult pattern of R wave progression (the R wave increases in size from V1 to V6) in newborns strongly suggests LVH. This pattern is consistent with left ventricular dominance that is abnormal at that age.

4 T wave abnormalities are most reliable measures of LVH. The "strain" pattern consists of inverted T waves in the inferior and left precordial leads (II, III, aVF, and V5–V6). T wave abnormalities in LVH may sometimes be associated with depression of the ST segment in the same leads.

5 Left axis deviation beyond normal limits for age supports LVH, especially in infancy. A left superior axis deviation is not a feature of LVH; it usually is a feature of abnormal His bundle pathways in the ventricle, as in complete atrioventricular canal.

6 Prominent Q waves in leads V5 and V6 may be secondary to interventricular septal hypertrophy.

Biventricular hypertrophy

The diagnosis of biventricular hypertrophy (BVH) is most easily made when criteria for both RVH and LVH are met. Large R and S waves should be seen in both leads V1 and V6. Prominent mid-precordial voltages may be secondary to

proximity effects of the neonatal heart and should not be interpreted as BVH unless voltages in leads V1 and V6 are large. However, if the total voltage R plus S in lead V4 is greater than 60 mm (6 mV), BVH is likely (Katz–Wachtel criterion).

The QRS complex can be abnormally small. It should exceed 5 mm in leads I, II, and III and 8 mm. in leads V1 and V6. Small voltages occur with pericardial effusions, pneumomediastinum, myocarditis, and anorexia nervosa, where it is accompanied by marked bradycardia.

Ventricular repolarization

Repolarization is the return of the cell membrane potential to baseline following depolarization. On the single-cell level, this is relatively simple concept. However, in the entire heart, many factors account for the complexities of ventricular repolarization [2]. The subepicardium repolarizes before subendocardium, leading to ST segments and T waves that in general have the same polarity as the QRS complex. An age-dependent overlap between the end of depolarization and the onset of repolarization produces the characteristic J point elevation seen particularly in the mid-precordial leads in childhood [3], also known as "early repolarization," a normal variant in children and adolescents.

QT intervals

The QT interval is defined as the time from the onset of the Q wave to the end of the T wave. It can be difficult to measure, as the T wave can fuse with the U wave [3]. When the U wave is smaller and clearly separated from the T wave, it is not included in the QT interval. The QT interval is age, gender, and heart rate dependent. Heart rate dependency may be corrected in several ways, most commonly by Bazett's formula (QT/square root of preceding RR) to derive the corrected QT (QTc) interval. This empiric correction is inaccurate with very low or high heart rates. An alternative formula is 656/(1 + 0.1 × heart rate) [4]. The corrected QT interval is the same in boys and girls until puberty, then it becomes 20 ms shorter in males, after which it gradually increases to equalize in men and women by 60 years of age.

It is difficult to determine the corrected QT when heart rate varies, as with normal sinus arrhythmia. Garson suggested that using the shortest RR interval on a tracing to determine the QTc, and using a cut-off of 460 ms, identifies 98.4% of known long QT syndrome patients, but only 3.8% of normal controls [5]. If the QT interval is prolonged by a wide QRS, an alternative is to measure the JTc interval as JT/√RR, where J is the end of the QRS interval [6]; the upper limit of normal is ~0.34 s. Although the QT interval is automatically calculated by the ECG machine, it is often wrong. It should always be measured manually.

A prolonged QT interval can be due to a genetic abnormality that causes a channelopathy (long QT syndrome) or secondary to antiarrhythmic drugs or electrolyte imbalance (acquired long QT syndrome) [7–9]. The diagnosis of long QT syndrome can be difficult, as the significance of a prolonged QT in an asymptomatic individual can be difficult to determine, and requires a careful family history and, often, other testing. The QT interval is often long in normal neonates on the first day of life and shortens quickly. The T wave has an unusual configuration in such neonates initially.

ST segment, T waves, and U waves

ST segment

Interpreting the ST segment depends on choosing a baseline, which can be difficult with fast heart rates. ST segments exceeding 1 mm are regarded as elevated, and less than −0.5 mm are depressed. However, ST segment elevation or depression depends on age, with maximal elevation during adolescence (early repolarization or J point elevation), especially in the anterior and mid-precordial leads (V2–V4). Hence it is important to pay attention to the clinical setting when interpreting ST segments.

T waves

Ventricular repolarization (represented by the T wave) is directly influenced by ventricular depolarization. In the frontal plane, the T wave axis is normally 15–75°. The meaning of an abnormal T wave axis must be interpreted in the light of abnormalities of the QRS complex. Thus, any abnormality of ventricular depolarization (such as a bundle branch block or ventricular pre-excitation) causes an abnormal T wave, termed a secondary T wave abnormality. In contrast, primary T wave abnormalities occur with normal ventricular depolarization and reflect actual abnormalities of repolarization. Normally in the frontal plane the T axis is within 60° of the QRS axis after 3 years of age; any greater difference suggests a primary T wave abnormality. Primary T wave abnormalities generally reflect a major metabolic abnormality and not an abnormality of the myocardium.

Sometimes abnormal T waves are seen soon after a subject has swallowed something ice-cold (possibly due to local cooling of the left ventricle), after eating a large meal, or even with anxiety or hyperventilation. Repeating the ECG some hours later may reveal normal T waves.

U waves

U waves are usually seen in the mid-precordial leads (V2–V5) and often overlap the end of the T wave, resulting in T–U fusion. U waves typically are about 10% of T wave amplitude, and become more prominent at slower heart rates. Large U waves that are difficult to separate from the T wave are common with long QT syndrome.

Abnormalities of the ST segment, T wave, and U wave

Pericarditis

Pericarditis is the commonest cause of ST segment elevation in children, once early repolarization is excluded. Initially the ST segment is elevated with a normal T wave (thought to be secondary to subepicardial myocarditis) (see Figure 59.5). The ST segment then returns to normal but the T wave becomes flattened and then inverted and symmetrical. Subsequently, the T wave returns to its upright configuration. In pericarditis, these finding are seen across the entire precordium, as opposed to ischemia, where ST segment elevation is localized [10].

Myocarditis

Myocarditis can present with flattened or inverted T waves and low-voltage QRS patterns. The QT interval may be prolonged, and AV block and intraventricular conduction delays may occur, as may arrhythmias, including ventricular tachycardia and PVCs.

Ischemia

Myocardial ischemia is rare in children, except for a few congenital or acquired coronary abnormalities. Myocardial ischemia presents initially as a peaked T wave on the surface ECG in the lead near the affected myocardial segment. If the ischemia disappears, these findings resolve. If ischemia persists, the myocardium becomes injured, and ST segments elevate or depress depending on whether the injury is endocardial or epicardial. This again resolves if the ischemia disappears. If the ischemia causes infarction, there are decreased R wave voltages and abnormal Q waves facing the infarcted segment [11]. Normal Q waves are <4 mm in amplitude and commonly seen in leads V5, V6, and aVF. To diagnose a myocardial infarction, the Q wave duration should be ≥40 ms and amplitude >4 mm [11].

The most common cause of neonatal infarction is anomalous left coronary artery from the pulmonary artery. These infants have ischemia of the anterior and septal region, or the apex (the distribution of the left anterior descending coronary artery). Deep Q waves in leads I, aVL, and V3–V6 are typical. They also show failure of normal R wave progression across the precordium.

Potassium imbalance

Hyperkalemia causes symmetrical tall-peaked T waves which are generally seen at concentrations >7 mEq l⁻¹. This, however, is not a very specific or sensitive finding, as normal children tend to have more peaked T waves than adults, but they are usually asymmetric. Usually, the average height of the T wave is 20% of the average amplitude of the QRS complexes. As potassium levels increase, the T wave becomes

more peaked, and an intraventricular conduction delay prolongs both the QRS and PR intervals. At concentrations $\geq 9\,mEq\,l^{-1}$, atrial standstill, AV block, and ventricular fibrillation occur. Hypokalemia decreases T wave amplitude. As potassium levels decrease, a U wave appears and the ST segment becomes depressed [12].

Calcium/magnesium imbalance

Hypercalcemia shortens the QT interval by shortening the ST segment. It can also slow sinus rates and cause sinoatrial block. Hypocalcemia lengthens the QT interval by prolonging the ST segment. Low magnesium levels potentiate the effect of a low calcium level [12].

The normal ECG

Developmental changes

Elctrocardiograms change drastically during childhood, most notably a decreased heart rate with a concomitant increase in PR interval and QRS duration [13,14]. The right ventricular dominance of infancy shifts to a left ventricular dominant system, shown by a shift of QRS axis in the frontal plane from right to left. Furthermore, R wave progression changes over the first year of life. In infancy, tall R waves with small S waves are seen in the right precordium (V3R, V4R, and V1) and deep S waves are found in the left precordium (V6 and V7). As the left ventricle becomes dominant, the child develops a more adult-looking ECG, with deeper S waves in the right and anterior precordium and taller R waves in the left precordium. However, an R/S ratio of <1 in lead V6 is rare at any age, occurring in <5% of normal subjects, and may indicate left ventricular hypoplasia.

T waves also change characteristically with age [13,15]. In the first minutes after birth, the T wave vector is anterior and leftward (upright in V1 and V6). Over the next few hours, the T wave vector swings more rightward, inverting the T wave in the left lateral leads. Over the next 5–7 days, the T wave vector moves posterior and leftward, with an inverted T wave in V1 and upright T wave in V6. Finally, the T wave often becomes upright again in V1 after 7–8 years of age, but may remain inverted through adolescence. This should not be misinterpreted as ischemia or pericardial disease.

Premature infants

Premature infants have shorter conduction times and faster resting heart rates than term infants. The QRS duration is shorter, as are the PR and QT intervals. There tends to be less right ventricular predominance in a preterm infant, and this finding persists until 1 year of age [15].

Athletes

Athletes may have "abnormal" ECG findings in the absence of disease. Oakley and Oakley found LVH criteria by voltage, nonspecific ST and T wave changes, and Q waves suggestive of myocardial infarction in 10 athletes [16]. No underlying cardiac abnormality, however, was ever found on extensive evaluation. Balady *et al.* also found similar findings in power-trained athletes [17]. Athletes also have slower heart rates and PR and QT prolongation compared with sedentary controls [18]. Many highly trained athletes have physiologic left ventricular hypertrophy [19].

Gender and race differences

Both sex and race differences appear in the ECG as children approach adolescence [20,21]. Racial differences are seen in the pre-teen years, and sex differences occur during puberty. Teenage girls and women tend to have longer QT intervals. QRS voltages are increased in males compared with females, and blacks compared with whites, associated with differences in left ventricular posterior wall thickness [20,21].

Echocardiography

Rajesh Punn[1], Mark K. Friedberg[2] & Norman H. Silverman[1]

[1]Stanford University, Lucile Packard Children's Hospital, Palo Alto, CA, USA
[2]The Labatt Family Heart Center and Department of Paediatrics, The Hospital for Sick Children and University of Toronto, Toronto, ON, Canada

Echocardiography is a diagnostic tool used by all pediatric cardiologists. This chapter describes its physical principles, strategies of anatomic and physiologic examination, limitations of the technique, and a description of some newer technologies. Features of the major congenital lesions are included in the relevant sections.

Physics

An electrical signal applied to a piezoelectric crystal makes it vibrate, transmitting ultrasound waves at its natural frequency, generally 2.5–15 MHz. Conversely, when ultrasound waves make the crystal vibrate, it emits an electrical impulse with an intensity correlated with the density of acoustic waves received. Because the instrument knows the timing of the pulse, the speed of sound in the body, when the signal returns, and how great the returning signal is, it can interpret the distance from the transducer and produce the appropriate image.

The primary mode of imaging is two-dimensional scanning, in which a sector is produced by aiming the ultrasound beam in a particular direction, sending the pulse, and receiving the echoes returning from the body. The beam is then redirected and the process repeated. This produces individual "scan lines" that are displayed on the screen to represent the image. Most instruments acquire and display a sector of 128 scan lines. A single scan line that traverses the heart perpendicularly is termed an M-mode.

Determinants of image quality

Penetration power
As ultrasound waves pass through the body, some are reflected (or echoed) back to the transducer from each tissue interface, some are reflected off at an angle (refracted) and cannot be detected by the transducer, and some are absorbed by the tissue. The degree of attenuation is inversely related to the frequency of the transducer. Higher frequency ultrasound transducers (7–10 MHz) lose significant penetration above 6–8 cm, whereas lower frequency transducers (2.5–5 MHz) can penetrate to 20 cm.

Resolution
Detail resolution is defined as the minimal separation needed for two structures to produce two separate acoustic echoes. *Axial* resolution describes the minimal distance along the direction of the beam, and depends on the physical length of the pulse. The echoes from two objects closer to each other than the length of the pulse merge and produce one long echo. The physical length of the pulse depends on its wavelength and duration. The speed (c) of electromagnetic waves in the body is constant (roughly 1560 m s^{-1}) and is expressed by the equation

$$c = f \times l$$

where f is the frequency of the wave in hertz (Hz, cycles s^{-1}) and l the wavelength in meters. Therefore, wavelength is inversely proportional to the transducer frequency. The wavelength is the absolute limit to resolution. Wavelengths for standard ultrasound transducers vary as ~0.80, ~0.30, and ~0.10 mm at a frequency of 2, 5, and 15 MHz, respectively. Most systems produce a pulse of 3–5 wavelengths. Therefore, a 5 MHz transducer with a pulse duration of three wavelengths has a physical pulse length of $3 \times 0.3 = 0.9$ mm, and two objects <1 mm apart are seen as one object. In practice, most systems produce a pulse with a physical length of 1.5 mm at any frequency, somewhat smaller for higher frequency transducers. However, an axial resolution of 1 mm serves as a rough guide for most ultrasound systems.

Lateral resolution is that perpendicular to the direction of the beam and depends upon the beam width. Two objects closer to each other than the beam width are seen as a single, broad echo. Like all waves, the ultrasound beam diverges as it passes through the tissue. Therefore, lateral resolution also depends on the depth of the tissue. Modern transducers are able to focus the beam electronically in order to narrow it at the optimum distance, or focal zone. The width of the beam in millimeters at the focal zone is expressed as

$$\text{width} = \frac{\lambda x}{d}$$

where λ is the wavelength of the wave, x the distance to the structure, and d the diameter of the transducer. Therefore, minimal beam diameter and lateral resolution are directly related to transducer frequency and depth of the structure, and inversely related to transducer size. An ideal transducer would then be of higher frequency and larger. However, because of the physics of beam formation, nearer to the focal zone (near-field) the beam has a wider diameter, and practical considerations limit the ability of large transducers to focus in the near-field. In addition, in smaller patients, a large transducer may produce rib artifacts when viewed from the parasternal planes. Therefore, in general, smaller, higher frequency transducers provide the best near-field resolution in smaller children, and larger, lower frequency transducers provide the best far-field resolution. For a standard size 5 MHz transducer, the minimal beam diameter at the focal zone is approximately 1.5 mm. In addition, better lateral resolution is achieved by using a scan plane that brings the structure closer to the transducer.

Contrast resolution, the ability to distinguish differences in tissue density, refers to the ability to distinguish faint structures next to brighter ones. The determinants of contrast resolution are similar to those for detail resolution, and axial resolution is better than lateral resolution. The manufacturer but not the operator controls these signals.

Artifacts

Artifacts, most commonly drop-out of parallel structures, side-lobing, and shadowing, degrade image quality. Images generated by waves echoed to the transducer depend upon an interface perpendicular to the ultrasound beam. Most structures are irregular so that even when nearly parallel to the beam, enough of the surface is perpendicular to generate an image. Very smooth structures parallel to the ultrasound beam generate very little echo, and therefore generate very weak signals, which can easily be lost. The best example of this is the atrial septum, which is parallel to the beam from the apical view, and often drops out. From the subcostal view, however, the septum is perpendicular and easily seen.

Side-lobing and shadows are both caused by very dense structures that produce bright echoes. These structures, such as the pericardium, reflect back a much greater proportion of the beam than do other structures. Side-lobing refers to the lateral spread of these very bright echoes, and is due to divergence of the beam in the far-field. Although we refer to beam diameter (see lateral resolution, above), the beam does not have distinct edges. Rather, the beam becomes less intense further away from the centerline. High-intensity echoes are therefore wider than less intense echoes, and can appear to extend more laterally than they actually do. This is most often seen when a bright structure, such as the pericardium, appears to extend into the lumen of a nearby vessel.

Shadows are caused when extremely bright echoes allow little of the ultrasound beam to pass through them. Thus a very bright object, such as a prosthetic valve, almost completely obscures all structures behind it.

Doppler ultrasound

The Doppler principle states that the frequency of transmitted sound is altered if the source is moving, as in the classic example of the moving train. This principle applies if either the source or the receiver of the sound is moving. The frequency is altered according to the Doppler equation:

$$f_d = \frac{2f_0 V \cos\theta}{c}$$

where f_d is the observed Doppler shift in hertz, f_0 the frequency of the source sound in hertz, V the velocity of the object (source or receiver) in meters per second, θ the intercept angle between the source and receiver in degrees, and c the velocity of sound in the body (1560 m s^{-1}). In echocardiography, the Doppler shift measures the velocity of moving blood. The frequency shift observed, usually several kilohertz, produces an audible signal. The signal is also processed and displayed graphically as the component velocities (Figure 8.1a and b). By convention, blood moving toward the transducer is shown as a signal above the baseline and that moving away as a signal below the baseline. In laminar flow, nearly all the blood streams move parallel at similar velocity, producing a musical tone and a narrow band on the graphical display (Figure 8.1b). However, with turbulent flow, the audible signal is harsher and the graphical display is "filled in". The velocity can be calculated by resolving the Doppler equation shown above for velocity:

$$V = \frac{f_d}{2f_0 \cos q}$$

Therefore, the velocity is proportional to the frequency shift, but inversely proportional to the originating frequency and the cosine of the angle of incidence, the latter the principle source of error in velocity measurements. Rarely is the blood flow parallel to the transducer beam, particularly in disturbed flow. In practice, if the angle of incidence is <20°, the error is minimal. If the angle is >20°, it should be minimized by using a different view, but also can be corrected in the instrument.

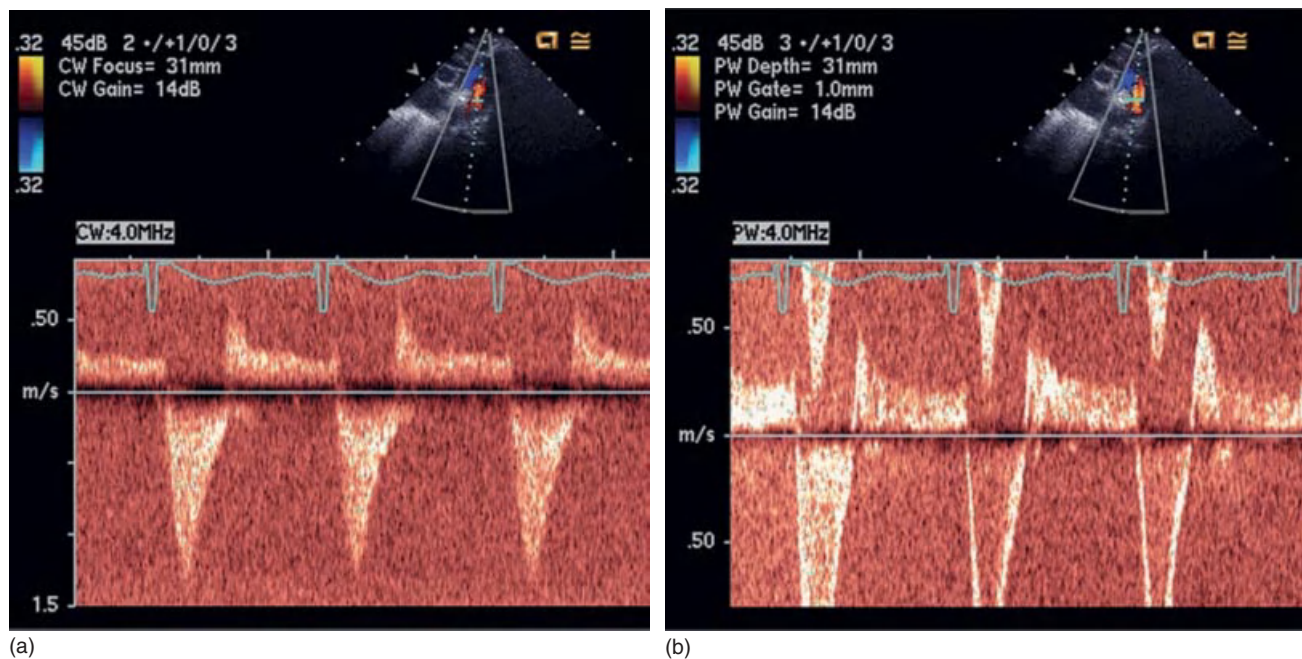
(a) (b)


Figure 8.1 Continuous wave and pulsed wave images of the same flow signal. (a) With continuous wave Doppler, continuous sampling allows measurement of higher velocities, but because multiple samples are being taken, the result is a "filled in" signal. (b) With pulsed wave Doppler, the limited sampling frequency prevents measurement of higher velocities, which leads to aliasing (wrapping around) of the signal.

Three types of Doppler applications are commonly employed: continuous wave, pulsed, and color Doppler.

Continuous wave doppler

One crystal is used as the transmitter and the other as the receiver. Signals are sent and received continuously so that the instrument cannot calculate the depth of the returning signal, and signals are received from the entire path of the beam, which may contain multiple flows. However, Doppler shifts of any magnitude can be received. To display a signal of a given frequency, it must be sampled at least at twice that frequency. Because sampling is continuous, any frequency can be sampled (Figure 8.1a). Therefore, continuous wave Doppler is accurate at any velocity, but inaccurate with respect to location.

Pulsed doppler

In pulsed Doppler, a single crystal alternately transmits pulses, then receives echoes that can be sampled within a time window established by the desired depth of sampling. Sampling must finish before the next pulse transmission. Therefore, the location can be accurately sampled, but because the sampling frequency is limited by the pulse repetition frequency, only a limited range of frequencies, and therefore a limited range of velocities, can be sampled. This limit is the Nyquist limit. Velocities above the Nyquist limit cannot be resolved accurately, and are therefore electronically cut off and "wrapped around," or aliased (Figure 8.1b). From the previous equation, the velocity is inversely proportional to the transmitted frequency. Therefore, lower frequency transducers can resolve higher velocities for a given Doppler shift, and hence are more useful in pulsed Doppler than are higher frequency transducers. A standard 5 MHz transducer has a Nyquist limit of $1–3 \, \text{m s}^{-1}$, depending upon the depth of sampling.

Color doppler

Color Doppler is pulsed Doppler in which a mean velocity for an area is calculated and represented by a color. Color Doppler detects very small defects that are impossible to see by two-dimensional imaging alone.

Color Doppler is subject to all the advantages and limitations of pulsed Doppler, but has additional advantages and limitations. A much broader area can be sampled using color Doppler, allowing quicker determination of velocities across a larger area, but the pulse repetition frequency is much lower, as is the Nyquist limit, or maximal detectable velocity. The same 5 MHz transducer that can sample $1–3 \, \text{m s}^{-1}$ by pulsed Doppler can achieve only $0.5–1 \, \text{m s}^{-1}$ by color Doppler. Decreasing the size of the sampling volume, a feature available on most commercial systems, can increase the Nyquist limit significantly.

Effective use of ultrasound

In cross-sectional imaging, a higher frequency transducer generally produces better resolution, but a lower frequency transducer provides better penetration. In Doppler sampling,

(b)   ORTHOGONAL PLANES OF HEART

Figure 8.2 (a) The standard echocardiographic windows on the body surface are oriented to the major axes of either the body or the heart. (b) The standard reference planes for cardiac long axis or short axis imaging. (Reproduced with permission from Silverman *et al*. *Br Heart J* 1983;**50**:421–31.)

a lower frequency transducer allows more accurate determination of velocity in spectral displays, and also provides more penetration for better color Doppler signals. The use of appropriate scan planes, particularly those bringing structures closer to the transducer, significantly increases the resolution by allowing the use of higher frequency transducers and by improving lateral resolution and penetration.

The echocardiographic examination

An echocardiographic examination is used to assess the morphology and physiology of the heart and great vessels. Because of the asymmetric position of the heart in the chest, and the sonographic interference by the lungs and thoracic
Figure 8.3 The three orthogonal planes of the body are the sagittal, coronal, and transverse planes. (Reproduced with permission from Silverman *et al. Br Heart J* 1983;**50**:421–31.)

skeleton, several standard acoustic windows are typically employed during a study: the parasternal, apical, subcostal, and suprasternal. The transesophageal route is an alternative.

Because the major cardiac axes differ from those of the body, we relate the spatial relationship of the heart and great vessels to other thoracic structures to perform an echocardiographic study or appreciate an image (Figures 8.2 and 8.3) [1]. The cardiac long axis runs from the apex to the base, approximately from the left hypochondrium anteroinferiorly through to the tip of the right scapula posterosuperiorly. Several standard echocardiographic views, such as the parasternal and apical, are oriented with respect to the cardiac axes, and orthogonal planes from these windows are described in terms of the cardiac long and short axis (parasternal) or two- and four-chamber (apical) views. Other windows, such as the subcostal and suprasternal, are more closely aligned with the major axes of the body, and are thus described in terms of coronal, sagittal, and transverse (horizontal) planes (Figures 8.2 and 8.3).

An echocardiographic examination may be performed in a sequential approach, the views being integrated to define the anatomy of the heart according to the segmental method. The morphologic information is complemented by physiologic information.

Morphologic evaluation

Cross-sectional two-dimensional echocardiography allows excellent delineation of morphology, and can be complemented with data obtained from Doppler color flow, Doppler speckle tracking, and M-mode ultrasound. Examples of morphologic evaluation in specific anomalies are discussed in later chapters discussing specific cardiac lesions, although selected examples will be given here to illustrate the capabilities of ultrasound.

Systemic veins

The relationships between the major abdominal systemic veins (inferior vena cava, hepatic veins, and azygos/hemiazygos system) and the abdominal aorta are central in determining visceroatrial situs (Figure 8.4). In situs solitus, the inferior vena cava is right-sided and to the right of the aorta, and the azygos and hemiazygos veins are more posterior in the right and left paravertebral spaces, respectively. These relationships are reversed in situs inversus. In patients with visceroatrial heterotaxy (atrial isomerism), these relationships are generally disturbed.

The positions of the abdominal systemic veins can be evaluated from the subcostal window with both transverse and sagittal views. A coronal image can also be used to identify the intrahepatic segment of the inferior vena cava and the entrance of the hepatic veins (Figure 8.5). The inferior vena cava must be imaged from below the liver to its junction with the right atrium in order to verify that it is truly the inferior cava and not a hepatic vein. With an interrupted inferior vena cava and azygos continuation, the intrahepatic segment of the inferior vena cava is absent, and the more posterior azygos vein is wider. Pulsed Doppler ultrasound and color flow mapping characterize flow patterns, helping to confirm the identity of the vessel in question (Figure 8.6).

The proximal superior vena cava, its tributaries, and both cavoatrial junctions can be imaged (Figure 8.7), and the position of the left innominate vein relative to the aortic arch can be appreciated (Figure 8.8). The azygos vein runs posteriorly and then over the right pulmonary artery to join the superior vena cava (Figure 8.9). A left superior vena cava can be identified readily (Figure 8.10). If it drains to the coronary sinus, the coronary sinus is usually enlarged and seen as a large annular structure above the mitral valve (Figure 8.11). When this occurs, a bridging vein is typically absent. The coronary sinus can be distinguished from the descending aorta by identifying the pericardium, which defines the coronary sinus as an intrapericardial structure (Figure 8.11). In addition, the coronary sinus passes anterior to the left pulmonary veins whereas the descending aorta is posterior to the left pulmonary veins.

Vascular arrangement in variations of body situs
Figure 8.4 Diagrammatic representation of the probable positions of the aorta, inferior vena cava, and azygos veins in the four possible forms of atrial situs. In left isomerism, the inferior vena cava is interrupted and drainage of lower extremity venous blood continues via either the azygos or hemiazygos. Left isomerism and right isomerism are both depicted here with the aorta and azygos/inferior vena cava on the left, although the vessels may also be located on the right. (Modified from Silverman, *Pediatric Echocardiography*. Baltimore: Williams & Wilkins, 1993.)
Figure 8.5 Subcostal coronal image demonstrating the confluence of the left (LHV) and right hepatic veins (RHV) with the inferior vena cava (IVC) just below the caval junction with the right atrium (RA). LA, left atrium.

Pulmonary veins

All four pulmonary veins and their venoatrial connections should be identified. With careful manipulation of the transducer, all four pulmonary veins can sometimes be seen at their confluence with the left atrium in a single plane ("crab view," Figure 8.12). It is important to remember that the descending aorta passes posterior to the left atrium between the left and right pulmonary veins, and should not be confused with the left pulmonary veins (Figure 8.13). Pulsed Doppler interrogation and color flow mapping can be used to demonstrate flow, and offer guidance regarding the anatomy of the pulmonary veins when their identity is otherwise not obvious.

Atria

The relationships of the major abdominal vessels and the connections of the systemic and pulmonary veins to the atria provide important information about atrial situs. The right atrial appendage is typically broad-based and triangular, whereas the left atrial appendage is thin and "finger-like" with a narrow base (Figure 8.14) [2]. Other typical features of the morphologic right atrium include the orifice of the coronary sinus, the limbus forming the superior border of the fossa ovalis on the right atrial aspect of the septum, and the Eustachian valve. The interatrial septum is investigated
(a)

(b)

Figure 8.6 (a) Parasternal long axis view demonstrates the superior vena cava (SVC) entering into the right atrium (RA) with the azygos vein (Az) entering posteriorly. (b) Subcostal sagittal view again shows the azygos vein entering the posterior aspect of the superior vena cava. The left atrium (LA) and descending aorta (DAo) are demonstrated further posteriorly.

from multiple windows, allowing all aspects of the septum to be identified (Figure 8.9).

Atrioventricular valves

The atrioventricular valvar apparatus consists of the annulus (or basal attachment of the leaflets to the atrioventricular junction), the valve leaflets proper, the chordae tendineae, and the papillary muscles.

The mitral valve, its annulus, and tensor apparatus are well defined using multiple views. (Figure 8.15). An image plane is directed through the mitral valve orifice, allowing assessment of orifice geometry and also anomalous structures such as clefts and accessory orifices or tissue (Figure 8.16).

The tricuspid valve and subvalvar apparatus can be investigated in the plane of the valve ring. The normal

offset appearance of the mitral and tricuspid valves, wherein the atrioventricular septum separates the right atrium from the left ventricular outflow tract, can be appreciated from the apical four-chamber view (Figure 8.15b).
The hinge points, thickness, and chordal attachments of the septal and antero-superior leaflets are clearly shown. All three leaflets can also be examined from the subcostal window. Anomalous attachments of tricuspid chordae, such as with straddling, may be seen from various windows.

Ventricles

Ventricular morphology, size, and position, and also atrioventricular and ventriculoarterial connections, are readily delineated. The echocardiographic hallmarks of the morphologic right ventricle are septal attachment of the right atrioventricular (tricuspid) valve, the triangular shape of the ventricle, the trabecular septal surface, and the septomarginal trabeculation (Figure 8.17). The characteristic features of the left ventricle are the lack of mitral valve chordal attachments to the septum (Figure 8.15a), the smooth septal surface, conical shape of the ventricle, and aortic–mitral fibrous continuity, the last not always definable. The inlet, body, and outlet components of the left ventricle can be seen in a single plane from several windows (Figures 8.7, 8.15a, and 8.18). The inlet, body and outlet components of the right ventricle can be depicted in a single subcostal plane (Figure 8.19).

Assessment of chamber size is based on geometric models that allow volume estimation from cross-sectional measurements (Figure 8.20). In our experience, the most reliable approach in children is the biplane Simpson's rule (method of discs), which can be applied irrespective of the shape of the chamber to be measured [3]. This method requires imaging in two orthogonal planes sharing a common long axis,

Figure 8.7 The subcostal coronal view shows the superior vena cava (SVC) entering the right atrium (RA) while the left ventricle (LV) is also imaged. The left coronary artery can also be imaged from this view (LCA).
Figure 8.8 In this oblique scan from the suprasternal notch, the left innominate vein (LIV) is identified running anterior to the ascending aorta (AAo). A coarctation (Coarc) is present at the proximal descending aorta (DAo). The posterior shelf is also imaged behind the coarctation.
(a)
(b)

Figure 8.9 (a) This subcostal sagittal image shows both the superior vena cava (SVC) and inferior vena cava (IVC) entering into the right atrium (RA) and the interatrial septum (IAS) anterior to the left atrium (LA). The azygos vein (Az) arches over the right pulmonary artery (RPA). (b) This subcostal sagittal image demonstrates a superior sinus venosus defect (*). The superior vena cava (SVC) overrides the crest of the interatrial septum. The right and left atria are labeled (RA and LA). The right pulmonary artery (RPA) runs posterior to the superior vena cava.

and reconstructs the chamber volume from the summed volumes of multiple elliptical slices of equal thickness that are defined by the two orthogonal short axis dimensions (Figure 8.20). For calculating left ventricular volume, we use apical four- and two-chamber views as the orthogonal planes. Estimating right ventricular volume is more complex because the right ventricle has an irregular shape that fits no simple geometric model and lies very close to the chest, which makes imaging of the entire ventricular outline difficult in older children. In children, however, orthogonal views of the right ventricle can be obtained easily from the subcostal window, and Simpson's rule can be applied for volume calculation from these images by using the common long axis from

the diaphragmatic surface to the pulmonary artery and the area outlines of the right ventricle from orthogonal subcostal cuts, which may be best obtained from slightly oblique views rather than true sagittal and coronal images [4]. These measurements appear to be accurate in small children since the ventricles can be imaged well using subcostal technique. These volumes are usually within 10–15% of volumes measured by angiography or casts of the ventricles [4a, 4b].

Semilunar valves

The semilunar valves are structures that include the leaflets, annuli, sinuses of Valsalva, and sinotubular junctions. The aortic root and the hinge points of the aortic valve
(a)
(b)

Figure 8.10 (a) This image from the high parasternal window shows a left superior vena cava (LSVC) draining via the coronary sinus to the right atrium (RA). The left atrium (LA) and aorta (Ao), are also shown. (b) Same figure with color Doppler.

Figure 8.11 Parasternal long axis view demonstrating a coronary sinus enlargement (CS) anterior to the descending aorta (DAO) in a patient with a superior vena cava–coronary sinus connection. AO, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.
Figure 8.12 This is a suprasternal notch (SSN) coronal view showing the confluence of the right upper (RUPV), right lower (RLPV), left upper (LUPV), and left lower (LLPV) pulmonary veins entering the left atrium. The ascending aorta (AAO) and main pulmonary artery (MPA) are also seen in cross-section cranial to the left atrium. The color Doppler view is on the right.

leaflets and also their thickness can be appreciated, as can the dimensions of the sinuses and sinotubular junction (Figures 8.15a and 8.18). The morphology of the aortic valve leaflets can be distinguished clearly from the parasternal short axis, in both systole and diastole, when the imaging plane passes through the sinuses of Valsalva (Figure 8.21). The leaflets may be of unequal size. A bicuspid aortic valve, which typically results from fusion of the left coronary leaflet with either the right or non-coronary leaflet, may appear to be a normal tricuspid valve from this view, as the raphe of the fused commissure is visible. However, the motion of this leaflet differs from this normal trileaflet configuration, and an asymmetric valvar orifice is typically present during

systole and can be distinguished using two-dimensional and Doppler color flow imaging.

The pulmonary valve leaflet thickness, hinge points, and dimensions of the sinuses and sinotubular junction are evaluated in the long axis of the pulmonary artery. The pulmonary valve is at the level of the aortic valve,

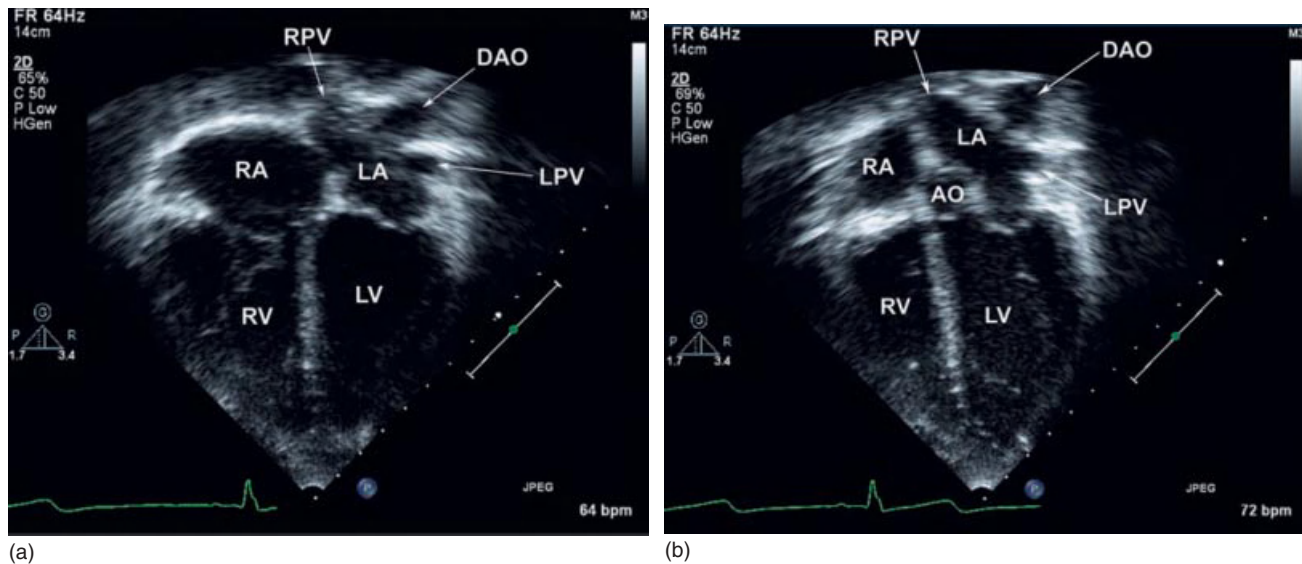
(a)   (b)


Figure 8.13 In these images from the apical view, the right and left lower pulmonary veins (RPV, LPV) can be seen entering the left atrium and straddling the descending aorta (DAO) from a 4-chamber (a) and 5-chamber view (b). Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.
Figure 8.14 This parasternal short axis view at the level of the left ventricular outflow tract demonstrates the characteristic morphology of the left atrial appendage (LAA). The "finger-like" left atrial appendage joins the body of the left atrium (LA) with a narrow connection. Other structures identified in this plane are the aortic valve (AOV), pulmonary valve (PV), left anterior descending coronary artery (LAD) and descending aorta (DAo).

to which it is oriented almost perpendicularly (Figures 8.21c, 8.22b, and 8.23a).

Coronary arteries

Depending on the cardiac anatomy, techniques must be modified to define the coronary arteries. Because the acoustic plane remains stable while the heart shifts in position through the cardiac cycle, the coronary arteries move in and out of the image plane, and segments that are displayed during the various parts of the cycle will differ. The coronary origins and proximal arteries are most reliably identified from the parasternal short axis and with anterior angulation from the apical four-chamber view (Figure 8.23a and b). The bifurcation of the left main coronary artery into the left anterior descending and circumflex arteries can also be appreciated from these views (Figure 8.23a and b). The right coronary and circumflex arteries run in the atrioventricular grooves, and can be seen in longitudinal section (Figures 8.23a and 8.24a). A variety of planes and windows are necessary to display all the peripheral coronary branches.

Great arteries

It is important to determine size, morphologic anomalies or variations, and the ventriculoarterial connections of the great arteries. The aorta, arch vessels, and main and branch pulmonary arteries are effectively assessed from most echocardiographic windows. Characteristic features that help distinguish the aorta from the pulmonary trunk include the origins of the coronary arteries, the arch and its branches, and the bifurcation of the pulmonary trunk into two separate branch pulmonary arteries.

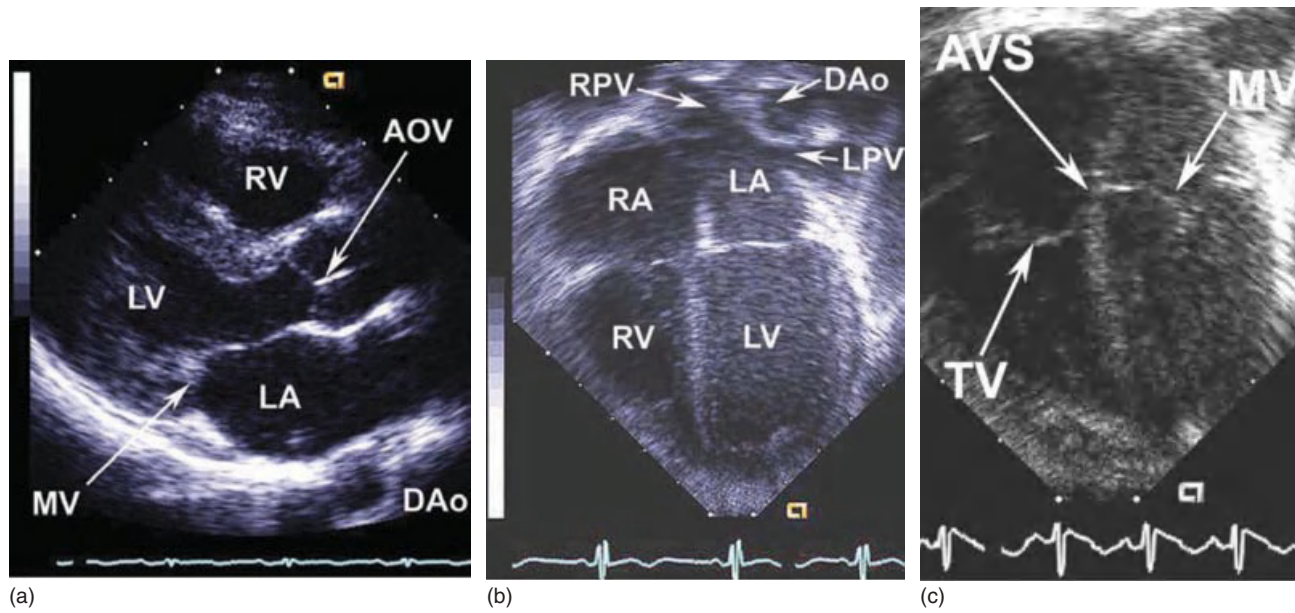
(a)　　　　　　　　　　　　(b)　　　　　　　　　　　　(c)


Figure 8.15 (a) This parasternal long axis view demonstrates the mitral valve between the left atrium (LA) and left ventricle (LV) during late diastole. The aortic valve (AOV) and descending aorta (DAo) are seen anterior and posterior to the left atrium (LA). The right ventricle (RV) is demonstrated anterior to the left ventricle. (b) In this image from the apical four-chamber view, both atria and ventricles (RA, RV, LA, LV) are clearly demonstrated while a right and left pulmonary vein (RPV, LPV) are visualized entering the left atrium (LA). Again the descending aorta (DAo) is noted posterior to the left atrium. (c) Another apical four-chamber view clearly delineates the normal separation between the tricuspid (TV) and mitral valves (MV) by the atrioventricular septum (AVS).

(a)　　　　　　　　　　　　　　　　　　(b)
Figure 8.16 (a) This parasternal short axis view shows a double-orifice mitral valve, with two different sized openings (MVO1 and MVO2). The interventricular septum (IVS) is located anterior to the mitral valve. (b) This image of a parasternal short axis images shows a lateral cleft (CL) in the anterior leaflet of the mitral valve (AMVL). The valve is shown open during diastole and attachments to the interventricular septum (IVS) help support the mitral valve apparatus (*). The posterior mitral leaflet (PMVL) is also shown.

The left ventricular origin of the ascending aorta and its proximal course can be demonstrated (Figure 8.25), as can the full course of the arch (Figure 8.25c). The arch is always on the side opposite the innominate artery, and can be seen to course posterior and lateral to the trachea. Arch laterality can be confirmed with progressive lateral angulation from the suprasternal sagittal view, which allows the transverse arch to be followed to either the left or the right of the trachea and esophagus. The innominate, carotid, and subclavian arteries can also be identified, and their recognition is essential for confirmation of arch identity (Figure 8.25b).

The main pulmonary artery can be imaged at its origin from the right ventricle, as can the branching of the pulmonary trunk into left and right pulmonary arteries. (Figure 8.26). The branch pulmonary arteries can be followed peripherally beyond the level of the upper lobe artery origin in many patients.

Pericardium and adnexae

The pericardium is present in most views. Pericardial effusion or thickening is best appreciated from multiple windows (Figure 8.27). The parasternal short axis view is the standard view for M-mode imaging of the pericardium. The diaphragm may also be evaluated. Abdominal and mediastinal organs may be abnormal in certain forms of congenital heart disease, such as those occurring with DiGeorge syndrome and atrial isomerism, respectively, and can be evaluated during the echocardiographic examination. It is also important to be aware of the anatomic relationships between these structures and the heart and great vessels. The thymus is visible in young children in whom the thymus is typically large (Figure 8.26). The liver, stomach, and spleen can be evaluated and are important to visualize with forms of heart disease consistent with visceroatrial heterotaxy.

Figure 8.17 With cranial angulation and orientation of the transducer to concentrate on right ventricular structure, the septomarginal trabeculation (SMT) can be seen lying within the right ventricular cavity separated from the ventricular septum, a common finding with right ventricular enlargement. LV, left ventricle; RV, right ventricle.
Figure 8.18 (a) In this subcostal coronal view in a patient with anomalous origin of the right pulmonary artery (RPA) from the ascending aorta (AAo), the aortic root dimensions are seen clearly. The tricuspid valve (TV), left coronary artery (LCA), and right (RA) and left (LA) atria can also be identified.

(a)

(*continued*)

(b)
Figure 8.18 (cont'd) (b) The parasternal long axis also demonstrates the right pulmonary artery off the ascending aorta. RV, right ventricle.

(a)

(b)
Figure 8.19 (a) From the parasternal short axis (PSAX) window, the most inferior cut is taken through the papillary muscle level and demonstrates the circular left ventricle (LV). AL, anterolateral; PM, posteromedial; RV, right ventricle. Because the transducer is oriented slightly to the left, minor rotation of the short axis occurs with the anterolateral and posteromedial papillary muscles being approximately in the 4 and 7 o'clock positions. (b) In this subcostal oblique view, the tricuspid valve (TV), right ventricle (RV), and outflow tract and main pulmonary artery (MPA) can be seen in a single plane.

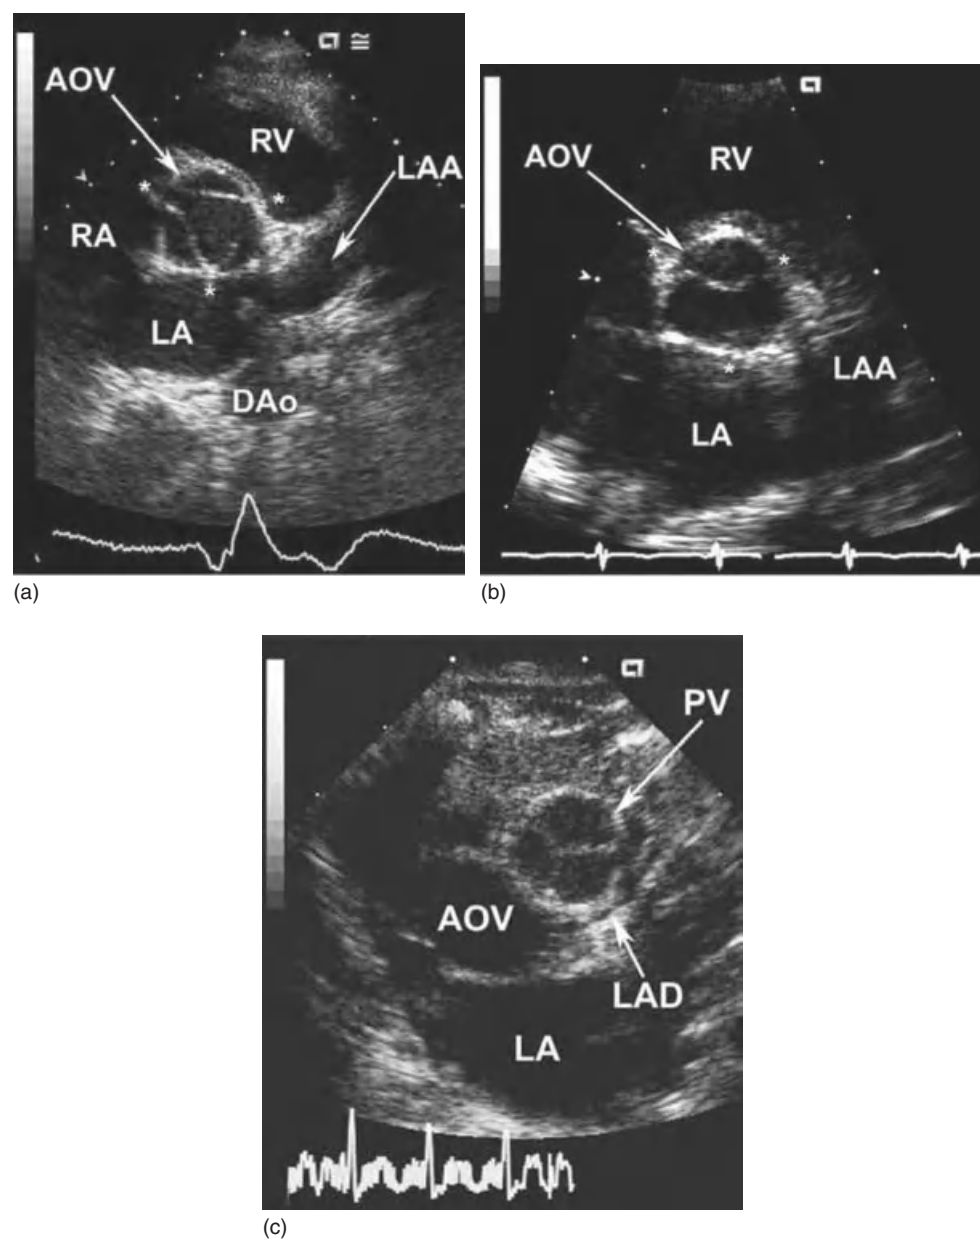
Figure 8.20 (cont'd) (II, III) The principle of Simpson's rule can be applied to a different method that calculates the chamber volume from three (II) or four (III) area measurements obtained in parasternal short axis; the height of the segments is taken from equivalents of the long axis measured from the apical window. The assumption, however, that all slices in the parasternal short axis are equidistant from each other and are perpendicular to the long axis is almost impossible to satisfy in practice. (IV) Using a biplane area–length method the areas A_1 and A_2 are traced in apical two- and four-chamber views; the long axis L is taken from either plane. The equation used in this calculation is that for an ellipse, which may be reasonable for the left ventricle, but not for the right ventricle. (V) The hemisphere–cylinder (or bullet) model uses a cross-sectional area of the left ventricle in a parasternal short axis at the level of the tips of the papillary muscles and a length taken from an apical view. The equation considers the chamber volume as the sum of a hemisphere and a cylinder, which also is not valid for the right ventricle. (VI) Biplane ellipsoidal method using the length L taken from an apical plane and the diameters D_1 (antero-posterior) and D_2 (lateral) taken from a parasternal short axis at the level of the tips of the papillary muscles. This model can also be used only for left ventricular volume calculation. (VII) The single area–length method is similar to the biplane area–length method (IV), but assumes both orthogonal areas to be equal; either the apical two- or four-chamber view may be used with this method. (Reproduced with permission from Silverman NH, Snider AR. *Two-Dimensional Echocardiography in Congenital Heart Disease*. Norwalk, CT: Appleton-Century-Crofts, 1982.)


Figure 8.21 (a) These frames demonstrate the aortic valve cusps (AOV) in systole within the aortic root from the parasternal short axis view. In the top frame these are identified by asterisks (*) adjacent to the junction of the commissures. The right atrium (RA), right ventricle (RV), left atrium (LA), and left atrial appendage (LAA) are also visualized with the descending aorta (DAo). (b) This parasternal short axis shows the aortic valve in diastole with the cusps in a closed position. (c) Moving the transducer further superior from the previous view can demonstrate the pulmonary valve (PV) with three cusps in the short axis during diastole. Additionally, the left anterior descending coronary artery (LAD) is also seen. The left atrium is still visualized posteriorly (LA).

Physiologic evaluation

Spectral and color flow Doppler techniques have the most to offer in terms of characterizing blood flow patterns, and two-dimensional and M-mode show myocardial and valvar motion in addition to the anatomic substrates of flow abnormalities. Contrast echocardiography is valuable for evaluating intracardiac or intrapulmonary shunts, and also anomalies of systemic venous return and certain forms of vascular obstruction that may otherwise be difficult to image.

Ventricular physiology

Systolic ventricular function

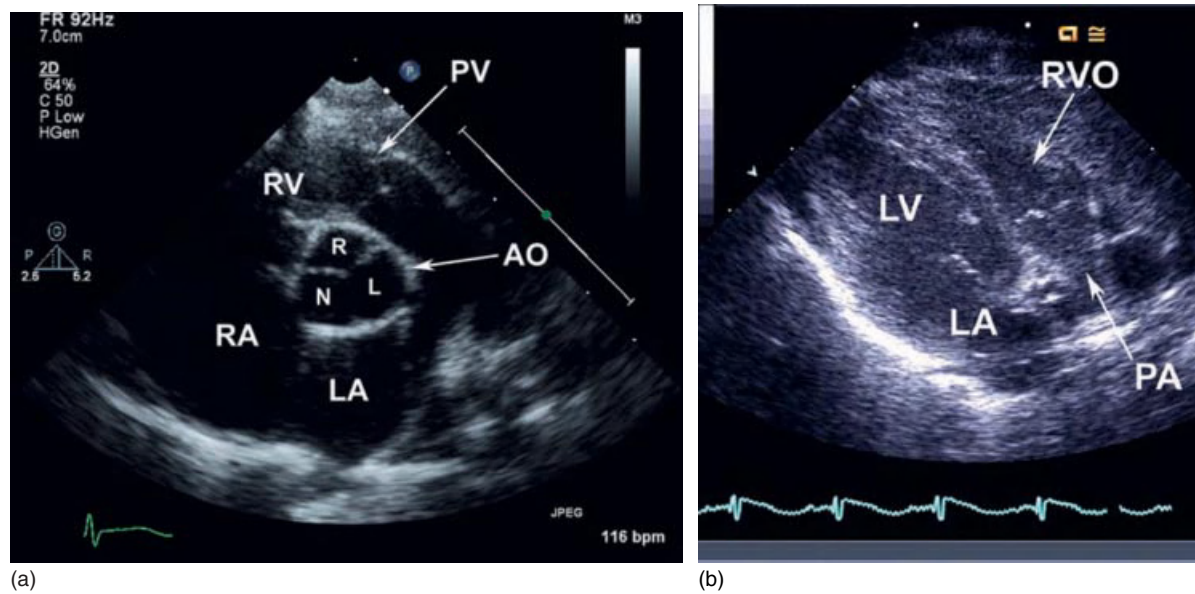
Ventricular contraction and ejection are collectively referred to as systolic function. The shortening fraction (SF) and ejection fraction (EF) are the most often used methods of assessing function because of their simplicity. The shortening fraction is the ratio of decrease in ventricular short axis dimension relative to the diastolic


Figure 8.22 (a) In this parasternal short axis view at the level of the semilunar valve roots, the aortic root (AO) can be seen in the center of the plane. Within the aortic root, the characteristic V at the junction between the non-coronary (N) and right coronary (R) leaflets and right and left (L) coronary leaflets is shown by dense bright lines, and a faint echo is seen where the non-coronary and left coronary leaflets abut. (b) Extreme leftward angulation from the parasternal long axis shows the pulmonary valve (PV) separating the right ventricular outflow tract (RVO) from the pulmonary artery (PA). The left atrium (LA), mitral valve, and left ventricle (LV) are also shown. RA, right atrium; RV, right ventricle.
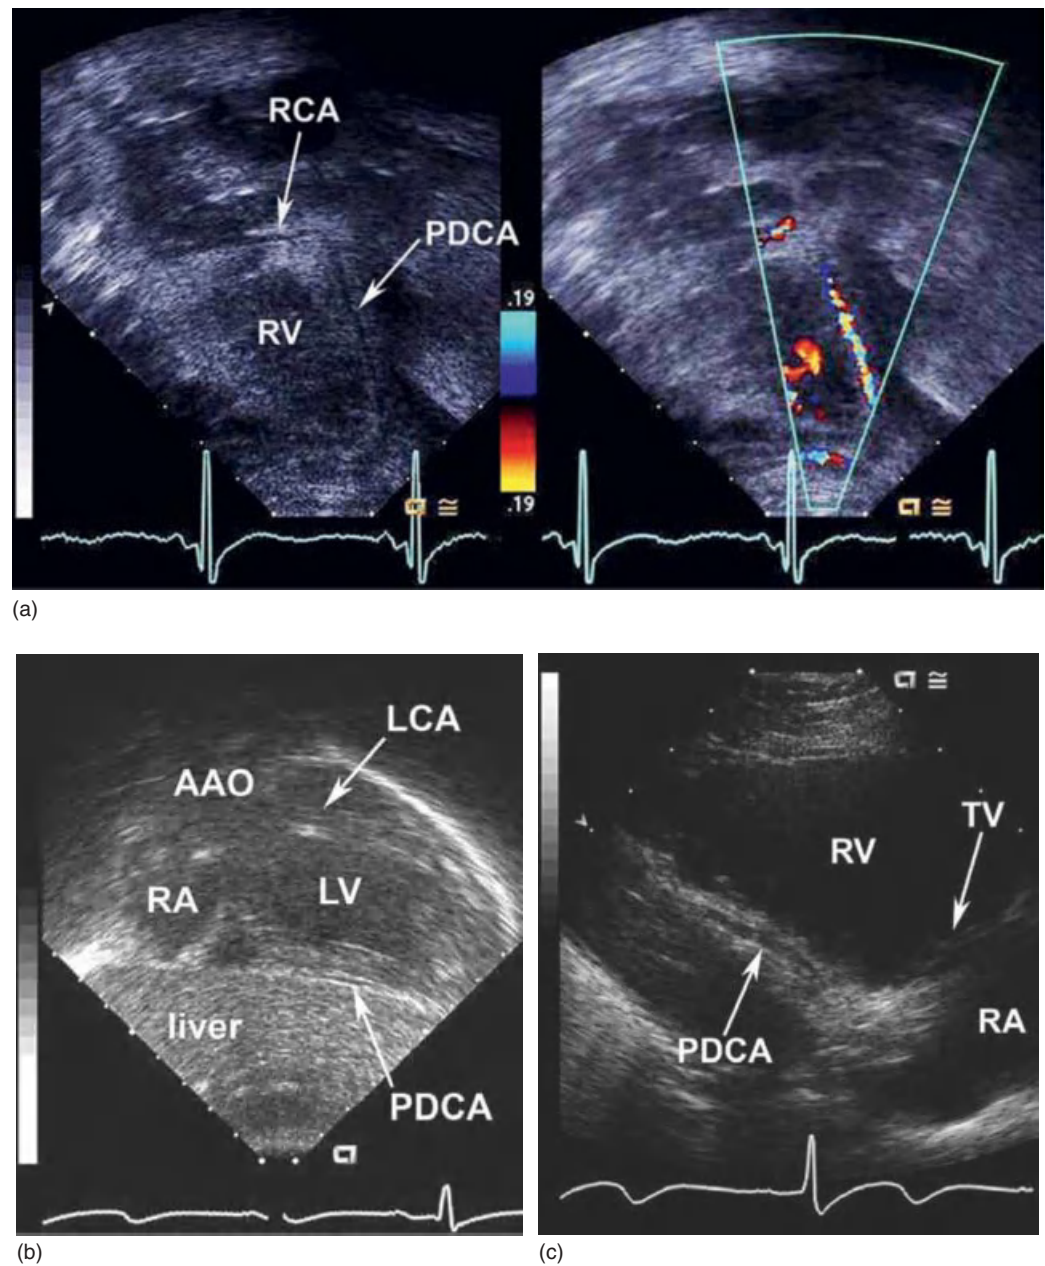
Figure 8.23 (a) Parasternal short axis view at the level of the coronary ostia shows the right (RCA) and left (LCA) coronary arteries arising from the aortic root (AOV). The bifurcation of the left coronary artery into the left anterior descending (LAD) and circumflex coronary arteries (CIRC) is also noted. The left atrial appendage is also visualized from this view (LAA). The pulmonary valve can be seen in its long axis (PV) from this view. (b) This parasternal short axis view shows the left main coronary artery (LCA) dividing into the left anterior descending branch (LAD), which then courses behind the pulmonary artery, and the circumflex (CIRC).


Figure 8.24 (a) This subcostal sagittal figure concentrates on the right coronary artery (RCA) lying posteriorly to the right ventricle in the right coronary groove and its extension into the posterior descending coronary artery (PDCA). (b) In this subcostal coronal cut, the posterior descending coronary artery (PDCA) can be identified. Other structures imaged in this view include the right atrium (RA), left ventricle (LV), ascending aorta (AAo), and left coronary artery (LCA). (c) The posterior descending coronary artery is also seen from the parasternal long axis tricuspid valve (TV) inflow view. The right atrium and ventricle are also displayed (RA, RV).

dimension. The ventricular end-diastolic (*EDD*) and end-systolic (*ESD*) short axis dimensions are measured in M-mode and the ratio of shortening to end-diastolic dimension is obtained:

$$SF = 100\frac{EDD - ESD}{EDD}$$

Ejection fraction is the change in ventricular volume from end-diastole to end-systole using M-mode or cross-sectional two-dimensional images. In M-mode measurements, a shape is assumed for the ventricle and a volume calculated based upon the measurements obtained for the shortening fraction. End-diastolic volume (*EDV*) and end-systolic volume (*ESV*) are measured from one or two planes, either by manual

(a)

(b)

(c)

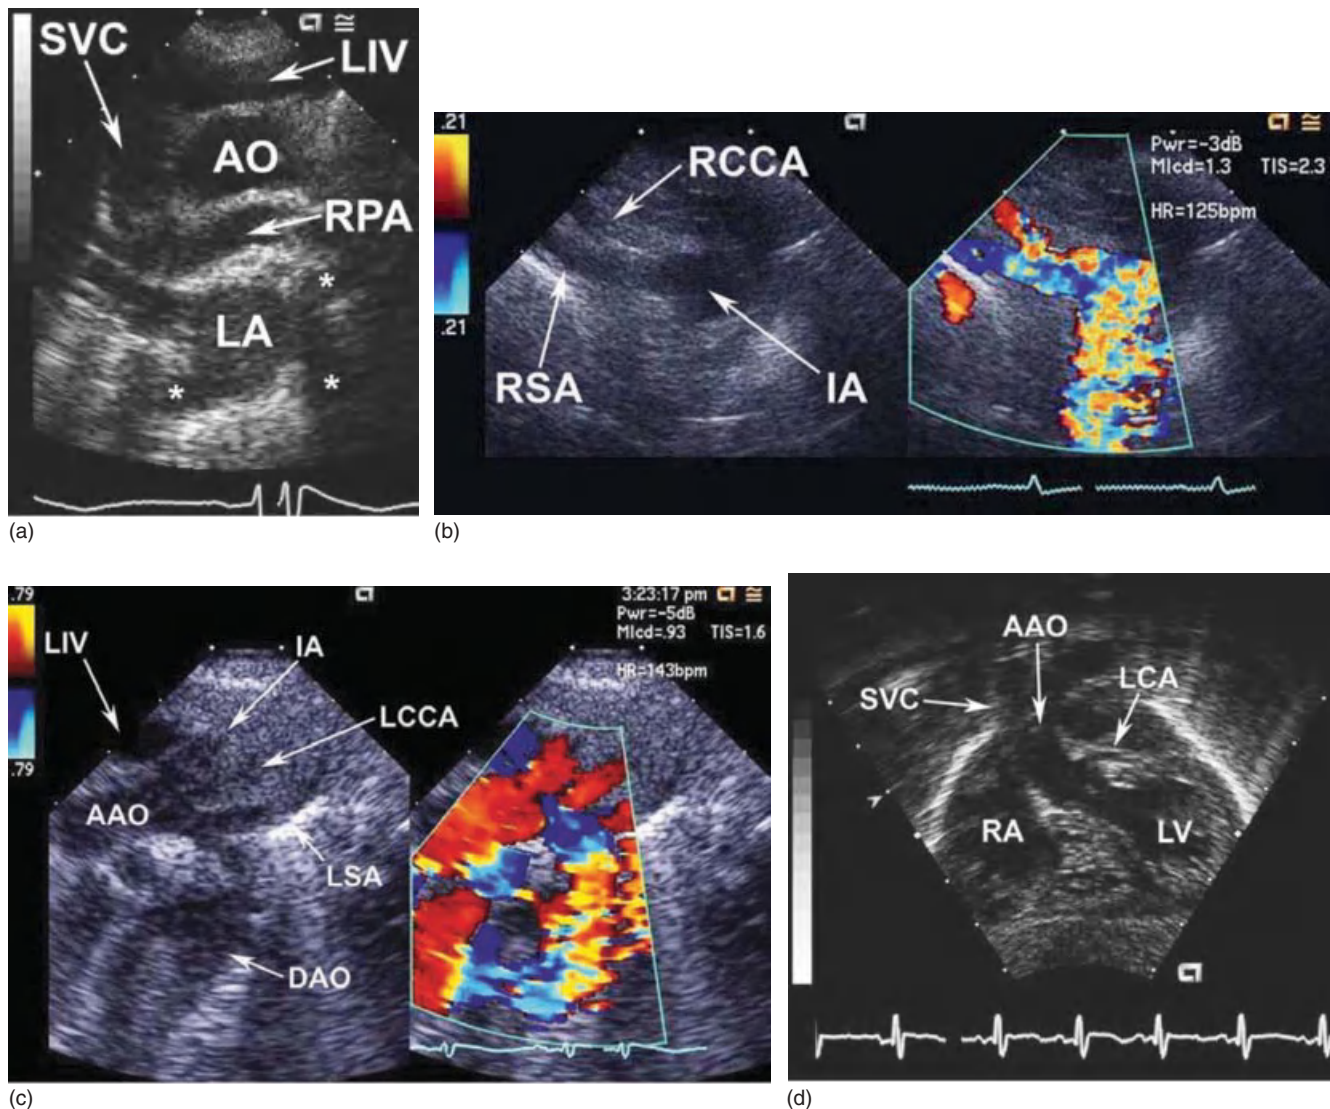
(d)


Figure 8.25 (a) Suprasternal coronal notch view shows the left innominate vein (LIV) draining in the superior vena cava (SVC). The ascending aorta (AO) is seen in the short axis while the right pulmonary artery (RPA) is in its long axis. Three pulmonary veins (*) drain appropriately into the left atrium (LA). (b) Angling the transducer more posterior provides a view of the first brachiocephalic artery or innominate artery (IA) which bifurcates rightwards into the right common carotid artery (RCCA) and right subclavian artery (RSA), indicating a left aortic arch. (c) The relationship of the ascending aorta (AAo), aortic arch, and descending aorta (DAo) can be appreciated from this suprasternal notch view. The innominate artery (IA), left common carotid artery (LCCA), and left subclavian artery (LSA) can be identified superiorly. (d) In this subcostal coronal view, the body of the left ventricle (LV) can be seen to be continuous with the ascending aorta (AAo). The position of the left main coronary artery (LCA) is clearly delineated. The superior vena cava (SVC) enters the right atrium (RA).

tracing or automated border detection, and the ejection fraction (*EF*) is obtained by dividing the volume difference (stroke volume) by end-diastolic volume and converting to a percentage:

$$EF = 100\frac{EDV - ESV}{EDV}$$

Automated border detection with integrated ultrasonic back-scatter may simplify and standardize this process for both left and right ventricular function. These indices are useful for simple estimation, but are less reliable than other methods because they depend on heart rate, ventricular preload, and assumptions of ventricular geometry. M-mode measurements of ventricular size and function can vary, due to variability both in the position of the left ventricle from which the measurements are made, and in positioning the measurement cursors. There is uncertainty about the exact position of the ventricular endocardial surface (as opposed to papillary muscles) and the timing of end-systole and end-diastole (relative to the R wave versus when the ventricle

131
Figure 8.26 This parasternal short axis view shows the main pulmonary artery (MPA) branching into the left (LPA) and right (RPA) pulmonary arteries. The ascending aorta (Ao) is also seen. The highly echogenic mass anterior and lateral to the pulmonary artery is the thymus.

reaches its maximum or minimum). Therefore, M-mode measurements should not be viewed as absolutes. Normal standards for children can be obtained from the literature [5,6]. Although M-mode appears to be the standard, new recommendations from the American Society of Echocardiography advise making all measurements using two-dimensional echocardiography and not M-mode [7]. Standard measurements are also available using the website http://parameterz.blogspot.com/

Dividing the shortening fraction by the heart rate-adjusted ejection time

$$ET_C = \frac{\text{ejection time}}{\sqrt{\text{electrocardiogram R} - \text{R interval}}}$$

yields a rate-corrected mean velocity of circumferential fiber shortening, VCF_C. This is related to end-systolic wall stress, which is calculated as

$$ESWS = \frac{1.35D_{ES}P_{ES}}{4h\left(1 + \dfrac{h}{D_{ES}}\right)}$$

where D_{ES}=end-systolic dimension, P_{ES}=end-systolic pressure, and h=end-systolic posterior wall thickness. $ESWS$ and VCF_C are inversely related in a linear fashion in most

physiologic ranges [8,9]. In addition, they depend less upon preload and afterload than do other indices, but require rather cumbersome data acquisition.

Doppler techniques for evaluating systolic ventricular function are independent of ventricular geometry. Measurements from Doppler-derived aortic velocity curves include peak velocity, acceleration time, ejection time, isovolumic contraction time, and the velocity-time integral. Indices derived from these measures include peak and mean acceleration (Figure 8.28), which correlate with systolic performance [10,11]. The ratios of acceleration time to ejection time and of isovolumic contraction time to acceleration time are also used as indices of ventricular function. Two other Doppler-based techniques for assessing ventricular function employ the continuity equation (flow=arterial cross-sectional area × mean velocity) to determine flow through the ascending aorta and by extension stroke volume and cardiac output. The area of the vessel is calculated from the diameter, and mean systolic velocity is calculated by integrating the area under the velocity–time curve measured with spectral Doppler (velocity–time integral, VTI). The product of area and VTI is flow for one cardiac cycle, or stroke volume. This can be multiplied by the heart rate to yield cardiac output, and divided by estimated body surface area to give the cardiac index, providing an estimate of cardiac performance.

Assessment of ventricular performance by tissue velocity and deformation imaging

Most conventional methods to assess cardiac function provide a global assessment of pump function using blood pool indices such as the ejection fraction. These measures do not directly assess myocardial performance and often depend on incorrect geometric assumptions. Many of these indices are greatly influenced by preload (ventricular filling) and afterload (the resistance the ventricle must overcome to eject blood), limiting their ability to reflect intrinsic myocardial contractility.

Tissue velocities

In contrast to the low-amplitude, high-velocity blood flow captured by conventional Doppler, myocardial motion generates low-velocity, high-amplitude signals captured by tissue Doppler imaging (TDI) using appropriate low wall filters and Nyquist limits of 15–30 cm s⁻¹. Myocardial motion and velocities reflect, at least in part, myocardial contraction, thereby providing a more direct assessment of contractility. However, a segment may move because the whole heart is moving (translational motion) or because it is being passively dragged by an adjacent contracting segment (tethering), even if it itself is not actively contracting. Nonetheless, in children where segmental infarction is uncommon, TDI is useful and easily obtained
Figure 8.27 Pericardial effusion (*) can be appreciated from many views, including (a) the parasternal long axis, (b) the parasternal short axis, (c) apical four chamber, and (d) subcostal views. The arrowheads represent fibrinous material within the pericardial effusion. AAo, ascending aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

with high temporal resolution and good intra- and inter-observer reliability [12].

Peak myocardial velocities can be acquired using pulsed wave TDI, using sample sizes between 3 and 8 mm (Figure 8.29). Alternatively, color Doppler myocardial images

may be acquired and stored for on-line/off-line analysis of regional myocardial mean velocities. This allows the simultaneous quantification of myocardial velocities from multiple cardiac segments during the same cardiac cycle. Mean velocities are ~15–20% lower than peak velocities.
Figure 8.28 Graphic representation of an aortic velocity curve from which the peak velocity (PkV), the acceleration time (AT), the ejection time (ET), and the velocity time integral (shaded area) can be measured. Indices of systolic left ventricular function that can be derived from these measurements include the peak rate of acceleration [Ac (dv/dt)], the mean acceleration (mAc = PkV/AT), and the ratio AT/ET. With the use of the electrocardiogram, the pre-ejection period (PEP) can also be measured and the PEP/ET ratio can be calculated as another index of systolic left ventricular function. (Reproduced with permission from Silverman NH, Schmidt KG. *Cardiol Clin* 1989;**7**:265–97.)
Figure 8.29 Pulsed TDI post wall. Pulsed tissue Doppler from the left ventricle showing a typical systolic (S'), early diastolic (E') and late diastolic (A') velocity. Also depicted (white bar) is the slope of the isovolumic acceleration (IVA), a relatively load-independent index of myocardial performance.

From tissue Doppler tracings, isovolumic acceleration (IVA) can be measured from the slope of the initial positive systolic wave that occurs during isovolumic contraction. IVA occurs just after onset of the ECG QRS complex and peaks before aortic valve opening.

Normal tissue Doppler velocity values have been published for children, including neonates and fetuses [13].

Deformation imaging: strain and strain rate

Deformation or strain is the percentage change in dimension of an object in response to stress (force per unit cross-sectional area). This is calculated as the instantaneous dimension minus the original dimension divided by the original dimension. For myocardium, the original dimension is the unstressed muscle dimension. However, *in vivo*, the absolute unstressed muscle length is difficult to measure and the end-diastolic length is often used. In the longitudinal and circumferential directions, strain measures myocardial lengthening or shortening, and in the radial direction thickening and thinning. Strain rate is the rate of deformation (strain over time). Deformation parameters allow a more direct assessment of myocardial contractility in that the change in muscle dimension and its rate of change are directly related to myocardial contractility and are not affected by tethering and translational motion. Although both strain and strain rate are affected by loading conditions, strain rate is less affected by loading as it peaks in early systole and has a short duration. The degree of posterior wall thickening obtained by M-mode echocardiography is an example of regional strain, albeit from a very limited scan line. Strain and strain rate from larger regions are currently obtained using one of two techniques, each with its advantages and disadvantages. Strain rate may be calculated from color tissue Doppler by calculating the instantaneous difference in myocardial velocities between two points. Strain is then derived from strain rate measurements. Advantages of color tissue Doppler include its wide availability, easy application, and high temporal resolution. Disadvantages include its low signal-to-noise ratio (especially for strain rate) and exquisite dependence on insonation angle. One such example is evaluating left ventricular basal lateral wall strain from the apical four-chamber view. The ultrasound beam is oriented laterally from the apex of the scan triangle. However, in dilated ventricles the basal curvature is exaggerated, rendering a poor insonation angle and unreliable strain values. To overcome these limitations, strain imaging from two-dimensional images has been implemented by speckle tracking and by vector velocity imaging [14] (Figure 8.30).

Although these techniques use different algorithms, both are based on computer software tracking unique ultrasound speckles caused by the tissue–sound wave interface through the cardiac cycle. This technique is independent of insonation angle but significant disadvantages include lower frame rates (lower temporal resolution) and relatively poor intra- and inter-observer reliability [15]. As compared with shortening indices, velocity and deformation indices are calculated without mathematical assumptions of ventricular geometry (although they are influenced by ventricular geometry). Therefore, tissue velocity and deformation imaging may be well suited for assessing RV function and congenital heart disease including single ventricles.
Figure 8.30 SAX strain rate normal. Left ventricular radial strain rate obtained by two-dimensional speckle tracking in a normal child. Peak systolic (arrow) and early diastolic (arrowhead) radial strain rate are depicted. At the bottom left, a color-coded M-mode display of the strain rate is depicted. The ventricle is displayed in a linear format with each color dot corresponding to the matching ventricular segment in the short axis image. Progression from left to right is through time, corresponding to the ECG display. As for Doppler flow imaging, the colors code the direction and magnitude of the strain rate. In this example, orange codes for positive radial strain rate in systole and blue codes for negative radial strain rate in diastole. Yellow and green code for lower strain rate intensities.

Furthermore, tissue velocities and deformation measure regional myocardial performance, whereas ejection and shortening fraction provide a global assessment. Regional assessment of function has been especially useful in ischemic heart disease and this is pertinent in certain congenital lesions such as anomalous left coronary artery from the pulmonary artery (ALCAPA), transposition of the great arteries after the arterial switch operation and tetralogy of Fallot (TOF). Although tissue velocities and deformation imaging measure regional function, they may correlate with measures of global function. For instance, regional RV and LV deformation or excursion correlate with stroke volume and are sometimes used to report "global" ventricular function. However, these measurements remain regional. Certain diseases are characterized by regional heterogeneity, hypertrophic cardiomyopathy being one example. Septal performance in this disease may not reflect the performance of other ventricular segments.

Velocity and deformation imaging may also be useful for detecting early ventricular dysfunction before patients develop symptoms and when shortening indices are still normal. Examples include early detection of heart graft rejection, early ventricular dysfunction in children with Duchenne muscular dystrophy, early dysfunction in aortic regurgitation, and early effects of pacing on regional myocardial performance [16–18].

In contracting, the left ventricle shortens and rotates along its long axis and thickens in the radial direction. The opposite rotation at the base and apex creates a twisting or torsional motion of the LV, akin to wringing a wet towel (Figures 8.31 and 8.32). Whereas conventional methods to assess ventricular function, such as M-mode assessment of ejection fraction, rely predominantly on the assessment of radial function, newer methods allow the quantification of myocardial motion and deformation in all vectors, providing a more comprehensive assessment of ventricular performance and the differential effects of disease. Quantifying longitudinal myocardial function may be especially important when assessing RV performance due to the predominantly longitudinal orientation of the RV myocytes.

Velocity and deformation measurements are relatively easily obtained at the bedside using standard echo systems in a relatively short period of time. There are now normal fetal [19] and pediatric [15,20] values available for reference.

Velocity and deformation imaging in CHD
Influence of volume and pressure loading on tissue velocities and deformation parameters in children.

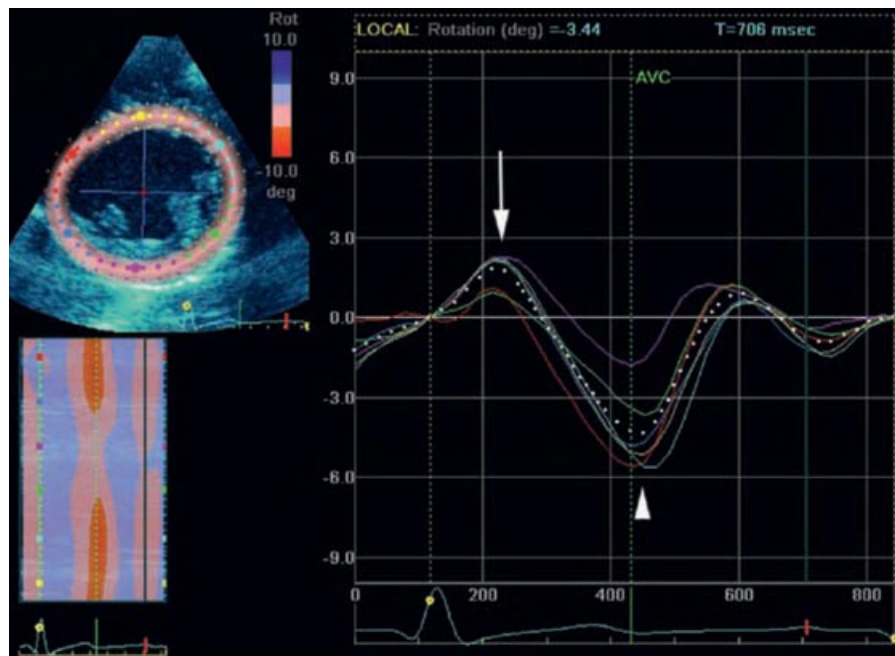
Although the ideal index of ventricular contractility should be independent of loading conditions, volume and/or pressure loading that lead to ventricular remodeling are central to many cardiac abnormalities affecting children. Tissue velocities and


Figure 8.31 SAX rotation normal. Normal left ventricular basal rotation obtained by two-dimensional speckle tracking in a child. An initial counterclockwise rotation (arrow) is followed by a predominant clockwise rotation (arrowhead) as viewed from the ventricular apex. Together with predominant counterclockwise rotation at the apex, this rotational motion produces systolic torsion (or twist). As in Figure 8.30, a color-coded M-mode display is depicted at the bottom left. The ventricle is displayed in a linear format with each color dot corresponding to the matching ventricular segment in the short axis image. Progression from left to right is through time, corresponding to the ECG display. The colors code the direction and magnitude of the rotation. In this example, the initial counterclockwise rotation is coded in blue and the predominant clockwise rotation in red–pink (depicting the magnitude of rotation).
Figure 8.32 SAX basal rotation. Abnormal low and counterclockwise basal left ventricular rotation in a child with dilated cardiomyopathy. Contrast these curves with the normal rotation shown in Figure 8.31. At the bottom left the color-coded M-mode display is shown as in Figure 8.31.
Figure 8.33 ALCAPA strain 1. Highly abnormal and dyssynchronous left ventricular longitudinal contraction in a child with severe left ventricular dysfunction secondary to anomalous left coronary artery from the pulmonary artery. Left ventricular dysfunction persists despite surgical repair. Longitudinal strain curves obtained by two-dimensional speckle tracking show early stretching of the lateral wall segments (positive strain, arrows). This occurs during early, albeit low, septal deformation (arrowheads) and increases wall stress in the delayed segments.

deformation are influenced by loading conditions, although isovolumic acceleration (IVA) and peak systolic strain rate are less dependent on loading as they occur during isovolumic contraction or early systole [21]. When interpreting loading effects, it is important to consider that acute changes affect myocardial indices differently from chronic changes, largely due to adaptive mechanisms such as hypertrophy.

When left ventricular volume loading is chronic, such as in moderate to large VSDs and patent arterial ducts, preload does not significantly influence either systolic or diastolic tissue velocities, likely due to LV myocardial adaptation [22]. This differs from mitral inflow indices, which are clearly affected by changes in volume load and atrial pressures. In contrast to chronic volume loading, increased LV afterload, such as in moderate to severe aortic stenosis, leads to reduced systolic and diastolic tissue velocities. This reduced longitudinal performance may also stem from secondary hypertrophy. Indeed, children with hypertrophic cardiomyopathy have regional reduction in deformation despite normal afterload [23].

Acute changes in loading conditions, either in the experimental setting or after ASD closure, affect peak systolic tissue velocities, but IVA remains unchanged [24]. Likewise, RV strain and strain rate are less affected by acute loading than are tissue velocities. This has been useful to demonstrate that patients who underwent device closure of an ASD had better left and right ventricular longitudinal deformation

than patients who underwent surgical closure, presumably related to the negative effects of cardiopulmonary bypass on myocardial function.

Tissue Doppler imaging has been useful for noninvasive assessment of left ventricular diastolic dysfunction and left ventricular filling pressures. In early diastolic dysfunction, impaired ventricular relaxation is characterized by a low mitral E wave (early diastolic filling), increased dependence on atrial contraction for ventricular filling and therefore reversal of the E/A ratio. With progression of diastolic dysfunction and increasing filling pressures, the E wave heightens, leading to so-called "pseudo-normalization" of the E/A ratio. However, tissue Doppler early diastolic velocities are less affected by the increased pressures and remain low. Therefore, the E/E′ ratio reflects filling pressures [25] and, in conjunction with left atrial volume, pulmonary vein Doppler, and other diastolic parameters, provides useful semiquantitative information. Although not validated in children to the same extent as in adults, in various settings the E/E′ ratio has been shown to be related to LAP [26]. However, this index likely is only useful when ventricular relaxation is impaired [25].

Velocity and deformation imaging in children may also be useful for longitudinal follow-up of ventricular function. Serial recovery of LV and RV strain after repair of anomalous coronary artery from the pulmonary artery has been demonstrated (Figure 8.33). Likewise, differences in recovery

of radial versus longitudinal function have been found after coronary re-implantation. This may be related to associated subendocardial fibroelastosis that reflects irreversible myocardial damage.

Use of tissue velocities to predict clinical outcomes in children

Reduced mitral diastolic velocity helps predict children at risk for adverse outcomes, including death and need for cardiac transplantation in dilated cardiomyopathy and left ventricular non-compaction. Likewise, the E/E′ ratio predicts adverse clinical outcomes, including death, cardiac arrest, VT, and significant cardiac symptoms in children with HCM. Reduced TV tissue velocities have also identified children with heart transplant at risk for graft failure secondary to rejection [17]. We have studied heterogeneous left ventricular contraction and relaxation (mechanical dyssynchrony) using tissue velocities and strain as predictors of outcomes in children with dilated cardiomyopathy. The timing of contraction was related to the degree of deformation in both normal children and in those with dilated cardiomyopathy [27]. Although mechanical dyssynchrony was prevalent in children with dilated cardiomyopathy, systolic dyssynchrony was not associated with need for transplant or death [28]. In contrast, diastolic dyssynchrony was associated with decreased transplant-free survival, although there were no obvious associations with other abnormalities of diastolic function [28].

Limitations of the newer techniques

Velocity and deformation imaging have important limitations. Their utility in specific clinical situations remains to be confirmed and solid validation in pediatrics is lacking. Difficulties in technical acquisition which affect data quality and interpretation, large inter- and intra-observer variability, large scatter and variation when compared with reference methods, conflicting data regarding load dependence of the various indices, standardization of what should be measured (regional versus global function, which and how many myocardial segments should be measured), which method should be used in routine practice (velocities, strain, strain rate, a combination of these), standardization within the method (peak versus mean velocities, color versus pulsed Doppler, TDI versus 2D speckle derived strain, radial versus longitudinal versus circumferential strain versus a combination of these), potential differences between data obtained from the use of systems from different commercial vendors, and long post-acquisition processing times remain issues for their use in routine clinical practice. Standardized reporting also remains a challenge.

Diastolic function

Ventricular relaxation and filling constitute diastolic function. All diastolic indices, both echocardiographic and invasive, are less developed than are their systolic
Figure 8.34 Display of left ventricular (LV) pressure and the relationship to transmitral Doppler flow patterns. Instantaneous left ventricular pressure (*PV*) follows an exponential pressure decay during early diastole (*PV = POe*$^{-t/T}$). Invasive isovolumic relaxation time (*) represents the period from peak −d*P*/d*t* (*PV = PO*) until mitral valve opening (*PV = PMV*). Doppler-derived isovolumic relaxation time (#) is the interval from the valve artifact at the end of left ventricular outflow (LVOT) until the beginning of transmitral inflow (E). LA, left atrium. (Reproduced with permission from Scalia *et al. Circulation* 1997;**95**:151–5.)

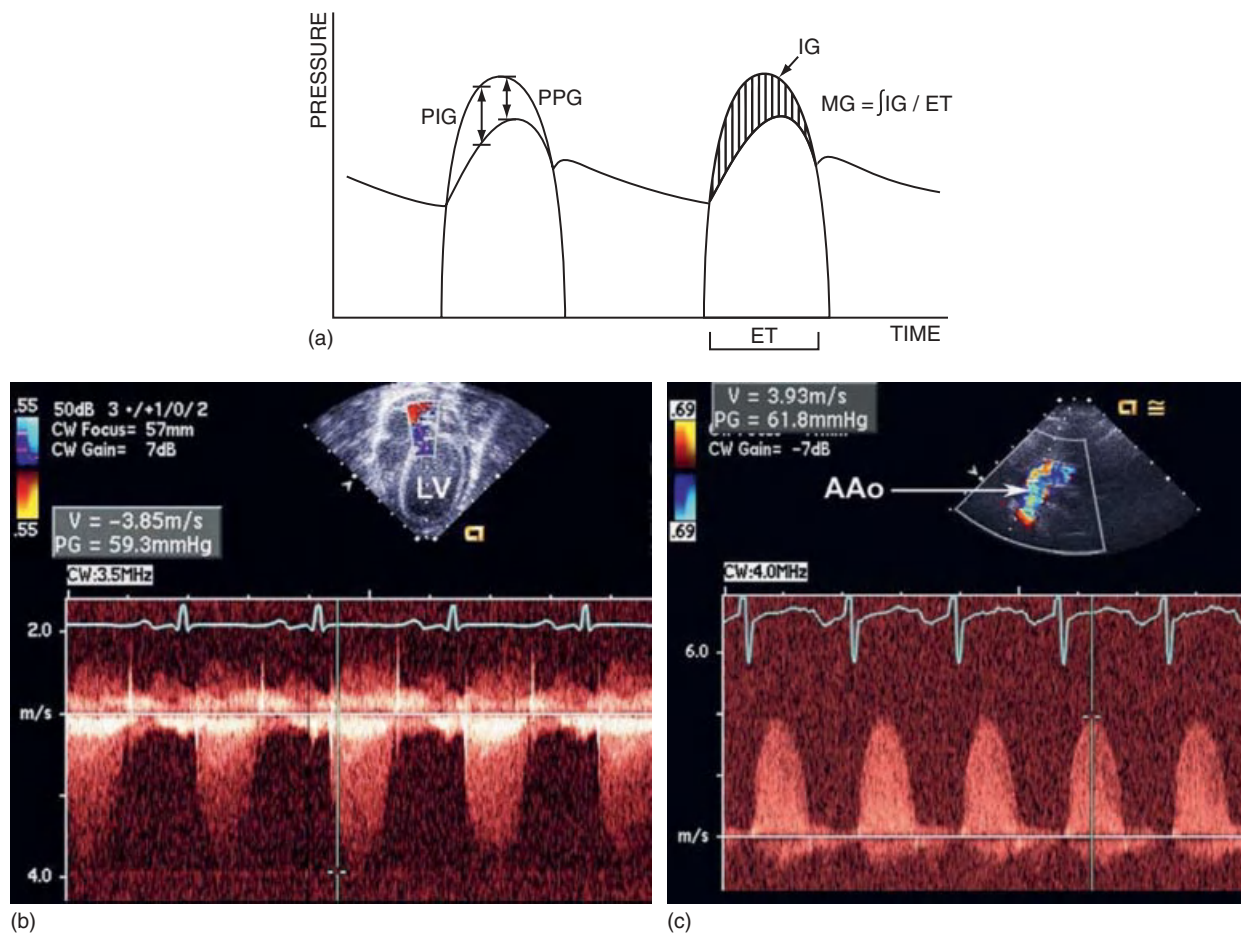
counterparts. Ventricular diastole is composed of an isovolumic relaxation phase, during which intracellular calcium is resequestered in the sarcoplasmic reticulum by energy-dependent means, and a filling phase, during which venous return passes from the atria into the ventricles. Diastolic dysfunction can manifest as either impaired isovolumic relaxation, impaired filling, or both. Isovolumic relaxation time is the interval from aortic valve closure to mitral valve opening, and can be measured using Doppler techniques (Figure 8.34) [29]. Ventricular filling may be assessed with Doppler analysis of mitral and tricuspid valve diastolic inflow patterns, composed of three phases. Early (rapid) filling is represented by Doppler as the upslope of the E wave. After the peak early filling velocity is reached, there is a transition to slow filling, represented by the deceleration of the E wave and measured as deceleration time. Atrial contraction produces late ventricular filling, represented by the A wave on the mitral/tricuspid inflow tracing. Pulmonary and hepatic venous flow Doppler velocity spectra can also provide insight into diastolic


Figure 8.35 (a) Graphic representation of the relationship between the variables of pressure drop that can be measured at cardiac catheterization and/or by Doppler. The tracings represented schematically are those from ventricular and arterial pressures. Doppler measures peak instantaneous gradient (PIG), whereas it is conventional to measure the peak-to-peak gradient (PPG) at catheterization, even though peak ventricular and arterial pressures are not simultaneous. At catheterization and by Doppler, the mean gradient throughout systole (MG) is obtained by integrating the area of all instantaneous gradients (IG) and dividing by ejection time (ET). For measurement of the mean gradient, Doppler and manometric values are the same. Continuous wave (CW) Doppler tracing recorded from an apical four-chamber (b) and suprasternal notch (c) position demonstrating an increased velocity in the ascending aorta in a patient with valvar aortic stenosis, LV, left ventricle; AAo, ascending aorta. Peak velocity is approximately 3.9 m s^{-1}. Using the modified Bernoulli equation, the instantaneous pressure drop is calculated to be approximately 60 mmHg. (Part (a) reproduced with permission from Silverman, *Pediatric Echocardiography*. Baltimore: Williams & Wilkins, 1993.)

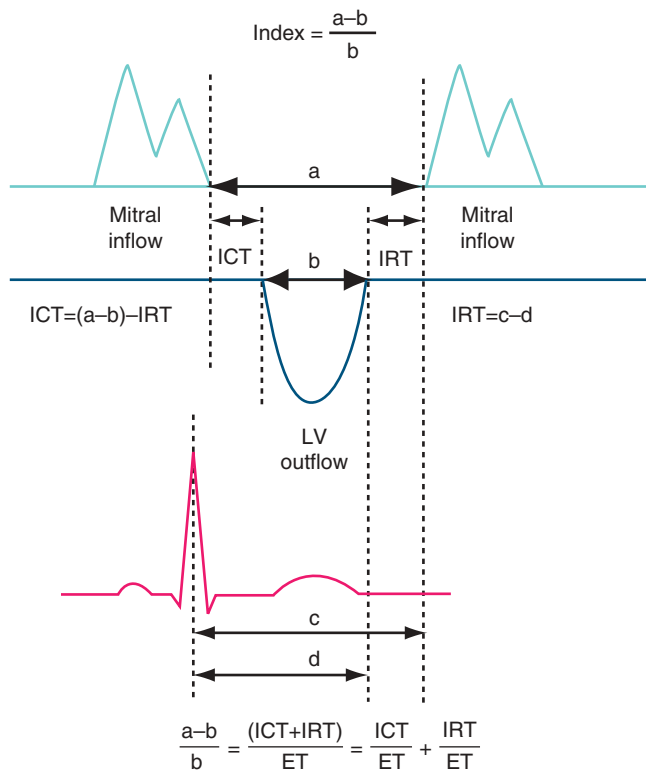
function, insofar as atrial inflow velocity is inversely related to pressure in the receiving chamber.

Isovolumic relaxation time is typically increased by impaired ventricular relaxation and decreased by a restrictive pattern. The ratio of early filling to atrial filling (E/A), normally between 1.9 and 2.5 in children, is decreased by impaired relaxation and increased by restrictive filling. Similarly, the deceleration time of the E wave is an indicator of ventricular compliance, being inversely related to the square of ventricular stiffness [30].

Ventricular relaxation during the isovolumic relaxation interval is characterized by the maximum negative slope of ventricular pressure decay ($-dP/dt$) and by the relaxation time constant (τ), which is the inverse slope of the natural logarithm of left ventricular pressure decay over time. The primary advantage of τ over isovolumic relaxation time and $-dP/dt$ as an indicator of diastolic function is its independence from heart rate and preload. Noninvasive estimates of these properties using Doppler technology correlate well with high-fidelity manometer-tipped catheter measurements [29]. More recently, color Doppler M-mode echocardiography of ventricular inflow has been proposed as a means of evaluating diastolic function, insofar as the slope of flow propagation in this mode is inversely related to $-dP/dt$ and τ (Figure 8.35) [31,32].

Tei *et al.* devised an index for assessing overall myocardial performance, including both systolic and diastolic components [33]. Using pulsed wave Doppler analysis of mitral


$$\text{Index} = \frac{a-b}{b}$$

a

Mitral inflow

Mitral inflow

ICT : b : IRT

$ICT = (a-b) - IRT$

$IRT = c - d$

LV outflow

c

$$\frac{a-b}{b} = \frac{(ICT+IRT)}{ET} = \frac{ICT}{ET} + \frac{IRT}{ET}$$

Figure 8.36 Schematic diagram of Doppler and electrocardiogram intervals used by Tei *et al.* [33] to determine a noninvasive index of myocardial performance. The index (*a* – *b*)/*b* is calculated by measuring *a* (interval between cessation of and onset of mitral inflow) and *b* [ejection time (ET) of left ventricular (LV) outflow]. The index is equivalent to the sum of isovolumic contraction time (ICT) and isovolumic relaxation time (IRT) divided by ejection time. The isovolumic relaxation time can be calculated as the difference between interval *d* (from the R wave of the electrocardiogram to cessation of left ventricular outflow) and interval *c* (from the R wave to onset of mitral inflow). Isovolumic contraction time can be calculated by subtracting isovolumic relaxation time from the quantity *a* – *b*. (Modified from Tei *et al. J Am Soc Echocardiogr* 1997;**10**:169–78.)

valve inflow and left ventricular outflow, two intervals are measured: from cessation of mitral inflow to onset of mitral inflow during the next cardiac cycle, and ejection time. The former represents the sum of isovolumic contraction time, ejection time, and isovolumic relaxation time. Ejection time is subtracted from this, and the difference is the sum of isovolumic contraction and relaxation times. The index of myocardial performance is the ratio of this duration (summed isovolumic contraction and relaxation times) to ejection time (Figure 8.36). Although this index has not been assessed in children, it correlates well with catheter-derived measurements of peak −d*P*/d*t*, +d*P*/d*t*, and τ, and is likely to prove useful in a variety of patient populations.

An additional method for establishing diastolic dysfunction is the ratio of mitral velocity to early diastolic velocity of the mitral annulus (E/E′ ratio). A measurement of >15 was

highly associated with elevated left ventricular end-diastolic pressure by cardiac catheterization [34].

Valvar physiology
Although cross-sectional methods are used to image the motion of the semilunar and atrioventricular valvar leaflets, Doppler technologies are the primary echocardiographic tools for evaluating valvar dysfunction, either stenosis or regurgitation.

Semilunar valvar stenosis
Valvar obstruction is identified with continuous or pulsed wave Doppler analysis, which shows increased flow velocity during systole when the sample volume is placed distal to the stenotic orifice. Evaluating the severity of flow obstruction is done by applying the simplified Bernoulli equation, which estimates the pressure gradient between two points as

$$P = 4\left(V_2{}^2 - V_1{}^2\right)$$

where V_1 and V_2 are the proximal and distal flow velocities, respectively. For practical application in the echocardiography laboratory, proximal flow velocity is generally negligible (<1 m s^{-1}) and this term is omitted, yielding the simplified equation $P = 4V_2{}^2$. This method is reasonably reproducible, but requires an understanding of the principles of Bernoulli's law. Viscous forces are assumed to be minimal relative to inertial forces in the system being studied, which does not occur in long-segment stenoses or mild stenoses in a patient with increased blood viscosity (e.g., polycythemia in cyanotic patients). This technique, which yields an estimate of peak instantaneous gradient, requires consistent placement of the sample volume at the vena contracta, the point of maximum velocity at the midline of the jet immediately downstream from the stenotic orifice. Continuous wave Doppler aids in minimizing variability due to sample volume placement, insofar as it detects the highest velocities as it passes axially along the jet length. The acoustic signal of the sample volume must also be aligned as closely as possible with the direction of the jet to optimize sensitivity. The sample volume is typically located with the aid of Doppler color flow mapping, which shows the direction and dimensions of the jet. The simplified Bernoulli method tends to overestimate the pressure gradient of a stenosis relative to direct catheter measurements due to methodological and physical factors [3,35,36]. Catheterization measurements are of peak-to-peak pressure gradient (non-simultaneous), whereas Doppler analysis estimates peak instantaneous gradient (Figure 8.35); pressure is lower at the vena contracta than it is at the site of pressure recovery further downstream, where catheter measurements are generally made due to the difficulty of maintaining the catheter in the center of the jet; and sedation during catheterization tends to decrease stroke

volume and hence flow velocity across the stenotic orifice. The mean systolic pressure gradient is less prone to systematic overestimation, but peak velocity measurements are less time consuming and we use this approach in our practice.

Another useful method of calculating pressure drop is to measure acceleration time (the duration from valve opening to peak flow velocity), although other physiologic conditions (such as severe mitral regurgitation and ventricular dysfunction) can also cause the gradual rise in the velocity profile characteristic of more severe stenosis. Valvar orifice area, an indirect indicator of function, can be estimated by several techniques, including planimetry, M-mode, the continuity equation, and measurement of pressure half-time. With an arterial level shunt, significant valvar obstruction may be indicated by diastolic flow reversal in the artery downstream from the affected valve. Color Doppler M-mode imaging may increase the temporal and spatial sensitivity for detecting flow disturbances and helping to break down complex outflow tract obstruction into its various components.

Valvar regurgitation

Unlike stenotic lesions, quantification of valvar regurgitation is complicated by several factors. Measuring the size of the regurgitant jet does allow gross characterization of the severity of regurgitation, but it is difficult to make fine distinctions between grades. Atrioventricular and semilunar valvar regurgitation pose different problems of quantification, due primarily to geometric features of the respective proximal and receiving chambers and to the flow dynamics in the proximal and receiving chambers.

The shape and size of a regurgitant jet are influenced by numerous factors, only one of which is the severity of regurgitation [37–40]. Pressure in the receiving chamber, atrial counterflow, and cardiac function influence the morphology of the jet. Geometric features of the proximal chamber, the valve itself, and the receiving chamber have a significant effect on the flow pattern of the jet and on the Doppler color map [37–39]. In addition, instrument settings such as color gain, transducer frequency, velocity scale, and filtration can all substantially alter the appearance of a regurgitant jet [40].

Determining semilunar valvar regurgitation severity employs both color flow and spectral Doppler imaging. The regurgitant jet is interrogated with continuous or pulsed wave Doppler at the center of the aortic or pulmonary valve. The velocity profile of the jet reflects the diastolic aorta–left ventricle (or pulmonary artery–right ventricle) pressure gradient, and the velocity decay rate ($-dV/dt$) is a function of the gradient change over time. Accordingly, more severe regurgitation is reflected by a steeper velocity decay of the jet, as the higher regurgitant volume leads to more rapid diminution of the ventriculo-arterial pressure gradient. Unfortunately, this method is not of great value in evaluating regurgitation in children. A better indication of the severity of aortic regurgitation is finding retrograde diastolic flow in the descending aorta. Pulmonary regurgitation correlates best with the width of the regurgitant jet and right ventricular size. Methods for estimating atrioventricular regurgitation according to the principles of free jet physics cannot be applied to semilunar valvar regurgitation, largely because the regurgitant volume originates as flow reversal after ejection in the restrictive confines of the great artery, which combine to create a nonideal proximal flow field. As with valvar stenosis, color Doppler M-mode imaging may be used to increase the sensitivity for detecting a regurgitant jet, whether atrioventricular or semilunar.

Vascular physiology

Vascular stenoses can be evaluated by Doppler estimation of the peak instantaneous pressure gradient. The simplified Bernoulli equation is the standard method, although it may not apply to serial or long-segment stenoses. Because pressure is estimated by measuring flow velocity at a single point, assuming that velocity proximal to the stenosis is negligible, high flow velocities distal to one stenosis and proximal to the next invalidate this assumption. Each successive stenosis must be measured separately, which is possible with continuous wave Doppler, where each separate point of acceleration is superimposed on the spectral display. In addition, with long-segment stenoses, viscous forces may exert a substantial effect on the pressure drop, but these are ignored by the simplified Bernoulli equation. Arterial flow patterns distal to the obstruction, such as damping of the pulse wave and diastolic flow reversal, may also indicate significant stenosis.

Pulmonary arterial pressures and flows can be estimated with echocardiography, although not with sufficient precision to obviate catheterization to assess the state of the pulmonary vasculature. Pressure is estimated by subtracting the right ventricle-pulmonary artery gradient (predicted with Doppler imaging and the simplified Bernoulli equation) from the estimated right ventricular pressure. Right ventricular pressure is calculated by determining the systolic right ventricle–right atrium pressure drop, estimated by applying the Bernoulli equation to the velocity of a tricuspid regurgitant jet (often present even without cardiac pathology) and assuming a right atrial pressure of 5–10 mmHg. Pulmonary arterial distensibility, estimated by measuring the diastolic–systolic diameter change, may also contribute information regarding pulmonary arterial pressure. In patients with decreased pulmonary vascular compliance, late diastolic flow reversal may be evident with Doppler analysis.

Shunt physiology

Doppler color flow mapping allows the visualization of most shunts at the cardiac or great vessel levels. The restrictiveness of a discrete anatomic shunt (such as a septal defect or patent ductus arteriosus) may be evaluated with spectral
Figure 8.37 (a) Apical four-chamber view showing right atrium (RA), left atrium (LA), right ventricle (RV), left ventricle (LV), and descending aorta (DAo). After injection of agitated saline into the right arm (b), microcavitations (arrow) appear in the right atrium and enter the right ventricle and left atrium (c). This obliteration of the atrial septum indicates a right–left interatrial communication. Eventually, microcavitations appear in the left ventricle and descending aorta (d). If there had been a right-to-left ventricular communication and mitral incompetence, the microbubbles would have appeared in the left ventricle before the left atrium.

Doppler to estimate the pressure gradient from the Bernoulli principle. Shunts more difficult to image with color flow, such as those from pulmonary or systemic arteriovenous malformations or small interatrial communications, can be analyzed by contrast echocardiography. Agitated saline is injected into a systemic vein or artery, and the echogenic microbubbles pass through all vessels or cardiac defects larger than their 8–15 μm diameter, and appear downstream or in the receiving chamber (Figure 8.37) [41]. Alternatively, interchamber defects that are difficult to distinguish from valvar regurgitation with standard Doppler color flow may sometimes be clarified by increasing the color gain in the Doppler color flow mode to highlight the proximal flow convergence region approaching the low-velocity defect. The diagnosis of an arteriovenous shunt can be verified by diastolic flow reversal in the descending aorta (distal to the

shunt) in the absence of semilunar valvar regurgitation, and by identifying high levels of output and associated chamber dilatation. Shunt lesions that are most likely to be missed on echocardiography are small defects occurring with a larger, non-restrictive defect, as in multiple muscular ventricular septal defects with a nonrestrictive inlet or perimembranous defect. In these patients, there may be no pressure gradient between the chambers and no accelerative flow shown with Doppler techniques.

Special techniques

Stress echocardiography

Echocardiography can be used to assess the effect of increased workload on ventricular performance and hemodynamics (stress echocardiography). The increased workload is generated either by exercise [42] or by giving dobutamine [43]. Dobutamine is particularly useful in smaller patients who cannot exercise on demand. Stress echocardiography provides information about the coronary reserve, ventricular function under increased output demands, and the response of ventricular outlet obstruction to increased output.

The procedure is similar to that performed in adults [44]. Views of the left ventricle are obtained from the parasternal short and long axis, and from the apical two- and four-chamber views. These views allow visualization of the entire ventricular wall. Images are obtained at rest, at multiple levels of stress, and after recovery. The images are then compared for changes in regional wall motion that suggest impaired myocardial perfusion. Stress echo compares favorably with nuclear medicine studies in adults [44]. When evaluating obstructive lesions, Doppler gradients are obtained at all stress levels and compared to assess the change in degree of obstruction. Response of the obstruction to stress is variable; some patients with minimal obstruction at rest can develop severe obstruction with stress. The increased cardiac motion, particularly when combined with the motion of exercise, can make image acquisition difficult. Anterior wall segments are most affected by motion, as they are the most difficult to image even at rest. In patients with obstructions, the examiner must measure both proximal and distal velocities, because with increased output the proximal velocity may increase to significantly greater than $1\,\mathrm{m\,s^{-1}}$. When this occurs, the longer version of the Bernoulli equation ($V_2{}^2 - V_1{}^2$) must be used to account for this increase.

Children who benefit most from stress echocardiography include patients who have undergone coronary manipulation, such as after the arterial switch, Ross procedure, or Konno procedure [45]; coronary anomalies, as in Kawasaki syndrome; abnormal ventricular function, as in anthracycline cardiotoxicity [46]; and left heart obstructions, such as aortic stenosis and coarctation [47].

Transesophageal echocardiography

With the development of miniaturized transducers suitable for patients weighing <20 kg, the application of transesophageal scanning in children expanded rapidly [48–51]. These studies demonstrated the suitability of transesophageal echocardiography for monitoring intraoperative cardiac function and evaluating the adequacy of surgical repair, demonstrating accurately most forms of normal and abnormal cardiac morphology, and evaluating physiology with pulsed wave Doppler and color flow Doppler features (Figures 8.38 and 8.39).

The primary application of transesophageal echocardiography in children is intraoperative monitoring and evaluating surgical repair [50]. Transesophageal echocardiography may also be valuable in larger children, adolescents, and the few smaller children who cannot be imaged completely with transthoracic transducers, or when surgical dressings preclude noninvasive imaging. The transesophageal approach does not interrupt the surgical procedure, provides multiple imaging windows for morphologic evaluation and Doppler analysis, and avoids causing dysrhythmias, hypotension, or potential infectious complications associated with direct transducer contact with the epicardium. Aside from intraoperative studies, transesophageal echocardiography is not a substitute for precordial echocardiography. It is an invasive procedure reserved for patients in whom a thorough precordial examination has proved inadequate, or during surgical and interventional cardiac catheterization procedures.

The transducer employed for transesophageal echocardiography is mounted on a standard flexible endoscope. The pediatric transesophageal probe can be manipulated in three directions: advanced or withdrawn, anteroflexed or retroflexed, and rotated clockwise or counter-clockwise (Figure 8.39). Biplane and multiplane transesophageal echocardiography probes provide an additional control that allows lateral flexion. These scan planes differ from those of precordial imaging but the same information can be acquired, especially in infants and children, whose hearts and thoracic dimensions are small relative to the depth resolution of the ultrasound technology used. For more detailed descriptions of transesophageal echocardiography, the reader is referred to other sources [50–54].

Fetal echocardiography

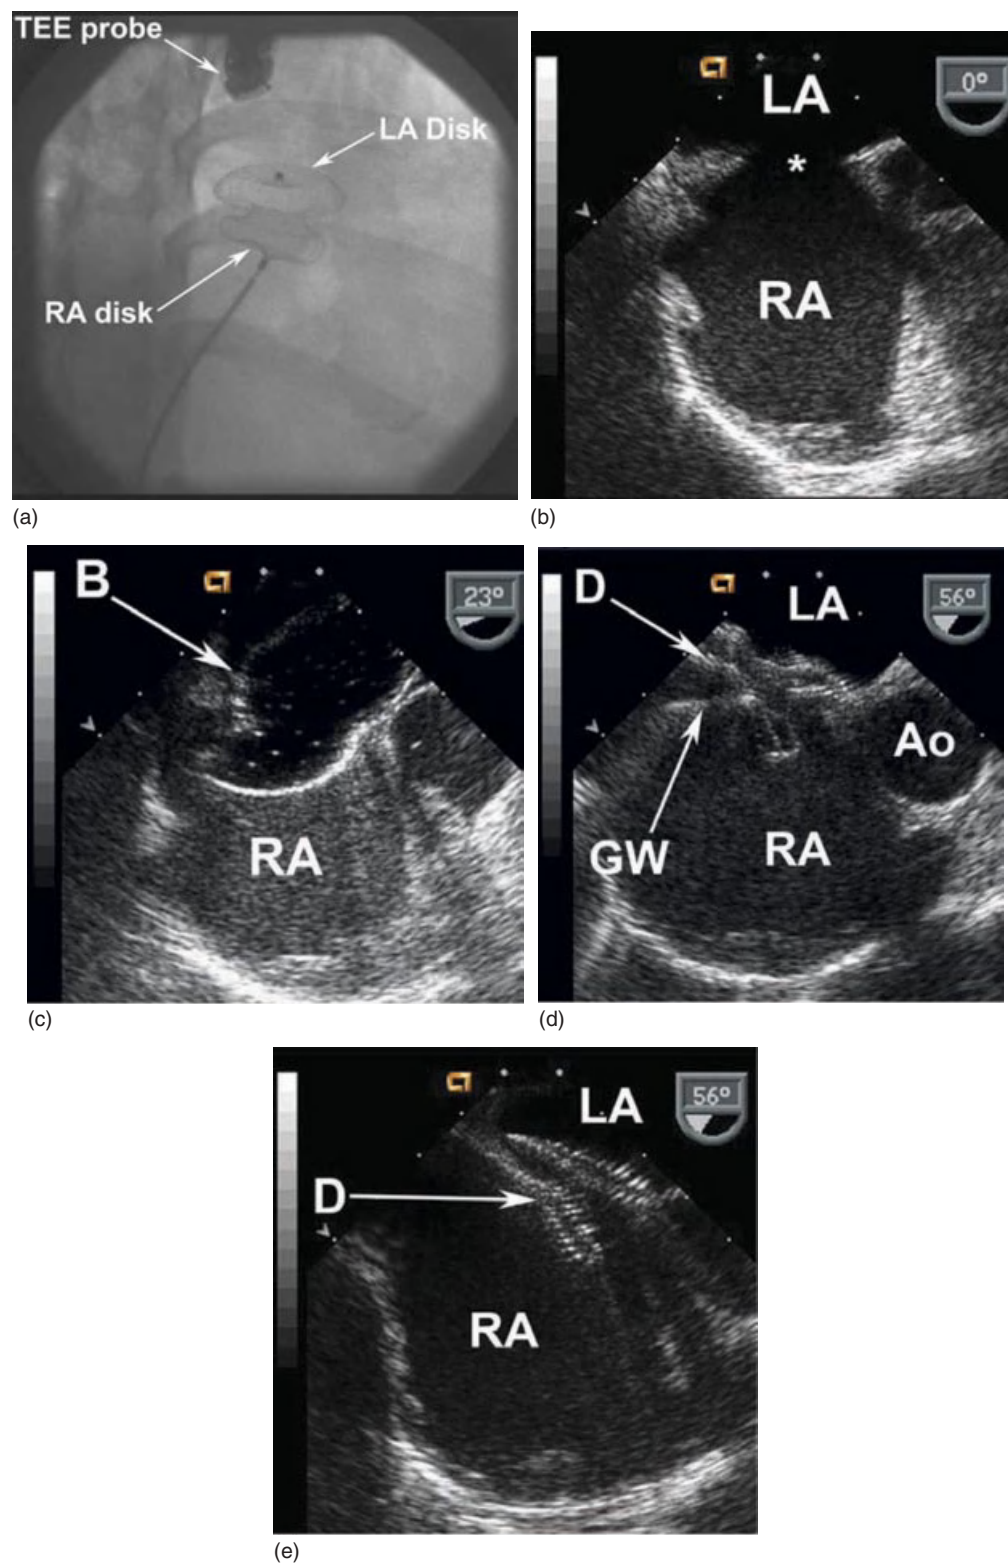
Fetal echocardiography in experienced hands detects most congenital heart disease and dysrhythmias [55–63]. Detecting structural heart disease becomes especially important for cyanotic congenital heart disease or ductal-dependent lesions [56,64,65]; diagnosing lesions such as complete transposition or hypoplastic left heart disease in the fetus has led to improved outcomes [66–68]. The primary indications include suspected congenital heart disease, fetal dysrhythmia, family


Figure 8.38 (a) This fluoroscopy image taken during transcatheter device closure of an atrial septal defect shows the catheter in the right atrium attached to the device. The left (LA) and right atrial (RA) disks are clearly demonstrated along with the end of the transesophageal (TEE) probe. (b) A transverse transesophageal image taken prior to deployment of the device; a secundum atrial septal defect is noted (*). (c) A sizing balloon (labeled B) is positioned across the defect. (d) The tip of the guide wire (GW) can be seen connected to the center of the device (labeled D). The left and right atrial disks are in the respective atria. (e) The device has been deployed across the atrial septal defect with appropriate position. Ao, aorta.
Figure 8.39 From top to bottom, this figure depicts adult omniplane, adult biplane, pediatric biplane, and pediatric single plane transesophageal ultrasound transducers. The differences in transducer diameter, which range from 13 mm for the adult omniplane transducer to 8 mm for the pediatric single plane transducer, can be appreciated, as can the increased flexion possible with pediatric transducers. The scale is indicated by the 5 cm markers on the probes.

Figure 8.40 This fetal apical four-chamber view demonstrates both atria (RA, LA) and ventricles (RV, LV) along with the descending aorta posteriorly (DAo). The left lung is identified and the apex is on the ipsilateral side, consistent with levocardia.

history of congenital heart disease, history of familial inherited disorders, maternal systemic lupus erythremotosis, maternal diabetes mellitus or phenylketonuria, increased nuchal thickening, exposure to teratogens or prostaglandin synthetase inhibitors, and *in vitro* fertilization [69–81]. Some studies suggest that a single umbilical cord or echogenic density in isolation is not an indication for a fetal echocardiogram because of the lack of associated congenital heart disease [73,74,76,81].

Approach to Fetal Morphology

Initially, the position of the cardiac mass and apex relative to the thorax is established (Figure 8.40). The cardiothoracic ratio is determined [82]. The connections of systemic and pulmonary veins to the atria are established, as are the atrioventricular and ventriculoarterial relationships. The great vessels should essentially cross each other at near right-angles (Figure 8.41).

Special anatomic considerations apply to the fetus. Both the ductus arteriosus and foramen ovale should have unobstructed right–left shunting across them, as the pulmonary blood flow is diminished *in utero*. Left–right shunting across the atrial septum represents left atrial obstruction such as mitral stenosis or atresia (Figure 8.42). A left–right shunt across the ductus arteriosus may indicate inadequate output from the right ventricle (Figure 8.43), as in tetralogy of Fallot with pulmonary atresia, severe Ebstein's anomaly, and severe pulmonary stenosis. Any obstruction to the ductus arteriosus flow may lead to significant tricuspid valve regurgitation and right ventricular dilation/failure (Figure 8.44), and subsequent pulmonary hypertension. Multiple medications and NSAIDs are known to cause ductal constriction that is, however, frequently idiopathic [83–85].
Approach to fetal rhythm

The fetal rhythm is established by M-mode, pulse wave, and tissue Doppler techniques to detect the type of ectopy, tachycardia, or bradycardia [86–89]. The absolute fetal heart rate can be established using the mitral inflow or aortic outflow. The mitral inflow and aortic outflow pulse wave Doppler indicate sinus rhythm and provide a surrogate for the PR interval for mothers with collagen vascular disorders such as lupus or Sjogren's disease [90–94] (Figure 8.45). Reference standards are available to establish prolonged atrioventricular intervals that suggest first-degree heart block [90,91,93–95]. An M-mode determination of atrioventricular association also helps to establish the fetal atrial and ventricular rates and their relationship. Second- or third-degree heart block can be determined (Figure 8.46). Multiple atrial beats compared with ventricular beats suggest atrial flutter; typically, the atrial rate measures about 400 beats per minute whereas the ventricular response is 200 beats per minute, consistent with 2:1 flutter (Figure 8.47). Orthodromic reentrant tachycardia is also highly likely when the atrioventricular relationship is 1:1 with a heart rate range of 220–300 beats per minute (Figure 8.48). The most common rhythm disturbance is premature atrial contractions (Figure 8.49), but ventricular tachycardia is exceedingly rare.

### Approach to fetal function

The systolic function of both ventricles may be evaluated qualitatively, but M-mode may be used to calculate a shortening fraction. Secondary signs of cardiac dysfunction are also useful. Makikallio *et al.* described a biophysical profile to determine fetal well-being through a scoring system [96]. This biophysical profile utilizes the presence or absence of
(a)
(b)
(c)

Figure 8.41 These images show normal ventriculoarterial relationships given that the left ventricle (LV) gives rise to the aorta (a) and the right ventricle (RV), in a different plane, connects to the pulmonary artery (b). This criss-cross of the great vessels can be imaged as a sweep and is essential to establish ventriculoarterial concordance. LVOT, left ventricular outflow tract; MV, mitral valve; RVOT, right ventricular outflow tract. Parallel outflow tracts and great vessels (Ao and PA) are noted in patients with complete transposition of the great vessels (c). Here the discordant ventriculoarterial relations are clear given that, in the same plane, the right ventricle (RV) gives rise to the anterior aorta (Ao) while the left ventricle (LV) gives rise to the posterior pulmonary artery (PA).

(a)   (b)
Figure 8.42 (a) The right atrium (RA) and right ventricle (RV) are visualized in the four-chamber view; however, there is no obvious left ventricle, consistent with mitral atresia and hypoplastic left heart syndrome. The tricuspid valve (TV) and descending aorta (DAo) are also demonstrated. (b) Left-right atrial shunt (*) is seen. LA, left atrium; RA, right atrium.

hydrops, atrioventricular valve regurgitation, and venous Doppler patterns. Examples of these lesions can be found in Figure 8.50.

Limitations to fetal echocardiography

Often due to maternal body habitus and fetal position, the fetal cardiologist is limited to lower frequency transducers that provide adequate depth but lack appropriate resolution. This lower resolution often leads to insufficient visualization of the ventricular septum and defects in this region may not be excluded. A patent foramen ovale and ductus arteriosus are normal in the fetus and their persistence in infancy cannot be predicted by fetal echocardiography. Given a patent ductus arteriosus, a coarctation of the aorta cannot be excluded.

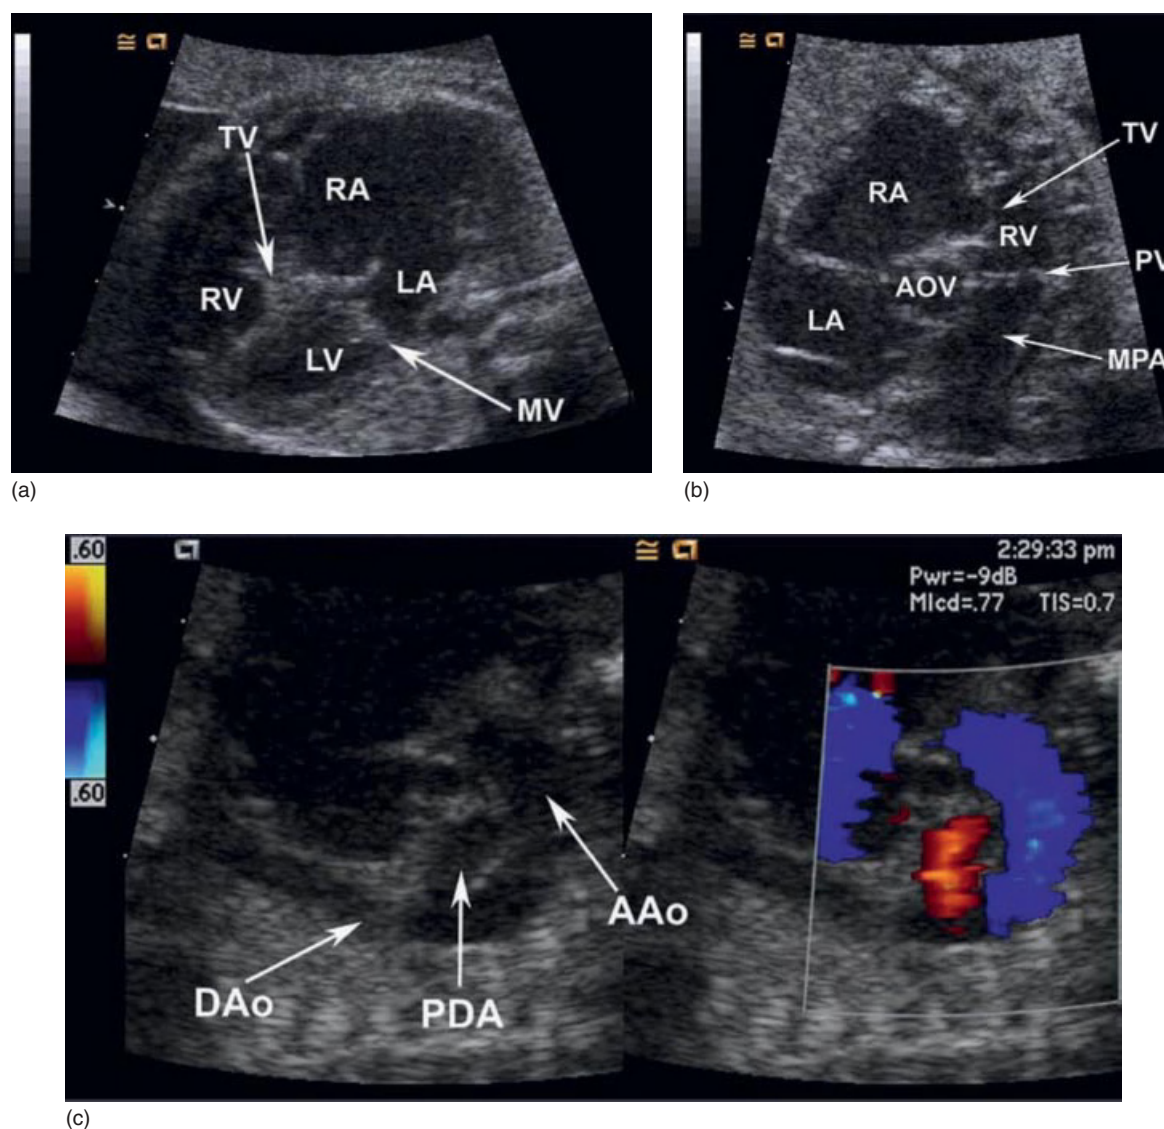
Fetal cardiac intervention

See Chapter 16.

Three-dimensional echocardiography

Two-dimensional echocardiography provides an excellent evaluation of the heart in children given that high-frequency probes may often be utilized. Multiple cross-sectional images yield a complete anatomic and physiologic evaluation of the heart. However, three-dimensional echocardiography may provide a more comprehensive evaluation of this complex organ. Currently, three-dimensional echocardiography is a useful adjunct to standard transthoracic imaging. Its primary applications include determining ventricular volume, valve morphology, and ventricular synchrony. The technique relies on excellent two-dimensional images and is helpful in quantifying ventricular size and function. Ventricular volume and ejection fraction are useful in patients with corrected transposition, physiologically corrected complete transposition, and cardiomyopathy. The advantage of this technique is that a true volume is obtained; however, the frame rates of 20–30 Hz are inferior to standard echocardiographic imaging. This technique may also give a real-time view of ventricular aneurysms or wall motion abnormalities (Figure 8.51).

Atrioventricular valve assessment can be readily performed; specific lesions include double orifice mitral valve, detecting mitral valve clefts, and mitral valve ring (Figure 8.52).

A more recent application of three-dimensional echocardiography is establishing ventricular synchrony. The various segments' time to minimal volume may be used to establish the level of dyssychrony through a graphical display (Figure 8.53). The time for segments to reach minimal dimension is automatically calculated and there are reference standards for anatomically normal hearts [97,98]. As there is more ventricular dysfunction or dilation, the time for segments to reach a minimal volume disperses, consistent with dyssynchrony.


(a)

(b)

(c)

Figure 8.43 (a) This four-chamber view of the fetus shows significant apical displacement of the tricuspid valve (TV) relative to the mitral valve (MV). The right atrium (RA) is fairly large compared with the left atrium (LA). (b) The short axis view at the base of the heart shows the tricuspid valve in the right ventricular outflow tract very near the pulmonary valve (PV), consistent with marked Ebstein's anomaly. The right ventricle is fairly small as a result of this tricuspid valve displacement. (c) The patent ductus arteriosus (PDA) shunts left to right (red color) from the descending aorta (DAo) to the pulmonary artery as a result of inadequate prograde flow from the diminutive right ventricle. AAo, ascending aorta; LV, left ventricle; MPA, main pulmonary artery; RV, right ventricle.

Intravascular ultrasound

A variety of transducer configurations are mounted on the tip of an endovascular catheter. The most commonly used designs provide 360° cross-sectional imaging at right-angles to the catheter, by means of either a rotating transducer or mirror, or an array of multiple crystals encircling the catheter with phased-array technology used to produce the image. Intravascular imaging is typically performed at frequencies of 20–30 MHz, allowing for much higher resolution than with other ultrasound techniques but limiting the scanning depth substantially. As such, currently available forms of this technology are most useful for demonstrating fine detail of relatively small-caliber vessels. With decreasing catheter:lumen diameter ratio, the potential for erroneous imaging is increased. Not only does this place the catheter at a greater distance from the arterial wall where lateral resolution is decreased, but it also increases the likelihood of cross-sectional distortion due to non-coaxial orientation of the ultrasound catheter within the vessel (Figure 8.54).

Cross-sectional imaging can be used to distinguish the intimal, medial, and adventitial layers of an artery, and also calcifications, atheromatous plaques, thrombi, tumors, and

(a)

(b)

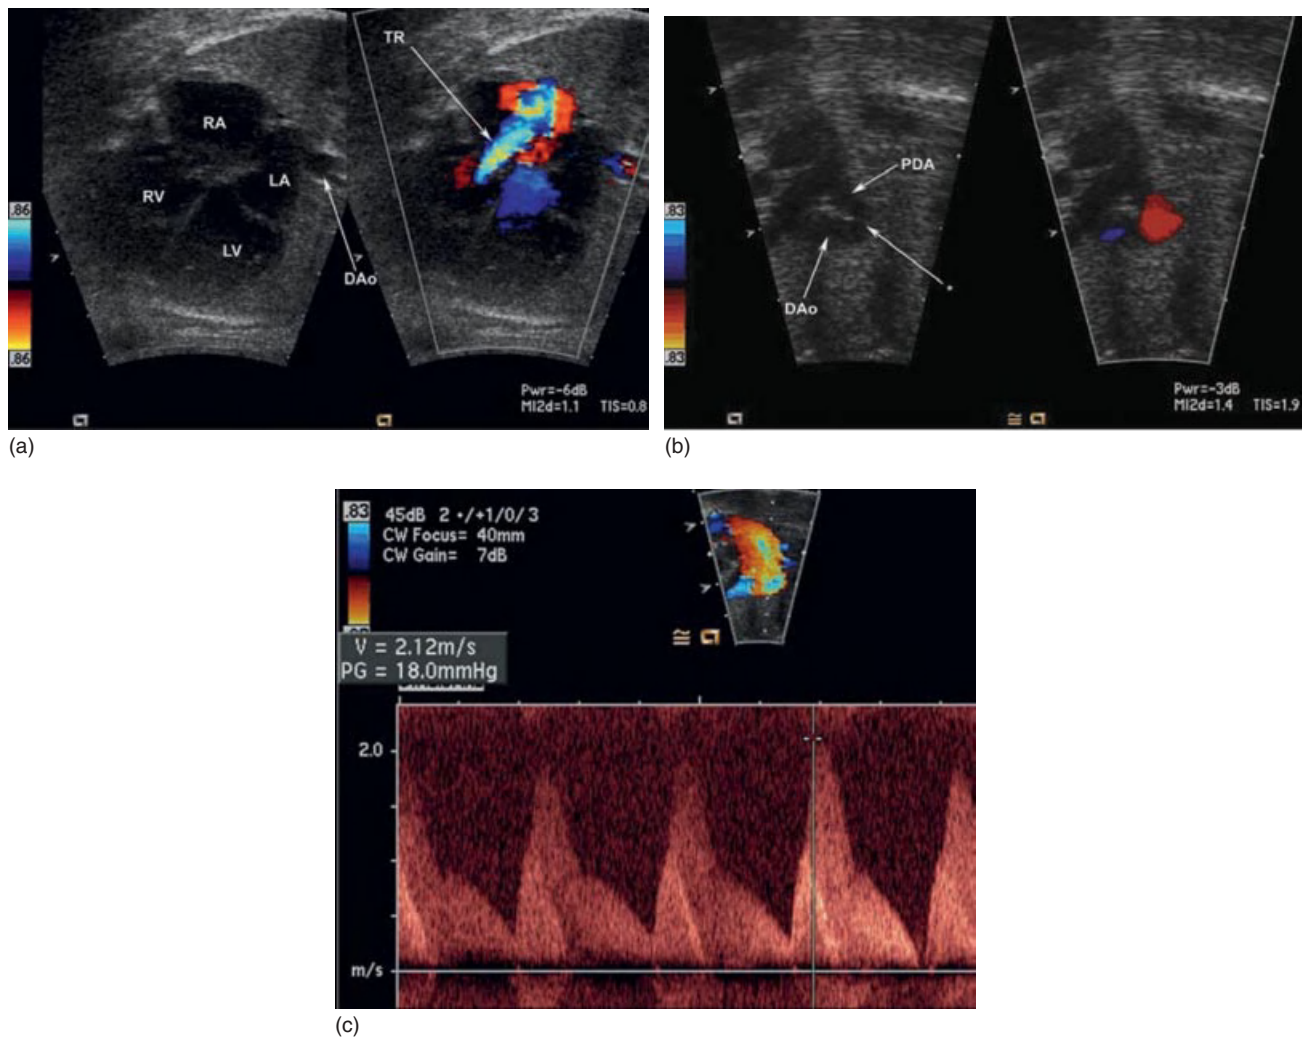
(c)


Figure 8.44 (a) This four-chamber view demonstrates severe tricuspid valve regurgitation (TR) with right atrial and right ventricular enlargement (RA, RV). LA, left atrium; LV, left ventricle. (b) The ductus arteriosus (PDA) has a focal narrowing (*) prior to its drainage into the descending aorta (DAo). (c) Spectral continuous-wave Doppler demonstrates an obstructive pattern given the extended flow into diastole and higher peak systolic velocity above 2 m s⁻¹.

(a)

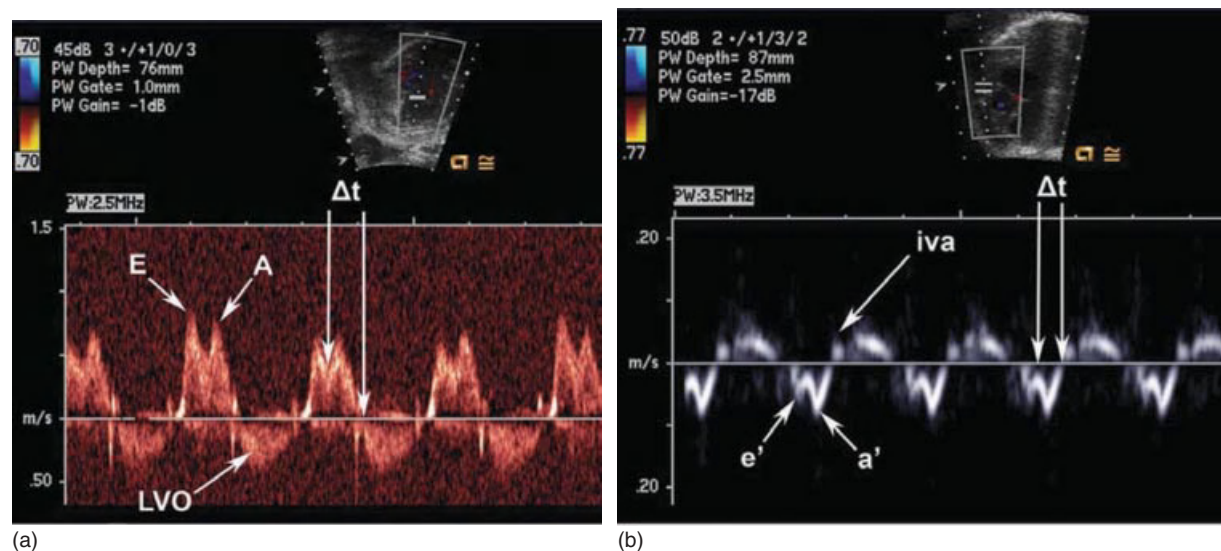
(b)


Figure 8.45 (a) Pulsed-wave Doppler at the mitral and aortic valve continuity region demonstrates mitral inflow (E, A) which is above the baseline and left ventricular outflow (LVO) which is the pattern below the baseline. The time between the onset of the A wave and the beginning of ejection (LVO) represents a surrogate for the PR interval (Δt). (b) Pulsed tissue Doppler at the tricuspid valve annular free wall yields tissue motion in systole and diastole. The diastolic motion (e' and a') represent diastole while motion above the baseline occurs during systole. The isovolumic acceleration (iva) region represents motion occurring during left ventricular isovolumic contraction. The time between the onset of the a' and the onset of the iva (Δt) is also a surrogate for the PR interval in the fetus.

149

(a)

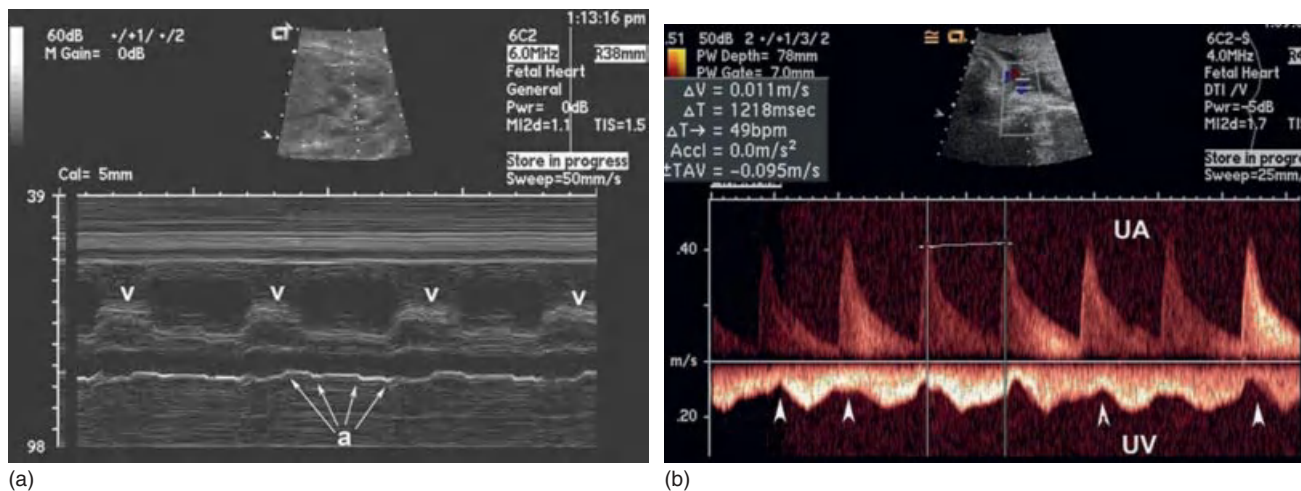
(b)


Figure 8.46 (a) An M-mode across the atria and ventricle from the short axis view of the fetal heart yields far fewer ventricular contractions (v) compared with the atrial contractions (a) with no relationship between atrial and ventricular beats, consistent with third-degree heart block. (b) Pulsed-wave Doppler of the umbilical artery (UA) and vein (UV) simultaneously shows notching (arrowheads) in the umbilical vein during systole. This phenomenon represents cannon a waves that occur with atrial contraction during a closed tricuspid valve due to the atrioventricular disassociation. The umbilical venous flow is thus blunted during these times manifesting as notching.

(a)

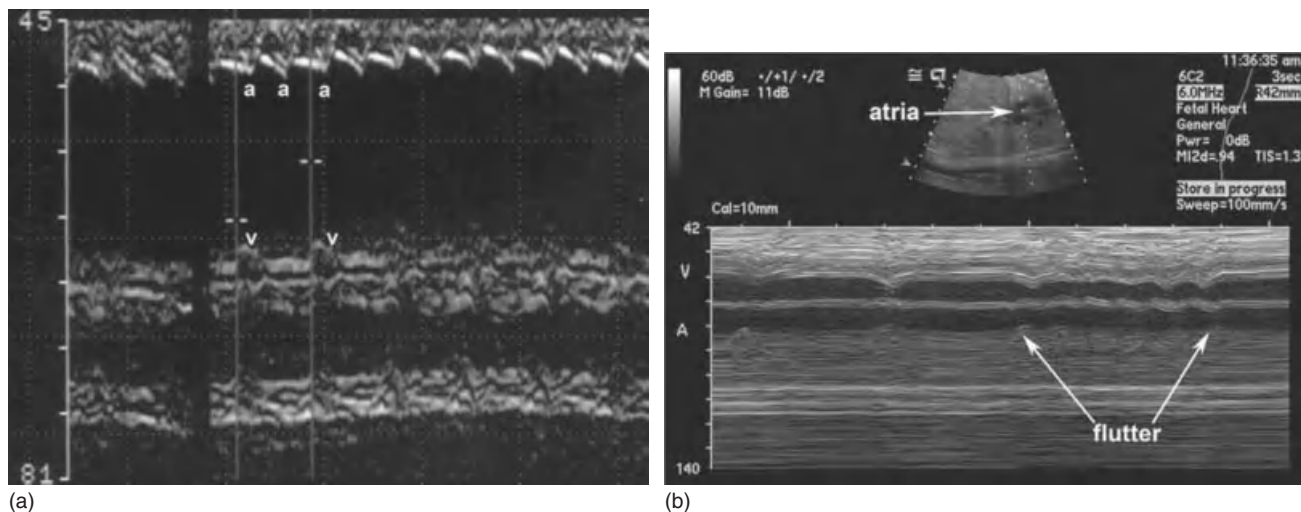
(b)


Figure 8.47 (a) M-mode of the atrial and ventricular wall demonstrates two atrial beats (a) for every one ventricular beat (v) with association, consistent with 2:1 flutter. (b) An M-mode through both atria shows the sudden onset and termination of atrial tachycardia, consistent with flutter.

(a)

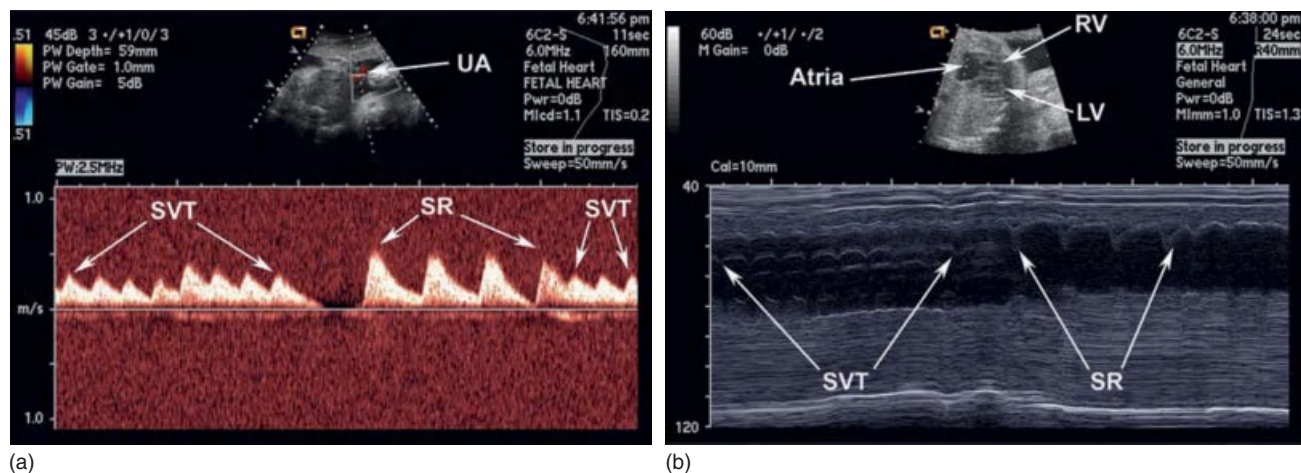
(b)


Figure 8.48 (a) The umbilical arterial Doppler shows the sudden termination and onset of supraventricular tachycardia (SVT), suggesting a reentrant mechanism. Sinus rhythm is also demonstrated (SR). (b) The M-mode through both atria again shows the sudden termination of supraventricular tachycardia in the same fetus who was diagnosed with orthodromic re-entrant tachycardia. LV, left ventricle; RV, right ventricle; UA, umbilical artery.

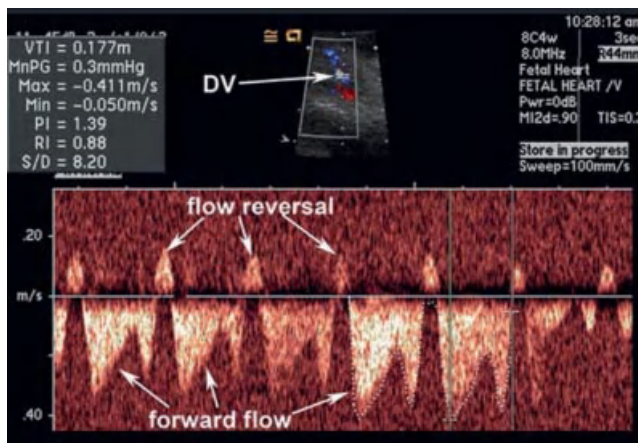
150

Figure 8.49 Premature atrial contractions (PAC) can be easily demonstrated by an M-mode through the atria. In this example, the atria contract regularly 'a' until a premature atrial contraction which causes a compensatory pause and a delay until the next atrial contraction (*).
(a)


(b)
(c)

Figure 8.50 The abnormal cardiovascular profile can be used to establish overall fetal well-being. In the first example (a), there is evidence of hydrops given the presence of pleural and pericardial effusion along with skin edema. The ductus venosus (DV) should have no flow reversal in the normal fetus; however, the second example (b) clearly shows flow reversal. Doppler of the umbilical vessels is important and in this example the normal diastolic flow in the umbilical artery (UA) cannot be seen, a marker for increased placental resistance. (c) Additionally, there is evidence of notching (arrowheads) in the umbilical vein (UV) just prior to the umbilical arterial systolic flow. The notching in this example probably represents increased right ventricular end-diastolic pressure resulting in diminished umbilical venous flow during that part of the cardiac cycle.

151
Figure 8.51 This example shows a three-dimensional rendition of the left ventricular chamber in systole by acquiring a full volume set. An aneurysm is clearly seen towards the apex. The wire frame surrounding the left ventricular model represents the position of the ventricle at end-diastole.

(a) (b)
Figure 8.52 (a) This three-dimensional view shows a cleft in the anterior leaflet of the mitral valve (CL); the posterior mitral valve leaflet (PMVL) is shown posteriorly. (b) A double-orifice mitral valve can also be visualized using three-dimensional echocardiography. In this example, there is a larger orifice mitral valve (MVO1) and an accessory orifice mitral valve (MVO2). The left ventricular posterior wall (LVPW) and interventricular septum (IVS) are also demonstrated.

foreign bodies. Precise measurements of luminal area are also possible. Blood flow velocity can be measured by Doppler velocimetry, using a flexible guide wire system with a piezoelectric Doppler crystal mounted in the tip. For simultaneous cross-sectional imaging and flow velocimetry, the ultrasound catheter may either be placed alongside or introduced over the Doppler guide wire.

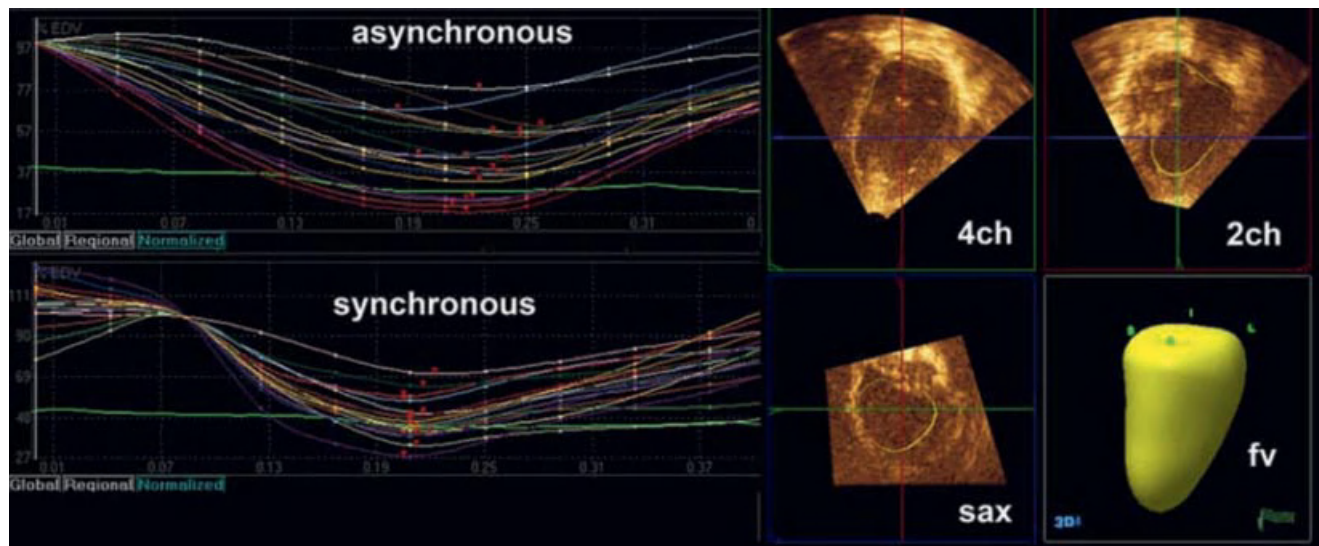
The widest clinical and experimental application of intravascular ultrasound has been in adult cardiology, where it is most often used to evaluate coronary arterial architecture before


Figure 8.53 After obtaining a full volume by three-dimensional echocardiography, the individual segments can be tracked throughout the cardiac cycle. In this example, a patient underwent biventricular pacemaker optimization for a dyssynchrony and the image labeled asynchronous shows that the segments achieve minimum size (*y*-axis) at various times (*x*-axis). After determining the optimal biventricular pacemaker settings, the segments achieve minimum size at nearly the same time (graph labeled synchronous).

Figure 8.54 This is a diagram to represent the implications of an intravascular ultrasound catheter oriented in the vessel in a non-coaxial fashion (longitudinal view). The resulting transverse scan image appears as an ellipse rather than a circle.

Figure 8.55 Intravascular ultrasound image after balloon dilatation of a native aortic coarctation showing an echogenic intimal flap (arrow). (Reproduced with permission from Sohn *et al*. *Circulation* 1994;**90**:340–7.)

and after transcatheter dilatation, stenting, and atherectomy [99]. In children, intravascular ultrasound has had limited clinical application. For the most part, it has been used to evaluate vascular and valvar lesions treated with transcatheter dilatation when the ability to visualize clearly intimal flaps following balloon dilatation of aortic coarctation or pulmonary arterial stenosis may help to define more clearly factors associated with successful dilatation and, ultimately, to guide the interventionalist in determining further management (Figure 8.55) [100,101]. Morphologic evaluation of the intermediate pulmonary arteries and the coronary arteries may also prove useful in
certain circumstances, such as in Williams syndrome, postoperative pulmonary atresia with unifocalized aortopulmonary collaterals, and Kawasaki disease [102,103].

San Francisco, CA, USA

Introduction

The complexity of the anatomy and physiology of patients surviving with congenital heart disease (CHD) is increasing exponentially. The majority will survive to adulthood, and the need for reintervention is common. As such, the field is placing new demands on imaging to diagnose and plan medical management, and also to identify the need for and timing of reintervention. There are a number of imaging modalities available to the clinician and radiologist.

Echocardiography has been, and remains, a mainstay of imaging in congenital heart disease. Despite its importance in rapid diagnosis and follow-up, it has limitations. A postoperative scar, chest wall deformities, overlying lung tissue, and large body size as the patient ages often result in suboptimal transthoracic echocardiographic windows. Transesophageal echocardiography, although providing improved acoustic windows, is limited by its small field of view and more invasive nature that often requires deep sedation or general anesthesia.

Cardiac catheterization, employing X-ray fluoroscopy and contrast angiography, has an expanding role in minimally invasive interventions, but its role as a diagnostic procedure is rapidly diminishing. This is partly due to its limitation as a 2D projection imaging technique with poor soft tissue contrast and the substantial ionizing radiation exposure involved, and partly because both diagnostic and functional analysis are often better performed with noninvasive imaging techniques.

This chapter focuses on the evolving and expanding roles of other imaging modalities in diagnosing and monitoring patients with CHD, including cardiac magnetic resonance imaging (MRI), cardiac computed tomography (CT), and radionuclide scintigraphy. It finishes with a reminder that the simple chest X-ray (CXR) is still useful.

Cardiac magnetic resonance imaging

Cardiac MRI has emerged as an alternative, complementary, and frequently superior imaging modality for investigating anatomy and function in the patient with CHD. It has many advantages over other imaging modalities. It neither requires the use of iodinated contrast agents nor involves exposure to ionizing radiation. This is particularly important in patients who have been, and continue to be, exposed to large doses of contrast agent and radiation during hemodynamic and interventional catheterization. Additionally, many of these patients are children, who are more susceptible to the adverse effects of radiation. Major advances in MRI hardware and software, including advanced coil design, faster gradients, new pulse sequences, and faster image reconstruction techniques, allow rapid, high-resolution imaging of complex anatomy and accurate, quantitative assessment of physiology and function.

Cardiac MRI techniques

Cine MRI

ECG-gated gradient-echo (GRE) sequences can be employed to provide multiple images throughout the cardiac cycle in prescribed anatomic locations. Display of these images in a cine mode demonstrates the dynamic motion of the heart and vessels [1–3]. Cine MRI techniques, at a minimum, allow the assessment of anatomy, but more importantly, allow qualitative and quantitative assessment of physiology and function by quantifying chamber volumes, myocardial mass, and ventricular function. Further, cine MRI allows qualitative assessment of focal and global wall motion abnormalities,

qualitative and quantitative assessment of valve pathology including the mechanism and severity of valve regurgitation and the location and severity of valve stenoses, identification and quantification of intra- and extracardiac shunts, and visualization of other areas of flow turbulence.

MRI techniques for quantifying chamber volumes, myocardial mass, and ventricular function, both fast GRE [4–7] and balanced steady-state free precession (SSFP) imaging [1,2], have been extensively evaluated and validated [8–10]. Briefly, evaluation of function begins with obtaining a series of contiguous slices (cines) along the short axis of the ventricles, extending from base to apex. These images are played back in a cine loop and the end-systolic and end-diastolic phases are chosen. The endocardial borders are traced at both time points and the epicardial borders are traced at one of the two time points (Figure 9.1). Ventricular volumes are then calculated as the sum of the traced volumes (area times slice thickness). Myocardial mass is calculated as the myocardial muscle volume times $1.05\,\mathrm{g\,mm^{-3}}$ (density of myocardium). From these data, ventricular end-diastolic volume, end-systolic volume, stroke volume, ejection fraction, myocardial mass, and mass:volume ratio can be calculated for both the right and left ventricles. Most computer workstation software packages for cardiac MRI analysis provide semi-automated post-processing tools to maximize efficiency.

Spin-echo (black blood) imaging

ECG-gated spin-echo (SE) sequences, or black blood imaging, despite being static, have many benefits in this patient population. It allows assessment of anatomy with thin slices, high spatial resolution, and excellent blood–myocardium and blood–vessel wall contrast (Figure 9.2). Black blood techniques are superb for evaluating the spatial relationship between cardiovascular and other intrathoracic structures such as the chest wall and the tracheobronchial tree. These features hold particular relevance when delineating complicated native and postsurgical cardiac anatomy. Such techniques are also less susceptible to artifacts from metallic implanted devices, commonly seen in the CHD patient, such as stents, coils, occluder devices, clips, and sternal wires.

Flow quantification

Cardiac-gated GRE sequences with flow encoding gradients are used to quantify the velocity and flow of blood (Figure 9.3) [11]. These sequences are referred to as velocity-encoded cine (VEC) MRI or phase contrast (PC) MRI. 2D VEC MRI sequences are the most commonly used in clinical practice. They can be used to quantify cardiac output, pulmonary to systemic flow ratio (shunt), valvar regurgitation, differential lung perfusion, and coronary flow reserve. They can be used to observe the location and severity of flow obstruction. In addition, VEC MRI assessment of flow is useful for corroborating volumetric data obtained with cine imaging to assure the clinician or radiologist that the data obtained are accurate.

Newer VEC MRI sequences allow resolution of velocity vectors in three directions, with spatial and coverage of a 3D volume, temporally throughout the cardiac cycle. Such techniques have been termed 4D flow encoding [11–13] and even "7D flow" [14], and have the advantage of providing complete spatial and temporal resolution of velocity with a higher signal-to-noise ratio than 2D methods. Post-processing tools allow the construction of vector field plots that highlight the intracardiac and intravascular nature of flow. Ultimately, these techniques may shed light on the mechanism of disease and disease progression [13]. Although currently limited by long scan durations, faster imaging techniques will likely soon allow such methods to reach clinical practice.

Gadolinium-enhanced 3D angiography (3D MRA)

3D MRA sequences are typically not cardiac gated, and therefore do not allow assessment of intracardiac structures. Nevertheless, they provide excellent depiction of arterial and venous vascular structures (Figure 9.4). In a CHD patient, 3D MRA plays a significant diagnostic role. It can diagnose systemic arterial anomalies such as aortopulmonary collaterals, shunts, vascular rings, and coarctation. It is useful in diagnosing pulmonary arterial abnormalities such as focal and diffuse stenoses and abnormal distal arborization patterns. 3D MRA methods are also useful for investigating systemic and pulmonary venous abnormalities, both congenital and postoperative. Finally, 3D MRA is useful for evaluating the relation between vascular and other thoracic structures. With faster techniques and navigator pulses, time-resolved 3D MRA and also noncontrast 3D MRA are becoming alternatives [12].

Coronary artery imaging, perfusion and stress imaging, and myocardial viability

Coronary artery abnormalities, ischemia, and myocardial fibrosis (scar) are important issues to be investigated in CHD patients who commonly have congenitally abnormal or postoperatively acquired coronary artery lesions. It is not uncommon to find an anomalous origin or course of the left or right coronary artery, postsurgical coronary obstruction (e.g., after arterial switch for transposition of the great arteries), coronary artery thrombus, and abnormal fistulous connections (e.g., pulmonary atresia with intact ventricular septum and right ventricular dependent coronary circulation). Identifying such abnormalities is often critical to planning of reintervention and/or medical management. In addition, the CHD population is aging sufficiently to develop atherosclerotic coronary artery disease. There is growing evidence to indicate that myocardial delayed enhancement in a number of subsets of postoperative CHD patients predicts poor outcome [15–18]. There are a number of MRI tools available to study coronary artery anatomy and screen for ischemia or previous infarction/scar.

(b)

Figure 9.1 (a) To obtain a stack of short axis cine images, a two-chamber (2C) view is prescribed from an axial cine, then a four-chamber view (4C) is prescribed from the two-chamber cine, then a short-axis stack is prescribed from the four-chamber cine at end-diastole. (b) Endocardial and epicardial borders traced on a stack of short-axis cine images at end-diastole.

(c)

Figure 9.1 (cont'd) (c) Endocardial borders traced on a stack of short-axis cine images at end-systole.

Coronary artery imaging

Coronary artery imaging is performed using a 3D SSFP (steady-state free precession) imaging sequence that is both cardiac gated (to end diastole) and respiratory gated (navigator pulse). Yielded are high-resolution, nearly isotropic 3D images that demonstrate the origins and proximal courses of the coronary arteries. Although motion artifacts preclude assessment of distal stenoses, this proves a useful technique for evaluating anomalous coronary arteries.

Perfusion imaging and stress imaging

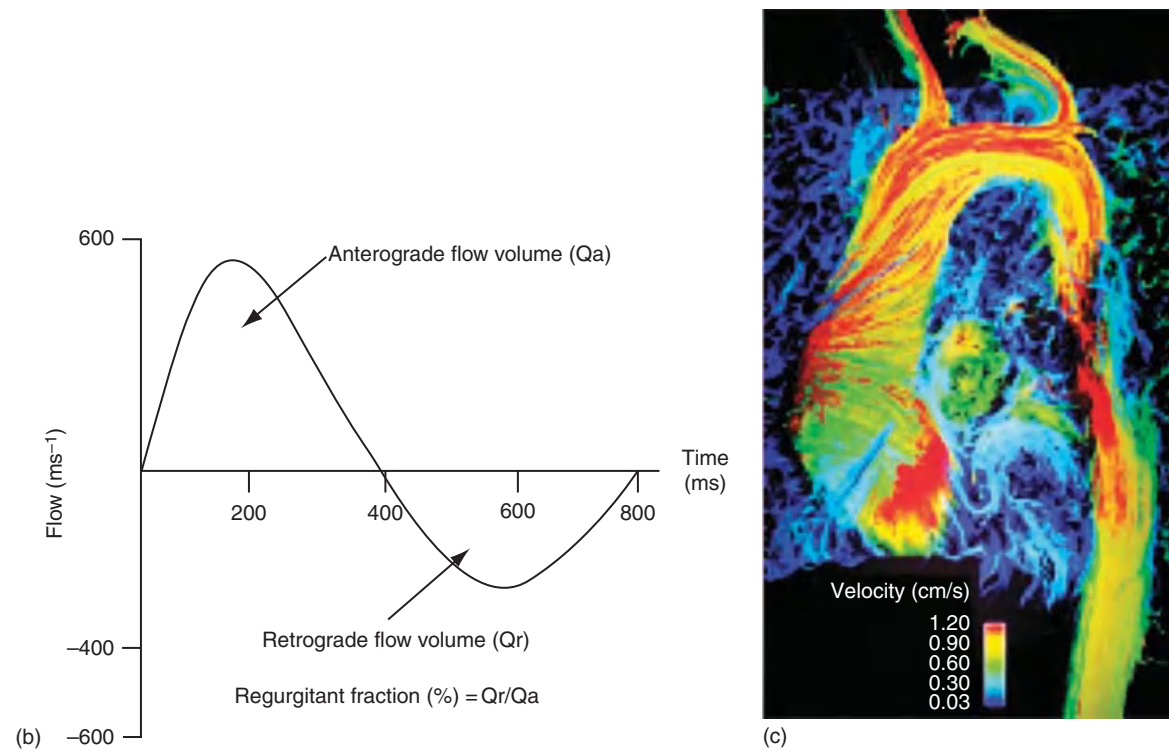
To perform perfusion imaging, pharmacologic stress with a continuous infusion of adenosine or a single bolus of dipyridamole is administered, a bolus of low-dose gadolinium contrast is given, and echo-planar (single-shot) images are collected in three short-axis planes covering the ventricular mass (base, mid, apex) to follow the contrast bolus as it makes its first pass through the heart and perfuses the myocardium. Adenosine is discontinued and, 10–15 min later, rest images are obtained with a second bolus of gadolinium. Alternatively, dobutamine stress can be performed. In this technique, rest cine images are obtained in the short-axis, vertical long-axis, and horizontal long-axis planes. Dobutamine is given in increasing doses (with an additional dose of atropine if necessary) to reach peak heart rate. Cine imaging is repeated at multiple time points as the heart rate rises and focal wall motion abnormalities are sought. In assessing atherosclerotic coronary artery disease,
Figure 9.2 (a) Axial and (b) sagittal BB (black blood) images in a patient with a sinus venosus defect and partial anomalous pulmonary venous return. (c) Coronal BB image in a patient with a double aortic arch and airway compression, demonstrating this technique's ability to assess the relationship of airway to vascular structures. Ao, aorta; LA, left atrium; RPA. right pulmonary artery; RVOT, right ventricular outflow tract; RUPV, right upper pulmonary vein; SVC, superior vena cava; SVD, sinus venosus defect.
Figure 9.3 An imaging plane is chosen perpendicular to the main pulmonary artery. (a) VEC MRI is then performed in this plane to produce magnitude and phase images. A region of interest encompassing the main pulmonary artery is chosen for each image in the cardiac cycle. From these data, a net flow is obtained.


Figure 9.3 (cont'd) (b) Flow is then displayed allowing the calculation of peak velocity, net forward flow, and regurgitant fraction. (c) a "7D" flow in a patient with coarctation of the aorta.
Figure 9.4 (a) MIP image of a 3D gadolinium-enhanced MRA in a patient with scimitar syndrome. (b) 3D reconstruction of a 3D gadolinium-enhanced MRA in a patient with severe native coarctation of the aorta (CoA) with significant collaterals.

adenosine MRI stress has a similar sensitivity and specificity to nuclear perfusion stress testing. Similarly, dobutamine MRI stress has similar sensitivity and specificity to dobutamine echocardiography. Finally, when combining both techniques in one cardiac MRI examination, there is added benefit in predicting poor outcomes [19–27].

The use of dobutamine MRI stress and adenosine MRI stress have been demonstrated in patients with repaired
Figure 9.5 Delayed enhancement (arrows) along the RV outflow tract in a patient with tetralogy of Fallot after repair with a transannular patch. RV, right ventrical.

tetralogy of Fallot, D-transposition of the great arteries following atrial switch procedures, and single-ventricle patients following Fontan procedures [28–31]. Often these studies have focused on reporting hemodynamic changes with stress rather than coronary ischemia. These have been small studies but they have demonstrated safety, accuracy, and reproducibility. Future studies are needed to demonstrate the usefulness of this technique in routine practice.

Myocardial viability (delayed hyperenhancement)

Myocardial viability imaging utilizes a T1-weighted inversion–recovery GRE sequence in which the inversion time is chosen to null signal from the myocardium. Imaging is performed 10–15 min after gadolinium administration. Gadolinium washes out of normal myocardium, but is trapped in tissue that has an increased extracellular space (fibrosis, scar, or inflammation) (Figure 9.5).

In summary, although still not as robust as routine coronary artery angiography with X-ray fluoroscopy or cardiac-gated CT angiography at investigating distal coronary artery lesions, MRI can image proximal coronary arteries well [32–35], evaluate myocardial perfusion and viability [36–39], and allow stress testing [40,41], all noninvasively and without exposure to contrast agents and ionizing radiation.

Indications

The indications for MRI in CHD patients are evolving and expanding as MRI technology advances and this population becomes more complex. In general, MRI is indicated in this population when transthoracic echocardiography is insufficient in providing adequate diagnostic information (e.g., postoperative CHD patients, adults with CHD), as an alternative to invasive and costly diagnostic catheterization, and when the unique capabilities of MRI can be exploited. For example, cardiac MRI is fairly effective in the segmental description of complex anatomy. It can diagnose and evaluate the severity of arterial and venous anomalies. Cardiac MRI is unrivaled in the quantitative evaluation of biventricular function, particularly the right ventricle, which is so often at risk in patients with CHD. It is frequently indicated to detect and quantify shunts, valvar and vascular stenoses, and regurgitant lesions. Finally, cardiac MRI is excellent at characterizing anomalous coronary arteries and evaluating myocardial perfusion and viability.

Cardiac computed tomography

Cardiac CT has historically been very useful in evaluating vascular anatomy. With the developments in high-resolution CT with broader anatomic coverage, faster speed, lower radiation dose, and flexible ECG synchronization, CT has emerged as a useful tool for assessing intracardiac anatomy, coronary anatomy, and myocardial function in CHD [42–44]. This newest technology allows faster acquisition times (often precluding the need for sedation in the young patient), improved spatial resolution, thinner slices, and decreased motion artifacts. Although such technology is proving invaluable in cardiovascular imaging in adults, its use in the pediatric population in the assessment of CHD has only just begun [45–47]. The CT imaging techniques for CHD are not the same as those for acquired heart disease and must be tailored to the specific anatomic structures and the purpose of the study.

Non-ECG-synchronized spiral CT

Since the development of multi-slice CT, non-ECG-synchronized spiral CT has been useful for assessing extracardiac vascular abnormalities in CHD (Figure 9.6) [42,43,48]. It is unparalleled in its ability to provide spatial relationships of intrathoracic structures, including the vasculature and the airways. Multi-slice CT produces submillimeter isotropic volume data and greatly improves the image quality of the multiplanar reformatted and three-dimensional CT images. Interestingly, with these newer techniques, the origins and proximal segments of the coronary arteries are observed in as many as 80% of CHD patients on the non-ECG-synchronized spiral CT images [49].

ECG-synchronized spiral CT

The introduction of the ECG-synchronized scan with either retrospective or, more recently, prospective triggering represents a dramatic advancement for CT imaging of CHD as it freezes the heart in motion and allows accurate assessment
(a)   (b)

Figure 9.6 (a) CT scan in a patient with tetralogy of Fallot after repair. This CT scan revealed a dilated right atrium (RA) and right ventricle (RV). (b) It also revealed a diffusely hypoplastic right pulmonary artery (RPA) and replaced ascending aorta (AAo), the complications of a previously placed Waterston shunt.

of intracardiac, conotruncal, and epicardial structures and also ventricular volumes, wall mass, and function. [42–44,50–52].

The relatively high radiation dose of retrospective ECG-synchronized spiral scanning is primarily attributed to the low pitch that is necessary to obtain gapless ECG-synchronized spiral data. Breath-holding is usually recommended because this scan mode is relatively vulnerable to respiratory motion artifacts. The effective dose estimates of this scan mode for dual-source CT with ECG-controlled tube current modulation are 2–6 mSv [50]. Retrospective ECG-synchronized spiral scanning, however, allows image capture at multiple phases in the cardiac cycle, thus allowing the evaluation of end-systolic and end-diastolic ventricular volumes, stroke volumes, ejection fraction, and wall mass. The analysis tools are similar to those for analyzing short-axis cardiac cine MRI.

Prospective ECG-synchronized sequential scanning is a low-dose technique that can reduce the CT dose to 1–3 mSv [53,54]. Degraded ECG synchronization (stair-step artifacts) may occur with irregular heart rates with this technique. The artifacts are less pronounced in the images acquired at the end-systolic phase because the phase is relatively constant regardless of the heart rate. A limitation of this technique is the inability to perform multi-phase functional evaluation compared with retrospective ECG-synchronized spiral scanning.

Contrast delivery

Shorter scan times have reduced the amounts of iodinated contrast agent needed to provide optimal enhancement of the cardiovascular structures. A larger amount is necessary for patients with a large intracardiac or extracardiac shunt, substantial valvar regurgitation, and/or a severe chamber enlargement. The iodine delivery rate (calculated from both the iodine concentration and the injection rate) should be maximized to optimize cardiovascular enhancement. The intravenous injection site is important and it should be carefully selected in advance: for example, a leg vein is preferred for evaluating the aortic arch and a left superior vena cava; simultaneous injection of 50% diluted contrast agent through the arm and leg veins is preferred for evaluating Fontan pathways; the leg vein should not be used in patients who have undergone bidirectional cavopulmonary connection [43,44].

In addition to achieving adequate vascular enhancement, proper CT imaging of CHD, requires minimization of perivenous artifacts. A triphasic intravenous injection protocol, in which undiluted contrast agent is followed by 50–60% diluted contrast agent and then by a saline chaser, was recently developed to improve the visualization of the right heart, minimize the amount of contrast agent required, and reduce the perivenous artifacts [55,56].

Clinical indications

The clinical applications of CT for CHD are rapidly growing and evolving. Classically, the extracardiac great vessels, including the aortic arch and the pulmonary vessels, have been evaluated with CT [42,43.48]. Evaluating the patency of vascular shunts, conduits, or stents is another traditional indication for CT [57]. A dedicated reconstruction algorithm for vascular stents has recently been introduced for better evaluation of in-stent stenosis [58]. Clear evaluation of the airways is a unique advantage of CT over other imaging modalities: vascular or nonvascular narrowing, anomalies,
(a)

(b)

(c)

Figure 9.7 A 56-year-old man with situs inversus, dextrocardia, and L-transposition of the great arteries developed chest pain, ECG changes, and a troponin elevation. (a) CT coronary angiography demonstrated not only the location of the coronary ostia but also (b) allowed reconstruction to define the anatomic location of the coronaries in question. (c) This allowed the interventional cardiologist to locate the lesions angiographically. Two bare metal stents were placed successfully, resolving the patient's symptoms.

and dynamic airway obstruction can be accurately evaluated with CT [59–61]. The introduction of the ECG-synchronized CT scan improves the visibility of those cardiovascular structures that are greatly affected by cardiac pulsation. They include the ascending aorta, the pulmonary trunk, the coronary arteries, and the heart itself [43,44,50,51]. In fact, some argue that CT provides equal or even better image quality of the epicardial coronary vessels than even invasive angiography (Figure 9.7). CT is particularly indicated in patients with pacemakers and defibrillators in whom cardiac

MRI is precluded, or in patients with metallic implants that create unmanageable artifacts on cardiac MRI (e.g., steel coils). It also can take the place of cardiac MRI if the question is strictly vascular anatomy and not intracardiac anatomy or cardiac function, because CT can answer these questions with a rapid study, often without sedation.

Limitations

There is less temporal resolution than with cardiac MRI or echocardiography. For this reason, its ability to characterize ventricular function is limited. There are no CT techniques to quantify flow. CT contrast agents, albeit improved and less toxic, still have well-documented renal toxicity. Finally, and importantly, there is significant radiation exposure associated with CT. It is critical for the clinician to consider this when ordering a CT, particularly in the young patient and the patient who has been, and continues to be, exposed to large doses of contrast agent and radiation during hemodynamic and interventional catheterization. Furthermore, gated studies and higher resolution studies are performed with higher radiation doses [62].

Radionuclide scintigraphy

Radionuclide methods often lack sufficient resolution to characterize complex morphology in CHD precisely, but can provide an accurate and reproducible quantitative assessment of the physiologic consequences of structural heart disease, including shunts, myocardial function, and myocardial perfusion.

Shunt

The radionuclide technique for shunt quantification was established and validated in 1973 [63]. The scintigraphic technique involves the rapid injection of a bolus of radionuclide (usually ^{99m}Tc-DTPA) into the circulation while monitoring the transit through the heart and lungs with a gamma camera (4–25 frames per second). The delivery of a compact, nonfragmented bolus of activity is critical to allow accurate determination of the size of the shunt. With good technique, the success rate should be >90%. It may be necessary to sedate infants and some children because crying simulates a Valsalva maneuver, which can impede entry into the thorax and lead to fragmentation of the bolus. As mentioned, ^{99m}Tc-DTPA is most commonly used for shunt studies. Doses are $200\,\mu\text{Ci}\,\text{kg}^{-1}$ body weight, with a minimum dose of 2 mCi. The advantage of ^{99m}Tc-DTPA over other technetium-based agents is the fairly rapid renal excretion, which leads to prompt clearance of background activity. This is important if a second injection is necessary to improve the quality of the bolus. In general, no more than two sequential injections are made because of dosimetry limitations.

In the absence of shunt, the appearance of contrast follows normal flow through the heart; right atrium, right ventricle, pulmonary artery, lungs, left atrium, left ventricle, and aorta. Persistence of pulmonary activity is consistent with a significant left-to-right shunt (usually with a pulmonary-to-systemic flow ratio of >1.6:1). For a clinically significant range (1.2:1 to 3.0:1), there is good correlation with catheterization [63]. In right-to-left shunt, there is premature appearance of tracer in the ascending aorta. Other radionuclide techniques for quantifying right-to-left shunt include (1) intravenous injection of an inert radioactive gas such as ^{133}Xe or ^{81}Kr, which are entirely extracted from the blood by the lungs; persistence in the systemic arterial system demonstrates shunting, or (2) intravenous injection of ^{99m}Tc-labeled macroaggregated albumin (MAA) particles. In the absence of right-to-left shunting, all particles are trapped in the lungs. In right-to-left shunt, the particles appear in the systemic circulation in proportion to the shunt flow, lodging in the capillary and precapillary beds of systemic organs (Figure 9.8). A series of whole-body images is taken to determine the percentage of right-to-left shunt as determined by the difference between whole-body counts and lung counts. The pulmonary-to-systemic flow ratio can be calculated as the ratio of lung counts and whole body counts. Administration of particles is safe, even in admixture lesions [64]. Finally, radionuclide techniques have a unique role in characterizing complex venous and arterial streaming; particularly useful in patients with surgical shunts [65,66].

Assessment of ventricular function

Radionuclide methods are well suited for assessing ventricular size and function in congenital heart lesions. Both first-pass and gated equilibrium methods for the determination of ejection fraction have been validated in children [67,68]. Quantitative assessment of absolute ventricular volumes [69] and determination of regurgitant fraction have also been reported in children [70,71]. For infants, the imaging is optimized by using a converging collimator to improve spatial resolution and increase the sensitivity. It is feasible to measure the ejection fraction even in tiny premature infants with the use of a pinhole collimator [72]. Ventricular size and function evaluations are useful at rest and with dynamic stress in a variety of congenital lesions, both before and after surgical correction [73,74].

Assessment of myocardial perfusion

The primary abnormality leading to the onset of myocardial ischemia is inadequate myocardial blood flow to meet the metabolic demands of the heart. The heart has limited energy stores and requires constant delivery of oxygen and substrates and removal of metabolic wastes via the coronary arteries in order to function properly. Moderate narrowing or stenosis of the coronary arteries is tolerated during the resting state without reductions in coronary flow or ischemia.
Figure 9.8 A posterior whole-body image. Technetium-labeled macroaggregated albumin particles were injected intravenously and show localization to lungs, kidneys, and brain, indicating a right-to-left shunt.

As myocardial demands are increased, such as during exercise, the resulting augmentation in blood flow in a stenotic coronary artery is often insufficient to maintain adequate perfusion. In this situation, the sequence of events is as follows: during exercise there is first a relative decrease in blood to a region of myocardium supplied by a stenotic vessel; second, a sudden decrease in contractile function due to the rapid exhaustion of energy stores and the accumulation of metabolites; third, electrocardiographic changes, including depression of the ST segments; and finally, the onset of chest pain. If normal blood flow is quickly restored, the chest pain resolves, electrocardiographic changes return to baseline, and contractile function returns. If there is some delay in restoration of flow, contractile function may remain depressed for up to weeks (stunned myocardium). If blood flow is chronically reduced at rest, resulting in a chronic state of ischemia, contractile function may remain chronically depressed (hibernating myocardium). If blood flow is not restored, irreversible damage leads to myocardial necrosis and the eventual replacement of myocytes with scar. This regional territory then has permanent functional abnormalities, and if much muscle is involved, heart dilatation and failure ensue and long-term prognosis is adversely affected. Detecting decreased myocardial perfusion by myocardial perfusion imaging, or scintigraphy, is therefore important in early prediction of these pathophysiologic changes.

Thallium

The most common agent for assessing myocardial perfusion is thallium, ^{201}Tl, which is a cyclotron-produced radionuclide with a half-life of 73 h and a predominant emission energy of 80 keV. It behaves physiologically like potassium and is transported into cells largely by the sodium–potassium ATPase pump located on cellular membranes [75]. Myocardial cells extract thallium to a high degree. On the first exposure to the heart (first pass), there is uptake of more than 85% of the dose that reaches the myocardial cells (extraction fraction). As a result, the initial distribution of thallium provides a static map of myocardial perfusion at the time of injection. Thallium extraction by the myocardium depends on the delivery of the tracer (perfusion) and viable myocytes. Ischemic myocytes retain the ability to extract thallium (provided that some degree of perfusion is present); however, when ischemia is of sufficient severity and duration to lead to loss of membrane integrity (necrosis), thallium will not be extracted [76]. Figure 9.9 provides an example in a patient with a 70% stenotic LAD lesions.

Thallium also redistributes [77]. After the initial accumulation in the heart, the intracellular concentration gradients of thallium in the heart tend to equalize. As a result, regions with high blood flow and high concentrations of thallium wash out faster than do regions with lower blood flow or low concentrations of thallium. In fact, thallium may leave the normal areas of the heart and enter the areas of low concentration (ischemic territory) over time. The resultant delayed thallium image shows a more homogeneous distribution if the initial region of reduced uptake represented ischemia in a region of viable myocytes (see Figure 9.9). If the initial region of reduced uptake represented scar, a persistent defect appears on the delayed images.

Technetium-99m-labeled tracers

Although thallium has gained widespread popularity as a useful myocardial perfusion agent, there are drawbacks. The relatively long half-life (72 h) limits the amount of activity that can be injected because of dosimetry concerns. The low energy (80 keV) of the major photon emission poses potential problems because of soft tissue attenuation. Also, thallium is cyclotron produced, which limits its availability. Relative to thallium, ^{99m}Tc has the advantage of higher energy (140 keV), leading to less attenuation, a shorter half-life (6 h), allowing the administration of larger doses, and ready availability because it is generator produced.
Figure 9.9 Diagrammatic illustration of the relationship between myocardial blood flow at rest and during exercise and regional myocardial ^{201}Tl uptake in zones perfused by normal and stenotic coronary arteries. When thallium is injected at rest, there is a uniform distribution of the radionuclide through the myocardium (upper left). When thallium is injected during exercise, there is a relative diminution in thallium uptake in the zone perfused by the stenotic vessel (middle). Several hours after ^{201}Tl injection with exercise, there is "redistribution" and normalization of thallium in normal and stenotic zones (top right). (Reproduced from Beller GA, in Gerson MC (ed.), *Cardiac Nuclear Medicine*. New York, McGraw-Hill, 1987, pp. 349–69, with permission from The McGraw-Hill Companies.)

A number of [99m]Tc -labeled myocardial perfusion tracers have been developed. Of these newer agents, sestamibi has been most extensively studied. ^{99m}Tc-sestamibi, or Cardiolite, is a lipophilic, cationic complex of a class of compounds called isonitriles [78]. Sestamibi, like thallium, is delivered to the myocardium in proportion to blood flow. Its uptake is different from that of thallium, however. Sestamibi passively crosses the sarcolemmal membrane, and the driving force for uptake appears to be a large electrochemical gradient provided by the largely negative charge on mitochondria. Sestamibi shows little significant redistribution within the heart [79]. Separate injections of sestamibi are required for rest and stress assessment of myocardial perfusion.

The extraction fraction of sestamibi is lower than that of thallium (65% versus 85%) [80]. As a result, sestamibi may underestimate myocardial blood flow at high flow rates ($>2\,\mathrm{ml\,min^{-1}\,g^{-1}}$) to a greater extent than does thallium [80]. In spite of this diffusion limitation, clinical results evaluating the sensitivity and specificity of thallium and sestamibi have been comparable [81]. Another property shared between sestamibi and thallium is the dependence on viable myocytes for extraction [82]. Sestamibi uptake is markedly diminished in irreversibly injured myocytes.

Application of perfusion scintigraphy in congenital heart disease

Myocardial perfusion scintigraphy has been applied extensively to adults and during recent years also to children [83]. In children, perfusion imaging has been most widely

Figure 9.10 Diagram showing the portion of left ventricular myocardium at risk for ischemia or necrosis when the left main, left anterior descending, or right coronary artery arises from the pulmonary trunk. (Reproduced with permission from Roberts WC, in Roberts WC (ed.), *Adult Congenital Heart Disease*. Philadelphia, FA Davis, 1987, pp. 583–629.)

used for the noninvasive identification of an anomalous left coronary artery from the pulmonary artery [84,85], as demonstrated in Figures 9.10 and 9.11. Perfusion abnormalities have also been induced with stress in adults with a variety of anomalous origins of the left coronary artery from the right.

Another clinical condition for which perfusion scintigraphy may be useful is Kawasaki disease [86]. Before the introduction of intravenous immune globulin therapy, up to 20% of these patients developed aneurysms of the coronary arteries. With treatment, this incidence is decreased to 4%. About 30–50% of such aneurysms spontaneously regress within the first 2 years. The remaining may later thrombose, resulting in myocardial ischemia and infarction.

Evaluating the resting pattern of ventricular perfusion and function can help differentiate a segmental pathologic process related to large-vessel coronary disease from other causes,
Animal studies have shown intense and uniform gallium accumulation in experimental myocarditis [92]. In addition, a high correlation between biopsy-proven myocarditis and gallium uptake has been demonstrated [93]. In nearly all reported instances of gallium uptake in myocarditis, the pattern of uptake is diffuse. even with characteristic electrocardiographic changes that mimic myocardial infarction [94]. Antimyosin antibody cardiac imaging has also shown success in detecting biopsy-proven myocarditis [95]. Antimyosin localizes to regions of myocyte necrosis in myocarditis, as opposed to the localization of ^{67}Ga to the inflammatory component. Few studies have examined thallium uptake in myocarditis; however, focal thallium uptake or perfusion defects have been reported [96]. These defects, however, tend to be in nonvascular distributions. Experimental and clinical studies have confirmed that gallium accumulates in regions of acute myocardial infarction [97,98].

Coronary artery disease in infants

Myocardial infarction in neonates is rare and associated with high mortality. It usually occurs in the absence of CHD. Congenital lesions associated with myocardial ischemia usually present with myocardial infarction in later infancy or in childhood [99]. In infants with structurally normal hearts and coronary arteries, the most common causes of myocardial infarction are perinatal asphyxia and thromboembolic occlusion.

Plain film

Plain film analysis used to be one of the most important diagnostic tools in the assessment of CHD. With the development of echocardiography, the importance of plain film findings has decreased; however, it remains a very simple, inexpensive method to obtain important information about cardiac size, pulmonary vasculature, concomitant pulmonary disease, bone abnormalities, situs, bronchomalacia, and other features. In many patients, the cardiac configuration is characteristic enough to allow a specific diagnosis. Serial radiographs are also important because changes in heart size and pulmonary vasculature have prognostic implications, particularly after an operation for the cardiac anomaly.

Technical factors

To evaluate the pulmonary vasculature, the chest radiograph must be properly exposed, neither overpenetrated nor underpenetrated. On an overpenetrated radiograph, the thoracic spine is clearly visible through the cardiac silhouette, whereas on underpenetrated X-ray films, the spine is not visible. In general, overpenetrated radiographs are interpreted as decreased pulmonary vasculature and underpenetrated radiograph as increased pulmonary vasculature.

Figure 9.11 Rest myocardial thallium uptake images by single-photon emission CT from a 2-month-old infant presenting with a left coronary artery originating from the pulmonary artery. On the left are preoperative images showing markedly decreased perfusion to the anterior and lateral walls (arrows) and dilatation of the left ventricle. Postoperative images on the right show almost complete normalization of perfusion and a dramatic reduction in the chamber size. (Reproduced with permission from Fernandez *et al.*, *Clin Nucl Med* 1992:**17**:177–9.)

including cardiomyopathy, myocarditis, and small-vessel embolization. The pattern of thallium uptake can also suggest right and left ventricular hypertrophy and suggest the diagnosis of asymmetric septal hypertrophy.

Assessment of myocardial perfusion is becoming increasingly important in evaluating and following patients with transposition of the great vessels status after an arterial switch procedure [87–89]. Concerns have been raised since the inception of the arterial switch procedure about the possibility that distortion or growth failure of the newly implanted coronary arteries may result in myocardial ischemia and possibly infarction. Some studies suggest that coronary artery manipulation and reimplantation do not cause late myocardial perfusion abnormalities, at least in those infants with successful initial results [89]. However, large perfusion abnormalities have been seen in the territories of occluded coronary arteries after the switch procedure [83].

Radionuclide assessment of inflammation

Gallium citrate (^{67}Ga) accumulates in both acute and chronic inflammatory lesions of bacterial and nonbacterial etiology [90]. Mechanisms leading to gallium uptake have been reviewed by Tsan [90]. Gallium uptake has been described in a number of causes of inflammatory heart disease, including bacterial endocarditis, myocardial abscess, and pericarditis [91].

The degree of inspiration is another technical factor affecting evaluation of pulmonary vasculature and cardiac size. During deep inspiration, the lung fields appear much darker because of the high content of air within the alveoli and are often interpreted as decreased pulmonary vasculature. In contrast, during expiration, a large amount of the air is expelled, and the lungs are denser and are often interpreted as increased vasculature or even pulmonary edema. A position of the diaphragm at the level of the ninth ribs posteriorly is considered to be an adequate respiratory effort. The degree of inspiration also has a profound influence on cardiac size. The heart is attached to the diaphragm by the cardiophrenic ligament and consequently follows diaphragmatic motion. In deep inspiration, the heart assumes a midline vertical position, giving the appearance of a small heart. In contrast, during expiration the heart assumes a more transverse position, simulating cardiomegaly.

Three features must be assessed when interpreting a chest radiograph: pulmonary vasculature, cardiac size, and cardiac contour.

Pulmonary vasculature

The pulmonary vasculature can be increased by distention of pulmonary arteries, pulmonary veins, or both. Radiographically increased arterial and increased venous pulmonary vasculature may be difficult or impossible to differentiate, but there are helpful secondary signs. If increased vascular markings are present, they are likely to be arterial because increased venous vasculature is comparatively rare in childhood. Furthermore, the appearance of increased pulmonary venous vasculature in infancy and childhood produces a very characteristic pattern that differs from that in increased arterial vasculature.

What is observed radiographically is not increased pulmonary flow but the size of the pulmonary arteries. Obviously, with enlargement of peripheral pulmonary arteries, an enlargement of the main pulmonary artery is also present, as evidenced by a prominent pulmonary arterial segment, if the great vessels are normally related (Figure 9.12).

If the peripheral pulmonary vasculature is increased and the main pulmonary arterial segment is not prominent, it may be either overshadowed by thymic tissue, common in infancy, or in an abnormal intramediastinal position, as with transposition complexes (Figure 9.13).

Increased pulmonary arterial vasculature may be difficult to diagnose in patients with a left-to-right shunt and normal pulmonary arterial pressure, as in patients with an atrial septal defect. Many young patients with an atrial septal defect have radiographically normal pulmonary vasculature but usually have right-sided cardiac enlargement.

The radiographic diagnosis of increased arterial vasculature becomes much more obvious if pulmonary hypertension is also present, as occurs with a shunt located beyond the level of the atrioventricular (AV) valves. In these conditions, enlargement

Figure 9.12 Typical left-to-right shunt with increased arterial vasculature. The arterial pattern is distinct. Numerous vessels are seen on end, suggesting tortuosity, which in turn indicates increased pulmonary artery pressure. With increased pulmonary artery vasculature, there must be enlargement of the main pulmonary artery, as seen here.

Figure 9.13 Posteroanterior radiograph showing transposition of the great arteries. The heart is enlarged and the pulmonary vasculature is increased. The main pulmonary artery, which is also enlarged, does not form a prominent pulmonary arterial segment because it is in an abnormal intramediastinal position. The mediastinum is narrow because of the small thymus.

of the pulmonary arteries occurs by both increased flow and pressure (Figure 9.12). In addition, increased pulmonary arterial pressure causes tortuosity of the pulmonary arteries, as evidenced by an increased number of arteries seen on end.
Figure 9.14 Posteroanterior radiograph of acute pulmonary venous obstruction. Diffuse haziness over both lung fields and indistinctness of the pulmonary vasculature indicate frank pulmonary edema. Marked prominence of the right upper lobe pulmonary vein (arrows) further confirms venous pulmonary obstruction.

Figure 9.15 Posteroanterior radiograph of pulmonary venous hypertension showing the redistribution of blood flow (cephalization). The upper lobe pulmonary veins are distinctly seen (arrows). The heart is not enlarged, as is typical for left-sided obstruction proximal to the mitral valve.

Increased pulmonary venous vasculature as a result of pulmonary venous occlusive disease produces a characteristic radiographic appearance, particularly in infancy. A typical example of pulmonary venous obstruction is total anomalous pulmonary venous connection below the diaphragm. This condition results in a characteristic granular pattern throughout both lung fields (Figure 9.14). This granularity is due to edema of the interlobar septa, and sometimes a small pleural effusion may be present. In general, pleural effusions caused by pulmonary venous obstruction are exceedingly rare in infants and children, in contrast to adults, who develop large pleural effusions with increased pulmonary venous pressure.

The radiographic appearance of pulmonary venous hypertension in neonates is difficult to distinguish from hyaline membrane disease. A small pleural effusion suggests venous obstruction, and pulmonary consolidation with an air bronchogram strongly favors the diagnosis of hyaline membrane disease.

In children who have chronic pulmonary venous hypertension, redistribution of blood flow occurs (see Figure 9.15). In a healthy individual, relatively little blood flows through the upper lobes because of the gravitational effect on pulmonary pressure. In pulmonary venous obstruction, preferential flow occurs through the upper lobes. The likely explanation for redistribution is increased resistance to flow through the lower lobes because of interstitial edema, alveolar hypoxia, or reflex vasoconstriction of arterioles.

Concurrently, or somewhat later, another characteristic and diagnostic finding appears, namely Kerley's B lines. These horizontal lines, best seen at the lung base and at the periphery of the lung, are caused by interstitial edema and later by fibrosis and hemosiderosis of the intralobular septa (Figure 9.16). Kerley's B lines occur when the pulmonary wedge pressure exceeds 20 mmHg. They are rarely seen in infants and young children.

Later in life, signs of pulmonary venous hypertension show a different radiographic pattern, with transudation of fluid into alveoli resulting in an indistinct fluffy appearance.

Bronchial vasculature

In patients with pulmonary atresia and ventricular septal defect, and also more complex conditions with pulmonary atresia, the lungs may be supplied with bronchial arteries that can be recognized on a plain chest radiograph. Normally, the pulmonary arteries form a characteristic shadow in the hila, but this density is absent in patients with pulmonary atresia. The pulmonary vasculature may not be decreased but has a unique appearance. In contrast to pulmonary arteries, which have a characteristic regular fan-like pattern emanating from the hila, bronchial arteries lack regularity and are much more tortuous. As a result, numerous pulmonary vessels are seen on end.

Cardiac size

The most important value of a chest radiograph is probably evaluating cardiac size. Proper interpretation requires an understanding of the technical factors and anatomy of the heart.
Figure 9.16 Close-up view of the right base. This shows typical horizontal lines (arrows) described as Lerley's B lines. This is good radiographic evidence for long-standing venous pulmonary hypertension with wedge pressures above 20 mmHg.

There are many causes of apparent cardiomegaly. First, a common technical problem is an anteroposterior (AP) rather than a PA projection. Because of the divergence of the X-ray beam emanating from the X-ray tube, structures that are further away from the radiographic film are magnified more than structures located closer to the film. Because the heart is located anteriorly in the thoracic cavity, it is magnified more on an AP projection than a PA projection. Because the chest of an infant is small, the projection is not as important in the evaluation of cardiac size.

Second, the divergence of the X-ray beam is more pronounced when the X-ray tube is closer to the film. By increasing the film distance to 6 ft, the divergence of the X-ray beam can be minimized and a true nonmagnified image of the chest can be obtained. Portable X-ray machines use a 40 in film distance. Therefore, a heart may appear enlarged with a portable machine.

A third factor influencing cardiac size is the patient's position. When the patient is supine, the diaphragm tends to be higher than when the patient is in the upright position. Therefore, the cardiac silhouette appears larger on a supine chest radiograph than in an upright radiographic study.

Another important factor is the degree of inspiration. The heart is attached to the diaphragm by the cardiophrenic ligament and moves with the left hemidiaphragm. On deep inspiration, the heart rotates into a left anterior oblique position, resulting in a small cardiac silhouette (Figure 9.17a). On expiration, it rotates into a right anterior oblique
(a)   (b)

Figure 9.17 Posteroanterior radiograph of a small ventricular septal defect. (a) No significant cardiomegaly (deep inspiration); (b) during expiration, the heart assumes a transverse position.

position, resulting in an apparent enlargement of the cardiac silhouette (Figure 9.17b). Typically, an individual with a low diaphragm, for example, a patient with asthma, has a vertical heart, which is pulled down by the low diaphragm; the cardiac silhouette appears radiographically small. However, a person with an elevated diaphragm, particularly an adult patient with obesity, shows an enlarged cardiac silhouette, although the heart may be normal in size. This variation in the radiographic appearance of the cardiac silhouette is a strong argument against the use of cardiothoracic ratio, in which the transverse diameter of the heart is related to the transverse diameter of the chest to assess cardiac size.

A final concept in the evaluation of cardiac size is the position of the heart within the thoracic cavity. The long axis of the heart passes obliquely to the sagittal plane of the thorax. Therefore, on a chest radiograph the long axis is foreshortened. Normally the cardiac axis is inclined about 45° to the sagittal plane. If this angle is greater, hearts appear large on a PA view and small on lateral view (for example, an obese patient with a high diaphragms or a patient with a pectus excavatum deformity). If this angle is smaller, hearts appear small on a PA view and large on lateral view (for example, a patient with pulmonary emphysema). Consequently, cardiac size cannot be evaluated on a PA chest film alone, and the commonly used cardiothoracic ratio is inaccurate for evaluating cardiac size.

Characteristic plain film findings in CHD

A synopsis of characteristic plain film findings in various CHD lesions is presented in the relevant figures in this chapter. Emphasis is placed on the characteristic radiographic appearance.

Conclusion

The future of MRI will involve parallel processing and navigator pulses, which will decrease scan times and decrease need for sedation/anesthesia. Real-time imaging, MRI-guided interventions, myocardial tagging assessment of wall strain, and 7D flow techniques will reach the clinical armamentarium in the near future, making MRI an even more useful tool in evaluating and managing this patient population. The evolution of higher field strength scanners (3 T) may augment some MRI tools.

CT techniques are continuously evolving. Second-generation dual-source CT will decrease scan times and radiation dose [100]. Large-coverage volume CT (256–320 slices) is emerging [101]. Other innovative technical developments include dual-energy lung perfusion and ventilation scan, new tube current modulation to reduce the radiation dose to superficial radiation-sensitive tissue, and combined ECG and respiration synchronization.

Nuclear medicine techniques are additionally growing in application and scope, with new radioisotopes and new applications being explored. Finally, the plain film is not just a historic imaging technique; rather, it remains an important diagnostic tool and also an important modality to monitor progression of disease and postoperative status.

10 Cardiac Catheterization and Angiography

John D. R. Thomson[1] & Shakeel A. Qureshi[2]

[1]Leeds General Infirmary, Leeds, UK
[2]Evelina Children's Hospital, Guy's and St. Thomas' Hospital, London, UK

Introduction

The nature of invasive study of the heart has changed dramatically. Catheterization was initially developed to understand the anatomy and physiology of the cardiovascular circulation. For anatomic diagnosis it has largely been superseded by echocardiography, cardiac computed tomography (CT), and magnetic resonance imaging (MRI).

Equipment for cardiac catheterization in congenital heart disease

The catheterization laboratory

A number of standards have been published for the structure and contents of a modern catheterization laboratory [1,2]. The physical requirements in such a laboratory depend on the procedures to be performed. Although it is possible to perform limited studies with a mobile fluoroscopy arm outside a formal laboratory environment, this is far from ideal and should not be used as the basis for a catheterization program. At the other extreme are complex "hybrid" catheter/operating suites facilitating catheterization, surgery, or both within a single space [3]. The physical requirements for this laboratory exceed those for a standard catheter laboratory and are beyond the scope of this chapter.

Physical considerations for a catheterization laboratory include:

1 Adequate floor space: for a biplane laboratory, ideally ~30 × 24 ft (~9 × 7.5 m) can reasonably accommodate the necessary staff and equipment. The catheterization equipment and monitors need to be situated so that there is enough space to access the patient easily for both anesthetic equipment and additional imaging, such as trans-esophageal echocardiography (TEE). The lateral fluoroscopic tube must be able to be removed easily before and after the procedure for safe access to the patient.

2 High-quality biplane fluoroscopic equipment with compound angulation, and intrinsic field size capabilities to cope with all sizes of patients with congenital heart disease.

3 Adequate numbers of high-quality, real-time monitors to display biplane images and hemodynamic data (ideally with additional monitoring to show directly TEE imaging and previous CT/MRI data on the main monitor rack simultaneously). Monitors should be installed on rails for easy movement and angulation so that operators can easily see them.

4 Sterile operative environment: although not strictly necessary for many catheterization procedures, a modern catheter laboratory, intended for increasingly complex interventional procedures in congenital and structural heart disease should have clean air filtration systems ideally on a par with a modern operating theater. This is particularly important for programs intending to perform trans-catheter valve replacements or "open" hybrid interventions.

5 Anesthetic equipment: in addition to the necessary space for general anesthesia, there should be piped-in anesthetic gas and oxygen supply, suction, and scavenging systems to remove escaped anesthetic gases.

6 Adequate room lighting that can be dimmed. An additional movable, powerful, and widely adjustable light should be available to illuminate vascular access sites, ideally on a ceiling-mounted boom to minimize the use of floor space.

7 Digital storage of angiographic data, so that they are immediately archived and available for review and on-line/off-line analysis.

8 Auxiliary space: a separate room with appropriate recording facilities for hemodynamic information along with a microphone system to allow communication between the

catheterizing physician and the technician (over the noise of a busy catheter laboratory).

Catheterization laboratory staff

Minimum standards exist in many countries regarding the numbers of staff considered necessary for safe cardiac catheterization. In addition to the primary operator and a skilled assistant, we consider the following staff necessary to perform a congenital cardiac catheterization safely:

1 Dedicated cardiac technician: responsible for pressure monitoring, oxygen saturation determination, hemodynamic calculations, monitoring a continuous electrocardiogram (ECG), and maintaining the defibrillator system including remote pads where appropriate.

2 Radiographer: to minimize radiation exposure actively, ensure accurate calibration and angiographic measurements, and for the mandatory calculation of radiation exposure [a requirement of the UK mandatory Central Cardiac Audit Database (CCAD)].

3 A "running" member of staff, without other duties, but with specific knowledge of the location of equipment required in congenital cardiac catheterization.

In addition, most laboratories have a catheter scrub nurse available.

Disposable equipment

Catheterization of patients with congenital heart disease requires a large inventory of consumables. Individual clinicians and programs develop preferences for particular pieces of equipment and inventories change over the years. Therefore, the stock list of consumables varies from center to center.

A large program may carry as much as £500 000 (~$800 000) worth of disposable equipment at any one time. Therefore, it is absolutely essential that the laboratory has an efficient system for restocking disposables and is realistic about minimum numbers of items necessary for safe procedures. Catheterizing cardiologists must ensure that the correct equipment is available before commencing a study, particularly if a patient requires general anesthesia.

Diagnostic catheterization

Until the capabilities of cardiac MRI reach their full potential, diagnostic catheterization remains the most reliable technique for obtaining hemodynamic and physiologic data in patients with congenital cardiac disease. As surgical techniques have improved, so too has the ability to treat increasingly complex patients and there is a continuing need for invasive cardiac assessment for this group of patients.

Precatheterization assessment

It is unnecessary and potentially unsafe to collect large, untargeted datasets routinely during a procedure, and therefore catheterization studies should be goal oriented and guided by a thorough review of the available information, including the patient's notes and other pre-procedural imaging.

The patient should be in the best possible physical condition for an invasive procedure. This does not mean that catheterization is contraindicated in sick patients; on the contrary, it sometimes can be the only investigation that allows an appropriate management plan. However, every effort should be made to deal with treatable co-morbidity such as acidosis, anemia, and heart failure prior to catheterization, and the catheterizing cardiologist, as always, must be mindful of the balance between risk and benefit for each patient [4].

As an absolute minimum, a contemporary two-dimensional echocardiogram should be reviewed before the procedure. Not only will this help guide the catheter study but it also identifies already established information that does not need further investigation, and decreases the use of unnecessary amounts of intravenous contrast material. Anomalies of the systemic venous and arterial circulation should be noted to plan the vascular access route [5].

An ECG may be required to establish the pre-procedural rhythm. An arrhythmia may need to be controlled prior to the procedure.

We do not routinely cross-match blood for diagnostic cardiac catheterization procedures, although stocks of universal donor blood are readily available in close proximity to our catheterization laboratory suite.

Most pediatric catheterizations require either general anesthesia or sedative agents. Either method is acceptable but each requires patient preparation and appropriate monitoring. Although some investigations can be performed under general anesthesia using a laryngeal airway, this has limitations and militates against the use of trans-esophageal imaging, which cannot be performed without endotracheal intubation. Sedative agents, such as ketamine, promethazine, and morphine analogs, should be administered by practitioners familiar with their use under the guidance of local protocols. There should be anesthetic support and on-site intensive care available in the event of a problem. All catheterization laboratories should be equipped with size-appropriate cardiopulmonary resuscitation equipment and staff properly trained to use it and apply resuscitation protocols.

The environment and monitoring during cardiac catheterization

Standard monitoring for all patients should include real-time ECG (two leads minimum), peripheral oxygen saturation, and blood pressure in addition to clearly displayed data obtained during the procedure. Neonates and infants require temperature monitoring and external warming devices to maintain body temperature even for the shortest of

procedures. Ventilated patients should have appropriate anesthetic monitoring including the display of end tidal carbon dioxide and inspired concentrations of anesthetic agents. Blood gas and saturation monitoring is essential for all congenital cardiac catheterizations. Keeping track of the amount of blood withdrawn is necessary, especially for infants.

Vascular access

The percutaneous femoral route is preferred for diagnostic catheterization for most patients with congenital heart disease [6]. Vascular cut-down procedures are rarely performed in the modern era, but catheterizing cardiologists should be familiar with the technique as occasionally a cut-down may be desirable or necessary. In general, however, the best approach is the Seldinger technique, using a needle to introduce a wire into the target vessel. Almost every operator of any experience has their own preferred method for this form of vascular access. Beyond the absolute principle of understanding the external anatomy, in general familiarity through repeated practice of a particular technique should be encouraged as the best way of obtaining consistent results. Over recent years, ultrasound evaluation of target vessels has become increasingly accepted as the gold standard for central venous access [7]. Although not always necessary for every catheter procedure, all invasive cardiologists should be trained in the technique and be prepared to use ultrasound-guided access in specific circumstances. Although even relatively large sheaths can be inserted into the femoral veins of small infants (a 7Fr sheath can be inserted into the femoral vein for an atrial septostomy in babies weighing as little as 1.5 kg), the general principle of "as small as possible" should be observed, particularly in patients who are likely to require repeat studies.

The umbilical vein can usually be accessed easily in a newborn infant up to ~10 days after birth and is appropriate for a balloon septostomy, provided that the operator is familiar with negotiating the catheter through the liver [8].

Brachial, carotid, jugular, and axillary approaches can be used if the femoral route is unavailable or if the anatomy dictates an approach from above the heart. Brachial venous puncture is straightforward and, provided that the correct vessel is cannulated, usually offers a straight route towards the heart and great vessels, although the capacity of the vessel is limited in infants and smaller children, and brachial venous spasm may make catheter manipulation difficult. Brachial artery cannulation can be performed either percutaneously or via a cut-down procedure. The axillary vein can be accessed percutaneously (usually lying medial to the arterial pulsation in the distal axillary crease), but for this approach and for access to the axillary artery a cut-down procedure is preferable, allowing the direct insertion of a needle and wire into the vessel [9]. The internal jugular veins can be easily cannulated and offer an excellent alternative approach to the central venous system in patients of all sizes if the femoral vessels are occluded or an approach from above the heart is preferable. Generally, the right internal jugular is the best access approach, although at times the left vessel offers a better route to the target, but operators should always be mindful of a persistent left superior vena cava to the coronary sinus, which is common in patients with congenital heart disease. Infraclavicular access to the subclavian vein is often used. Although external landmarks are reasonably consistent, now we always use ultrasound to facilitate access of the jugular veins [7]. Vascular access is effected with lidocaine analgesia, the injection often being preceded by lidocaine cream.

Systemic anticoagulation with heparin is not performed for purely venous catheterization, but should be used in diagnostic procedures with arterial access at a dose of 50 IU kg^{-1}. If it is used, check activated clothing time every 30–60 min. Some cardiologists apply anticoagulation if a venous procedure uses guidewires or for prolonged left-sided catheterization.

Vascular complications

Although the incidence of vascular complications after pediatric cardiac catheterization has fallen over the years, probably due to both greater awareness and progressive miniaturization of catheterization equipment, some problems remain [10–12]. In a recent report of over 11 000 patients reflecting contemporary practice, complications occurred in 7.3% of patients; one-third were vascular complications and of these 20% were designated major [12]. All pediatric vascular access sites should be treated with care from the point of access to the equally important hemostasis after removing the access sheath. Although arterial access complications are clearly the more important, having the capacity to threaten both life and limb, central venous access points are also precious. There is an increasing capacity to deliver trans-catheter treatment as an alternative to surgery in complex patients, but this requires access to the central venous system.

Other complications of cardiac catheterization

Vascular and other complications during cardiac catheterization have fallen dramatically over the years [12–14]. The reasons for this are numerous: techniques have been refined, cardiologists are better trained and supervised, equipment is more suited to the needs of infants and children, improvements have been made in intravenous contrast agents, and there is greater awareness of the dangers of catheterization in sick patients. A moribund, acidotic, poorly perfused neonate who has not responded to precatheterization measures may die in spite of, rather than because of, catheterization [14]. Complications that can occur include death, cerebral or systemic embolus, cardiac perforation potentially leading to tamponade, heart block, arrhythmia (ventricular or supraventricular), hypercyanotic spells, sepsis, and vascular damage.

Angiography

Although contrast medium-enhanced fluoroscopy is no longer the mainstay of anatomic imaging in congenital cardiology, angiograms remain an essential part of interventional pediatric catheterization. A working knowledge of how images are generated and also radiation protection issues for both patients and catheter laboratory staff are essential for all catheterizing cardiologists [15,16].

Generating X-rays and images

Current systems for generating X-rays consist of a rotating rhenium–tungsten anode target and a cathode made from a tungsten filament housed in a focusing apparatus. Voltage and current from the generator heat the tungsten cathode, generating electrons that flow from the cathode to the anode (with the patient in between). The electron flow is related directly to the number of photons produced by the tube, and measured in milliamperes (mA). Current multiplied by exposure time in milliseconds gives milliampere-seconds (mAs), a measure of total exposure to X-rays. The penetrating power of each photon depends on the electrical potential across the X-ray tube and is measured in kilovolts (kV). Picture density doubles with about a 10 kV increase in voltage or a doubling of mAs. Lower energy photons that do not participate in image production are prevented from entering the patient by a thin aluminum screen. In general, increasing kV produces greater penetration of X-rays whereas increasing mA increases image sharpness and the amount of scatter. To minimize blurring, the image intensifier should be as close to the patient's chest as possible. In addition, a lead grid between the intensifier and the patient reduces the amount of scattered X-rays reaching the image receptor. The X-ray beam is attenuated by 50% by ~4 cm of tissue. To obtain adequate tissue density in larger patients or some angulated views, either the voltage must be increased by 10 kV or the exposure in mAs must be doubled.

The X-ray is automatically collimated so that the beam is directed within the confines of the image intensifier on the opposite side of the patient. Further manual collimation allows the beam to cone around the structure of interest, thus improving the quality of image by decreasing the amount of stray radiation striking the intensifier. Almost without exception, the X-ray tube is mounted such that the beam passes from under the patient to an intensifier above and from the right to left side of the patient in biplane systems. Modern equipment uses increasingly complex microprocessors both to control the delivery of energy to the X-ray tube and for the interpretation of the data generated.

The image intensifier is the key receptor in the system, increasing the brightness of the image several thousand-fold. The light produced by the image intensifier is electronically boosted and directed to a camera with an optical lens to produce the final image in analog systems. In digital systems there is no optical lens, rather a microprocessor that processes the data and facilitates the display of the final image. The relative advantages and disadvantages of digital and analog systems are hotly debated, but in reality digital fluoroscopic image generation, manipulation, and storage are here to stay, and in time analog imaging systems will become obsolete.

Radiation protection

Direct primary exposure to ionizing radiation affects the patient for limited periods of time and cumulative secondary exposure leads to risk for personnel in the catheter laboratory [15,16]. There are a number of methods for measuring radiation exposure, the most practical and commonly used being photographic film (badges) usually worn underneath the protective lead used by catheterization laboratory staff.

The units used to measure radiation are complicated by overlapping terminology, particularly as the unit of exposure (the roentgen) differs from the unit of protection that describes the absorbed dose [16]. The roentgen (R) is the ionization that the beam from an X-ray tube produces in air and is the amount of radiation that produces 2.58×10^{-4} coulombs (C) per kilogram of air. Exposure (rad and gray) and equivalent (rem and sievert) doses describe absorbed radiation and are essentially a semantic distinction as the factor to convert the former to the latter for X-rays is one. The absorbed dose describes how much heating the X-rays produce in each unit of a specified material. The unit for absorbed dose is the familiar rad, which is 100 erg of energy deposited in 1 g of tissue, with the SI unit being the gray (Gy), which is 1J kg^{-1}. The equivalent dose is the rem, which measures effective biologic radiation, and the analogous SI unit is the sievert (Sv). Equivalent doses are generally used in radiation protection as they describe the absorbed dose in biologic tissue. Fortunately, conversion between units is generally simplified in that under normal circumstances in the laboratory 1 R approximates 1 rad = 1 cGy = 1 rem = 10 mSv.

The patient is exposed to radiation directly from the X-ray beam. Only ~1% of the original X-ray beam reaches the image intensifier. Soft tissues absorb less radiation than denser tissues such as bone. Very roughly, when considering analog systems used in children, X-ray exposure has been estimated at between 50 and 1000 times that of plain chest X-ray exposure, depending on the type and length of procedure performed [17]. Radiation exposure with modern digital systems is significantly lower, and the dose savings are generally much greater for children than adults. The radiation dose is at least 10 times greater per unit time for cineangiography than fluoroscopy. Therefore, the additional advantage to the patient of a digital laboratory that obviates the need for cineangiography is self-evident.

Somatic effects of X-radiation are related to the radiosensitivities of tissues. The thyroid gland, gonads, bone

marrow, breast, and eye lens are more sensitive than are other tissues. Effects such as fibrosis, inflammation, cataracts, atrophy, ulceration, and malignancy (especially of the thyroid and involving bone marrow) have all been described [18,19].

Measures to decrease radiation effects start with the primary exposure to the patient. All equipment must be used in a specifically designed suite that contains the radiation produced. Vulnerable gonadal tissue should be protected in patients directly, where possible using lead shields. The use of the minimum amount of X-ray energy to produce the required image is important for point source reduction. Equipment must be well maintained and calibrated regularly. Magnification should be used judiciously. If a digital system is available, post-processing magnification is preferable to using a smaller intensifier. The X-ray should be collimated carefully with filters, and lead bars should be utilized to cone the beam around the area of interest. The image intensifier should be as close to the patient as possible. Importantly, every second of fluoroscopy should have a purpose, with intermittent screening providing the additional benefit of prolonging the life of the X-ray tube. Digital review of previously saved fluoroscopy scenes can significantly reduce exposure. As always, each study should be carefully planned to minimize catheter exchanges and therefore the use of catheters for multiple purposes can also help [20].

Short diagnostic angiograms are preferable to prolonged acquisitions, with the need for more than 6–8 s runs rarely indicated. Axial projections require more X-ray energy and are associated with additional radiation scatter, hence the operator must use these projections judiciously, especially during prolonged interventional procedures. Secondary exposure is caused predominantly by scatter and affects both the patient and staff. Catheterization laboratory staff are exposed to cumulative long-term permanent doses of radiation and so clear and effective policies to regulate and control radiation exposure must be in place. Shielding equivalent to 0.5 mm of lead decreases the exposure by a factor of 50; hence its use over radiation-sensitive areas with aprons, shields or collars, and glasses provides substantial protection. The protective equipment should be screened regularly for defects. Steerable lead screens for use in prolonged procedures should be available. Staff should be aware of the inverse square law (the radiation exposure decreases proportionally to the inverse square of the distance from the X-ray beam) and should step away from the field during angiography. In addition, they should understand the areas of greatest exposure to scatter.

Contrast media

Contrast agents are based on iodine and function to increase the innate contrast that exists between tissues. Blood solubility and the side effects of these compounds are to a large extent a function of their chemical properties, primarily the capacity of

a central benzene ring to bind to iodine atoms. Modern contrast agents contain benzene rings with the capacity to hold large numbers of iodine atoms and this reduces osmolality. However, these agents are more expensive than the standard higher osmolality contrast agents. Because of the higher osmolality (approximately six times that of blood), ordinary contrast agents cause far more side effects than low- or nonionic contrast agents [21–23]. The lower osmolality agents, including "nonionic" or water-soluble agents, are much safer (even though still hyperosmolar with respect to blood) and are used almost exclusively in pediatric catheterization laboratories in the developed world, particularly in patients with renal failure or ventricular dysfunction.

The incidence of major side effects with contrast agents is low, with death occurring in ~1/40 000 injections and serious but nonfatal reactions in ~1/14 000 injections [24]. Pulmonary effects include an increase in pulmonary artery pressure and edema. Systemic effects include hypotension, peripheral vasodilation, and allergic reactions. Very rarely, massive histamine release can be encountered and individuals with previous documented reactions to intravenous contrast agents require particular care. All contrast agents can lengthen the QT interval.

Safe absolute amounts of contrast agent in any patient depend on specific individual circumstances, but cumulative doses >6 ml kg^{-1} should be given with great care.

Injection techniques

Angiograms can be performed either manually (using a Luer-lock syringe) or using a power injector. Many operators prefer the tactile "feedback" of a syringe injection in smaller patients, but there is clearly a size limit beyond which a manual injection cannot opacify a vessel. Power injectors vary in design but all essentially deliver a constant pressure allowing for greater flow of contrast into the vessel. Many injectors (particularly those designed to work in modern digital systems) specifically interface with the fluoroscopy system, and so are not necessarily interchangeable with other injectors in a laboratory facility. Power injectors are set to deliver a user-defined volume of contrast agent over a period of time (in children always ml s^{-1}) and most can be programmed to give a gradual step up in pressure ("rate rise") to avoid catheter recoil, although in practical terms the physical properties of injector systems mean that a "square-wave" injection is not possible. Deciding upon the correct amount of contrast agent for any particular injection requires a mental calculation based on the chamber to be filled, the size of the patient, the presence or absence of a shunt, and the particular angiographic settings within the laboratory. Suffice it to say that this is learned with experience. The basic rule of thumb is that within a modern laboratory, in most children an injection of 1 ml kg^{-1} into a large vessel or chamber without a shunt is normally adequate. Injections into

ventricular chambers should be performed using either a pigtail or non-end hole catheter, for example, an NIH, or, if this is not possible, an end hole catheter, such as a Gensini, with sufficient side holes to deliver a large bolus of contrast agent. Other catheters can and have been used to provide satisfactory angiograms, but as is often the case in cardiac catheterization, attention to detail and applying the extra effort to execute each element of a study to the highest standards yield the best results. Before any power injection, a small test shot should be performed to ensure that the catheter is not wedged in the myocardium or entangled in another structure into which a large bolus of contrast may cause harm.

Occasionally, particularly in complex catheter interventions, to maintain position it is desirable to perform angiography over a guidewire. In these circumstances, it is preferable to use either a long sheath (e.g., a Mullins sheath, Cook Medical, Bloomington, IN, USA) with sufficient additional volume or a Multitrack catheter (NuMed, Hopkinton, NY, USA), specifically designed to provide high volumes of contrast agent over a guidewire.

Angiographic projections (Table 10.1)

Prior to the late 1960s, all angiography was performed in frontal and lateral projections (Figure 10.1a and b). Subsequently, axial angiography became valuable in cardiac malformations [25,26]. In standard nomenclature, the straight frontal projection is designated as 0°. Movement of the frontal intensifier to the left or right constitutes left or right anterior oblique projections (LAO or RAO), respectively, often further quantified by the degree of rotation. A rotation of 90° from the frontal projection designates the lateral view. The X-ray tube head can also be angulated towards either the patient's head or feet, adding additional cranial or caudal tilt, respectively.

The ventricular septum is best defined in LAO (Figure 10.1c), with the inlet moving to outlet with additional tilt to the left. LAO with cranial tilt also profiles the course of the atrial septum and the main and proximal branch pulmonary arteries. Ventriculo-arterial connections and branch pulmonary arteries are best seen in their respective axial tilts (for the normally positioned right heart in RAO and left heart in LAO) (Figure 10.1c and d). Pulmonary venous connections are variable but are again often best profiled in their respective axial angulation. Optimal angiographic projections require tailoring to each individual heart and the information required from a particular study. This is particularly true for patients with atypical cardiac position or connections. When precisely defining anatomic position, biplane angiography, particularly in "ordinary" frontal and lateral projections, is extremely useful, allowing a composite calculation in two interfacing planes (Figure 10.1a and b).

The need for complex and involved diagnostic angiography is relatively rare, being superseded by other forms of

Table 10.1 Common cineangiographic projections[a].

View	A plane (°)	B plane (°)
Posteroanterior and lateral	0	90 (LAO)
Long axial (LV and PA)	30 RAO	60 LAO
		20 cranial

imaging. However, every cardiologist must understand the basic axial angiographic views. Because of the sigmoid nature of the inter-ventricular septum and separation of the pulmonary artery tree, the most commonly used view for showing these structures is the LAO projection, often with additional cranial tilt, commonly known as the "sitting view" referring to earlier days when the patient, not the X-ray tube, moved to achieve the required projection) [27] (Figure 10.1e and f). Atrioventricular connections in the normally positioned and connected heart are usually obtained in LAO projection.

3D Rotational angiography

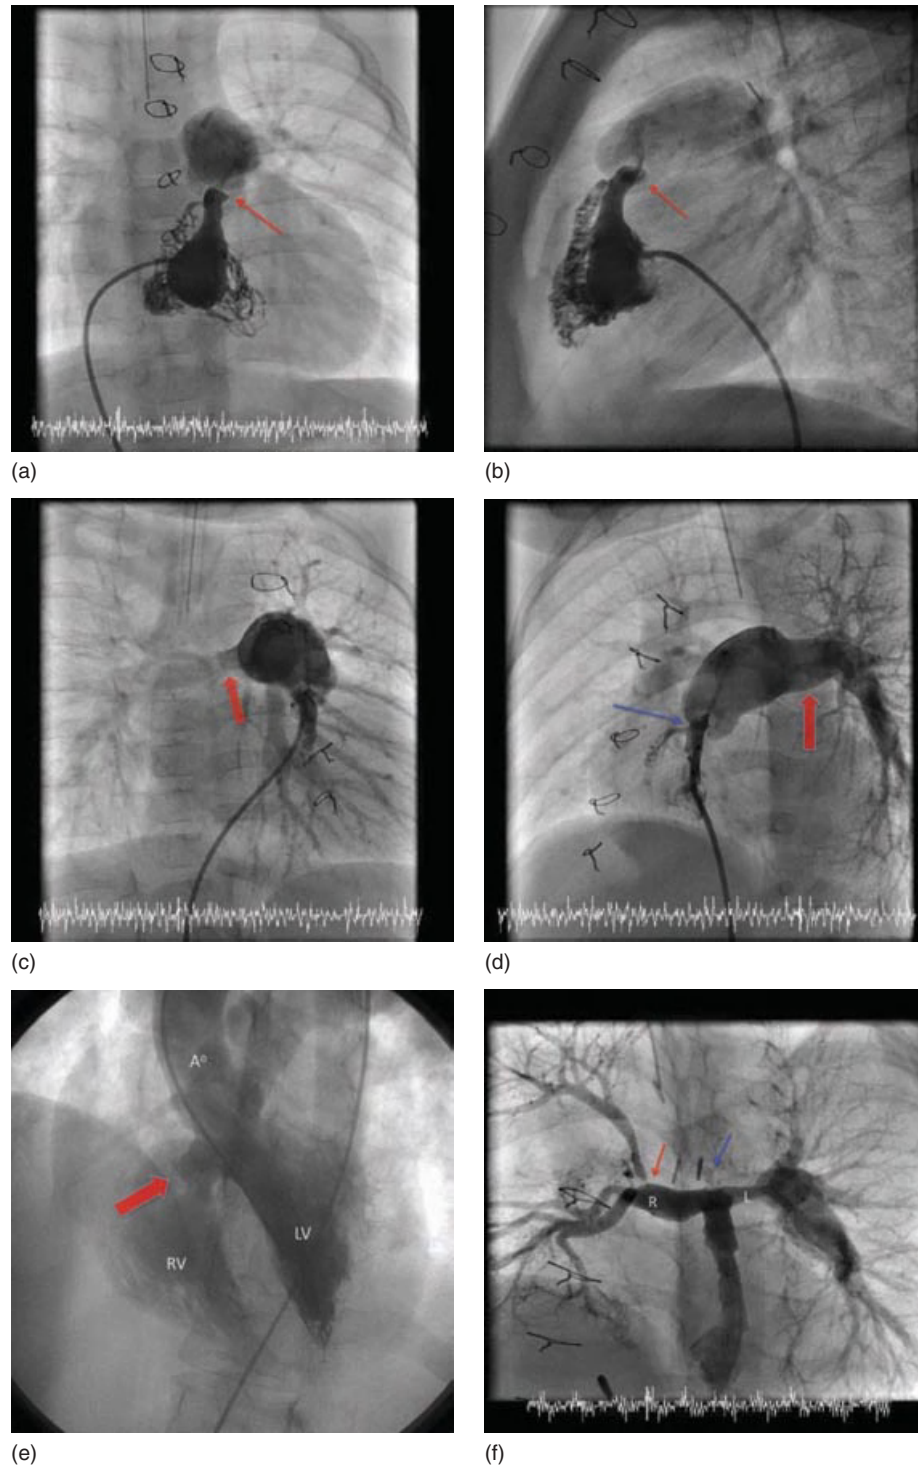
Recent advances in commercially available angiographic technology have made 3D rotational angiography a realistic prospect in modern congenital cardiac catheterization laboratories. Data sets akin to those obtainable with high resolution multi-slice CT can now be obtained within a catheterization study allowing increased diagnostic accuracy,


Figure 10.1 (a) Biplane right ventricular angiogram in the anteroposterior ("frontal") projection in a patient with pulmonary atresia with intact ventricular septum after ventricular decompression. Note the dysplastic pulmonary valve (thin red arrow). (b) Lateral projection [at 90° to (a)] in the same patient. (c) Pulmonary artery angiogram in the right anterior oblique projection (RAO) in the same patient. This view profiles the right pulmonary artery (RPA) (arrowed). Note the RPA appears faint because of "washout" from an aortopulmonary shunt. (d) Pulmonary artery angiogram in the same patient as in (a)–(c), but here in the LAO projection, showing the left pulmonary artery (red arrow). Note the extremely dysplastic pulmonary valve demonstrated on this angiogram (thin blue arrow). (e) Pigtail injection into the left ventricle in the left anterior oblique projection (LAO with cranial angulation) outlining the ventricular septum and the left ventricular outflow tract, here a patient with a perimembraneous ventricular septal defect (arrow). LV, left ventricle; RV, right ventricle; A°, aorta. (f) "Sitting view" (LAO with cranial angulation) showing the pulmonary artery tree in a patient after unifocalization of pulmonary arteries and connection to the right ventricle with a restrictive right ventricle to pulmonary artery conduit. Note the stenosed origins of previous aortopulmonary collaterals (red arrow) and the remnants of a previous ductal stent (blue arrow) used to maintain ductal blood flow into the native left pulmonary artery. R, right pulmonary artery; L, left pulmonary artery.

a better understanding of the relationships between structures and improved understanding of the anatomy underlying targets for therapeutic intervention. Experience is currently limited and enthusiasm for the technique needs to be viewed in the light of the increased radiation doses required, technical difficulties in image acquisition (mainly movement artifact making general anesthesia a necessity) along with the need for post processing which currently takes minutes rather than seconds. However, there is certainly the potential for rotational angiography to develop into a clinically useful technique in mainstream practice in the future [27a].

Hemodynamic calculations

Physiologic recordings

It is very difficult to measure blood flow directly within the heart and great vessels. Therefore, calculations based on surrogates are used. The most important element for hemodynamic calculations in the laboratory is the accuracy of the readings and measurements themselves, Therefore, all equipment, including pressure recording transducers and oxygen saturation measuring devices, should be thoroughly checked and calibrated before any procedure.

Shunt calculations

Although many catheter laboratories and computerized reporting systems provide automated calculations, cardiologists must understand the fundamentals of hemodynamic calculations, many of which are simple and can be roughly but readily applied and adapted during the catheterization itself [28].

Flow and shunt calculations often depend on manipulating values for oxygen in the blood, and the following information is essential:

1 Oxygen-carrying capacity of blood (ml l^{-1})=13.6 ml O_2 g^{-1}Hb L^{-1}blood.

2 Dissolved oxygen (ml l^{-1}) = 0.03 ml l^{-1} $mmHg^{-1}$ partial pressure of oxygen.

3 Oxygen saturation (%) = percentage of oxygenated hemoglobin.

4 Oxygen content of blood (ml l^{-1}) = [oxygen-carrying capacity (ml l^{-1}) × oxygen saturation] + dissolved oxygen (ml l^{-1}).

Of most practical value is the pulmonary to systemic flow ratio (Qp:Qs). This is an important index upon which many of the early indications for intervention in congenital heart disease were based. To calculate Qp:Qs, heparinized blood from the aorta (or ideally a pulmonary vein), main pulmonary artery, superior vena cava, and inferior vena cava is obtained with the patient ventilated, preferably on normal inspired FiO_2 concentrations, but not >30% inspired oxygen. The calculations should be based on samples obtained within a brief period, rather than random samples which may reflect differing hemodynamics. Patients breathing higher concentrations of oxygen are likely to have raised pulmonary artery oxygen concentrations, artificially elevating the calculated left-to-right shunt. From these measurements, the following can be calculated.

The pulmonary to systemic flow ratio (Qp:Qs) is based on the Fick principle and although the oxygen-carrying capacity of the blood and oxygen consumption (see later) are important parts of the calculation of both pulmonary and systemic flow, they cancel each other out in the final analysis to give a simple equation [28,29]:

$$Qp : Qs = \frac{Sao - Smv}{Spv - Spa}$$

where S is percentage saturation, ao = aorta, mv = mixed venous, pv = pulmonary vein, and pa = pulmonary artery, and

$$Smv = \frac{3 \times SVC + 1 \times IVC}{4}$$

where Smv is mixed venous saturation, SVC is superior vena cava, and IVC is inferior vena cava.

The IVC saturation should be taken at the level of the diaphragm to take into account hepatic venous return. Mixed venous saturation is to some extent inaccurate because of unmixed streams of blood with different oxygen saturations in the venae cavae and even in the right atrium. Because of this streaming, an increase in oxygen saturation of 7% at the atrial level, 5% at the ventricular level, and 2% at the pulmonary arterial level is needed to diagnose left-to-right shunting at that level.

Assessing pulmonary venous saturation can also be difficult. A saturation measured within the left atrium can be substituted for the pulmonary venous saturation assuming that there is no shunt at the atrial level. In most patients, it is unreasonable to perform a transeptal puncture purely to measure a pulmonary venous saturation and so frequently the pulmonary venous saturation is assumed to be 98%. Patients with a left-to-right shunt are usually fully saturated and therefore the systemic saturation is always about 98%. Under these circumstances, the shunt equation becomes even simpler and an approximation of the calculation can readily be performed mentally without even writing the figures down! The same equation allows an assessment of right-to-left shunt, but clearly in a desaturated patient, no assumptions can be made about systemic or pulmonary venous saturations.

Cardiac output, flow, and resistance

Thermodilution is the easiest technique with which to calculate cardiac output. The procedure requires introducing cold injectate of known temperature into the blood stream

and measuring the temperature further downstream, leading to a time–temperature curve that can be related to cardiac output [30]. Cardiac output determined by thermodilution is largely automated and correlates well with the Fick technique.

The dye dilution method uses indicator dye, usually indocyanine green, injected into the circulation. The concentration of the indicator is measured continuously and allows the construction of a first-pass indicator concentration curve [31]. The Stewart–Hamilton equation is then used to calculate cardiac output:

$$Q(\text{l min}^{-1}) = \frac{I(\text{mg}) \times 60}{\overline{C}(\text{mg l}^{-1}) \times t(s)}$$

where I is the quantity of dye (mg), $\overline{C}$ is the mean concentration in the absence of recirculation (mg l^{-1}), and t is the duration of the curve (s).

Both thermodilution and indicator dye techniques require training and practice to produce reliable results. However, both rely on the assumption that pulmonary and systemic flow ratios are the same, which does not occur in patients with an intracardiac shunt, invalidating the techniques in many patients with a congenital cardiac defect.

Systemic and pulmonary flow

The Fick technique for calculating cardiac output is the most reliable in patients with intracardiac shunts but relies fundamentally on measuring oxygen consumption (VO$_2$ ml min^{-1}), a highly involved (and expensive) technique in its own right with a number of inbuilt potential errors [28,32]. Many laboratories rely on assumed oxygen consumption based on the age and gender of the patient rather than a direct measurement when calculating pulmonary vascular resistance. This approach introduces a fundamental and systematic error to all subsequent calculations [32]. Studies have shown a poor correlation between assumed and calculated oxygen consumption values, which many operators believe militates against the use of assumed oxygen consumption in calculating cardiac output and also flow and resistance [32].

The Fick technique assumes that the oxygen uptake in the lungs is in equilibrium with oxygen usage in the systemic tissues. As such, the difference between arterial and venous blood oxygen concentrations across a "circuit" (either the pulmonary or systemic beds) represents tissue oxygen utilization. Pulmonary blood flow can then be determined by the following equation:

$$Qp \ (\text{l min}^{-1}) = \frac{\text{VO}_2(\text{ml min}^{-1})}{(\text{PV} - \text{PA}) \text{ oxygen content } (\text{ml l}^{-1})}$$

Where Qp is pulmonary blood flow, VO$_2$ is oxygen consumption, PV is pulmonary vein, and PA is pulmonary artery.

Table 10.2 Calculation of flows and shunts.

Parameter[a]	No shunt	Left–right shunt	Right–left shunt	Bidirectional shunt
VO$_2$ (ml min^{-1})	250	250	250	250
Cpv (ml l^{-1})	200	200	200	200
Cao (ml l^{-1})	200	200	175	175
Cpa (ml l^{-1})	150	175	125	125
Cmv (ml l^{-1})	150	150	125	100
Qp (l min^{-1})	5.0	10.0	3. 33	10.0
Qs (l min^{-1})	5.0	5.0	5.0	3.33
Qep (l min^{-1})	5.0	5.0	3.33	2.5
Qlr (l min^{-1})		5.0	–	7.5
Qrl (l min^{-1})	–		1.67	0.83

[a]C, oxygen content.

Oxygen consumption should ideally be directly measured, but if this cannot be done then oxygen consumption tables can be used [33]. Usually these values are then indexed for body surface area as this correction allows a natural progression to figures for pulmonary vascular resistance in Wood units. To perform this calculation, the calculated absolute flow is divided by body surface area. Thus in small child with a body surface area of 0.3 m^2 an absolute flow of 2l min^{-1} gives an index of 2/0.3 = 6.7 l min^{-1} m^{-2}, about double the normal resting value, but which is very low for an adult with a body surface area of 1.5 m^2, because that cardiac index is 2/1.5 = 1.3 l min^{-1} m^{-2}. The normal index is approximately 3.5 l min^{-1}. The second crucial element in the equation is the oxygen content of the blood samples; this requires a calculation based upon the hemoglobin (g l^{-1}) multiplied by 1.36. The oxygen content of each sample is then calculated by multiplying the oxygen-carrying capacity by the saturation. Using this technique, the difference between arterial and venous oxygen contents across a circuit (either pulmonary or systemic) can be readily calculated and applied to the equation above.

Systemic flow (Qs) can be calculated by substituting the difference between pulmonary venous and arterial oxygen in the equation above with those for systemic venous and arterial oxygen contents. Examples of calculations are given in Table 10.2.

If pulmonary flow exceeds systemic flow, that is, if $Qp > Qs$, then the difference $Qp - Qs$ is the amount of the left-to-right shunt. If $Qs > Qp$, then the difference $Qs - Qp$ is the amount of the right-to-left shunt. If there are both left-to-right and right-to-left shunts, then oxygen saturation in the pulmonary veins exceeds that in the aorta, and oxygen saturation in the pulmonary artery exceeds the mixed

Table 10.3 Data for calculation of multiple left-to-right shunts.

Parameter[a]	Oxygen saturation (%)	Oxygen content (ml l⁻¹)
Cpv (ml l⁻¹)	95	193.8
Cao (ml l⁻¹)	95	193.8
Cpa (ml l⁻¹)	85	173.4
Crv (ml l⁻¹)	80	163.2
Cra (ml l⁻¹)	75	153
Cmv (ml l⁻¹)	70	142.8

[a]C, oxygen content.

venous saturation. Then the concept of effective pulmonary flow (Qep), which is the amount of desaturated venous blood that is oxygenated in the lungs, is used:

$$Q\text{ep}(\text{l min}^{-1}) = \frac{\text{VO}_2(\text{ml min}^{-1})}{(\text{pulmonary vein - mixed venous})\text{oxygen content}(\text{ml l}^{-1})}$$

Then Qp – Qep is the left-to-right shunt and Qs – Qep is the right-to-left shunt. For examples, see Table 10.2.

If there are left-to-right shunts at different levels, the pulmonary blood flow at each level is calculated as if the saturation in that chamber was the final saturation entering the lungs. Consider left-to right-shunts at atrial, ventricular and pulmonary arterial levels (Table 10.3).

Assume perfect mixing in each chamber and $\text{VO}_2 = 196$ ml min⁻¹. Calculate Qs as usual:

$$Q\text{s} = \frac{196}{193.8 - 142.8} = 3.84 \text{ l min}^{-1}$$

If there had been no shunt beyond the right atrium, then the oxygen contents in the pulmonary artery and right atrium would have been the same. Therefore, Qp would have been

$$Q\text{p} = \frac{196}{193.8 - 153} = 4.80 \text{ l min}^{-1}$$

and the left-to-right shunt would have been 4.8–3.84 = 0.96 l min⁻¹. This is the shunt through the ASD.

If there been a shunt through the VSD, then Qp would have been

$$Q\text{p} = \frac{196}{193.8 - 163.2} = 6.40 \text{ l min}^{-1}$$

Then the difference 6.40–4.80 = 1.6 l min⁻¹ must have been due to the extra flow across the VSD.

If we add in the ductus shunt, then Qp becomes

$$Q\text{p} = \frac{196}{193.8 - 173.4} = 9.61 \text{ l min}^{-1}$$

The added flow comes from the ductus, so that the ductus shunt is 9.61–6.4 = 3.21 l min⁻¹.

Note that for equal increments of saturation from one level to the next the shunt becomes larger and larger. This means that a small shunt beyond a large shunt may be difficult to detect because of the variability of saturations due to streaming.

Pulmonary Vascular Resistance

The calculations for pulmonary flow as described above are in themselves not particularly useful. In most patients, these calculations are performed to derive measurements of pulmonary vascular resistance, which is of fundamental importance in decisions in many patients with congenital heart disease.

Pulmonary vascular resistance (Rp) is expressed as

$$R\text{p} = \frac{\overline{P}_{\text{PA}} - \overline{P}_{\text{LA}}}{Q\text{p}}$$

where $\overline{P}_{\text{PA}}$ and $\overline{P}_{\text{LA}}$ are mean pulmonary arterial and left atrial pressures (mmHg), respectively, and Qp is pulmonary flow (l min⁻¹).

If the left atrium cannot be accessed, then the pulmonary capillary wedge pressure can be substituted. Assuming that the pulmonary blood flow has been calculated as above and indexed correctly for body surface area, calculation of the equation becomes simple and leads to a pulmonary vascular resistance in mmHg l⁻¹ min⁻¹, commonly referred to as Wood units.

Trans-Pulmonary Gradient

Many operators prefer to use the "trans-pulmonary" gradient (the difference between the mean pulmonary artery pressure and the mean left atrial pressure) as an index of pulmonary vascular resistance, rather than Wood units. This approach removes all of the assumptions and potential inaccuracies related to the calculation of pulmonary blood flow. The normal pulmonary vascular resistance is <2 Wood units m⁻², but that is only if flow is normal. If pulmonary blood flow is increased in normal subjects, as with exercise, the pressure in the pulmonary

artery barely changes because Rp decreases. Therefore, a child with a large VSD, high pulmonary blood flow and Rp = 2 Wood units m^{-2} has abnormal resistance, because at those flows Rp should be <1 Wood unit m^{-2}. Using the transpulmonary pressure avoids this source of error.

Calculations of Rp should also consider the effect of blood viscosity. Resistance to flow of blood through a tube is a function of tube geometry (mainly length and radius) multiplied by blood viscosity. To assess the geometric factor alone, the resistance is divided by the viscosity to derive what is termed "hindrance." For constant hindrance, halving the viscosity halves the resistance, and doubling the viscosity doubles resistance. Hence in patients with polycythemia and a hematocrit of 70% the viscosity is about doubled, and Rp is correspondingly increased. To assess what Rp would be at normal hematocrit (as in a child after a successful single ventricle repair), the calculated value for Rp is divided by the relative viscosity, as determined by Figure 10.2.

Consider interpreting a pulmonary vascular resistance in the two patients illustrated in Table 10.4. Patient A with a
Figure 10.2 Relationship of hematocrit to changes in blood viscosity both relative to plasma and to a standard viscosity at 45% hematocrit. P, poise.

resistance of 4 Wood units m^{-2} normally would be a candidate for a Fontan repair. If, however, the preoperative hematocrit was 20% and the hindrance was actually elevated to 195, then after operation if the hematocrit returns to a normal value of 45%, with that same geometric factor (hindrance) the resistance would be ~8 Wood units m^{-2}. In patient B, a resistance of 8 Wood units m^{-2} might normally preclude a single ventricle repair. The preoperative hematocrit of 70%, however, indicates a lower hindrance and therefore favors a good outcome, because the postoperative resistance at a normal hematocrit would be ~4 Wood units m^{-2}.

Pressure measurements in chambers and vessels ideally require high-fidelity recordings that are difficult to achieve through long, narrow catheters. Catheter movement, especially in the right ventricle, may distort tracings and give a sharp, excessively large systolic peak referred to as "fling" that must be allowed for. Furthermore, formation of air bubbles in the catheter from air dissolved in the saline damps the pressure tracing, so that frequent flushing with saline is required. A discussion of damping and its determination during clinical procedures was provided by Glantz and Tyberg [34].

Important weaknesses and sources of error in physiological calculations

When carrying out a diagnostic study in which the primary objective is to calculate physiological variables, it is important to be mindful of the following:

1 Ensure that the patient is appropriately ventilated because high end tidal CO_2 and high FiO_2 can both exert a significant influence on the figures generated.

2 Ensure that the patient is stable and that there is no acidosis (check an arterial gas at the beginning and the end of the procedure).

3 Ensure that you are familiar with the techniques. Calculations of outputs and in particular measurement of oxygen consumption require considerable expertise.

4 Do not assume that pulmonary artery pressure is analogous with resistance.

Table 10.4 Effect of viscosity on Rp.

Parameter	Patient A		Patient B	
	Preoperation	**Postoperation**	**Preoperation**	**Postoperation**
Hematocrit (%)	20	45	70	45
Rp (Wood units m^{-2})	4	8	8	4
Relative viscosity	0.5	1	2.0	1.0
Hindrance (mmHg l^{-1} min^{-1} m^{-2} P^{-1})	195	195	100	100

5 Take care with calculations, particularly corrections for body surface area, which if inserted at the wrong point can invalidate the calculations.

6 Although dissolved oxygen contributes little to calculated flows when the patients are breathing air, the amount increases considerably when they are breathing 100% oxygen. At a partial pressure of 500 mmHg, there will be 15 ml of dissolved oxygen per liter of blood. Disregarding this contribution to the arteriovenous difference in oxygen content will give a falsely high value for Qp and a falsely low value for Qs.

Therapeutic cardiac catheterization

Introduction

Cardiac catheterization is also a means of treating congenital cardiac anomalies. The first attempt to perform a therapeutic catheter procedure was in 1953, when Rubio-Alvarez *et al*. tried to perforate a pulmonary valve with a wire [35]. This procedure was far before its time and was not repeated. In 1966, Rashkind and Miller performed a balloon septostomy in an infant with transposition of the great arteries, and the era of transcatheter intervention was born [36]. The 1970s saw a significant expansion of therapeutic possibilities in the catheterization laboratory. By the 1980s and 1990s, interventional cardiac catheterization had moved well beyond the "proof of concept" stage and for many lesions a transcatheter approach had achieved acceptance, either as the preferred treatment or as an acceptable alternative to surgery depending on specific clinical circumstances. The latter half of the 1990s saw the maturation of technology leading to an explosion of devices and equipment, vastly expanding treatment options in the catheterization laboratory. Current practice of cardiac catheterization in congenital heart disease bears little resemblance to that of even 15 years ago, and the drive for development shows little sign of slowing.

All therapeutic catheterization procedures need the skills of specialists who have had additional training [1,37]. The wide variety of techniques and the large inventory of equipment necessary for modern catheterization in congenital heart disease mean that these are no longer techniques that should be carried out by every pediatric cardiologist or even every unit practicing pediatric cardiology. Pediatric cardiologists performing therapeutic catheterization and congenital cardiac surgeons increasingly rely on each other to obtain the best results for patients [38]. In the modern era, neither discipline should exist in a particular cardiac unit without the availability of the other [1,37].

Balloon atrial septostomy

This is a potentially life-saving procedure in a newborn infant with transposition of the great arteries and restrictive atrial septum (~10% of these patients). These infants can be desperately sick very soon after birth from lack of mixing at atrial level, and balloon atrial septostomy is the only procedure to prevent the inevitable decline of progressive cyanosis and acidosis. In addition, there are a small number of babies with hypoplastic left heart syndrome and a restrictive atrial septum who may require a balloon septostomy. The need to relieve an inter-atrial restriction in other forms of single ventricle physiology is debated. In our opinion, there is no role for routine atrial septostomy in these patients, although the atrial septum should be carefully examined using echocardiography and the procedure performed if there are concerns.

The most commonly used balloon for atrial septostomy is the Miller–Edwards balloon (Edwards Lifesciences, Irvine, CA, USA). The balloon has changed very little since the original design attributable to William Rashkind. It is a single lumen latex balloon with an angle of approximately 30° at the distal end to facilitate passage across the atrial septum. The balloon is available in two inflation sizes (1.8 and 4 ml) and requires a 7Fr introducer sheath. The alternative to the Miller–Edwards balloon is the Z5 atrioseptostomy balloon (NuMed), a non-compliant balloon available in two sizes designed to be introduced over the wire through a 6Fr sheath.

In a neonate with simple transposition of the great arteries, a balloon septostomy, using a Miller–Edwards balloon can be safely performed either in the catheter laboratory or at the bedside using trans-thoracic ultrasound guidance [39]. Access must be from either the femoral vein or the umbilical vein, as this balloon cannot be negotiated across the atrial septum from the internal jugular route. After venous access has been established, the balloon is passed up through the inferior vena cava with the stylet inside. Once in the right atrium, the stylet is removed and the balloon passed into the left atrium using the distal tip angle. Within the left atrium, the balloon is inflated to the maximum diameter and rapidly withdrawn to the right atrium with a "jerk" or "tug" while making an effort to control the distance of the withdrawal so that the balloon does not enter the IVC. This should be repeated 2–3 times until there is a wide jet across the atrial septum on color Doppler. Potential complications of the technique are damage to the mitral or tricuspid valve (particularly if the balloon is mistakenly inflated in the left ventricle rather than the atrium), damage to the IVC if the balloon is forcibly pulled too far back, femoral vascular damage, and stroke, although generally these complications are rare [40–42].

Static balloon dilation

Although a relatively limited technique, because of the high incidence of recurrence, there are patients in whom a static "over the wire" dilation of the atrial septum with a standard angioplasty balloon can be employed. An advantage of this approach is that a much larger balloon can be used compared

with a standard septostomy catheter where only two sizes are available. Therefore, a larger opening can be created, although the technique is bedeviled by recurrence, particularly in older patients with a thick atrial septum. The procedure is relatively simple and essentially analogous to a balloon atrial septostomy except that a wire is passed across the atrial septum and positioned in one of the left pulmonary veins. A balloon, or multiple balloons, if necessary can then passed over the wire and inflated within the atrial septum. The procedure should be performed in the catheter laboratory and, because of the space constraints, generally a shorter balloon should be used.

Blade atrial septostomy

When balloon septostomy was extended to lesions other than transposition of the great arteries, particularly in infants and children older than 1 month, the results were less satisfactory and only temporary. At that age, the septum is usually too thick or tough, and the balloon stretches the existing hole only temporarily, if at all. As a nonoperative solution to this problem, the Park blade septostomy catheter was developed [43]. At the distal end of a Park catheter, a small recessed blade can be extended and retracted by a slide mechanism at the proximal end. There are three blade lengths: 1.0 and 1.34 cm in a 6Fr catheter and 2.0 cm in an 8Fr catheter. The purpose of the blade is first to create a small incision in the septum, which can then be torn further with a standard balloon atrial septostomy as described above.

The blade catheter is positioned in the left atrium through a long sheath that has been passed into the left atrium either through a pre-existing opening or by a trans-septal puncture. The blade is opened carefully in the left atrium with the tip facing either the patient's right or left, but always anteriorly. The blade is withdrawn slowly and forcefully through the septum into the right atrium. This process is repeated one or more times, changing the angle of the blade with each withdrawal. When little or no resistance to the blade pull-through is apparent, the blade procedure is followed by a balloon atrial septostomy.

Not surprisingly, complications, such as atrial perforation or damage to other cardiac structures, can occur, so blade septostomy catheters should only be used by operators who have considerable experience with the technique.

Stenting of the atrial septum

This technique has become increasingly popular over recent years, often as an alternative when blade septostomy is seen to have unacceptably high risk (very small infants) or for patients (again usually infants) who require temporary relief of atrial obstruction, usually following recurrence after standard balloon atrial septostomy. An example is infants with hypoplastic left heart syndrome who have undergone "hybrid" palliation and require completely unrestrictive flow across the atrial septum for 3–6 months before definitive

palliative surgery [38,44] The technique has also been used with some success to improve mixing in adults with uncorrectable cyanotic cardiac lesions.

Generally, patients selected for this procedure have a thicker muscular atrial septum. If there is no atrial communication, a trans-septal needle is used to perforate the septum. Once across the septum, a supportive wire is positioned in one of the left pulmonary veins and a long sheath placed in the left atrium. A balloon-mounted stent [in our experience currently either a Palmaz–Genesis (Cordis, Bridgewater, NJ, USA) or an LD Max stent (EV3, Plymouth, MN, USA)] is positioned across the septum. Clearly, the correct length of stent is critical; as a general principle, shorter lengths are preferable considering stent shortening at the desired final diameter. Using both angiography through the sheath and echocardiography to assist, the stent is positioned evenly across the septum before dilation. Complications include stent embolization and in smaller patients interference with adjacent valvar structures.

Balloon dilation procedures

Kan *et al.*, using a newly developed dilation balloon, first reported successful dilation of the pulmonary valve in 1982 [45]. This led to a number of reports in quick succession describing successful pulmonary valve dilation followed subsequently by balloon dilation of aortic and mitral valve stenosis. Many publications, including registry data of large numbers of patients, attest to the success and durability of balloon dilation procedures [46,47]. A number of commercially available balloons are suitable for valvoplasty and other forms of balloon dilation. Most are made from polyurethane or polyethylene and are noncompliant (or in some "semi-compliant") at the stated inflation diameters. A desirable characteristic in modern balloons is relatively short tapering ends. There is a trend towards smaller shafts, shorter tips, and better profiles both before and after inflation. Currently available balloons are available in diameters ranging from 2.5 to 30+ mm, and fit through sheaths as small as 3Fr and deliver circumferential pressures between 2.5 and 20 atm.

Specific descriptions of pulmonary, aortic, mitral, and tricuspid valve dilation and also coarctation angioplasty are given in their respective chapters.

Systemic venous dilation

Obstruction to superior vena caval (SVC) flow often follows scarring related to surgery or previous intravenous lines. Although these stenoses can be dilated with a balloon, usually a stent is required to reduce the risk of recurrence in the long-term [48]. Intra-atrial obstruction is relatively common after atrial switch procedures to correct transposition of the great arteries. The onset is usually gradual, giving time for the formation of collateral vessels if the obstruction is severe, so that symptoms are rare, although there have been reports

of edema, ascites, and protein-losing enteropathy. Treatment is indicated for the relief of such symptoms, or to preserve patency of the superior baffle limb in patients who may require endocardial pacing later.

Technically, balloon dilation of these stenoses is straightforward. The lesion is crossed and a stiff support wire positioned. Balloon angioplasty is then performed with an appropriately sized balloon. Acute improvement in the narrowing results, but often this is not maintained long-term. Currently, most operators advocate primary stenting rather than balloon angioplasty for these lesions [49]. Published series suggest that angioplasty alone can be effective and safe [50], but major complications have been reported [50].

Pulmonary venous dilation

Obstruction in pulmonary veins of any nature, either primary or secondary to previous surgical correction, responds only transiently to either balloon dilation or the insertion of stents [51,52]. The only exception is pulmonary venous stenosis occurring after radiofrequency pulmonary venous isolation for atrial fibrillation. These lesions occur because of fibrous scarring and may respond to cutting balloon angioplasty [53]. This indication aside, generally the technique has been abandoned by most centers.

Intravascular stents

Often following apparently successful balloon dilation of vessels, the stenosis recurs either immediately after deflating the balloon or in the subsequent weeks or months. Since the late 1980s, balloon-expandable stents have been deployed to prevent elastic recoil and dramatically improved results [54]. Most stents used to treat patients with congenital heart disease were originally designed for placement in the iliac or renal arteries, but are also effective in other vessels such as the pulmonary artery and the aorta (Figure 10.3a and b). Over recent years, stents specifically designed for use in congenital heart disease populations (e.g., the Cheatham-Platinum stent, NuMed) have become commercially available. Covered stents are also routinely used for excluding aneurysms and unwanted/abnormal vascular structures (Figure 10.3c and d).

Stenosis of systemic veins, pulmonary arteries, and coarctation of the aorta are examples of lesions that can be treated using stents with good long-term results [49,50,54,55]. In addition to long-term treatment, stents have also been used as effective short-term palliation within the right ventricular outflow tract (tetralogy of Fallot) [56] and the patent ductus arteriosus (duct-dependent congenital heart disease) [57].

Stent delivery is a more involved technical procedure than standard balloon dilation, with the addition risks of stent embolism and jailing of adjacent vessels. Stent delivery requires a mastery of specific techniques and knowledge of the technical characteristics of equipment, both of which are beyond the scope of this chapter.

Radiofrequency perforation in pulmonary atresia intact ventricular septum

A biventricular circulation can be established in patients with pulmonary atresia and intact ventricular septum provided that patients are correctly selected [58]. Transcatheter decompression of the right ventricular outflow tract is one of the most technically demanding catheter procedures. Continuity between the pulmonary artery and the right ventricle can be established using a number of approaches, although in recent years perforation of the valve plate using a radiofrequency wire has become by far the most common [59]. After thoroughly evaluating the anatomy, a guide catheter is placed in the right ventricular cavity and manipulated into the right ventricular outflow tract. The catheter must be positioned directly under the middle of the valve plate, most importantly at a right-angle. Obtaining the correct catheter position takes time and often a number of catheter shapes. Many operators prefer to pass an additional catheter or even a small snare through the ductus via an arterial approach to provide distal angiography and a target for perforation. Once in a satisfactory position, the radiofrequency wire is advanced through the guide catheter within a small coaxial catheter. When under the valve plate, a short pulse of radiofrequency energy is delivered through the wire, which should then pass easily into the pulmonary artery, provided that the positioning has been correct. Once in the pulmonary artery, the radiofrequency wire and its coaxial housing are manipulated across the ductus and into the descending aorta, using a snare if necessary. The radiofrequency wire is then exchanged for a stiff support wire and the valve is serially dilated using balloons. Most patients remain ductus dependent for some time following the procedure while the right ventricle adapts to new loading and unloading conditions. In the past, prolonged prostaglandin infusions were used, but increasingly there is interest in ductal stenting either at the time of right ventricular decompression or shortly after to avoid long-term prostaglandin infusion [57,60].

In patients with pulmonary atresia with intact ventricular septum, the direction of the main pulmonary artery is usually relatively horizontal, and the guide catheter is naturally directed more anteriorly so it is very easy to perforate the pulmonary artery and enter the pericardium, with potentially serious results. This can occur even if the catheter is only a fraction of a millimeter out of position. Recognizing and quickly treating this complication are absolutely essential as accumulation of even 10–15 ml of blood in the pericardial sac acutely leads to tamponade and hemodynamic collapse.

This procedure, when correctly applied, results in right ventricular growth and ultimately a biventricular circulation [57,61]. In some patients, when the right heart is borderline in size, a so-called "one and a half" circulation is created by an operation, in which anterograde flow through the right heart is supported by a bidirectional Glenn shunt.

Percutaneous valve replacement

The first human trans-catheter valve replacement was performed in 2000, where a stent containing a bovine jugular vein was implanted into the right ventricular outflow tract of a patient with congenital heart disease [62]. The technology has the ability to reduce the need for repeated cardiac operations in a subset of patients with significant congenital heart disease by rehabilitating surgically positioned conduits. Since the original description, over 700 percutaneous pulmonary valve replacements have been performed worldwide, and the technology has sparked the development of other valve replacement procedures such as trans-catheter aortic valve replacement (TAVI). Percutaneous pulmonary valve replacement is effective in reducing the gradient and restoring pulmonary valve competence [63]. There have been concerns about stent fracture leading to valve dysfunction, but these have been resolved to some extent by the use of bare metal stents within the outflow tract to provide a rigid implantation tube [63,64]. The most commonly used valve, the Melody trans-catheter pulmonary valve (Medtronic, Minneapolis, MN, USA), can be reimplanted so a dysfunctional valve stent can "re-habilitate" itself using another valve planted within it. The other commercially available valve for use in the right ventricular outflow tract is the Edwards SAPIEN valve (Edwards Lifesciences, Irvine, CA, USA), a balloon-expandable stainless-steel stent containing a bovine pericardial valve. Experience with its use in the right ventricular outflow tract is extremely limited. It has an advantage of maintaining valve function at larger diameters than the Melody valve [65].

Although the use of these prostheses requires specific training, technically implanting percutaneous pulmonary valves is very similar to implanting any large stent into the right ventricular outflow tract. Before implantation, care must be taken to ensure that there is not a coronary anomaly that may be affected by expansion of the right ventricular outflow tract. Other potential complications include conduit rupture and vascular damage related to the large-bore venous access sheath (24Fr).

Occlusion devices

Patent Ductus Arteriosus (PDA) occlusion

Porstmann *et al*. first described a percutaneous technique for permanent closure of the ductus arteriosus in 1968 [66]. The procedure was technically complicated, unsuitable for certain types of ductal morphology, and required a large-bore sheath in the femoral artery, Therefore, this plug never achieved widespread use. The Rashkind device was the first occluder to be used in significant numbers for transcatheter ductal occlusion. It was introduced commercially in 1979. The device was associated with significant problems, including occlusion of the left pulmonary artery and a high rate of residual shunting (15–20%). These factors eventually rendered it obsolete.

Controlled release coils such as the Flipper (Cook, Bloomington, IN, USA) or one of the Amplatzer family of PDA occlusion plugs (AGA Medical, Plymouth, MN, USA) are most commonly used currently for ductal occlusion (Figure 10.4a–d). Transcatheter coils have the advantage of deliverability through a small sheath from either a transvenous or trans-arterial approach. They are inexpensive and effective, particularly in smaller ducts. In a large PDA, there is the possibility of residual shunting, which necessitates the use of more than one coil, and hemolysis is relatively common [67]. For this reason, most operators now prefer Amplatzer plugs for ductal connections more than 2.5–3 mm in diameter at the pulmonary artery end. The original Amplatzer duct plug (ADO 1) has been available for over a decade, is easy to use, and is highly effective. The shape of the plug means, by necessity, that it has to be delivered from the venous side of the ductus. This results in the potential for obstruction of adjacent vascular structures (left pulmonary artery and descending aorta), particularly when large plugs are used in smaller children. Recently, a second Amplatzer duct plug (the ADO 2) has been introduced [68]. Primarily designed for smaller ducts, this device has two retention skirts (as opposed to one in the ADO 1) and can be delivered from either the venous or arterial end of the duct, through a sheath as small as 4Fr. Because of the second retention skirt, the length of the center of the device must be considered when deploying this device. Experience with the device is limited and operators are currently assessing what this new device adds to the existing armamentarium.

In addition to Cook coils and the Amplatzer ductal plugs, other devices such as Amplatzer atrial septal occluders, muscular ventricular septal defect occluders (generally very large ducts), vascular plugs, and other types of coils have all been used to occlude ducts.

Atrial septal defect closure

In 1974, King and Mills reported the first successful transcatheter atrial septal defect (ASD) closure [69]. The device used consisted of two umbrella-like prostheses which were independently opened inside the left atrium and then snapped together. Although the system was deployed with success in five adolescent and adult patients, it never developed into routine clinical use mainly because of the complexity of deployment and the size of the delivery system (22Fr). Subsequently, Rashkind introduced an atrial septal occluder in 1987, but it was not until it had been modified into a device known as the clamshell occluder that the first device used in significant numbers for ASD closure was born. This device has undergone a number of design iterations and is still used clinically [70,71].

Although a number of ASD closure devices are currently available for clinical use, by far the most frequently implanted is the Amplatzer septal occluder (ASO) that was introduced in the mid-1990s. In common with other occluders in the Amplatzer family, the device is made of a weave of Nitinol (an alloy of 55% nickel and 45% titanium), shaped, in this model, into a design resembling two buttons joined by a central core (Figure 10.5a and b). The central core means that the device self-centers within an atrial septal defect. Deployment of this device is straightforward provided that the defect to be closed is properly selected. For successful closure, there must be a margin of at least 5 mm around the important adjacent structures, the hole should be single (multiple defects can be closed, but require very careful assessment), the defect must be <40 mm in diameter (in practical terms usually less than this), and it is only suitable for secundum defects.

Delivery is via the femoral vein (with venous occlusion, a trans-hepatic approach can be used) under both fluoroscopic and ultrasound (either trans-esophageal or intracardiac echocardiographic) control. The device is loaded into a delivery catheter and the left atrial disk extruded into the left atrium before withdrawing it back to the atrial septum. Once the left disc is engaged, the central core and then the right atrial disk are deployed before releasing the device from the delivery cable. Other self-centering devices currently commercially available include:

- Occlutech Figulla device (Occlutech, Helsingbord, Sweden) – a Nitinol wire device similar to the Amplatzer occluder (Figure 10.5c and d).
- Lifetech Cera device (Lifetech Scientific, Shenzhen, China) – a Nitinol wire device with a ceramic coating similar to the Amplatzer occluder.
Figure 10.4 (a) Aortogram in the right anterior oblique projection (RAO) showing a small tubular patent ductus arteriosus (red arrow). (b) Repeat angiogram after occlusion with a Cook controlled-release (Flipper) coil. (c) Aortogram in the right anterior oblique projection (RAO) showing a larger ductus (red arrow). (d) After occlusion with an Amplatzer ductal occluder 1 (ADO 1). DA, descending aorta.

• Cardia Atriasept device (Cardia, Eagen, MN, USA)– the latest iteration of the Cardia family of devices with an internal Nitinol and titanium frame covered by poly(vinyl alcohol) (PVA) sails.

Non centering devices (essentially two disks but no central core) include:

• Gore Helex device (Gore Medical, Flagstaff, AZ, USA) – a single Nitinol wire frame with polytetrafluoroethylene (PTFE) patch along its length. The device cork-screws into two discs which can be deployed on either side of the atrial septum (Figure 10.5e and f).

A large amount published data attests to the safety and long-term effectiveness of percutaneous ASD closure, particularly with the Amplatzer septal occluder [72,73]. Device fracture has not been reported with the ASO but occurs with other designs, particularly where wire limbs are an integral design feature. Device closure is as effective as surgery [74]. Risks include device embolization (generally the ASO can be removed percutaneously if this happens) and, most importantly with the ASO, cardiac erosion, which although a very rare complication is potentially life threatening and thought to be related to over-sizing of the device [75].

Ventricular septal defect closure

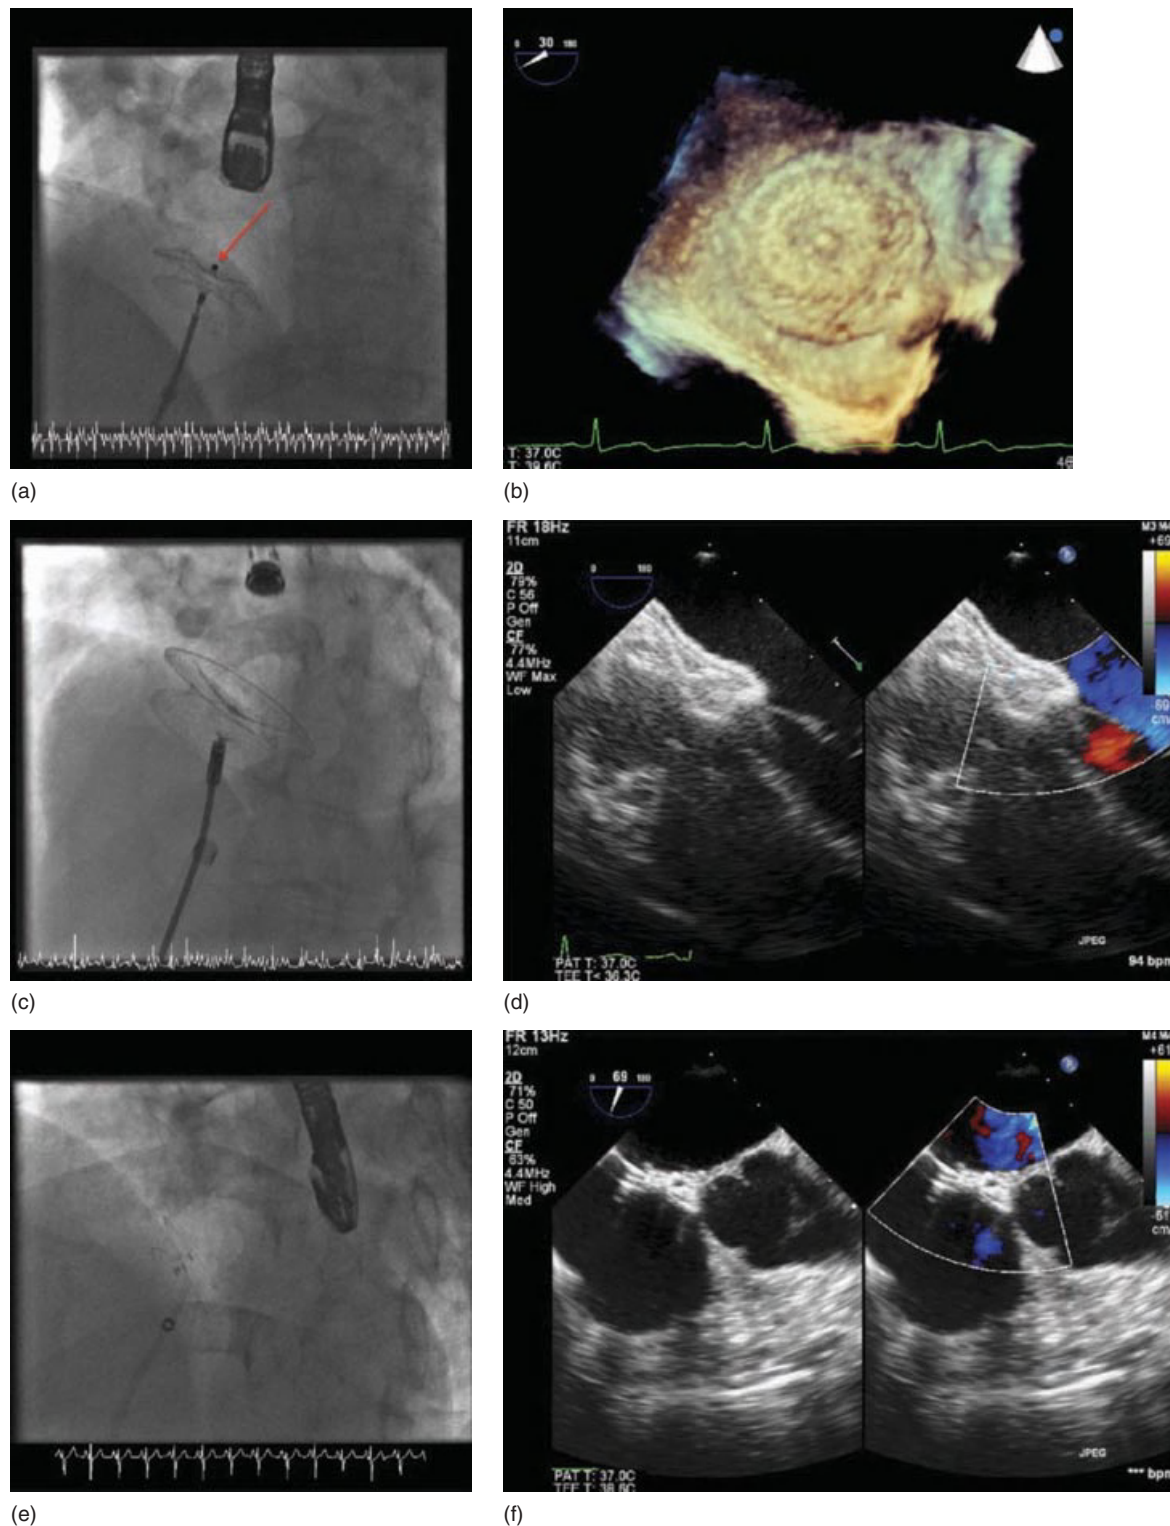
The ventricular septum is a complex structure and device closure of any ventricular septal defect (VSD) is technically challenging. Muscular VSDs can occur in various positions in the septum and may be multiple. They are often difficult for cardiac surgeons to find and close. Although a number of


Figure 10.5 (a) Amplatzer septal occluder during atrial septal defect occlusion prior to release from delivery cable. Note the left retention nipple on the left atrial disc (arrow). (b) Three-dimensional echocardiographic view of the left atrial aspect of the Amplatzer device immediately after deployment. (c) Occlutech Figulla septal occluder during atrial septal defect occlusion prior to release from the delivery cable. Note the absence of the retention nipple on the left atrial disc and the different delivery cable allowing increased articulation of the device against the atrial septum. (d) Trans-esophageal echocardiography after release of the Occlutech device. No left-to-right shunt is seen. (e) Gore Helex occluder during occlusion of an atrial septal defect. This device is composed of an PTFE patch supported by a single Nitinol wire frame. (f) Trans-esophageal echocardiography following release of the Helex septal occluder. Note the low profile of this device compared with the Amplatzer septal occluder and the Occlutech device.

trans-catheter-delivered devices have been used to close muscular VSDs, by far the most commonly deployed is the Amplatzer muscular VSD occluder (mVSD) [76]. This device is similar in design to the atrial septal occluder (ASO) but has symmetrical and wider occlusion disks and a larger, squarer waist. It comes in eight sizes up to 18 mm with a few larger devices specifically designed for occlusion of post-myocardial infarction-related ventricular septal defect. TEE guidance is essential. The device is deployed either from the femoral vein (for defects higher up in the septum) or from the jugular vein (if the defect is positioned towards the apex). The occluder can also be delivered using a hybrid approach through the wall of the right ventricle (see later) [76]. For trans-catheter delivery, the minimum patient weight is ~10 kg. In most patients, it is very difficult to cross the defect directly from the right ventricle, so creating an arteriovenous loop is advantageous. This technique allows the defect to be crossed from the smooth left ventricular side, after which the wire is positioned in either the pulmonary artery or the superior vena cava and snared and externalized through the venous sheath. The delivery sheath is introduced through the venous sheath and guided through the VSD along the guidewire. The device is then introduced and deployed, very much in the manner of an ASD occluder, relying on the ultrasound imaging for position before release. A number of other devices have been used for muscular VSD closure, including the CardioSEAL device (NMT Medical, Boston, MA, USA), various coils, and Amplatzer vascular plugs.

Complications can occur during trans-catheter VSD closure, one of the most common being hemodynamic instability relating to entanglement of the tricuspid valve apparatus in the arteriovenous loop. This problem often occurs if an ordinary end hole catheter is used to move from the right atrium to the right ventricle. The use of a Swan–Ganz catheter makes this less likely. The only solution once this problem has occurred is to remove the guidewire, wait for stability to return, and start again. Other complications include blood loss, arrhythmia, aortic valve damage, cardiac perforation, hemolysis, and the inevitable risk of access site injury and damage [76].

The anatomic margins of perimembraneous ventricular septal defects (PMVSDs) and their proximity to conducting tissue make them a very different prospect for percutaneous closure. AGA Medical produces an occluder with a deficient rim specifically designed for PMVSD occlusion, allowing the device to occupy a defect without interfering with the function of the aortic valve. Although readily implantable, the main concern has been the occurrence of heart block, presumed to be due to pressure exerted on the atrioventricular node by a stiff occlusion device. Long-term atrioventricular block (AVB) and the need for permanent pacing after device closure of perimembraneous VSD varies in incidence from 0.23 to 8.6% in reported series [77–79], despite efforts to

ensure that over-sized devices are not used. Large registry data suggest that this complication is less frequent in the hands of an experienced, higher volume operator. In some centers, the results are comparable to the <1% heart block rate achieved in large surgical series [77]. However, of more concern than the overall incidence of AVB is the occurrence of symptomatic late heart block long after device deployment in patients without previous evidence of post-deployment dysrhythmia [79,80]. Although perimembraneous VSD closure is still performed by a number of centers with particular enthusiasm for the technique, many cardiologists, because of the unpredictable nature of this complication, have returned to surgical closure of perimembraneous VSDs.

Occlusion of other structures

Nonoperative occlusion of vascular structures can be accomplished with a number of catheter-delivered devices. Initial procedures were performed in the 1970s using Gianturco coils (segments of 0.025–0.038 in spring wire with filaments of nylon embedded and preformed into coils of diameters ranging from 2 to 15 mm), which were created for occluding bleeding end arteries but were found useful in congenital heart disease patients [81]. This technology has developed and diversified such that a huge range of vascular occlusion devices are now available, including coils of varying sizes and consistency with differing release technology, Nitinol vascular plugs, and injectable microparticles for embolizing smaller bore vascular beds.

Embolization procedures frequently performed in congenital heart disease include occluding venous collaterals (e.g., in patients with venous shunts), arteriopulmonary collaterals (e.g., in patients with pulmonary atresia), coronary artery fistulas, and bronchial arterial systems in patients presenting with hemoptysis.

Technical details depend on the anatomy and the occlusion device used and are highly varied and beyond the scope of this chapter.

Foreign body removal

Indwelling catheters for chemotherapy, in addition to therapeutic devices implanted in the catheterization laboratory, have the potential to embolize. Therefore, transcatheter removal of foreign bodies is an essential part of the armamentarium of the interventional pediatric cardiologist. Most intravascular foreign bodies originate in the systemic venous circulation and lodge in the right side of the heart or pulmonary arterial bed. A high-resolution biplane imaging system is absolutely essential for foreign body removal. The operator must be able to localize the foreign body within millimeters and in three dimensions. Without this capability, the likelihood of successful retrieval is small.

Many catheter devices are available for intravascular foreign body removal. Most have been adapted from other

specialties, particularly urology and radiology. Retrieval devices include snares, retrieval baskets, and grabber devices of various diameters and configurations. In general snare devices are most useful, but each device has a special application for different types of foreign bodies in different locations. The retrieval device needs to be deployed through a sheath large enough to accommodate the captured foreign body. In general, it is best to use a long sheath where the tip is positioned immediately adjacent to the foreign body, and the retrieval device is delivered to the foreign body through the sheath.

With the proper equipment and technique, virtually all intravascular foreign bodies should be retrievable in the cardiac catheterization laboratory without the need for operative intervention.

Hybrid procedures

A combined operative–catheter approach to treat a patient with pulmonary atresia–intact ventricular septum was described as early as 1987 [82]. Over recent years, pediatric cardiologists and pediatric cardiac surgeons have recognized the limitations of each discipline, and that to treat some complicated patients with congenital heart disease a joint approach is best. As a result, a number of new joint therapeutic strategies have developed over recent years.

Hybrid palliation for hypoplastic left heart syndrome

Small babies with hypoplastic left heart syndrome are at high risk with conventional Norwood stage 1 palliation [83]. As a result, there has been a move to reapply the principles first described by Gibbs *et al*. [84] in which pulmonary blood flow would be controlled by the application of branch pulmonary artery (PA) bands while ductal patency (and hence systemic perfusion) is maintained using a stent. The procedure is possible even in very small infants. Although initially the procedures were performed separately, recently the entire palliative procedure has been performed through a single median sternotomy [85,86]. Following bilateral PA banding using slices of a standard Gore-Tex shunt, a purse string is applied to the external main pulmonary artery. Through this a sheath is placed and a guidewire passed through the PA, across the ductus and into the descending aorta. Angiography is then performed and an appropriately sized stent is delivered into the ductus to ensure patency. An unrestrictive atrial septum is essential, so balloon septostomy may also need to be performed.

The procedure allows palliation and somatic growth in babies for a number of months, allowing the child to reach a size where both Norwood stage 1 and 2 procedures can be performed, leading to surgical creation of a neo-aorta and a

Glenn shunt to maintain pulmonary blood flow. The hybrid palliation procedure has undoubtedly expanded the repertoire of treatment for a group of patients with an otherwise poor outlook. Complications include obstruction of retrograde blood flow to the head and neck from the position of the stent and anatomic narrowing and pulmonary artery stenosis (particularly the left pulmonary artery) related to the surgically placed band.

Intraoperative pulmonary artery stenting

Percutaneous pulmonary artery stenting for branch pulmonary stenosis is accepted therapy for correctly selected patients. Occasionally the technique is limited by difficult access to the target lesion (particularly the left pulmonary artery), balloon/stent stability, vascular size, and hemodynamic stability in smaller patients. These can be overcome by a hybrid approach. Good imaging is essential for accurate sizing of the stent/balloon. The procedure requires a short period of low-flow cardiopulmonary bypass or circulatory arrest. After surgical exposure of the pulmonary artery, a J tipped guidewire is passed distally across the stenosis. A balloon-expandable stent is then deployed. If facilities are available, the result can be immediately evaluated angiographically. A number of reports, in small cohorts of patients, have described the results of intraoperative PA stenting [87–89] and showed that the procedure is technically feasible in patients as small as 2.5 kg.

Hybrid ventricular septal defect closure

Muscular ventricular septal defects (mVSDs) can be closed by direct delivery of a device through the right ventricular wall. The technique is applicable in patients who are small, have vascular access issues, in whom trans-catheter closure of a particular defect is technically unfeasible, or undergoing concomitant cardiac surgery where device closure will shorten the cardiopulmonary bypass [76].

The procedure is performed through a median sternotomy, with trans-esophageal echocardiographic control. A portion of the right ventricle directly opposite the ventricular septal defect is identified. The surgeon then places a purse string suture in this area through which a needle is passed. Under ultrasound control, a guidewire is passed from the right ventricle, across the mVSD, and into the left ventricular cavity. Over this wire a standard sheath is positioned and the device is deployed.

Although the literature shows that the procedure is effective and safe, there are potential problems and complications shared with trans-catheter mVSD closure. For mVSD it is not infrequent for the right ventricular disk of the device not to conform fully to the septum in very apical defects. Also, the heart can be perforated with either a stiff wire or sheath, but since the heart is in direct vision this is obvious and can be surgically treated. Heart block is unlikely unless a very high defect is closed.

Other hybrid procedures

Many other lesions have been treated using combined approaches, generally in small numbers of patients, so relatively limited data are available in the literature. Valvar dilation procedures have been described, including treatment of pulmonary atresia with intact ventricular septum, where the difficult angle of approach to the pulmonary valve from the right ventricle can be addressed by a hybrid approach directly through a surgically placed purse string [90]. Hybrid ASD closure and treatment of coarctation have both been described [91].

11 Exercise Testing

Per Morten Frederiksen
Oslo University Hospital, Nydalen, Oslo, Norway

Introduction

Over the last 30 years, treatment of congenital heart disease has developed markedly, moving from issues of survival to quality of life and challenges to be met as adults [1,2]. Most children with congenital heart disease (CHD) experience reduced physical capacity that may affect their quality of life [3–7]. In most hospitals, consultation at a CHD center includes physical examination, cardiac ultrasound, ECG, X-ray, and conversation with the cardiologist. Recently, more centers have included an exercise test, often regarded as synonymous with testing aerobic capacity. However, physical limitations are not restricted to impaired aerobic capacity but also involve static and dynamic balance, muscle strength in arms and legs, and motor skills [8]. These functions receive little or no attention in daily medical practice, but are nonetheless important for the child's welfare. Limited motor skills and strength may restrict a child's activity level as much as reduced aerobic capacity.

Performing strenuous exercise requires transport of large amounts of oxygen to and carbon dioxide from working muscles. The maximum amount of oxygen transported before anaerobic metabolism begins (the anaerobic threshold) is termed the aerobic capacity. Maximal oxygen transport depends on:

- Excellent lung function to take in oxygen and excrete carbon dioxide.
- Excellent cardiac function that can be broken down into components via a rearranged Fick equation:

VO_2 = cardiac output × arteriovenous difference in oxygen content ($\Delta A\text{-}V_{oxygen\ content}$):

(a) cardiac output = HR × stroke volume = HR × LVEDV × EF

where HR = heart rate, LVEDV = left ventricular end-diastolic volume, and EF = ejection fraction.

(b) $\Delta A\text{-}V_{oxygen\ content} = \Delta A\text{-}V\% \times [Hb] \times 1.36$

where $\Delta A\text{-}V\%$ = arteriovenous difference in oxygen saturation and [Hb] = hemoglobin concentration. Therefore,

$VO_2 = HR \times LVEDV \times EF \times \Delta A\text{-}V\% \times [Hb] \times 1.36$

At maximal exercise in highly trained erect individuals, heart rate can triple, stroke volume can increase by 50–100%, and arterial oxygen extraction (a function of muscle perfusion and metabolism) can double. Aerobic capacity is therefore reduced if lung function is reduced, with anemia, with deconditioned (untrained) muscles, or if the heart cannot increase rate or stroke volume appropriately. An exercise test allows these components to be evaluated.

The onset of anaerobic metabolism is detected by measuring the respiratory exchange ratio (RER), the ratio of CO_2 produced to O_2 used. The RER reflects muscle metabolism and is normally 0.8; a value of 0.7 indicates that fat supplies all the energy, and a value of 1.0 indicates pure carbohydrate sources. A rise in RER from 0.8 to 1.0 reflects anaerobic glycolysis.

An aerobic exercise test gives instant knowledge about progression of the disease and is widely used to estimate timing of surgery. It may also assess the result of a surgical procedure, and determine if drug treatment is effective. An exercise test is also useful for detecting arrhythmia, particularly at higher heart rates. Perhaps the most important aspect of an exercise test is reassurance for the child and the parents about the safety of exercising. Many parents and indeed cardiologists are afraid of letting a child with CHD perform high workloads. The patients themselves may be anxious and an exercise test may allay concerns.

An exercise test of aerobic capacity is believed to be the most informative and important physical test for children

with CHD. It gives instant information about the changes in blood pressure, oxygen saturation, heart rhythm, and heart rate with exercise. The heart's ability to increase its cardiac output is the central limitation of aerobic capacity [9]. Together with spirometry, an exercise test gives extended information about a child's lung and heart status. This chapter describes different methods, protocols, and guidelines for performing an aerobic exercise test in children with CHD.

In the complex interaction between the heart and lung, a heart defect may mask a lung disease (primary or secondary to longstanding heart problem), and it may sometimes be difficult to distinguish between heart and lung disability in children with CHD. Spirometry before, during, and after the exercise test may be helpful. It is also sometimes difficult to distinguish between general deconditioning (unfitness) and heart disease. which may be distinguished by the maximal heart rate. Healthy children in poor physical shape usually show a pattern of rapidly increasing heart rate at low levels of resistance, reaching a normal heart rate maximum near 200 beats per minute. A child with a heart disease usually has maximal heart rate below 180–200 beats per minute.

Test methods

Various methods and protocols give different results. Depending on age, diagnosis, and physical ability, one should choose the method and protocol with care. The first consideration is the method that ideally should reflect the activity that the test subject normally participates in, usually bicycling, walking, or running. Bicycle and treadmill are the most extensively used methods worldwide. Both have advantages and disadvantages (Table 11.1). For sport there are several methods in use for exercise testing, for example, an ergometer for rowing, paddling, skiing, stair climbing, swimming pools with resistance, and others.

Reclining bicycle

A reclining bicycle may be used to test response to exercise, but not maximal effort. This bicycle is extensively used for measuring heart function during exercise with ultrasound while the patient's upper body is fixed in one position. The patient reclines and a tilt to the left gives good images, even during heavy exercise [9]. The exercise values are not comparable to ordinary bicycle test results because of differences

Table 11.1 Comparison between bicycle and treadmill.

Parameter	Bicycle	Treadmill [10]
Body movement	Less	More
Comfort	Patients feel safer as no risk of falling	Risk of falling may make patients hold bars, lengthening the test and reducing work load[a]
Acceptability	Good because of familiarity	Children learn more quickly than adults
BP measurement	Easier with still upper body	Less easy, but can synchronize Korotkoff sounds with R of QRS complex.
BP level	Often higher, because of continuous leg movement and holding tightly to handle bars	
Maximal VO_2	Lower because fewer muscles active, and leg fatigue might cause early cessation of exercise[b]	Higher due to more muscle activity. May be lower if patient holds bars
Onset of anaerobic metabolism	Earlier because static (isometric) contraction of muscles around ankle and arms impedes flow	
Ease of measuring ECG	Easier with still upper body	Less easy
Ease of measuring SpO_2	Finger probe may mislead because of tight grip on handle bars[c]	Reflector probe on forehead avoids problem
Power measurement (watts)	Exact	Approximate
Effect of leg length	Fixed pedal arm gives patients with longer legs an advantage, making comparisons difficult	Leg length does not affect test
Effect of obesity	Support of body weight on seat reduces work load	Full weight involved. More like daily activity

[a]Close contact between the test supervisor and the patient eliminates falls and reduces the need for holding the handle bars [11].
[b]When using a bicycle, VO_2 might increase after the ending of the test. This is caused by the high resistance when pedaling that forces the muscle to have continuous high pressure on the pedals during every cycle. This reduces the venous return. When the pressure of pedaling is released, venous return increases and as a result a rise in VO_2 occurs 30–60 s after the end of pedaling.
[c]Do not have finger probe on same arm as BP cuff; preferably use an ear oximeter or reflector probe on forehead.

in body position and heart rate. In aortic or pulmonic steno-sis, an increase in gradient may be measured. Pulmonary hypertension may be estimated with this method [9].

Test protocols

There are numerous exercise protocols for both bicycle and treadmill [12,13]. The most extensively used protocol for treadmill is the Bruce protocol with its modifications [14]. Few protocols are designed especially for children [15]. In most protocols, there are mainly two types of incremental choices, step and ramp.

Step

Most protocols traditionally increase the workload in steps by increasing speed, incline, or both periodically. If only speed is used to increase work, the patients' motor skills may hinder them from achieving a high speed [8]. An increase in incline, especially if steep, may hinder patients with less muscle mass. The initial speed and incline are crucial for the outcome of the test. Too steep an incline may cause leg fatigue and premature termination of the test, similarly to a test on a bicycle, and too high a speed may cause coordina-tion problems.

A simultaneous increase in both speed and incline often gives large steps in workload, and may lead to stopping the test prematurely. Some protocols alternate between increase in speed and incline every other step [14]. The protocols should be designed to reduce the stepwise increase in workload, as this may make it easier for patients to achieve maximal effort. The time on each step is impor-tant. Steps should exceed 2 min because the metabolism in the working muscle mass needs to reach a steady state. There is a time lag from the metabolism in the muscles to the measurement of metabolic markers at the mouth and oxygen analyzer. A protocol with too short steps will not register correct results at each step. Too long steps might tire the patient. Usually 2–3 min steps are used.

Ramp

A ramp protocol gives a continuous load during the whole protocol until fatigue occurs [16]. This has advantages in estimating ventilatory threshold. Most treadmills have a program that smoothes out a step protocol and permits the performance of a ramp protocol [17,18].

Risks

There are small risks when testing children with CHD. Some experience dizziness due to a vasovagal reaction (often due to anxiety before the test), but it is very rare (personal expe-rience: eight of 1800 tests). An abnormal cardiac rhythm

Table 11.2 Indications for terminating a test.

Parameter	Indications for terminating a test	
	Relative	Absolute
Fall in BP as workload increases (mmHg)	>10	>20
Systolic BP (mmHg)	>250	
Cardiac rhythm	Multifocal PVC, triple PVC, supraventricular tachycardia or bradycardia	Sustained ventricular tachycardia
Chest pain	Increasing	Moderate to severe angina
Other signs, symptoms		Dizziness, severe cyanosis
Electrocardiogram	ST depression >2 mm with horizontal or down-sloping curve	

is more common; however, many tests are performed to provoke arrhythmias Ventricular tachycardia is not common, and is easy to detect. Exercise testing of children with CHD is fairly safe and gives extensive information.

Despite a low risk of incidents, it is advisable for at least two persons to attend the test. A defibrillator must be avail-able. The test supervisors should receive regular training in resuscitation.

Criteria for terminating a test

The criteria for ending a test are extensively described in guidelines [10]. Experience has shown that many children may continue exercising despite reaching the target level [11]. This is a challenge for the supervisor, who should urge the patients to complete a test as near exhaustion as possible despite reaching or exceeding the predetermined criteria. If supervisors from different laboratories use the criteria as end points and do not encourage the patients to continue the test, lower values may result. In addition to the guidelines, there are relative and absolute criteria for ending a test based on medical reasons (Table 11.2).

Interpreting VO$_2$ values

In most oxygen analyzers used in exercise testing, there is a nine-plot page of significant graphs. This gives important information with regard to the heart and lung status during exercise, and is described in a book by Cooper and Storer [19]. There are, however, a few factors that are seldom described, especially the differences between tests that may

be considered significant clinically. The cardiologist should not accept as a significant change a difference of less than 10% from a previous test. There are several issues to be considered:

1 There is an error within any system independent of calibration. In most oxygen analyzers, there is a drift and error measurement of around 3–5%.

2 The values from a bicycle are on average 10% (3–18%) [20] lower than for treadmills. This may be very misleading when interpreting the results.

3 Reference values differ considerably between countries or cultures. Various cultures regard physical activity during childhood differently. Test supervisors may differ regarding the acceptability of forcing a child to exhaustion. Even though there are criteria for ending tests [10], studies show that it may be the supervisor's ability to encourage the child to fatigue that has a large effect on the results [11]. Therefore, the reference material used should be from the same geographic area as the child and preferably done by the same supervisor. All laboratories covering an extended geographic area should have their own reference material.

4 When retesting a child after one to several years, the growth and increase in body weight must be considered. Because the increase in VO_2 does not vary linearly with weight, a correction factor must be used. Several correction factors are available, the easiest being $kg^{-0.67}$ or $kg^{-0.75}$, based on theories of body size and body production of heat, respectively [21].

5 The child's motivation during the test may play an important role in the results.

Considering all these factors, several pitfalls in interpreting a test are evident. For example, if the system has drifted 3%, the reference material is for a different method or a different country, a correction factor to account for the relationship between VO_2 and body weight is not used, or the patient has not been pushed to the limit of exhaustion, the result may be adversely affected and lead to misinterpretation.

Precautions regarding some cardiac diagnoses

In most patients with simple lesions, there are few or no special precautions to be taken before an exercise test, except for those already mentioned. A few lesions, however, need special attention.

Left ventricular outflow tract obstruction

Patients with left ventricle outlet tract obstruction (LVOTO) are at increased risk of serious complications or death during an exercise test. Aortic stenosis and coarctation of the aorta are the most common causes of LVOTO. When severe,

several factors must be considered while testing. Due to the increased left ventricular systolic pressure, nerve impulses and blood flow may be hampered in the left ventricular wall. These patients are in danger of arrhythmias or complete loss of heart rhythm during strenuous physical activity. Some patients may experience pressure or pain behind sternum during heavy exercise, but others have no symptoms.

A drop in blood pressure more than 20 mmHg from one measurement to the next may be one indication of overload of the left ventricle. This occurs most often in patients with the most severe obstruction, and the blood pressure drop may be difficult to detect due to the difficulty in measuring BP during exercise. A better indication of severe LVOTO during exercise is ST depression. The development of an ST segment depression of more than 2 mm may indicate severity, especially if it occurs in leads V_{4-6}. Other symptoms of severity include dizziness and chest pain, but these are rare. The use of VO_2 as an indicator of the severity of a stenosis is often not useful in children since they maintain a nearly normal cardiac output.

Patients with severe coarctation of the aorta may develop significant upper body hypertension that may cause a subarachnoid hemorrhage during a heavy workload. Blood pressure should be evaluated carefully before an exercise test, and the workload kept lower until the coarctation has been treated. In comparison with valvar stenosis with its fixed orifice size, in muscular subaortic stenosis the obstruction becomes more stenotic with increased heart rate. If the goal in patients with aortic stenosis is to estimate the gradient, a reclining bicycle protocol with continuous ultrasound measurement is recommended because it gives instant information about the severity of a stenosis.

Fontan

Testing a patient with a Fontan circulation requires special attention. The VO_2 values in these patients mirror the cardiac output. Their severely reduced chronotropic response further affects the aerobic capacity. Their reduced pulmonary function, due to insufficient diffusing capacity, also affects the aerobic capacity [22]. An exercise test with its VO_2 values is therefore a good indicator of the functional status of the heart in Fontan patients. In general they have a limited ability to increase the cardiac output compared with patients with other cardiac lesions [23,24]. Their aerobic capacity drops significantly with age, so that this group of patients should have periodical exercise tests.

Atrial and ventricular septal defects

Patients with a small ASD usually have no limitations in their exercise activity. Those with a moderate or large ASD may be limited, but are usually not tested before the defect

is closed. Surgically corrected ASD and VSD have been considered not to be limited during vigorous exercise. Patients with pulmonary hypertension following closure of the defect [9] should have more frequent exercise testing, preferably with a reclining bicycle with ultrasound to assess the level of pulmonary hypertension.

Transposition of the great arteries

The arterial switch correction of TGA is believed to be preferable to the older atrial switch operation. It is certainly better for maintaining sinus rhythm, but the expected improvement in aerobic capacity is not evident. A study by Fredriksen *et al.* indicated that the atrial switch patients displayed a lower than normal aerobic capacity [25]. The low values may be explained by a failing systemic right ventricle. The anatomically more correct arterial switch heart should theoretically be better able to increase cardiac output with exercise, and have higher aerobic capacity values. Patients following an arterial switch group, however, also have reduced aerobic capacity. Chronotropic incompetence may be a plausible explanation. In addition, patients following both procedures show a decrease in VO_2 with increasing age. Although there are fewer older patients following an arterial switch, there are indications that their aerobic capacity declines with increasing age [26].

Conclusion

An exercise test is an important tool for assessing the functional status of children, adolescents, and adults with CHD. It provides vital information about any decline of cardiac function and also improvement following surgery, drug treatment, and exercise training. Several methods and protocols are used and these give different results. Therefore, an expert in exercise physiology should join with a cardiologist to evaluate these results. Exercise tests should not be limited to a few diagnostic groups, but rather be performed regularly in a variety of conditions to follow the patient's status across the years.

12 Thrombosis in Congenital and Acquired Disease

Lindsay M. Ryerson, M. Patricia Massicotte & Mary E. Bauman
University of Alberta, Stollery Children's Hospital, Edmonton, AB, Canada

Introduction

Advances in medical, surgical, and interventional therapy in children with acquired and congenital heart disease have increased survival. However, most of these children have an increased risk of thrombosis, with many ultimately developing this potentially life-threatening problem [1]. As a result, antithrombotic therapy, including anticoagulation and thrombolytic therapy, now plays a major role in the management of many children in a cardiac intensive care unit. Particular problems include mechanical circulatory support, systemic to pulmonary artery shunts, bidirectional cavopulmonary anastomosis, Fontan palliation, mechanical valves, central arterial or venous line-related thrombosis, and less commonly pulmonary embolism. Concurrently, these children have a high risk of bleeding, hence the risks and benefits of the use of antithrombotic therapy must be carefully considered, with the objective of maintaining balanced hemostasis.

Hemostasis is the reparative process for damaged vasculature in a closed high-pressure circulatory system [2]. The process restoring vascular integrity is modulated by regulatory mechanisms that prevent over-compensation which could lead to thrombosis. However, if these mechanisms are overwhelmed, excessive amounts of thrombin are produced and cause thrombus formation [2]. For understanding thrombus formation, the following discussion is limited to the most salient participating hemostatic components.

Normal hemostasis

Hemostasis is maintained through vessel wall, blood composition, and blood flow. Much of our knowledge of the physiology of hemostasis has come from the study of mouse models [2].

Normal physiologic hemostasis depends upon maintaining a fine balance between thrombosis (clotting) and hemorrhage (bleeding), the fundamentals being shown in Figure 12.1. The original model of hemostasis is the cascade model [3] where procoagulant proteins present in the blood [factors (F) XII, XI, HMWK, X, IX, VIII, VII, V, and II, and fibrinogen] are activated by a stimulus (e.g., sepsis, trauma, surgery) with thrombin (FIIa) being produced. Three pathways are described: the intrinsic pathway (FXII, XI, IX, and VIII), the extrinsic pathway (tissue factor and FVII), and the common pathway (FX, V, II, and I). where these pathways converge. Sequential activation of the factors within each pathway occurs, followed by thrombin activation of fibrinogen into fibrin, the precursor of a polymerized clot. The fibrinolytic system is then activated to break down the clot. Inhibitor proteins of hemostasis (antithrombin, protein C, protein S, α_2-macroglobulin) and fibrinolysis (plasminogen activator inhibitor 1) prevent massive clot formation or clot lysis, respectively (Figure 12.1).

Hemostasis involves the complex interaction of platelets with damaged vascular endothelium followed by activation of specific proteins to produce a fibrin platelet plug that will prevent bleeding, but not result in pathologic thrombosis. The cascade model of hemostasis (coagulation and fibrinolysis) excluded important cellular involvement in coagulation [4,5], and has therefore been revised to the cell-based model (Figure 12.2), which is a more accurate reflection of *in vivo* processes [5]. The endothelium of the vessel wall plays a major role in ensuring patency of vasculature by secreting three thrombo-regulating substances, nitric oxide, prostacyclin, and ectonucleosidase or CD39, which inhibit platelet adhesion and activation.

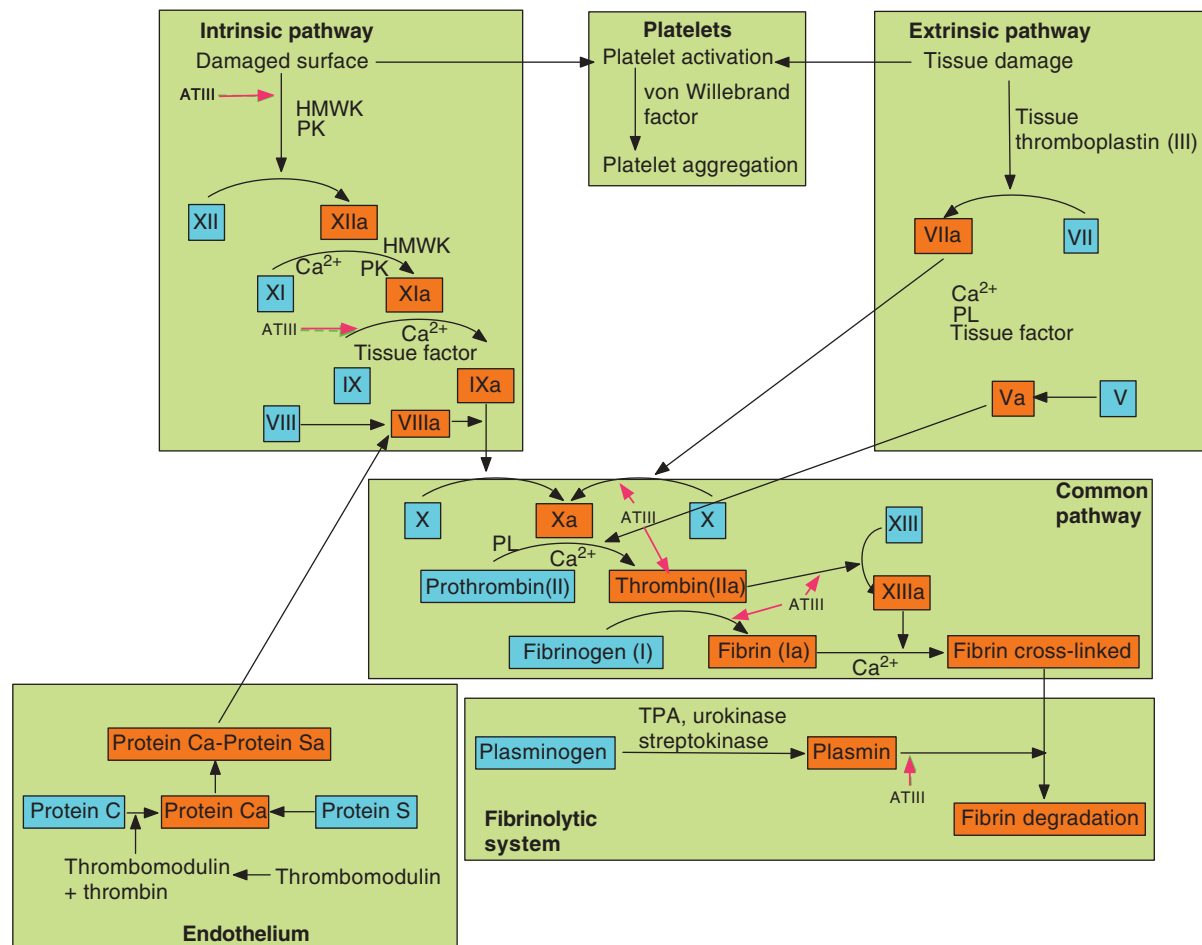
Vessel wall damage may occur from disruption, or more subtle endothelial cell alterations as hypothesized by Sacco *et al*. [2], resulting in activation of hemostasis. When vessel wall damage occurs, initiation of platelet activation occurs


Figure 12.1 Schema of coagulation cascade. Inactive proteins in blue; activated proteins in orange. Antithrombin III (ATIII) inhibition shown by red arrows. HMWK, high molecular weight kininogen; PK, prekalikrein; PL, activated phospholipids from platelets TPA, tissue plasminogen activator. Many of these components are involved in feedback systems (not shown) that modulate the response. The platelets play two roles: (1) they are activated by tissue factors and then with von Willebrand factor are aggregated; (2) most of the reactions in the common pathway take place at the platelet surface.
Figure 12.2 Coagulation phase of hemostasis. The coagulation phase of hemostasis occurs in three phases: initiation, amplification, and propagation. TF, tissue factor; vWF, von Willebrand factor. (Adapted from Becker *J Thromb Thrombol* 2005;**20**:65–8, with kind permission from Springer Science+Business Media.)

via two separate mechanisms, one invoked by collagen and the other by tissue factor (TF). Either or both mechanisms may predominate depending on the type of vasculature damaged or disease entity [6,7]. Exposed collagen in the subendothelial matrix interacts with platelets resulting in adhesion by two mechanisms: binding to von Willebrand factor (vWF) followed by platelet glycoprotein (GP) 1b–IX–V, and through direct interaction with platelet GPVI [8]. Shear force influences which receptor plays the foremost role in platelet tethering to the vessel wall, but GPVI and GP1b are essential for platelet adhesion [6,9,10]. Integrin $\alpha_2\beta_1$ also plays a lesser role in platelet adhesion [11,12].

Tissue factor in microparticles [13,14] circulates in its inactive form [15,16] and requires activation, which may occur through protein disulfide isomerase (PDI) released by activated endothelial cells and platelets [2,14]. Transformed TF activates FVII and FIX. The combination of FXa and FVIII, known as the tenase complex, activates FX. Activated FX (FXa) then combines with FV to form the prothrombinase complex, which in turn activates a small amount of prothrombin to thrombin. The minute amount of thrombin generated is a catalyst that activates FV and VIII to their most active cofactor forms, FVIIIa and FVa. Large amounts of thrombin are then generated as a result of the continued action of the tenase and prothrombinase complexes [17] (Figure 12.1). Thrombin activates fibrinogen to form nonpolymerized thrombus, but also activates platelets [18] (Figure 12.2) through cleaving protease-activating receptor 1 (PAR1), causing platelet granule release [adenosine diphosphate (ADP), which is stored in the dense granules, and serotonin and thromboxane A_2 which are stored in the α-granules) and further platelet activation. The compound ADP activates platelets through receptors P2Y1 and P2Y12 (Figure 12.3). Serotonin activates platelets through 5-hydroxytryptamine 2A (FHT-2A) receptors (Figure 12.3). Thromboxane A_2 activates platelets through the thromboxane receptor (TP) (Figure 12.3).

In addition to activating TF, PDI activates GP IIb IIIa ($\alpha_{IIb}\beta_3$) on platelets which binds to the ligands fibrinogen and vWF, thus promoting platelet recruitment to the thrombus and platelet–platelet interactions [19–21]. Increased affinity for the ligands occurs when platelets bound to the damaged vessel wall are activated and GP IIb IIIa undergoes a transformational change [22]. Blood flow shear rates determine the binding ligand with low and high shear rates binding with fibrinogen and vWF, respectively [8].

Microparticles circulate in the blood and carry proteins associated with their derived cell type (e.g., leucocytes, platelets, endothelial cells, smooth muscle cells, and monocytes). Activated platelets expose the protein P selectin [23] on their surface, which binds to circulating microparticles derived from monocytes that have the counter receptor displayed, P selectin glycoprotein ligand 1 (PSGL-1) [13]. Through this mechanism, TF exposed on these microparticles [13,14] is responsible for further thrombin generation and thrombus extension.

Developmental hemostasis

Children have physiologic differences in hemostasis and fibrinolysis compared with adults. Known as developmental hemostasis [24,25], the levels of activating and inhibiting proteins are decreased in both pathways (Figure 12.1). Differences include decreased levels of thrombus precursor proteins (FXII, XI, X, IX, VII, II), and inhibitor proteins protein C, protein S, antithrombin), and proteins of fibrinolysis (plasminogen and tissue plasminogen activator, tPA), and inhibitor proteins of fibrinolysis (plasminogen activator inhibitor, PAI-1). In addition, children generate less thrombin, FIIa, than do adults during hemostasis, with the composition of thrombi reflecting this. These differences affect the etiology, dosing, and management of anticoagulant and thrombolytic therapy, and also outcomes of thrombosis in children [26–28]. Understanding hemostasis and the differences in children compared with adults allows more informed antithrombotic therapeutic decisions.

Thrombophilia

Congenital thrombophilia refers to alterations in the levels of proteins that facilitate and inhibit clotting. Congenital prothrombotic disorders are relatively rare, but most commonly include FV Leiden, prothrombin gene G20210A, deficiencies of protein C, protein S, and antithrombin, FXII deficiency, and increased FVIII [17,19–25,27]. The influence of congenital thrombophilia on childhood thrombosis remains controversial. Furthermore, the need to screen for prothrombotic disorders in children with a major illness, undergoing an invasive procedure, or with a history of confirmed thrombosis, especially in the presence of clinical risk factors, remains uncertain. Most children with thrombotic abnormalities without an additional risk factor, such as central venous lines, arterial lines, prosthetic heart valves, systemic to pulmonary artery shunts, or superior or bicaval pulmonary-arterial anastamoses, do not develop thrombosis until adulthood [17].

Common measurement of hemostasis

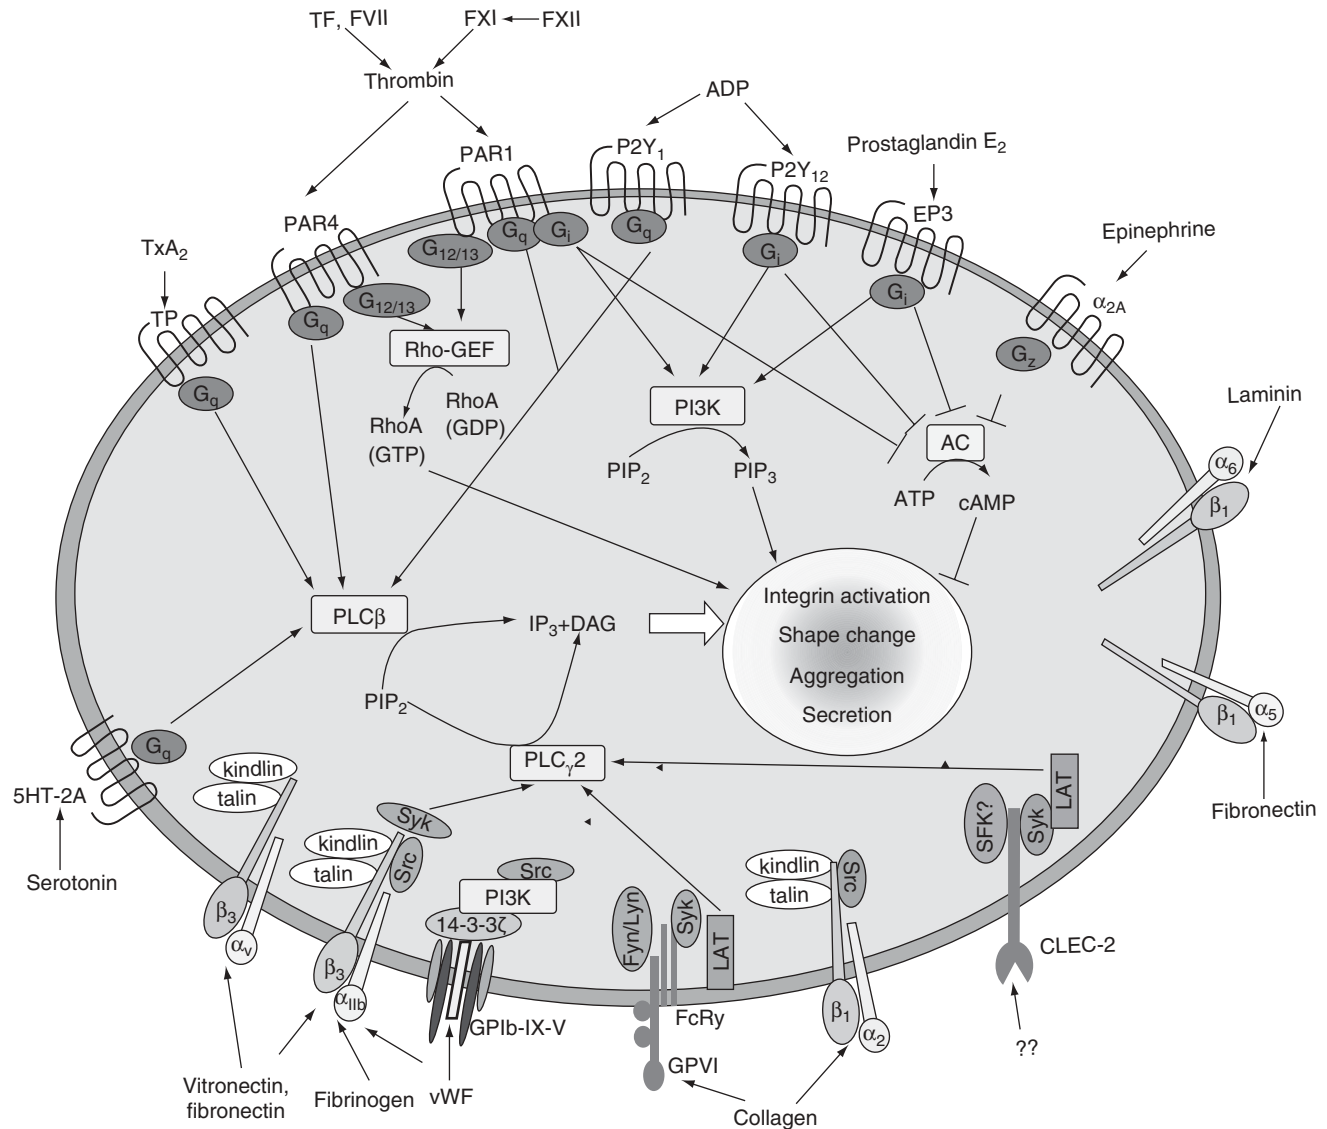
For measurements of hemostasis, blood should be obtained peripherally, particularly if low-dose heparin is administered through a central line to maintain its patency. Test results on samples drawn from central lines may be artificially prolonged from heparin contamination.


Figure 12.3 There are 2 principal pathways leading to platelet activation, adhesion and aggregation. Pathway 1: Soluble agonists [thrombin, adenosine diphosphate (ADP), thromboxane A_2 (TXA_2), serotonin] stimulate specific G protein-coupled receptors (eg. PAR, protease-activated receptor, 5HT-2A, 5-hydroxytryptamine 2A receptor, TP, TXA_2 receptor) and induce signaling pathways. Pathway 2: GPVI and C-type lectin receptor 2 (CLEC-2) trigger tyrosine phosphorylation reactions. Crosslinking of GPVI or CLEC-2 when binding to their respective ligands; collagen or unknown receptor, brings the SRc family tyrosine kinases, Fyn and Lyn, into contact with the FcRy chain starting a tyrosine phosphorylation cascade via Syk, the linker of activated T cells (LAT). These reactions result in activation of phospholipase (PL) Cy2, calcium mobilization and ultimately platelet aggregation. All platelet signaling events end in the final common pathway of platelet activation, up regulation of integrin adhesion receptors leading to stable adhesion and platelet aggregation. Integrins consist of 2 distinct chains known as α chain and β chain. TF, Tissue factor; TxA2, Thromboxane A2; TP, TxA2 receptor; PAR, protease-activated receptor; RhoGEF, Rho-specific guanine nucleotide exchange factor; PL3K, phosphoinositide-3-kinase; AC, adenylyl cyclase; PIP2, phosphatidylinositol-4, 5-biphosphate; PIP3, phosphatidylinositol-3,4,5-triphosphate;IP3, inositol-1,4,5-triphosphate; DAG, diacylglycerol. (With kind permission from Springer Science+Business Media: Stegner and Nieswandt, *J Mol Med* 2011;**89**:109–21.)

The partial thromboplastin time (PTT) and prothrombin time–International Normalized Ratio (PT–INR) are the most common tests. They are based on the cascade model of anticoagulation, and do not reflect the complexity of hemostasis. The PTT measures contact factors (FXI, XII), FII, VIII, and X, and the conversion of fibrinogen to fibrin. The PT–INR measures factors synthesized in the liver, including vitamin K-dependent factors (FII, VII, IX, X). The conversion to the use of INR is an attempt to account for different analyzers and thromboplastin reagents used in PT testing. In children and neonates, the normal PTT and PT–INR values are age-dependent secondary to hemostatic protein differences present during normal developmental hemostasis [24,25,29].

Hemostatic assessment (including preoperative or preinvasive procedure)

The laboratory tests included in the initial hemostatic work-up of a child should include the PT–INR, PTT, fibrinogen levels, and platelet count. A prolonged PTT or INR can result from several different phenomena and does not necessarily predict the clinical risk of bleeding. Furthermore, clinical bleeding may occur in a patient with normal age-appropriate test results. An example of a patient at increased risk of bleeding with normal screening hemostatic testing (INR, PTT, platelet count, and fibrinogen) occurs in congenital or acquired von Willebrand disease (vWD). Currently, unless there is a patient or family history of bleeding, vWD is not screened for preoperatively.

vWD occurs as a result of qualitative or quantitative deficiency in vWF. *In vivo*, vWF binds with FVIII as a stabilizer, protecting it from degradation, and, as discussed above, participates in platelet adhesion to damaged or altered vascular endothelium. If vWF is unable to carry out these functions, mild or major bleeding may occur. Congenital vWD has a heterogeneous phenotype ranging from mild to severe. Acquired vWD has been demonstrated to occur in situations of high shear stress, for example, mechanical heart valves and ventricular assist devices in adults. Treatment includes agents which cause either increased release of FVIII and vWF from endothelial stores (desmopressin, DDAVP) or replacement of vWF with vWF concentrates.

Prolongation of the INR or PTT requires formal evaluation to determine the etiology. These patients are sometimes felt to be "auto anticoagulated;" however, this may be a misnomer because these patients may be at risk for developing thrombosis depending on the etiology of the abnormal test. In a patient who is not anticoagulated, a number of clinical situations may prolong the INR or PTT and affect the risk for bleeding and/or thrombosis or have no effect (heparin contamination of a central line blood sample used for testing).

In adults, elevated D-dimer levels indicate active coagulation, fibrin production, and fibrinolysis. D-dimers have not been formally evaluated in children and therefore the pretest likelihood of confirmed thrombosis is unknown [30,31]. Furthermore, following cardiac surgery, D-dimers are always elevated, so the test is an unreliable measure of the presence of thrombosis. If baseline hemostatic test results are abnormal, experts in hemostasis (e.g., hematology) should be consulted for further evaluation.

Global measures of hemostasis

Global measures of hemostasis, the activated clotting time, and the thromboelastogram may be more representative of hemostasis as these tests use whole blood that includes cellular components in the test systems.

Activated clotting time (ACT)

The ACT uses activated whole blood and measures clotting time in seconds. This point of care test is used during cardiopulmonary bypass (CPB) and extracorporeal membrane oxygenation (ECMO) to monitor anticoagulation, specifically heparin effect. No well-designed studies have evaluated the safety and efficacy of ACTs to monitor anticoagulation in children. The ACT does not solely or accurately reflect the effect of heparin [32–34].

Thromboelastogram (TEG)

The TEG uses activated whole blood to measure hemostasis (formation of a clot) and also fibrinolysis (clot degradation). The most common devices used to measure thromboelastography are the ROTEM (Pentapharm, Munich, Germany) and the TEG (Haemonetics, Braintree, MA, USA). Although some normative TEG data are available in children, formal well-designed studies are required to evaluate the precision, accuracy, and application of this measure in children [35,36].

Thrombosis in children with congenital heart disease

Levels of coagulation proteins, fibrinolytic proteins, and inhibitors have been found to be abnormal in children with congenital heart disease (acyanotic and cyanotic) compared with age-matched controls. Depending on the specific coagulation abnormality, these children can bleed and/or thrombose. Decreased production of coagulation proteins (anticoagulant and procoagulant factors) have been implicated from delayed liver maturation, liver failure, and/or vitamin K deficiency. Children with acyanotic congenital heart disease achieve age-appropriate levels of their hemostatic proteins similarly to age-matched controls (1 year of age), whereas children with cyanotic congenital heart disease achieve age-appropriate levels by 4 years of age [27,28].

The following section describes the thrombotic risk in children after congenital heart surgery. The American Heart Association Guidelines [37] for antithrombotic/antiplatelet therapy are very useful.

Systemic–pulmonary artery shunts

Systemic–pulmonary artery shunts are a necessary part of first-stage palliation in neonates and infants with complex congenital heart disease. The classic Blalock–Taussig shunt (BTS) [38] has since been modified to include the use of prosthetic material. The modified Blalock–Taussig shunt (MBTS) interposes a Gore-Tex graft between the subclavian artery and ispilateral pulmonary artery. Shunt size depends primarily on patient weight, varying from 3.0 mm in smaller infants to 4.0 mm. Longer shunts have an

Table 12.1 Published incidence of systemic to pulmonary artery shunt occlusion.

Study	Year	Population	N	Occluded (%)
Al Jubair *et al.* [41]	1998	Mixed	418	6.7
Motz *et al.* [44]	1999	Mixed	46	33
Fenton *et al.* [43]	2003	Mixed	169	5.9
De Oliveira *et al.* [42]	2004	Post-Norwood	105	3.8
Li *et al.* [45]	2007	Mixed	954	10
Ahmad *et al.* [40]	2008	Mixed	22	9

increased risk of thrombosis; therefore, both size and length are important factors.

Several factors may lead to shunt occlusion. Neointimal hyperplasia, followed by platelet aggregation and adherence to the subendothelium, and then proliferation of smooth muscle cells is induced by the artificial material [39]. Turbulence may affect platelet aggregation by increasing platelet hyper-reactivity. Increased wall shear stress may lead to a prothrombotic state. The rate of shunt occlusion varies between 0 and 33% [40–45] (Table 12.1). This wide discrepancy in shunt failure may or may not be explained by different postoperative anticoagulation regimes [39,41,44,45]. The only prospective study found that patients receiving aspirin [acetylsalicylic acid (ASA)] had a lower risk of shunt thrombosis and lower rate of interstage death compared with the group without ASA [45]. Factors that increase the incidence of shunt failure include smaller conduit size [43,44], smaller patients [41], younger patients [41], and small pulmonary artery size [41]. The CLARINET trial, a randomized, double-blind, placebo-controlled trial, examined the efficacy and safety of clopidogrel and ticlopidine in neonates and infants with systemic to pulmonary artery shunt palliation (www.clinicaltrials.gov, NCT00396877). Most patients were also taking aspirin. The primary outcome was a composite end point including death, shunt thrombosis, and cardiac procedure prior to 120 days following an event considered thrombotic in nature. No difference in the composite endpoint was found between the two groups.

There are limited prospective data about direct antithrombotic management after a systemic-pulmonary artery shunt. Recommendations for infants with an MBTS as part of a Norwood procedure are similar to those for infants with an MBTS. On the other hand, the Norwood procedure with an RV–PA shunt may have a decreased rate of thrombosis because of the increased conduit diameter, but the increasing turbulence from the longer conduit may offset this. Some infants are palliated with a central shunt with a Gore-Tex graft between the ascending aorta and the main pulmonary artery. A central shunt has an advantage of being short (3.5 or 4 mm long).

Bidirectional cavopulmonary anastomosis (BCPA)

Thrombotic complications are rarely reported after BCPA [46–48]. There are no prospective data to support routine thromboprophylaxis; however, antiplatelet therapy may be considered.

Fontan procedure

Fontan palliation (total cavopulmonary anastomosis) is the final operation for children with a univentricular heart. Optimal surgical technique is unknown and includes the lateral tunnel Fontan procedure, the extracardiac conduit, or more recently the intra–extracardiac Fontan procedure. Each surgical connection has its own advantages and disadvantages, but no one technique eliminates the thrombotic risk. All three procedures expose patients to prosthetic material. The lateral tunnel Fontan procedure uses a Gore-Tex intra-atrial baffle to divert blood from the inferior vena cava to the pulmonary arteries. As such, prosthetic material is exposed to the left-sided circulation that may increase the risk of systemic embolization. The extracardiac and intra–extracardiac Fontan procedures use a 16–18 mm Gore-Tex conduit to baffle blood to the pulmonary artery. These prosthetic conduits have no growth potential. There is a theoretical risk of flow obstruction secondary to thrombus formation or the development of fibrosis and/or calcification.. Turbulence of blood and lost kinetic energy may predispose to right atrial dilation, stagnation of blood flow, and thrombosis. Hydrodynamics depend primarily on the connection geometry or, more specifically, the horizontal offset of the cavopulmonary anastomoses to avoid flow collision.

Venous thrombosis is a major cause of morbidity and mortality after the Fontan procedure [49,50]. An acquired prothrombotic state may occur secondary to increased levels of FVIII [27]. Additional hypotheses for these thromboembolic phenomena include low flow states, stasis in the venous pathway, right-to-left shunts, blind cul-de-sacs, prosthetic materials, and atrial arrhythmias. The reported incidence of thromboembolic events varies from 7 to 23% [51–55]. The incidence of intracardiac thrombus is >33% [56–58]. There is insufficient prospective evidence to anticoagulate children routinely after the Fontan procedure. McCrindle *et al.* performed a multicenter, international randomized trial of anticoagulation with aspirin versus heparin/warfarin for a 2 year period after the Fontan procedure in children [53]. Unfortunately, the study was underpowered and showed no difference in thrombosis, either intra- or extracardiac, between the two groups. Current prophylactic anticoagulation practices are based on theory and expert opinion.

Right ventricle to pulmonary artery (RV–PA) conduits

RV–PA conduits to direct pulmonary blood flow are common in patients with various forms of tetralogy of Fallot and pulmonary atresia, truncus arteriosus, aortic valve disease

following a Ross procedure, and D-transposition of the great arteries with ventricular septal defect and pulmonary stenosis. Little information is available about the thrombosis risk in these patients. There is no indication for long-term anticoagulation, but antiplatelet therapy may be considered.

Cardiomyopathies

Anticoagulation may be considered in infants and children with normal structural cardiac anatomy, but decreased ventricular function as with idiopathic, post-viral, or dilated cardiomyopathy. A left ventricular ejection fraction of <30% increases the risk for stagnant blood flow and intracardiac thrombus.

Valve replacement

A prosthetic valve is necessary when a child's native valve cannot be repaired surgically [59,60]. Biologic prosthetic valves (allograft or xenograft tissue valves) are typically placed on the right side (tricuspid or pulmonary positions). In contrast, mechanical prosthetic valves are preferred for the mitral and aortic positions, given the higher pressure and velocity of blood flow, the potential for rapid deterioration of tissue valves, and the dire consequences of valve failure in this anatomic position. Mechanical valves are generally contraindicated on the right side of the heart because of the lower blood pressure and flow velocity that may precipitate valve thrombosis and failure. Mechanical valves are sometimes used on the right side of the heart when the right ventricle is functioning as the systemic ventricle.

Long-term anticoagulation is unnecessary for tissue valves, but imperative for mechanical valves. Most studies examining mechanical prosthetic valve anticoagulation are retrospective and include small numbers of patients, hence high-grade evidence for prophylactic agent choice is unavailable. Most providers use a vitamin K antagonist with or without an antiplatelet agent. Valves placed in the mitral position pose an increased risk for thrombosis. The recommendations of the ACC/AHA Guidelines for Management of Patients with Valvular Heart Disease [37] are extremely valuable.

Intracardiac, arterial, or venous thrombosis

Symptoms of thrombosis depend upon the location of the thrombus. Intracardiac thrombus may be asymptomatic or cause congestive heart failure, pulmonary embolism, or sequelae secondary to an embolus, including stroke and organ or limb compromise. Intracardiac thrombosis is often an incidental finding for children with compromised cardiac function [56,61,62] and may be identified through echocardiogram, cardiac catheterization, angiogram, or cardiac MRI or CT.

Deep venous thrombosis in a limb commonly occurs in vessels where central catheters (venous or arterial) have been attempted or placed, including cardiac catheterization [63,64].

Symptoms include pain, swelling, skin discoloration, and altered perfusion [65,66]. The most sensitive methods for diagnosing upper system thrombosis are ultrasound for jugular venous thrombosis and venography for intrathoracic vessels. For symptomatic thrombosis of both the upper and lower system, ultrasound may be used; however, if the clinical suspicion for thrombosis is high and the ultrasound is negative, further imaging should be considered by magnetic resonance imaging (MRI) [67,68], computed tomography (CT), and/or venography of the suspicious venous or arterial system. No studies have determined the sensitivity and specificity of these imaging techniques in children, but they are commonly used.

Thromboses require rapid diagnosis and treatment to prevent thrombus extension or embolism. Management of children with venous or arterial thrombosis focuses on preventing extension, recurrence, or embolization of thrombus. The duration and intensity of therapy are based on recommendations for adults that may be excessive in children. It is reasonable to base therapy on adult recommendations [69]. Newly diagnosed thrombosis is treated with 5–7 days of heparin therapy and may be followed by continued heparin or warfarin treatment.

Anticoagulant agents

Therapeutic agents commonly used in children include heparin and oral vitamin K antagonists (warfarin). When patients are maintained within their defined therapeutic range, they will be adequately protected from the risk of thrombosis without unacceptable risk of side effects [26,70,71]. Newer agents, such as direct thrombin inhibitors, are available, although there are limited data available to support their use. Despite this, there are clinical situations, for example, in confirmed heparin-induced thrombocytopenia (HIT) [69,72,73], where these agents must be used.

Therapeutic agents (Table 12.2)

Heparin is a term that describes unfractionated heparin (standard heparin) and low molecular weight heparins (LMWH). Both are heparins with LMWH being modified using enzymes to reduce molecular size. This smaller molecular size results in a more specific inhibition of activated Xa.

Unfractionated heparin (UFH)

Unfractionated heparin (standard heparin) remains a commonly used anticoagulant agent in hospitals for children at increased risk of hemorrhage (i.e., postoperatively) or when rapid reversal of anticoagulant effect is required [69]. Heparin is not absorbed orally, so it must be administered intravenously or subcutaneously.

Table 12.2 Anticoagulant agents. Heparin (unfractionated or low molecular weight) and warfarin are commonly used in children. There is little evidence supporting the use of direct thrombin inhibitors and therefore they should be reserved for patients with HIT. Currently bivalirudin or argatroban are the agents of choice for adults with HIT. Lytic therapy should be reserved for patients where there is a risk to life, limb or organ.

Anticoagulant and mechanism of action	Properties	Indications	Contraindications	Dose	Target range	Monitoring	Side effects
Unfractionated heparin (UFH)							
Potentiates antithrombin's inhibition of factors XIIa, XIa, Xa, IIa	$t_{1/2}$ dose dependent (max. 150 min) Hepatic and renal clearance Completely reversible with protamine sulfate Poorly bioavailable, requires frequent blood monitoring Antithrombin required to achieve heparin effect. If no heparin effect achieved with high doses of heparin, determine antithrombin level as antithrombin supplement may be required	Treatment of thrombosis or increased risk of thrombosis when the risk of bleeding is considerable (i.e., postoperative period) or when the child undergoes frequent invasive procedures requiring reversal of anticoagulation	HIT (heparin-induced thrombocytopenia) Poor venous access due to parenteral administration and frequent monitoring is required	Age-dependent dosing: age <12 mo = 28 U kg^{-1} h^{-1} age ≥12 mo = 20 U kg^{-1} h^{-1}	Gold standard measure is anti-Xa 0.35–0.7 U ml^{-1} If anti-Xa not possible, then PTT 1.5–3 × baseline PTT	q 24h at minimum UFH (anti-XA) level is gold standard (0.35–0.70 U ml^{-1}) If it is necessary to use a PTT to monitor therapy, the PTT range must be determined by each hospital to correspond to UFH 0.35–0.7 U ml^{-1}	Hemorrhage reported as 1.5% (95% CI 0.0–8.3) HIT 0–2.5% May be associated with osteoporosis
Low molecular weight heparin (LMWH)							
Same as UFH, but greatest inhibition on factor Xa	$t_{1/2}$ = 5 h Highly bioavailable, "stable drug" Renally cleared Not fully reversible Low dependence on antithrombin. Requires 24h to clear anticoagulant effect	For treatment of thrombosis or as thromboprophylaxis when bleeding risk considered stable or as a bridge between heparin and warfarin postoperative or when child has poor venous access	High risk for bleeding Reversal required frequently for interventions Hold LMWH × 24h pre-procedure Renal insufficiency	Age-dependent dosing	Doses are titrated to target LMWH level (anti-Xa) of 0.5–1 U ml^{-1}	LMWH level (anti-Xa) Target 0.5–1 U ml^{-1} Dose titrated to achieve level Minimum monthly levels INR or PTT will not be affected	Hemorrhage reported as 4.8–8.1% No evaluation of risk for HIT or osteoporosis
Enoxaparin q 12h	$t_{1/2}$ = 3–6h	Stable anticoagulant effect required		Age-dependent dosing: age <3 mo = ~1.5 mg kg^{-1} per dose age ≥3 mo = ~1.0 mg kg^{-1} per dose		LMWH level 4–6h post-dose	
Tinzaparin q 24h	$t_{1/2}$ = 3–6h	Needle phobic children on long-term therapy		200 U kg^{-1} per dose		LMWH level age <5 years 2h post-dose, ≥5 years 4h post-dose	
Vitamin K antagonists (VKA)							
Warfarin VKA specifically inhibit the γ-carboxylation of the vitamin K-dependent proteins II, VII, IX, X, proteins C, S and Z	$t_{1/2}$ = 160h Oral administration Hepatic metabolism	Long-term anticoagulant therapy	Relative: <1 years of age unless mechanical valve in situ	Load: 0.2 mg kg^{-1} day^{-1} except for patients with Fontan, then 0.1 mg kg^{-1} day^{-1}. Maintenance: individualized dosing titrated to INR No studies in children evaluating warfarin dosing based on pharmacogenomics	Target INR range 2–3 Mechanical mitral valves 2.5–3.5	INR daily until therapeutic then decreased frequency when stable with minimum monthly testing Test INR with illness, medication, or diet change	Hemorrhage 0.5% per patient-year Increases with INR >8 Tracheal calcification, hair loss, decreased bone mineral density Consider administering vitamin K for INR >8

Table 12.2 (cont'd)

Warfarin dosing nomogram^a: maintenance phase

	Target INR 2.5 (2–3)	Target INR 3 (2.5–3.5)	Dose adjustment
INR	1.1–1.4	1.1–2.0	Increase dose by 20%
INR	1.5–1.9	2.1–2.4	Dose increase by 10%
INR	2.0–3.0	2.5–3.5	No change
INR	3.1–3.5	3.6–4.0	Decrease dose by 10%
INR	>3.5–4.0	4.1–4.5	Administer one dose at 50% < maintenance dose, *then* restart at 20% < previous maintenance dose
INR	4.1–5.0	4.6–5	Hold 1 dose, *then* restart at 20% < previous maintenance dose
INR	>5.0		Hold 1 dose. Check INR next day. Consider reversal if bleeding or if high risk for hemorrhage

^aThis nomogram is intended for use once the loading phase is completed. Prior to each dose adjustment, assess the patient for medication change, illness (cold, flu), and adherence. New oral agents that inhibit either factor Xa or IIa are being tested in children and have advantages over VKA (e.g. less monitoring, no interactions). Completion of clinical studies using these agents in adults has allowed approval of many of these agents for specific clinical indications [101].

Antiplatelet therapy

Antiplatelet	Properties	Indications	Contraindications	Dose	Target range	Monitoring	Side effects
Aspirin (ASA) Inhibition of COX-1 and COX-2 activity	Oral Oral $t_{1/2}$ = 2 h Irreversible platelet inhibition Discontinue ASA 7 days preoperation to allow if full platelet regeneration required	Platelet inhibition Thromboprophylaxis of stents Shunts: Blalock–Taussig Norwood, Glenn, bi-cavopulmonary Fontan Valves: bioprosthetic mechanical in addition to oral antithrombotic therapy for patients at high risk for thrombosis Kawasaki disease	Hemorrhage Ibuprofen within 4 h of ASA dose Bleeding Varicella, fever due to risk for Reye syndrome Lack of pharmacokinetic/pharmacodynamic data	1–5 mg kg^{-1} day^{-1} Max. 81–325 mg 80–100 mg kg^{-1} day^{-1} during acute phase of illness then 3–5 mg kg^{-1} day^{-1} for additional 6–8 weeks	None studied	There are no studies that link outcome to measuring ASA effect	Bruising, confusion, vertigo, nausea, vomiting, tinnitus, abdominal pain, cramping, burning, fatigue, bleeding

Anticoagulant and mechanism of action	Properties	Indications	Contraindications	Dose	Target range	Monitoring	Side effects
Clopidogrel Inhibition of ADP-induced platelet aggregation. No effects on arachidonic acid metabolism	$t_{1/2}$ = 7 h Renal clearance Discontinue clopidogrel 7 days preoperation to allow if full platelet regeneration is required	Failure of antiplatelet therapy in select circumstances. Antiplatelet therapy in varicella or 1 week pre- and 6 weeks post-varicella vaccine in place of ASA	Lack of pharmacokinetic and pharmacodynamic data (in progress, PICOLO/ CLARINET)	0.2–1 mg kg⁻¹ day⁻¹	None studied	There are no studies that link outcome to measuring clopidogrel effect	Fatigue, vertigo, stomach upset or pain, bruising, bleeding, diarrhea
Dipyridamole Adenosine reuptake inhibitor Two mechanisms have been proposed for increase in cyclic AMP, a platelet inhibitor	$t_{1/2}$ 2–4 min or 2.5h	Ventricular assist devices	Lack of pharmacokinetic and pharmacodynamic data	1–5 mg kg⁻¹ day⁻¹ 4 mg kg⁻¹ day⁻¹ divided q.i.d. Max. 15 mg kg⁻¹ day⁻¹	None studied	There are no studies that link outcome to measuring dipyridamole effect	Chest pain, angina pectoris, headache, vertigo, ECG abnormalities
Abciximab IIb–IIIa inhibitor	Kawasaki disease (lysis of thrombosed coronary aneurysms)	Kawasaki disease in addition to standard therapy	Lack of pharmacokinetic and pharmacodynamic data	0.25 mg kg⁻¹ bolus then 0.125 µg kg⁻¹ min⁻¹ ×12 h	None studied	There are no studies that link outcome to measuring abciximab effect	Nausea, vomiting, vertigo, irritation at injection site
Anticoagulant and mechanism of action	**Properties**	**Indications**	**Contraindications**	**Dose**	**Target range**	**Monitoring**	**Side effects**
Heparinoid Danaparoid Inhibition of Xa	Renal clearance $t_{1/2}$ = 24 h	HIT treatment	Lack of pharmacokinetic and pharmacodynamic data	30 U kg⁻¹ i.v. bolus then 1.2–2 U kg⁻¹ h⁻¹	Anti-Xa 0.4–0.8 U ml⁻¹	4–6 h post-bolus or each dose change	Hemorrhage
Direct thrombin inhibitors[b] Argatroban	Hepatic clearance $t_{1/2}$ 40–50 min Not reversible	HIT	Lack of pharmacokinetic and pharmacodynamic data	Age-dependent dosing: Age 6 mo–6 years = 0.5–1 µg kg⁻¹ min⁻¹ Age 6–16 years = 1–2 µg kg⁻¹ min⁻¹ Continuous infusion (max. 10µ/kg/min)	1.5–3 × baseline PTT (not to exceed 100s	PTT 2 h post-start of infusion and each dose change	Hemorrhage 6–15% with therapeutic PTT, prolongation of baseline PT (INR)
		ECMO		ECMO 50µg kg⁻¹ per 750ml circuit prime then 100µg kg⁻¹ per bolus if not already anticoagulated, then 1–2 µg kg⁻¹ min⁻¹	ACT 180–220 or 250–300		

Table 12.2 (cont'd)

Anticoagulant and mechanism of action	Properties	Indications	Contraindications	Dose	Target range	Monitoring	Side effects
		Cardiac catheterization/coil PCI		$150\,\mu g\,kg^{-1}$ $350\,\mu g\,kg^{-1}$ per bolus then $25\,\mu g\,kg^{-1}\,min^{-1}$			
Bivalirudin (Angiomax)	Enzymatic 80% and renal 20% clearance $t_{1/2}$ 25 min Reversible	Treatment	Lack of pharmacokinetic and pharmacodynamic data	Age <6 months[c] = $0.125\,mg\,kg^{-1}$ i.v. bolus, then $1.25\,mg\,kg^{-1}\,h^{-1}$	ACT 2.5 × baseline	Activated clotting time (ACT) 5 min post-i.v. bolus	2.4% hemorrhage
		CPB		50 mg to circuit, then $1\,mg\,kg^{-1}$ i.v. bolus, then $2.5\,mg\,kg^{-1}\,h^{-1}$	ACT 400–500 s		
		PCI		$0.75\,mg\,kg^{-1}$ i.v. bolus then $1.75\,mg\,kg^{-1}\,h^{-1}$ for duration of procedure May continue infusion for 4 h post-procedure or at $0.2\,mg\,kg^{-1}\,h^{-1}$ for an additional 20 h			
Lepirudin (Refludan)	Renal clearance $t_{1/2}$ = 80 min Not reversible	HIT	Lack of pharmacokinetic and pharmacodynamic data	$0.2\,mg\,kg^{-1}$ (max. 44 mg h^{-1}) i.v. bolus, then $0.1\,mg\,kg^{-1}\,h^{-1}$ (max. $16.5\,mg\,h^{-1}$)	PTT 1.5–2 × baseline Optimal PTT <65 s	PTT 2 h post-start of therapy and each dose change	Not reported in children. In adults 17% hemorrhage 30% develop anti-lepirudin antibodies

[b]There are no pharmacokinetic, pharmacodynamic, safety, or efficacy data for direct thrombin inhibitor use in infants and children. These agents should be reserved for circumstances where no other agent can be used and the Pediatric Thrombosis Program at Stollery Children's Hospital should be consulted prior to the use of direct thrombin inhibitors.

[c]No data available for children >6 months of age.

Unfractionated heparin therapy: dosing and monitoring

Dosing of UFH in children is age dependent (Table 12.2). Heparin doses are titrated based on laboratory measure of anti-factor Xa or PTT if anti-factor Xa measures are unavailable. Anti-Xa levels are commonly referred to as "heparin levels."

The internationally accepted standard measure of UFH is the anti-factor Xa level, with a target range of 0.35–0.7 U ml^{-1} [74] to reflect a therapeutic heparin level. Using the PTT to monitor heparin in pediatric patients is likely to be invalid because normal PTTs in infants and children are increased secondary to developmental hemostasis [75–78]. Equally, children have a different response to heparin than adults; therefore, the use of the PTT to monitor heparin therapy may be inaccurate. In addition, *in vitro* and *in vivo* data demonstrate significant variations in correlation of the PTT to the anti-Xa level in children [75–78]. Unfractionated heparin has a short half-life, clearing within 4–6 h of cessation of heparin administration, and is fully reversible with protamine sulfate. Venous access is required for administration and heparin infusions should not be interrupted for medication administration or blood sampling (due to the short half-life). Daily monitoring of the PTT and anti-Xa levels is required because of the poor bioavailability of heparin.

Heparin-induced thrombocytopenia (HIT) is an immune-mediated platelet reaction response to heparin. HIT is characterized by a sudden drop in platelets by more than 50% after 5 days of first-time heparin exposure or any time after a previous heparin exposure. The incidence among children is <0.1% [79–81].

Low molecular weight heparins

Low molecular weight heparins have rapidly become the anticoagulants of choice for pediatric patients without a bleeding risk [82–87]. These heparins have increased bioavailability and result in a more stable anticoagulant effect. Adult reports show equal efficacy to the higher molecular weight UFH and a decreased risk for hemorrhage. No well-designed studies have evaluated their safety and efficacy in children. There are three commonly used LMWHs (Table 12.2).

Low molecular weight heparin: dosing and monitoring

Dosing of LMWHs is age dependent [69]. Recent publications describing enoxaparin dosing have suggested that age-dependent dose requirements [88,89] may be higher than suggested in Table 12.2.

Monitoring the LMWH effect can only be performed using an anti-factor Xa level as LMWH maximally inhibits the activation of procoagulant FX. The influence of LMWH on the activation of FII is diminutive and therefore a PTT will not measure LMWH effect. Anti-factor Xa levels should be monitored monthly and dose adjustments be made to maintain an anti-factor Xa (LMWH level) (Table 12.2) as children often outgrow their current dose or some accumulation occurs over time due to insufficient renal clearance.

Low molecular weight heparins: reversal

If anticoagulation with LWMHs needs to be terminated for clinical reasons, discontinuation of LMWH injections for 24 h usually suffices. If an immediate reversal of effect is required, protamine sulfate reverses 80% of the anti-factor Xa activity of LMWHs.

Oral vitamin K antagonists

The most commonly prescribed oral vitamin K antagonist (VKA) is warfarin. Alternatively, in Europe and South America, phenprocoumon is commonly prescribed. Target INRs are specific to the indication for anticoagulation (Table 12.2). Frequent INR monitoring is important because of the variability of INRs in children from the following challenges:

• There is no pediatric formulation available, so accurate dosing is difficult.

• Children with congenital heart disease have complex underlying health problems that may require frequent reversal for invasive procedures, multiple medication changes, or illness-effect dose requirements.

• Inconsistent nutritional intake such as breast milk which contains little vitamin K, bottled formula with varying amounts of vitamin K, and normal age-appropriate fluctuations in daily intake.

• Increased susceptibility to respiratory infections and influenza as part of childhood which interferes with VKA metabolism.

• Poor venous access limits monitoring of VKAs that have a narrow therapeutic index.

• Anxiety and needle phobias.

• The unreported use of complementary alternative medications that may interfere with VKA metabolism.

• Possibility of life-long monitoring (i.e., mechanical heart valve), which results in many more patient years of anticoagulation.

A warfarin dosing algorithm is presented in Table 12.2. There are data among adults that indicate that the therapeutic range expands by 10% without a warfarin dose adjustment and increases over time in the therapeutic range [90]. The side effects of oral anticoagulant therapy (bleeding and new or extension of thrombus) increase with poor oral anticoagulant control. The event rate of side effects in children ranges from 0 to 0.5% per patient year and from 0 to 1.3% per patient year for bleeding and thrombosis, respectively [91,92]. Long-term VKA therapy in children may be associated with osteoporosis [69].

Vitamin K antagonist: reversal

The antidote for warfarin depends whether urgent or nonurgent reversal is necessary. For children at high risk for thrombosis (i.e., with mechanical valves), bridge anticoagulant therapy using *heparin* may be considered [69].

• Non-urgent reversal requires holding warfarin for 3 days pre-procedure [93].

• For semi-urgent reversal, vitamin K may be administered at a dose of 0.5–1 mg orally depending upon patient size [69,94]. Administering vitamin K either intravenously or intramuscularly is less efficacious than orally, provided that gut absorption is not severely compromised [95].

• For urgent reversal (major bleeding or interventional procedure), FVIIa 50 U kg^{-1} i.v. or FFP 20 ml kg^{-1} is administered. Octaplex is approved for VKA reversal in adults in various countries. The composition of 20 ml of Octaplex includes the human coagulation factors FII (220–760 IU), VII (180–480 IU), IX (400–620 IU), X (360–600 IU), protein C (140–620 IU), protein S (140–640 IU), and heparin (80–310 IU) and sodium citrate (17–276 mmol l^{-1}). Although not currently evaluated or approved for use in children, dose recommendations are 40 ml i.v. for a patient of adult size/weight [70]. For further dosing guidelines, see Ansell *et al.* [70].

POC INR monitoring: a solution to VKA therapy

The use of the POC INR meter represents a solution to manage VKA therapy effectively in children [96]. The POC INR meter uses a capillary sample to determine the INR, may be performed at home, and facilitates more frequent testing. As a result, the time in the therapeutic range is better than in children using laboratory INR testing [97,98]. POC INR meter use is believed to improve quality of life.

Direct thrombin inhibitors

Heparin-induced thrombocytopenia (HIT), developing rarely in children (less than 1% of those who receive UFH) is an extremely hypercoagulable state which occurs from development of an IgG antibody to the combination of platelet factor 4, presented on the surface of activated platelets, and glycosaminoglycan units of UFH. In a child who develops the HIT antibody, all UFH must be discontinued to avoid the antigen–antibody reaction that can result in massive thrombosis. In adults with HIT, the direct thrombin inhibitors (DTIs) argatroban and bivalirudin are recommended. In children, few studies have been completed with these agents [72,73,99]; however, they are used if HIT is confirmed and anticoagulation is required. Different clearance mechanisms exist with renal and hepatic clearance for bivalirudin and argatroban, respectively. Advantages include no reactivity with HIT antibodies and short half-life (in adult volunteers, 39–51 min for argatroban and 25 min for bivalirudin). Challenges of both agents include the inability to reverse the anticoagulant effect and inaccurate monitoring methods. Both agents should be monitored by an echarin (snake venom) clotting time, but currently this test is available only in research laboratories. The agents are monitored mostly by PTT and less often by activated clotting time [100].

Thrombolytic therapy

In life-, organ- or limb-threatening thrombosis, including pulmonary embolism, thrombolytic therapy is an appropriate therapeutic choice [26]. Tissue plasminogen activator (tPA) administered intravenously activates plasminogen, which then degrades thrombus. Few prospective studies in children have examined the dosing (range 0.01–0.6 mg kg^{-1} h^{-1} for 6–24 h), safety, and efficacy of this therapy. Reports of >30% major bleeding exist in the literature, hence discussion with parents before therapy is strongly recommended with documentation of informed consent. Monitoring the fibrinogen level should be carried out with replacement if levels are less than 100 mg dl^{-1} to avoid hemorrhage. The administration of fresh frozen plasma at 10–20 ml kg^{-1} every 8–12 h during therapy will maximize thrombolysis by ensuring an adequate plasminogen level.

Antiplatelet therapy

Multiple receptors participate in platelet activation, so single-target therapeutic agents may not protect against all mechanisms of platelet activation. The most common antiplatelets used are ASA, dipyridamole, and clopidogrel.

ASA acetylates enzyme cyclooxygenase, inhibits thromboxane A2, and causes irreversible inhibition of this enzyme, thus impairing platelet aggregation until the death of the platelets. Dipyridamole inhibits platelet phosphodiesterase. Clopidogrel inhibits platelet aggregation induced by ADP.

Antiplatelet therapy: dosing

• ASA 1–5 mg kg day^{-1}
• Dipyridamole 2–5 mg kg day^{-1}
• Clopidogrel 0.2 mg kg day^{-1}.

Various methods have been used to monitor antiplatelet effect (platelet aggregation, PFA100, Accumetrics, TEG); however, none have been associated with improved safety and efficacy outcomes.

Antiplatelet therapy: reversal

• Discontinuation of therapy is sufficient to clear effect (may take up to 7 days).

• Special consideration should be given to withholding aspirin with fever or exposure to chickenpox due to the small risk of developing Reyes syndrome.

• Immunizations and injections may be administered while on antiplatelet therapy. However, firm pressure must be applied to the injection site to minimize bruising.

• The manufacturer of the varicella vaccine recommends withholding ASA for 1 week before and for 6 weeks following varicella immunization.

Conclusion

The incidence of thrombotic complications continues to increase as a result of continued advances in medical and surgical cardiac therapy. Currently, there are few properly designed clinical studies to determine the *best* prevention and treatment in children with congenital or acquired heart disease with or at risk for thrombosis.

13 Genetic Testing

Nitin Madan & Bruce D. Gelb

Mount Sinai School of Medicine, New York, NY, USA

Knowledge concerning the genetic basis of congenital heart defects (CHDs) has expanded rapidly over the past decade and genetic testing has become an increasingly common part of clinical care for patients with CHDs. Established genotype–phenotype associations rationalize the screening of other organ systems and provide important prognostic information about clinical outcomes. Genetic information can be used to identify reproductive risks in families and recommend testing for other at-risk family members.

A wide array of genetic tests is available to assist the clinician in diagnosing genetic alterations in children with CHDs. Genomic technological breakthroughs are making today's laboratory methods outdated faster than ever. To remain current with the latest advances in this rapidly evolving field, the reader is encouraged to visit web sites that are updated regularly, such as Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim/) and Gene-Tests (http://www.genetests.org/), resources supported by the National Library of Medicine and the National Institutes of Health [1].

The objective of this chapter is to discuss techniques currently available for genetic testing. These include chromosomal analysis, fluorescence *in situ* hybridization (FISH), array comparative genomic hybridization (CGH) or chromosomal microarray analysis and DNA sequencing (Table 13.1). Commoner disorders with CHDs that illustrate their use are highlighted.

Chromosome analysis

In the mid-1950s, Levan and Tjio established that the diploid human genome consisted of 46 chromosomes [2]. The development of improved culture and slide preparations and the subsequent introduction of chromosomal banding techniques in the 1970s facilitated the identification of each individual chromosome. It was soon established that chromosome aberrations are present in 8–13% of neonates with CHDs [3]. Among all children with chromosomal abnormalities, at least 30% are born with CHDs with rates that vary with the specific genetic defect, ranging from that observed in the general population to nearly 100% for certain forms of aneuploidy, such as trisomy 18 [4]. Therefore, chromosomal analysis is now routine in children with various types of CHDs, especially if they have a recognizable syndrome associated with chromosomal defects.

GTG banding with metaphase chromosomes based on application of trypsin followed by Giemsa staining is the most accepted method for routine clinical settings [5]. Higher resolution banding of longer pro-metaphase chromosomes [6] has increased the number of identifiable bands in a haploid genome to over 550 (providing a resolution of ~5–10 million nucleotides). This technique better defines structural chromosomal abnormalities such as duplications, inversions, translocations, and interstitial or terminal deletions. In most laboratories, the required time for standard karyotyping is 1–2 weeks and up to 3 weeks for high-resolution banding. Postnatal chromosomal analysis is most commonly performed on peripheral blood lymphocytes. A number of other sources can be exploited, including skin fibroblasts, bone marrow, cord blood, amniotic fluid, and chorionic villi, the last two being relevant for prenatal assessments. Prior blood product transfusions are unlikely to impede chromosome testing considering the small volume of transfusion in relation to the total blood volume of the patient, especially if leukoreduced and/or irradiated blood products have been used. Many clinicians will defer testing in newborns and young infants after cardiac surgery with cardiopulmonary bypass due to the relatively larger blood volume loss and replacement.

Table 13.1 Genetic tests for congenital heart defects (CHDs).

Genetic test	Indications	Limitations
Chromosome analysis	CHD in a child with syndromic features and multiple organ system involvement	Inadequate resolution for visualizing aberrations smaller than 5–10 Mb
FISH	Specific heart defects or features suspicious for microdeletion syndromes	Limited number of probes can be used in parallel, clinical presentation must suggest area of genome to be tested, time consuming, difficult to automate
aCGH	CHD+[a], research setting towards the identification of novel loci in patients with identical malformations	Inability to detect balanced chromosomal translocations and inversions, cost, establishing the pathogenicity of identified copy number variations
DNA sequencing	Presence of CHD, particularly syndromic, previously associated with point mutations, research setting towards the identification of novel mutations causing CHD	Cost, relatively slow turnaround times, uncertain interpretation for novel sequence variants particularly missense changes

[a]CHD+: CHDs in association with other malformations.

The rate of association of CHDs with chromosomal abnormalities is higher prenatally (22–26%) than postnatally [7,8]. The likelihood of detecting aneuploidy increases with certain heart defects (e.g., atrioventricular canal defects) and if extracardiac anomalies are found [8]. Hence prenatal chromosome testing is generally indicated after detecting a fetal cardiac malformation, excluding small muscular VSDs. Amniocentesis and chorionic villus sampling (CVS) are the primary methods used to obtain cells for prenatal chromosomal diagnosis. An amniocentesis for chromosome analysis at 15–24 weeks gestation is considered optimal with respect to cell growth rates and the success rates with cell culture. CVS involves the biopsy of chorionic villi from the placenta at 10–14 weeks gestation via a transabdominal or transcervical catheter. The major advantage of CVS over amniocentesis is the ability to obtain a result earlier in pregnancy. The major drawback, however, is the relatively increased incidence of maternal cell contamination, estimated at 1–2% for CVS compared with <0.5% for cultured amniotic fluid samples [9]. Karyotyping of amniocytes and chorionic villi yields diagnostic accuracy for trisomies and sex chromosome aneuploidy of >99%. More rapid analysis to identify common aneuploidies can be accomplished in 1–2 days using interphase fluorescence *in situ* hybridization (FISH) with uncultured amniocytes or chorionic villi.

Clinical applications

Chromosomal analysis identifies structural chromosomal abnormalities, such as duplications, inversions, translocations, and interstitial or terminal deletions. Chromosome aberrations such as trisomy 21 in Down syndrome, 45,X in Turner syndrome, 47,XXY in Klinefelter syndrome, trisomy 13, and trisomy 18 are readily recognized. For certain

chromosomal abnormalities such as an unbalanced translocation, the parents should be analyzed for balanced translocations that indicate high recurrence risks.

FISH

FISH tests use fluorophore-labeled nucleic acid probes to visualize specific DNA sequences on chromosomes in metaphase or interphase. An appropriately sized probe that hybridizes specifically with the intended genomic target is tagged either indirectly with nucleotides containing haptens or directly using nucleotides containing fluorophores. Then interphase or metaphase chromosomes from the patient are prepared and attached to a substrate, usually a glass slide, and. the labeled probe is hybridized to the chromosomal DNA and visualized using a fluorescent microscope (Figure 13.1).

Subtelomeric FISH

Telomeres are thymine- and guanine-rich repetitive DNA sequences at the end of chromosomes that protect against degradation and also end-to-end fusion of chromosomes [10]. Because the adjacent subtelomeric regions are exceptionally gene rich [11], deletions, duplications, and subtle translocations involving these regions often have important phenotypic effects. Detecting abnormalities in these regions has improved significantly with the development of FISH probes for the entire set of human telomeres [12]. Subtelomeric FISH has been investigated in children with non-specific mental retardation and a normal karyotype, and detected 2.5% with submicroscopic abnormalities [13]. Of note, 50% of those defects are inherited from parents
Figure 13.1 FISH for 22q11 deletion. A metaphase spread obtained from cultured chorionic villi is hybridized with *TUPLE1* from the 22q11 critical region (orange) and a control probe from elsewhere on chromosome 22 (green). Absence of orange signal on one copy of chromosome 22 (arrow) indicates a deletion causing DiGeorge or velocardiofacial syndrome.

who are carriers of a balanced translocation and, therefore, the recurrence risk in offspring is high .Children with mental retardation and CHD may have these chromosomal anomalies, but subtelomeric FISH has not been studied systematically in large cohorts of children with CHD *per se*. Array CGH is supplanting subtelomeric FISH as it detects these lesions plus others affecting other portions of chromosomes [14].

Multicolor FISH

This technique involves the simultaneous visualization of all chromosomes using different fluorophores. Routine application of such techniques to human chromosomes started in 1996 with the simultaneous use of 24 human whole chromosome painting probes in multiplex-FISH (M-FISH) [15] and spectral karyotyping (SKY) [16]. Multicolor FISH techniques are extremely useful for detecting the origin of marker chromosomes, translocations, and complex rearrangements, especially those identified in hematologic malignancies and solid tumors [17].

Clinical applications

FISH is a sensitive technique capable of detecting chromosomal abnormalities with resolution down to 1–10 kb [18,19], and is widely used clinically [20]. Increasing numbers of probes can specifically identify regions of chromosomes especially vulnerable to deletion and/or duplication. In particular, FISH testing is now commonly used to confirm many microdeletion syndromes associated with CHDs.

DiGeorge, velocardiofacial (Shprintzen), or conotruncal anomaly face syndromes (DGS/VCFS/CAFS) are clinically related syndromes with overlapping features including CHDs, the most common ones being tetralogy of Fallot, truncus arteriosus, interrupted aortic arch type B, conoventricular VSDs, and aortic arch anomalies. Cardiac involvement with DGS is seen in ≥90% of patients [21]. Deletions of 22q11 are identified using FISH testing in 88–90% of patients with DGS [22,23] and 76% of patients with VCFS [22]. The deletions constitute the second most common chromosomal cause of significant CHDs and occur in one in every 68 children born with CHDs [24,25]. Because of co-morbidities associated with these syndromes, FISH for 22q11 deletions is commonly performed for evaluating fetuses and patients with the forms of CHDs associated with them.

Most 22q11 deletions occur *de novo*, although ~6% of affected children have an undiagnosed parent who is often mildly affected. Therefore, FISH testing is frequently offered to parents of affected offspring, particularly if they possess any potentially related clinical features. Those with a deletion are counseled for a 50% recurrence risk in each successive pregnancy [25]. The high spontaneous deletion rate of this segment of the genome arises from the existence of flanking, nearly identical blocks of DNA sequences, called low-copy repeats or segmental duplications, that result in meiotic errors (non-allelic homologous recombination) [26]. With an apparently *de novo* deletion, there is a small increase in recurrence risk for siblings, resulting from rare occurrences of parental gonadal mosaicism.

Williams–Beuren syndrome (WBS) is a contiguous gene deletion syndrome characterized by distinctive clinical features corresponding to deletion of specific genes. Associated cardiovascular manifestations include supravalvar aortic stenosis (SVAS in ≤70% of patients), peripheral pulmonic stenosis, and hypertension.

In this disorder, submicroscopic deletions in the chromosomal band 7q11.23 extend across a region of 1.5 Mb and encode 26–28 genes [27]. Rarely, smaller or very large deletions in this region are associated with milder and severe clinical phenotypes, respectively [27,28]. Deletion of the elastin (*ELN*) gene at this locus is the primary cause of the cardiovascular pathology. This was established by the discovery that individuals with intragenic *ELN* deletions or *ELN* point mutations have familial SVAS syndrome, which shares the same cardiovascular involvement as WBS. FISH testing for WBS using an *ELN* probe detects deletions in 96% of WBS patients.

Most instances of WBS occur sporadically, but autosomal dominant transmission has been described occasionally [29]. The WBS critical region is flanked by low-copy repeats rendering the region vulnerable to non-allelic homologous recombination. Asymptomatic parents do not carry the deletion and their likelihood of having a subsequent child with

WBS is <1%, slightly higher than the general population due to the possibility of gonadal mosaicism [27].

Limitations

FISH testing is useful for identifying specific genomic defects, but only a limited number of probes can be applied simultaneously. Detecting abnormalities of regions beyond the subtelomeres requires specifying the most probable probe(s) to use for hybridization. As most lesions detected with FISH are *de novo*, recurrence risks for parents are near the population level, so the benefit is for the affected child, including counseling for reproductive risks.

Array Comparative Genomic Hybridization (aCGH)

aCGH overcomes these FISH limitations by interrogating the entire genome simultaneously for deletions or duplications without any prior bias as to the regions of interest. The method requires genomic DNA from the patient, usually from blood leukocytes postnatally and amniocytes or CVS cells prenatally (Figure 13.2). The patient's DNA and control DNA, generally from a pool of normal individuals, are labeled with different fluorophores [often cyanine 3 (cy3) and cyanine 5
Figure 13.2 Array CGH. Genomic DNA from the patient (Test, red) and control (Reference, green) are labeled with different fluorescent colors and mixed in equal amounts. The mixture is hybridized to oligonucleotides (Target) that have been printed on to a glass slide. Computer imaging programs assess the relative fluorescence levels of each DNA for each target on the array (lower left). The ratio between control and test DNA for each clone is plotted linearly using data analysis software to visualize dosage variations, consistent with either a gain or loss of the genome (lower right), indicated by a deviation from the normal $\log_2$ ratio of zero. (Reproduced from Bejjani and Shaffer, *J Mol Diagn* 2006;**8**:528–33, with permission from the American Society for Investigative Pathology and the Association for Molecular Pathology.)

(cy5)]. The labeled DNAs are competitively hybridized to microarrays, on which oligonucleotides representing unique sequences spaced across the human genome are printed. After hybridization, the arrays are scanned to detect the fluorescence intensity at each oligonucleotide location and the cy3-to-cy5 ratio is established. Analysis then determines the genomic locations at which the cy3-to-cy5 ratios at consecutive oligonucleotides are skewed, consistent with either a gain or loss of the genome. The resolution of aCGH is determined by the number of oligonucleotides used. Current aCGH for clinical purposes relies on microarrays with 44 000–135 000 elements, providing resolution down to around 100 kb.

Applications

Clinically, aCGH detects aneuploidies, microdeletion/microduplication syndromes, and other unbalanced chromosomal rearrangements. Molecular karyotyping using aCGH also provides a platform for identifying new candidate disease genes. Examples are discussed below.

CHARGE syndrome has features that include ocular colobomata (C), heart defects (H), choanal atresia (A), retarded growth and/or anomalies of the central nervous system (R), genito-urinary defects and/ or hypogonadism (G), and ear anomalies and/or deafness (E). The estimated incidence of CHARGE syndrome ranges from 0.1 to 1.2 per 10 000 with CHDs reported in 75–80% of patients [30]. The cardiovascular malformations include tetralogy of Fallot, patent ductus arteriosus, septal defects, coarctation of the aorta, and complete and partial atrioventricular canal defects [31].

Identifying an overlapping microdeletion on chromosome 8q12 region in two affected individuals using aCGH [32] defined a critical region. Subsequently, DNA sequencing of positional candidate genes in other patients with CHARGE syndrome who were without apparent deletion led to the identification of point mutations in the chromodomain helicase DNA-binding gene (*CHD7*) as the primary cause of CHARGE syndrome. DNA sequence analysis can now reliably detect *CHD7* mutations in up to 75% of patients with the clinical diagnosis of CHARGE syndrome [30].

Congenital Heart Defects with other associated malformations

CHDs are commonly associated with dysmorphic facial features, developmental delay/mental retardation, and involvement of multiple other organ systems (sometimes called CHD+). When aCGH was performed in a cohort of children with CHD+ with normal karyotypes and no identifiable syndrome, putatively pathologic copy number variations (CNVs) were reported in 25% [33,34]. Some of these CNVs altered genes that had previously been implicated in causing CHDs.

Limitations of aCGH testing

Despite increasing use and excellent resolution, aCGH techniques are limited by their inability to identify balanced rearrangements such as translocations and inversions. In addition, genome-wide testing with aCGH uncovers numerous CNVs of unclear significance. Systematic studies have revealed large CNVs in apparently normal individuals, altering up to 12% of the human genome [35–37]. Their widespread presence can make the interpretation of clinical aCGH tests challenging. Most pathologic CNVs of interest clinically, however, are large (>500 kb), a size at which the number of benign CNVs in the general population is limited and most are robustly covered by survey studies.

A novel CNV in a patient with CHD does not necessarily indicate pathogenicity. Studying parental samples may help distinguish a pathogenic CNV from an inherited benign variation. Electronic resources that warehouse CNV data are important in establishing the clinical significance of submicroscopic aberrations detected by aCGH tests. Useful CNV databases include the Database of Genomic Variants (http://projects.tcag.ca/variation/), Children's Hospital of Philadelphia CNV (http://cnv.chop.edu/), and DECIPHER (https://decipher.sanger.ac.uk/application/).

DNA sequencing

Using DNA sequencing, the human genome sequence has been essentially decoded, identifying 20 000–25 000 genes and the regions controlling them. The Human Genome Project accomplished this using Sanger sequencing, still the primary method for sequencing-based mutation testing. Recently, new DNA sequencing techniques have been developed, which expand sequencing capacity, permitting the discovery of complex genetic traits including CHDs.

Sanger sequencing

Sanger sequencing, described in 1977, uses chain terminator nucleotides [38]. These dideoxynucleoside triphosphate (ddNTP) analogs of the normal deoxynucleoside triphosphates (dNTPs) lack a 3'-hydroxyl group, which is essential to the formation of an ester bond with an incoming nucleotide and resultant elongation of the DNA strand. In the sequencing process, fluorescently labeled ddNTP analogs of the four dNTPs (ATP, TTP, CTP, and GTP) are added to a medium containing a DNA template, a short primer, DNA polymerase enzyme, and the four dNTPs. The incorporation of a ddNTP in the elongating DNA strand results in its premature termination and formation of DNA fragments truncated to different lengths (Figure 13.3). The separation processes now use ultrathin gel and thin-walled capillary tubes, which lowers separation times by a factor of 25 relative to standard gels.

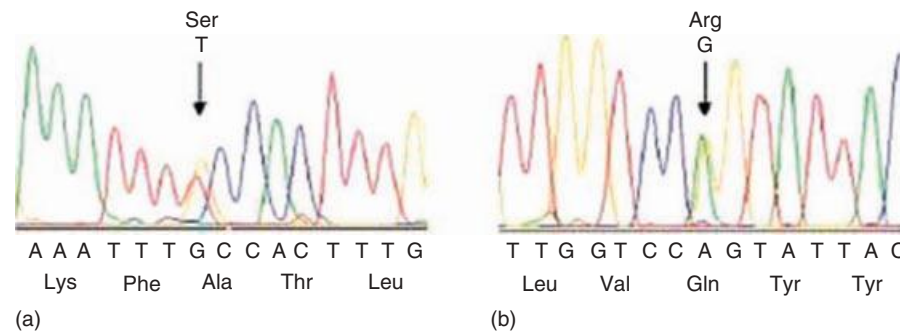
For most clinical applications, polymerase chain reaction (PCR) is used to amplify target sequences from genomic DNA prior to Sanger sequencing. Genes are comprised of variable numbers of protein-encoding exons, for example,


Figure 13.3 Sanger sequence analysis detecting point mutations. Shown are two examples of point mutations in exon 3 of the *PTPN11* gene causing Noonan syndrome. A G-to-T transversion (a) and an A-to-G transition (b) and the resulting changes in the amino acid sequences are indicated with arrows (note the double peaks). (Reproduced with permission from Pierpont ME, Basson CT, Benson DW Jr, *et al. Circulation*, 2007;**115**:3015–38.)

the *NKX2.5* gene has two exons whereas the *FBN1* gene has 65. DNA mutation testing of genes generally requires separate PCR and sequencing reactions for each exon with its flanking intron boundaries. Furthermore, this process is more extensive if a group of genes need to be tested, as occurs with genetically heterogeneous disorders such as Noonan and Alagille syndromes.

Clinical applications of Sanger sequencing-based techniques

Recent studies using familial linkage analysis and direct DNA sequencing identified several single-gene defects resulting in nonsyndromic CHDs. Mutations in *NKX2.5* have been identified in some familial and sporadic patients with atrial septal defects, especially associated with atrioventricular conduction abnormalities [39]. Transcription factor *GATA4* gene mutations were identified in two large families, one having multiple family members with atrial septal defects and the other with atrial septal defects, ventricular septal defects, and pulmonary valve stenosis [40].

Holt–Oram syndrome (HOS) is an autosomal dominant syndrome caused by mutations in the *TBX5* gene. Most patients have skeletal anomalies of the upper limb with preaxial radial ray malformation (e.g., triphalangeal, hypoplastic, or absent thumb and/or radial dysplasia) and 85–95% of patients have CHDs, most commonly ostium secundum atrial septal defects and muscular ventricular septal defects. Cardiac conduction disturbances ranging from asymptomatic first-degree heart block to complete heart block and sudden deaths are also important cardiovascular features [41]. Among patients who meet strict phenotypic criteria for HOS, mutation testing for *TBX5* gene reveals mutations in 54–74% of subjects [42,43]. Direct DNA sequencing of *TBX5* is available clinically.

Alagille syndrome (AGS) is an autosomal dominant disorder characterized by paucity of intrahepatic bile ducts, vertebral anomalies (butterfly vertebrae), ocular abnormalities (pigmentary retinal anomalies and anterior chamber defects,

particularly posterior embryotoxon), facial dysmorphism, renal anomalies, hematologic abnormalities (bleeding tendency), vascular anomalies, and CHDs. Cardiovascular involvement is observed in >90% patients with AGS, the most common pathology being pulmonary branch stenosis [44]. Other forms of CHD include tetralogy of Fallot, pulmonary valve stenosis, left-sided lesions, and septal defects. Point mutations in the *JAG1* gene and also large deletions or rearrangements of 20p12 which include *JAG1* have been demonstrated as pathogenic for this disorder. *JAG1* mutations can be identified in 94% of individuals with AGS [45]. Mutations in *NOTCH2* were reported in two of 11 *JAG1* mutation-negative probands [46]. *JAG1* mutations have been found in patients with a strong family history of isolated right-sided heart defects without other classic phenotypic features of AGS [47,48]. DNA sequencing of *JAG1* and *NOTCH2* is available clinically and *JAG1* FISH testing is needed to detect larger genomic events.

Limitations of Sanger sequencing techniques

Despite recent improvements, the throughput of Sanger sequencing is still limited. Read lengths of less than 1000 nucleotides are achieved in a single reaction and current sequencers can simultaneously process 30 lanes per run. The need to PCR amplify exons and their intron boundaries separately limits the number of assays that can be practically performed in parallel. Hence this approach is best for DNA mutation testing for one or two genes of modest size.

Microarray sequencing

The recent development of microarray sequencing techniques has allowed parallel sequencing, thereby immensely increasing throughputs and overcoming some of the limitations of Sanger sequencing. In clinical mutation testing, thousands of oligonucleotide probes (~18–20 nucleotides) are printed on the microarray chip followed by hybridization with the target DNA of interest prelabeled with a fluorescent

probe. The pattern of hybridization allows the target DNA sequence to be deciphered in a single analysis. Current microarray chips include more than 50 000 oligonucleotides on a 1.28 × 1.28 cm chip. The process is automated and many samples are run in parallel, generating large amounts of data rapidly.

Clinical application of microarray sequencing

Noonan syndrome (NS) is an autosomal dominant trait characterized by short stature, hypertelorism, ptosis, and CHDs. Some 80–90% of individuals with NS have valvar pulmonic stenosis and hypertrophic cardiomyopathy. Seven genes encoding proteins in the RAS signaling pathway (*PTPN11*, *KRAS*, *NRAS*, *SOS1*, *SHOC2*, *RAF1*, and *BRAF*) are causal in patients with this syndrome [49–51]. Moreover, a spectrum of disorders phenotypically related to NS, including LEOPARD, Costello, and cardiofaciocutaneous syndromes, also result from genetic alterations in this signaling pathway. In addition to mutations in some genes causing NS (*KRAS*, *BRAF)*, changes are observed in *HRAS*, *MEK1*, and *MEK2*. The proportions of these disorders accounted for by the currently known genes are variable. For instance, *HRAS* mutations are found in essentially all patients with Costello syndrome whereas the seven NS genes cover ~70% of instances of this disorder. RAS pathway mutation testing using a custom microarray chip design is available clinically. The test assesses the coding regions and splice sites of eight genes (*PTPN11*, *SOS1*, *RAF1*, *KRAS*, *BRAF*, *MEK1*, *MEK2*, and *HRAS*).

Limitations of microarray sequencing

For microarray sequencing, individual exons and their intron boundaries are still PCR amplified, limiting the number that can practically be assayed. This technique is also not robust for detecting small insertions and deletions, which is relevant for certain disorders, particularly those with loss of function.

Exome sequencing

The exome refers to the portion of the human genome formed by all of the exons that are translated into proteins and other purposeful gene products. The exome comprises 1% of the total human genome (30 million base pairs), but 85% of mutations with resultant disease-related traits occur in it. Hence exome sequencing is a potentially efficient strategy for identifying point mutations and CNVs and will drive genetic discovery of common birth defects, including CHDs.

The goal of exome sequencing required the development of two technological advances. First, generating the exon fragments for sequencing was not practical using PCR because it required nearly 200 000 separate reactions. Second, the sequencing capacity of the Sanger sequencing-based machines required impractically long periods of time

to complete this task. These problems have been overcome by the development of DNA sequence capture methods and so-called next-generation sequencing.

1 In targeted DNA sequence capture, specific DNA sequences are enriched from a larger pool of sequences by physically separating DNA fragments containing the target sequences from those that are not of interest. The process begins with oligonucleotide-based exome capture from a pool of sheared human genome. Currently available technologies use microarray chips or in-solution methods for hybridization and selection. This step of fishing through the genome requires a modest-sized sample (<10 μg) and provides an exome-specific catch of 90%. The captured DNA, to which short universal primer sequences are ligated on their ends, can be amplified simultaneously in a single PCR reaction and subsequently sequenced *en masse*. The same technology can be applied in a customized fashion for other genomic subsets (e.g., all genes known to cause CHDs).

2 Next-generation sequencing refers to novel approaches to achieve dramatically higher sequencing capacity. Currently available next-generation sequencers use various approaches to amplify DNA sequences clonally (emulsion PCR, solid-phase amplification) and then sequence the amplified clones (cyclic reversible termination, sequencing by ligation), which are then imaged with lasers. Additional approaches that avoid clonal amplification (i.e., use single-molecule templates) are approaching the market as this chapter is being written. The interested reader should consult one of the excellent reviews of this topic [52,53].

Current next-generation sequencers provide 60 million paired-end reads of 75 bp per lane, providing roughly 4.5 Gb of sequence in 9 days per machine. Using one lane per human exome results in a mean 40× coverage per base, 90% of targeted bases are read 10 or more times and 80% are read 20 or more times. These read depths are necessary in order to assure that both alleles are sequenced and to overcome the substantially higher read error rate of next-generation sequencing compared with Sanger sequencing. Recent studies using exome sequencing have demonstrated the speed, cost-effectiveness, sensitivity, and specificity of this method [54,55]. Discoveries of new gene mutations underlying human Mendelian disorders using exome sequencing have recently been published and larger numbers will emerge rapidly in the coming years.

Conclusions

In summary, cytogenetics is rapidly moving into the direction of molecular approaches and DNA sequencing capacity is dramatically increasing. These developments have improved diagnostic services as well as provided unprecedented research opportunities. The clinical indications for genetic testing for fetuses and patients with CHDs have

expanded dramatically, a trend that will continue in the years ahead. New genetic tests utilizing next-generation sequencing are likely to enter the clinical setting soon. Finally, affordable sequencing of the entire human genome appears within reach. Awareness of the wide array of genetic tests, including their utility and limitations, will assist providers caring for patients with CHDs.

Practices in Congenital Cardiac Surgery: Pulmonary Artery Banding, Systemic to Pulmonary Artery Shunting, Cardiopulmonary Bypass, and Mechanical Ventricular Assist Devices

James D. St. Louis & Roosevelt Bryant III
University of Minnesota, Amplatz Children's Hospital, Minneapolis, MN, USA

Introduction

This chapter has two sections. The first deals with cardiac operations that are not specific to a particular condition but are used to palliate anomalies with hemodynamic abnormalities of pulmonary blood flow. The second focuses on issues related to cardiopulmonary bypass and the principles and techniques of ventricular assist devices,

In the section on cardiac operations, pulmonary artery banding and aortopulmonary shunts are discussed because they are applied to a variety of cardiac malformations with increased or decreased pulmonary blood flow, respectively. The general principles are discussed here and specific applications to individual lesions are presented in the respective chapters. The Glenn and Fontan operations are also used for various conditions but are discussed in Chapters 35 and 39.

Pulmonary artery band

A pulmonary artery band (PAB) is a constrictor placed around a pulmonary artery:

1 It can decrease excessive pulmonary blood flow and pulmonary arterial pressure in patients with a large left-to-right shunt, thereby ameliorating congestive heart failure and decreasing the risk of pulmonary vascular disease. The main pulmonary artery is almost always used except for banding separately the left and right pulmonary arteries in the hybrid treatment of the hypoplastic left heart syndrome.

    a. Most patients who require biventricular repair today can have it performed as a single stage in early infancy, but at one time banding was performed as a palliative first stage [1–4], with complete correction delayed until the patient was large enough. A PAB is still needed for a few patients whose correction must be deferred because of the specific lesions, for example, multiple muscular ventricular septal defects, or because of co-morbidity such as intracranial hemorrhage, sepsis, or necrotizing enterocolitis.

    b. Patients who will eventually have a single ventricle repair must be protected against any increase in pulmonary vascular resistance that would jeopardize their outcomes [5,6]. In some patients with tricuspid atresia or double inlet left ventricle, subaortic stenosis may develop after PAB and a Damus-Kaye-Stansel procedure needs to be performed [7–9].

2 Patients who are to have an arterial switch for D-transposition or congenitally corrected transposition of the great arteries but have a low-pressure, thin-walled left ventricle must have the left ventricle conditioned by raising its pressure with a PAB placed on the main pulmonary artery [10,11]. An aortopulmonary shunt is often added to prevent severe systemic hypoxemia [12].

The band is a tape made from one of a number of materials. It is difficult to gauge the degree of constriction needed because the main pulmonary artery is narrowed by the intimal folds, which adds to the obstruction in an unpredictable way. Decisions are often based on body size or changes in systemic blood pressure or oxygen saturation. Intraoperative Doppler measurement has been used to assess the degree of constriction.

Despite its uses, a PAB has many complications. Because it is usually used in very small infants, a band ideal at the time of placement becomes too small as the child grows, and may

need to be revised. Some surgeons have used bands tied with clips or sutures in such a way that the band that becomes too tight can be dilated by a balloon. Others have used a variety of bands that can be adjusted after implantation, so that the band can be tightened or loosened as required.

PABs frequently distort and scar the main pulmonary artery, and may migrate distally and obstruct a branch pulmonary artery (usually the right). They have eroded through the arterial wall so that the constriction is abolished. Occasionally there may be formation of a pseudoaneurysm or a periarterial abscess, infective endarteritis at the site of the band, or thrombosis of the main pulmonary artery. There may be thickening of the pulmonary valve leaflets, and in some patients severe infundibular hypertrophy occurs. Scarring may make debanding difficult.

A few attempts have been made to insert flow restrictors into the branch pulmonary arteries by catheter.

Systemic to pulmonary shunt

Providing an alternative source of pulmonary blood flow by a palliative procedure has been practiced for the past five decades. As with the pulmonary artery band, the systemic to pulmonary artery anastomosis has been largely supplanted by the belief that early definitive repair of complex lesions is now regarded as better than an initial palliative and a secondary corrective procedure [13], although this has been questioned [14].

The first clinical application of the systemic to pulmonary shunt was accomplished by Alfred Blalock and Helen Taussig in 1944 when they anastomosed a subclavian artery to the ipsilateral pulmonary artery [15]. This operation is usually done on the side opposite the aortic arch to avoid kinking, and the subclavian artery is tied off to avoid a vascular steal. There were sometimes deleterious effects on the affected arm due to ischemia. Furthermore, although the shunts were seldom too large, their effect was impossible to predict [16,17]. Interestingly, the development of pulmonary vascular changes was slow [17]. Therefore, although many children benefited from this procedure, alternative approaches were sought.

Other operative techniques were developed to address these issues. One modification was Pott's procedure, in which an opening was made between the descending aorta where it crossed behind the left pulmonary artery. Although improving oxygenation, pulmonary vascular disease often developed, the left pulmonary artery could be distorted, and if the patient was ultimately to have eventually a corrective operation through a sternotomy it was difficult to take down this anastomosis. Another procedure was the Cooley–Waterston shunt, in which a communication was made between the aorta and the right pulmonary artery where it passes behind the ascending aorta. Unfortunately, the

openings were either too small and the patient did not get sufficient relief or too large and the patient could develop heart failure and ultimately pulmonary vascular disease [18]. Also, blood flow could be predominantly to one lung, which then developed pulmonary vascular disease while the other pulmonary artery could become stenotic or hypoplastic. Both procedures had a moderate mortality rate. Their importance, apart from historic interest, is that some older adult patients currently seen in ACHD clinics had these procedures during childhood and may manifest their long-term complications.

Almost all of these procedures have now been replaced by the modified Blalock–Taussig shunt. Through a lateral or posterolateral thoracotomy, the surgeon places a short segment of PTFE (usually 3.4–4 mm in diameter) between the subclavian artery and the ipsilateral pulmonary artery. This anastomosis can be performed with a partial occlusion clamp and a continuous monofilament suture. Placement on the side of the aortic arch is technically easier to construct, but more difficult to take down during the next staged procedure. Although flow through this shunt is controlled by the size of the subclavian artery, the length and diameter of the prosthetic material add an additional resistance to the blood flow. Tubes with diameters of 3–6 mm are available, but those <4 mm have a higher risk of thrombosis (see Chapter 12). The advantages of the modified BT shunt include less deformation of hypoplastic pulmonary arteries, less mediastinal dissection, preservation of arterial circulation to the upper extremity, and consistent shunt flow regardless of anatomic distance between the aorta and the pulmonary arteries.

Complications include those of any thoracotomy: pericardial or pleural effusions, chylothorax, sepsis, and occasionally Horner syndrome or phrenic palsy. In addition, there can be stenosis at the anastomotic site, true or false aneurysms (sometimes years after the operation), infective endarteritis, or thrombosis of the shunt. PTFE tubes are porous and sometimes cause seromas, a collection of peritubular fluid that may sometimes compress mediastinal structures.

Cardiopulmonary bypass

Extracorporeal mechanical support in infants and children has undergone a dramatic evolution in the past five decades that has allowed both the correction of intracardiac defects in small infants and the support of the failing myocardium for extended periods of time.

The first half of the twentieth century was marred by failure to support completely the circulatory system to the extent required to have timely and accurate repair of intracardiac defects. The materials utilized to construct these early devices were the same as those that were used in various

industries. Progress was also hampered by the inability to prevent blood from coagulating on contact with an artificial surface. With the introduction of heparin and protamine, the problem of safely anticoagulating a patient and then being able quickly to reverse these effects, coagulation became less of an issue. The greatest barrier was inability to oxygenate blood and dissipate carbon dioxide during the time that the patient's heart and lungs were not functioning.

In 1952, while working in Philadelphia, John Gibbon supported the circulation of a dog while performing an extended operative intervention within the heart. The machine that he used was a heavy stainless-steel device weighing >90 kg. Blood was pumped by three crude roller heads. The oxygenator was an enclosed battery of stainless-steel screens, each 40 cm tall and 25 cm wide. Blood flowed over each side of the six screens while being exposed to oxygen. This provided a surface area of 8 m² to expose blood to oxygen. The monitoring and safety systems were very sophisticated for the period, with the ability to monitor constantly the volume and pH of the blood. In February 1952, Gibbon applied his technology to repair an atrial septal defect in a 15-month-old child. The chest was opened via a right thoracotomy, the child was placed on the machine, and the heart was opened. Unfortunately, the diagnosis was incorrect, the child rapidly deteriorated, and postmortem examination revealed a large patent ductus arteriosus. A second attempt was made in an 18-year-old college student with repeated episodes of heart failure. A cardiac catheterization confirmed an atrial septal defect. On 6 May 1953, the complete closure of this atrial level defect was achieved utilizing the heart–lung machine. The patient was on the bypass machine for 45 min and awoke within 1 h following the procedure [19]. This successful closure of an intracardiac defect marked the beginning of the surgical treatment of both acquired and congenital cardiac disease.

The cardiopulmonary bypass circuit

Although the structure of the modern cardiopulmonary bypass machines varies significantly from the early Gibbon oxygenator, the basic design is very similar. Deoxygenated blood is removed from the circulation through a cannula usually placed in the right atrial appendage or occasionally the individual venae cavae. Blood is withdrawn either passively or under vacuum assistance to a venous reservoir. The blood level in the reservoir is closely monitored and can be manipulated as desired. This blood is pumped to a membrane oxygenator that incorporates a heat exchanger, which allows the patient to be cooled and subsequently warmed at the procedure's conclusion. The oxygen-enriched blood from the oxygenator is returned to the patient through a cannula in the distal ascending aorta. A hemofilter is often placed in the circuit to ultrafilter the blood either during or at the conclusion of the operation. The liquid in the cardiopulmonary bypass circuit prior to initiating extracorporeal

support is referred to as bypass prime. Important issues about specific components of the bypass circuit and the volume utilized will be reviewed.

In a 2 kg neonate whose total blood volume may be as low as 170 ml, the prime volume at the initiation of cardiopulmonary bypass may exceed the patient's blood volume by >200%. This results in dramatic hemodilution and an abrupt fall in the circulating hemoglobin concentration. What constitutes the lowest acceptable circuiting hemoglobin during support remains debatable. Generally, the hematocrit concentration is maintained at >25% regardless of the lowest temperature used during support [20]. Some maintain a higher hematocrit, up to 35% based on improved long-term neurological outcomes [21,22]. Banked packed red blood cells are usually used to maintain an appropriate hematocrit level in the prime solution. Packed red cells, especially if a few days old [23], have higher levels of lactate and potassium. Therefore, they may contribute to and worsen inflammatory response and increase hemodynamic instability upon initiation of cardiopulmonary bypass. Some institutions wash all packed red cells before adding them to the prime solution and only use red cells <5 days from donation [24]. Fresh whole blood used in the prime solution maintains colloid oncotic pressure and increases the level of circulating clotting factors[25]. Using transfused fresh whole blood following bypass has the advantage of maintaining more appropriate hemostasis, although the current literature does not completely support this idea [26]. Fresh whole blood has a higher glucose content in the prime solution, and hyperglycemia may be a risk factor for increased neurologic injury following bypass. Systems that harvest and maintain stores of fresh whole blood are expensive and logistically difficult to maintain. Using packed red cells to achieve the desired hematocrit level by the addition of fresh frozen plasma (FFP) optimizes appropriate coagulation in the presence of the hemodilution upon initiation of CPB. In one study, the addition of FFP to the prime solution significantly limited dilutional hypofibrinogenemia, decreased the need for cryoprecipitate after bypass, and decreased patient exposure to blood products [27].

Additional components of the prime solution include variable levels of electrolytes, buffers, calcium, glucose, and lactate. Calcium levels are generally maintained at a sub-physiologic level to prevent deleterious myocardial effects of ionized calcium during periods of arrest. More controversial additives include mannitol and steroids. Steroids may reduce the inflammatory response to cardiopulmonary bypass, but recent studies have questioned this common practice [28].

Ultrafiltration is an important process that removes both water and solutes during and after cardiopulmonary bypass. Conventional ultrafiltration (CUF) during the rewarming period of cardiopulmonary bypass uses a filter connected in parallel and allows the continual removal of excess fluid from the circuit [29]. Modified ultrafiltration (MUF)

is a similar process instituted at the conclusion of cardiopulmonary bypass with the circuit connected in series, for greater efficiency of filtration and increased concentration of red cells [30]. The major drawback of CUF is that the volume of fluid removed is limited by the circuit volume, because the volume in the venous reservoir must be sufficient to maintain adequate arterial blood flow. An advantage of MUF is that greater volumes can be removed from the bypass circuit.

The evolution of our ability to support infants and neonates has improved significantly the success with repair of congenital cardiac lesions. In-hospital mortality for repair of most congenital lesions is <2%. With these achievements, a significant emphasis has shifted to the long-term neurologic sequel and outcomes. The incidence of significant neurologic injury has been reported to be between 10 and 25% [31–34]. The occurrence of minor long-term neurodevelopmental deficits is likely to be even higher. These issues are discussed in detail in Chapter 52.

Myocardial protection

The ability of a surgeon to repair accurately and effectively even the most complex intracardiac lesions has been significantly enhanced by protecting myocardial tissue during periods of controlled cardiac arrest. The neonatal myocardium is immature, both structurally and metabolically. It differs significantly from the mature adult myocardium, particularly in its response to myocardial arrest and acute ischemia. Myofibrils are organized more randomly and sarcomeres are incomplete. T tubules and the sarcoplasmic reticulum are rudimentary, so that the neonatal myocardium is exquisitely sensitive to extracellular calcium levels, often depending on serum calcium to maintain adequate function. There are fewer mitochondria and these lack well-developed cristae. These structural differences lead to reduced oxidative capacity [35]. These differences from adults become less pronounced as a child matures.

The fetal and early immature cardiac metabolism depends on the consumption and breakdown of carbohydrates [36]. This is in sharp contrast to adult myocardium, which depends on free fatty acid oxidation. This ability to utilize energy stores anaerobically allows the immature myocardium to tolerate ischemia and recover myocardial function following a brief periods without coronary blood flow.

The ability to achieve an excellent result often depends on a motionless heart. Although techniques vary, electromechanical arrest is achieved by utilizing a potassium-based cardioplegia solution. While maintaining a clear operative field, continued myocardial protection is achieved by intermittent dosing of maintenance cardioplegia solution [37].

Cardioplegia is administered in two dosing regimens. An induction dose of 30 ml kg^{-1} is used to achieve rapid electromechanical arrest while at the same time reversing any metabolic anomalies that may have occurred within the myocardium. Cardioplegia solution is generally perfused anterograde under a strictly controlled pressure >120 mmHg [38]. The initial arrest can be achieved rapidly and consistently with a potassium dose of 15–30 mequiv per liter of solution. A potassium concentration >30 mequiv l^{-1} should never be used as it injures the myocardium. Decompressing the immature heart is critical during the initial arrest, as coronary perfusion pressure is indirectly related to intraventricular pressure, with a relaxed, empty heart having the greatest coronary perfusion. Once the initial delivery of cardioplegia solution is complete and the myocardium relaxed, subsequent dosing of maintenance cardioplegia is provided either anterograde or retrograde via the coronary sinus. Blood at a 1:4 blood:crystalloid volume ratio is often added to the cardioplegia solution to increase its buffering capacity.

Preventing ischemia depends on safe maintenance of electromechanical arrest. The accumulation of injurious byproducts of hypoxia has a dramatic effect on postoperative myocardial function and must be avoided by providing a periodic oxygen supply by intermittent administration of cardioplegia with a potassium concentration of 15 mequiv l^{-1} every 20–25 min during the arrest period. Also critical to myocardial protection is reducing myocardial energy demands by lowering the temperature of the heart by a combination of systemic and local hypothermia, maintaining the electromechanical arrested state of the myocardium, and keeping blood flow to the myocardium from noncoronary sources to a minimum. Although hypothermia has been considered to have the greatest effect on the reduction in oxygen demand, a great reduction comes from maintained cardiac arrest and preventing ventricular distension [39].

There is evidence that postoperative myocardial damage is due more to reperfusion injury caused by free radicals than to ischemia *per se* [40,41], so that myocardial protection is a function of not only of how the heart is arrested, but also how it is reperfused and restarted.

Left heart bypass

The incidence of paraplegia associated with operations on the aortic arch and proximal descending aorta has been reported to be 0.2–0.4% in children [42]. The occurrence of this devastating complication may result from several factors: age, degree of aortic obstruction, lack of collateral arteries, number of previous operations on the aorta, and duration of operative interruption of distal perfusion. Each factor can contribute to the development of spinal cord ischemia [43]. The use of partial cardiac bypass during blood flow interruption to the spinal cord theoretically protects against irreversible spinal cord ischemia [44]. Because the incidence of ischemia and the resultant paraplegia is extremely low and the number of patients who would require these techniques is small, it is unlikely that an unbiased, randomized clinical study will be accomplished. Therefore, the use of partial cardiac bypass has been based on retrospective and

small case studies [44]. "Partial cardiac heart bypass" during the repair of aortic arch anomalies represents a method to bypass the area of surgical repair while maintaining distal perfusion.

The procedure is often performed through a posterior-lateral thoracotomy with the side depending on the position of the aortic arch The technique is accomplished by removing oxygenated blood from the left atrium, either through the appendage or left upper pulmonary vein, augmenting perfusion pressure with a simple bio-centrifugal pump, and perfusing it into the distal aorta. At the time of cannulation, the patient is systemically anticoagulated with 50–100 U kg^{-1} of heparin. Depending on the patient's size, the outflow end of the circuit is placed into either the distal descending thoracic aorta or the femoral artery via a separate incision. The circuit is then meticulously de-aired as there is often no inline mechanism to capture air. The pump is started and distal flow and pressure are measured appropriately. During the procedure, it is critical to realize that pulmonary support must be given by a ventilator and cerebral blood flow maintained as it would be without the adjunct use of this bypass circuit. Once the cross clamp period is finished and the repair completed, the circuit is removed. Usually, it is unnecessary to reverse the heparin effects with protamine as the duration and degree of anticoagulation are usually minimal.

The considerations for use of this technique include the patient's age, degree of aortic obstruction, and the maturity of the collateral vessels. In general, newborns with a ductus arteriosus supplying the distal systemic circulation will not require bypass support during the aortic cross clamp period. An older child with a mild gradient across a coarctation and an insufficient collateral bed often needs perfusion to the distal aorta during cross clamping. Although specific data about minimal perfusion pressure are lacking, a mean arterial blood pressure of <40 mmHg during a test clamp is usually considered an indication for augmenting distal perfusion [45].

Mechanical ventricular assistance in the failing heart

Extracorporeal membrane oxygenator (ECMO)

ECMO has been used for ~25 years to treat a variety of conditions in children, but predominately in newborns. The general application of ECMO is for conditions that are believed to resolve either naturally or by surgery or other interventions. Realistically, a patient can be maintained for >2 weeks, and occasionally even longer. However, it is a temporary management option and if longer support is required the patient is often switched to a "Berlin" heart.

Its major use has been to support neonates with respiratory failure from meconium aspiration, persistent fetal circulation, diaphragmatic hernia, hyaline membrane disease, and cardiovascular conditions such as refractory septic shock or congenial heart disease, often postoperatively for severe cardiovascular instability. Neonates must weigh >2 kg and have a gestational age >35 weeks. From the Extracorporeal Life Support Organization (ELSO) Registry Report 2004, of 29 000 patients reported to date, ~19 000 were for neonatal respiratory diseases [46]. The survival rate for neonates with pulmonary problems is ~80%, whereas in neonates with congenital heart disease it is ~40%, but one report had a 64% survival following Norwood stage I procedure [47]. For congenital heart disease, the rate of ECMO usage has remained constant at 200 per year for the decade preceding 2005 [46]. ECMO is being used more often after the Norwood stage I procedure (28%) in one series [48].

For infants and children, ECMO is used for rapid resuscitation for respiratory arrest, postoperative support for cardiac lesions, support for failing myocardium, such as from myocarditis or acute ischemia, and for patients awaiting transplantation. A study of 279 children with a cardiac anomaly found an overall survival of 42% [49]. Pre-ECMO predictors of death included single ventricle physiology, history of a Norwood stage I operation, and significant acidosis, and major complications of ECMO were associated with death [49].

ECMO requires medical, nursing, and technical staff dedicated almost exclusively to the patient. The equipment is large and complex, being the size of a pump–oxygenator. Cannulae are placed in the right carotid artery and jugular vein and blood is circulated through a membrane oxygenator. The patient, sedated and on a ventilator, is constantly monitored, especially for mixed venous oxygen level and coagulation. The major complications are infections, bleeding, and renal insufficiency. Intracranial hemorrhage is the most devastating and one reason besides size that neonates under 35 weeks' gestation do not receive ECMO, because of cerebral vascular immaturity.

Neonates who have undergone ECMO management may have significant long-term respiratory and neurologic morbidity. The pre-ECMO mortality risk and prematurity were important factors. The post-ECMO abnormalities usually do not progress after ~3 years [50]. In infants and children there is a high readmission rate, 62% in one study, These were for respiratory problems in 41% and neurologically significant causes in another 21% (the latter being epilepsy or developmental delay).

For a comprehensive review of ECMO see Pearson GA, Firmin RK, 1995 [51].

Mechanical ventricular assistance is a reliable modality as a bridge to cardiac transplantation in children with heart failure. The recent introduction into the United States of the Berlin Heart EXCOR Pediatric Ventricular Assist Device has extended our ability to support neonates, infants, and young children. Of >600 EXCOR devices placed world-wide, 270 have been in the United States. The Berlin Heart EXCOR is an extracorporeal ventricular assist device (VAD) initially used to support mechanically adult patients with heart

failure [52]. The experience with EXCOR as a bridge to cardiac transplantation or as destination therapy in adult patients with heart failure led to modifications specific for children. The EXCOR system has three primary components, and it can be implanted in either a left ventricular or biventricular configuration. The components are a *blood pump*, *cannulae* for connecting the device to the great vessels and cardiac chambers, and a *pneumatic drive unit*. The *blood pump* is made of transparent polyurethane. It has two polyurethane trileaflet valves, which allow unidirectional blood flow into and out of the pump. A pneumatic compressor-operated diaphragm separates the blood chamber from an air chamber. Multiple pump sizes allow for different body weights in pediatrics. For instance, a 10 ml pump can support infants weighing <9 kg or with a body surface area of 0.43 m², and a 25 ml pump can support patients weighing <30 kg or with a body surface area of 0.95 m² [53]. Because the device is transparent, it can be evaluated daily for clot formation. The extracorporeal position of the pump allows straightforward exchange under conscious sedation should the need arise. Silicone cannulae are designed with several internal diameters (4, 6, 9 mm) for children. A layer of Dacron velour covers the mid-portion of the cannulae. The velour bridges the skin exit site and allows for rapid tissue in-growth, preventing an ascending infection. For a left ventricular configuration (LVAD), two cannulation sites are used. Usually, the left ventricular apex is cannulated for inflow to the pump, but the left atrium is an alternative site [54]. Left ventricular apical cannulation results in lower left ventricular end-diastolic pressure (LVEDP) and consequently lowers the right ventricular afterload by 15–25 mmHg [55]. The ascending aorta is cannulated for pump outflow. For a right ventricular configuration (RVAD), the right atrium is cannulated for inflow to the device, and the main pulmonary artery is cannulated for outflow. A biventricular configuration (BVAD) involves the use of both an LVAD and RVAD. The EXCOR ventricular assist device has an electropneumatic driving unit called IKUS that uses compressed air to move the diaphragm separating the blood and air chambers. This movement provides pulsatile blood flow. A positive driving pressure of >350 mmHg can be used to compress the diaphragm to end-systole, allowing ejection of blood from the device. A negative driving pressure up to −100 mmHg is used to expand the diaphragm to end-diastole, allowing the device to fill. The high driving pressures are necessary because of the small cannula sizes [56]. The driver can function in either a left ventricular mode or a biventricular mode. The system can also function in an asynchronous mode that allows separate rates for the RVAD and LVAD when biventricular support is necessary. This asynchronous mode allows the rate of the RVAD to be less than that of the LVAD with a smaller stroke volume (blood pump) to prevent pulmonary edema. Finally, all blood-contacting surfaces are heparin coated [57].

The first successful report of a left ventricular assist device (a centrifugal flow device) was for 12 h as a bridge to cardiac transplantation in a child [58], and another report also described the use of an adult EXCOR device (50 ml blood pump) as a bridge to cardiac transplantation in an 8-year-old [59]. The disadvantages of using an adult EXCOR device in children quickly became apparent and modifications were made, including a range of blood pump and cannula sizes to meet the sizes of infants and young children.

The indications for implanting EXCOR in infants and children include progressive heart failure refractory to medical therapy, cardiac index <2.0 l min⁻¹ m⁻², development of metabolic acidosis, and signs of end organ dysfunction, such as renal insufficiency or elevation of liver enzymes. Other indications are the need for mechanical ventilation or a mixed venous oxygen saturation <40%. In many children, the goal of implantation is to provide the recipient time for end organ recovery to make the patient a better transplant candidate.

The major use of the Berlin Heart EXCOR ventricular assist device has been as a bridge to cardiac transplantation, although other uses have been for end-stage congenital heart disease, post-cardiotomy heart failure and myocarditis. In a 15 year experience with pediatric EXCOR systems, 68 patients <18 years of age were supported for a mean duration of 35 days [60]. Thirty-one (45%) received cardiac transplantation. Eleven other patients (16%) recovered. Thirty-seven (54%) of the patients were discharged home. Only four patients had neurologic injury [60]. In the largest American experience at a single center with the EXCOR pediatric ventricular assist system[61], 17 patients <18 years of age received either an LVAD (*n* = 13] or BVAD (*n* = 4). Eleven patients were transplanted, one recovered, one remained on support, and four died. When the EXCOR system was compared with extracorporeal membrane oxygenation (ECMO) as a bridge to cardiac transplantation, the survival to transplant and recovery was significantly higher in the EXCOR group (86%) than the ECMO group (57%). Despite this excellent result, 40% of the patients sustained neurologic injury [62]. A series of nine patients, each with right ventricular dysfunction, with biventricular support (BVAD) ultimately received a transplant [63]. The mean duration of support was 31 days and eight patients (89%) survived to transplant without acute neurologic injury, thromboembolic events, or hemolysis. All patients in this series had significantly elevated (>90%) panel reactive antibodies and 12 pump exchanges were performed because of fibrin deposits or clot formation in the device. Other series [64,65] reported small sets of patients in whom neurologic injury occurred and device exchanges were needed.

The EXCOR system has also been used for fulminant myocarditis [65] either to bridge the child to transplantation or until recovery from the disease. Because it may take months for the myocardium to recover in patients with fulminant myocarditis, the EXCOR system provides an

excellent means for long-term mechanical support [66]. Among its advantages are the ability to extubate the patient, give physical therapy, including ambulation, and feed the patient. Feeding enhances the integrity of the gastrointestinal tract mucosa, preventing bacterial translocation and decreasing the risk for infection.

The EXCOR system has been used in patients with hypoplastic left heart syndrome after a BDG and Fontan with mixed results [67]. Its versatility makes it ideal for children because it can be tailored to the size and needs of the patient. The Berlin Heart EXCOR ventricular assist device has become a widely accepted form of mechanical circulatory support for children in Europe and the United States. Questions remain regarding the ideal anticoagulation strategy and the neurologic outcomes. The Berlin Heart EXCOR ventricular assist use of partial cardiac bypass support during aortic arch-related surgical procedures has filled a void for the increasing number of pediatric patients with end-stage heart disease.

This chapter covers a number of developmental abnormalities and acquired problems of the gastrointestinal and renal systems that may afflict the perioperative pediatric cardiac patient. In a few patients, therapy for these conditions needs to consider the cardiovascular status of the patient, and this is covered here.

Gastrointestinal complications

Gastrointestinal complications are associated with the gastrointestinal tract and organs supplied by the celiac, superior mesenteric, and inferior mesenteric arteries. These include the esophagus, stomach, small intestine, colon, liver, gallbladder, spleen, and pancreas. An extensive list of proposed definitions for potential gastrointestinal complications occurring following pediatric cardiac surgery has been published [1]. Although serious gastrointestinal complications following pediatric cardiac operations are relatively uncommon, precise estimates of occurrence rates are limited because of the lack of standardized nomenclature and reporting, difficulties in identifying temporal associations with operation and the assignment of causality in complex patients. Children recovering from heart transplantation are an exception, since a variety of serious early and late gastrointestinal complications, including pancreatitis, cholecystitis, recurrent abdominal infections, intestinal pneumatosis, and abdominal malignancies occur in 18% of patients [2]. This section focuses on selected gastrointestinal complications linked to congenital heart disease and its treatment. These complications include necrotizing enterocolitis (NEC), malrotation and midgut volvulus, abdominal compartment syndrome, and inability to eat.

Necrotizing Enterocolitis (NEC)

NEC is a neonatal disease in which the intestinal mucosal barrier is compromised, leading to inflammation and bacterial translocation, and sometimes to mucosal or transmural necrosis and sepsis (see also Chapter 18). The pathogenesis of NEC is multifactorial and incompletely understood. General risk factors include hypoxic–ischemic injury to the gastrointestinal tract, physiological immaturity of the gastrointestinal tract, and alterations of the normal microbiological flora of the intestines [3]. With systemic hypoperfusion in a neonate, reduced mesenteric perfusion occurs as blood is shunted preferentially to the heart and brain and away from the splanchnic circulation. Reperfusion may promote inflammation and exacerbate intestinal injury. In premature patients, compromised integrity of epithelial tight junctions and deficient intestinal IgA production may be contributory. Impaired peristalsis may facilitate bacterial overgrowth and increase the contact time between bacterial antigens and enterocytes. Finally, alteration of the normal bacterial colonization of the intestines, perpetuated by exposure to broad-spectrum antibiotics or rapid increases in volume of feedings, may predispose patients to developing NEC.

Given these physiologic considerations, it is not surprising that 90% of NEC affects premature neonates. Neonates with a complex cardiac malformation have at least a 10-fold greater risk of developing NEC than neonates without congenital heart disease [4]. The rate of NEC in neonates with critical congenital heart disease is approximately 3%, and is higher in prematures [4–6]. Neonates with a cardiac lesion with significant diastolic runoff through a ductus arteriosus or a surgically created systemic to pulmonary shunt, such as in hypoplastic left heart syndrome, are also at increased risk

[4,7]. NEC may occur before or after cardiac intervention, and mucosal ischemia and inflammation related to cardiopulmonary bypass may be contributory [8]. Preventive measures to reduce the occurrence of NEC include administering antenatal maternal corticosteroids for threatened preterm delivery and feeding with breast milk [3].

The common signs and symptoms of NEC, along with laboratory and radiographic findings, have been used to assign stages of NEC based on the modified Bell's criteria [3] (see Chapter 18, Table 18.3). Higher stages of disease have a greater risk of mortality. Potential secondary complications of NEC include short gut syndrome, stricture formation, problems related to the use of parenteral nutrition (e.g., catheter-associated bloodstream infection, cholestasis, and liver failure), prolonged hospitalization, and worse neurodevelopmental outcomes [4,9]. In addition to close monitoring and supportive care, treatment for NEC includes bowel rest and antibiotic therapy directed at aerobic and anaerobic organisms. Surgical intervention, either peritoneal drainage or laparotomy, is generally reserved for patients with intestinal perforation (Bell's stage III-B) or clinical deterioration despite maximum medical therapy [10,11]. Mortality directly attributable to NEC in neonates with congenital heart disease is approximately 10% [4,7,12].

Abdominal compartment syndrome

Abdominal compartment syndrome (ACS) may be defined as a sustained increase in intra-abdominal pressure (>17–20 mmHg in children) associated with dysfunction or failure of an organ not previously involved [13]. In children recovering from a cardiac operation, ACS often results from a combination of factors: ascites, postoperative ileus, and visceral edema from elevated central venous pressure and renal insufficiency. Intra-abdominal pressure can be measured directly via an intraperitoneal catheter or indirectly via the bladder (intravesical). Palpation of a tense abdomen may be all that is needed to make the diagnosis. Increased intra-abdominal pressure may contribute to further deterioration of cardiac, respiratory, renal, and hepatic function. Elevation of the diaphragm reduces lung compliance, which requires higher ventilator settings, exacerbates lung injury, and causes pulmonary hypertension and other adverse cardiopulmonary interactions. Renal dysfunction may be caused by direct compression of renal vessels and be exacerbated by low cardiac output. Similar hemodynamic changes may lead to hepatic dysfunction.

Management of ACS involves serial measurement or estimation of intra-abdominal pressure, maintaining adequate end-organ perfusion, and, for refractory patients, percutaneous or surgical decompression. Elevating the head of the bed and prone positioning increase intra-abdominal pressure and should be avoided. Patients with evolving ACS should be kept flat and supine. Meticulous management of fluid overload with diuretics or dialysis, and nasogastric and colonic decompression may help. Inserting a percutaneous catheter to drain ascites, air, or other fluid collections may decrease intra-abdominal pressure and remarkably increase urine output. We have observed marked improvement in ACS in some patients who had reached a critical intra-abdominal pressure threshold that was alleviated by drainage of a minimal amount of ascitic fluid. Similarly, we have observed rapid improvement in ACS following the onset of venoarterial extracorporeal membrane oxygenation (ECMO) in children recovering from a complex cardiac operation, presumably from improved cardiac output and systemic venous decompression.

Malrotation and midgut volvulus

In addition to complex cardiac malformations, children with heterotaxia syndrome often have gastrointestinal abnormalities, the most prominent being abnormalities of intestinal fixation. Early in gestation, the midgut rotates around the axis of the superior mesenteric artery such that the proximal jejunum is anchored by the ligament of Treitz to the retroperitoneum in the left upper quadrant and the cecum is anchored to the retroperitoneum in the right lower quadrant. The resultant broad-based small bowel mesentery is at minimal risk for volvulus. In patients with malrotation, there is either no rotation or reverse rotation of the midgut loop, such that the proximal jejunum and cecum are both affixed close to each other in the upper abdomen, on either the right or left. The resultant narrow-based small bowel mesentery is thereby predisposed to volvulus and potentially fatal necrosis of the entire midgut [14].

Malrotation is usually diagnosed with an upper gastrointestinal contrast study, by which the distance between the ligament of Treitz and ileocecal junction is estimated. When diagnostic uncertainty persists, a contrast enema may be useful to locate the displaced cecum [15]. The symptoms most commonly develop in the neonatal period, and 90% of patients present within the first year of life. Evaluation and treatment must be undertaken urgently in patients with signs and symptoms suggestive of midgut volvulus (e.g., bilious emesis). Definitive treatment involves an open or laparoscopic Ladd procedure, in which the malrotation is reduced, abnormally positioned bands are released, and the bowel is repositioned.

Screening all patients with heterotaxia syndrome for malrotation and performing an elective operation to prevent midgut volvulus are controversial. Volvulus occurs in only 1–7% of patients with malrotation, and between the two extremes of normal rotation and malrotation is a spectrum of rotational abnormalities, some of which may not predispose to the development of volvulus. Therefore, the potential for false-positive radiologic diagnosis, the complexity of the associated cardiac anomalies, and the risk of developing adhesions leading to bowel obstruction (up to 15%) must be considered when contemplating an elective operation. Many physicians do not screen asymptomatic heterotaxia patients for malrotation, and follow them conservatively when malrotation is diagnosed incidentally

[14,16]. Others suggest that all patients with heterotaxia syndrome be evaluated for malrotation, and that a Ladd procedure be performed in those with malrotation regardless of the presence or absence of symptoms [17].

Inability to eat

The inability to ingest adequate liquid and caloric intake is common following cardiac surgery in neonates and infants. In one prospective study, new-onset dysphagia was diagnosed by a speech pathologist in 18% of children recovering from a cardiac operation [18]. Contributing factors include innate poor suck–swallow coordination (e.g., prematurity, DiGeorge syndrome), anomalies of the oropharynx or airway (e.g., cleft lip or palate), use of transesophageal echocardiogram, prolonged intubation, gastroesophageal reflux, and central nervous system injury [18,19]. Vocal cord dysfunction associated with dysphagia contributes to aspiration risk. Vocal cord dysfunction may be caused by congenital laryngotracheal anomalies, prolonged intubation, and central nervous system anomalies. In cardiac surgery patients, however, the most likely etiology is recurrent laryngeal nerve injury in neonates following ductus arteriosus surgery or aortic arch reconstruction. It also may follow cervical ECMO cannulation.

Evaluating dysphagia may include assessment by a speech pathologist, videofluoroscopic swallowing study, upper gastrointestinal contrast study, or flexible fiber-optic laryngoscopy. Children whose postoperative course is complicated by inability to eat have increased hospitalization and prolonged hospitalization [19]. Management of children with inability to eat following cardiac surgery is guided by the underlying etiologies and expected time course for improvement. Options include thickening of feeds, nasogastric feedings, and gastrostomy tube placement with or without Nissen fundoplication.

Disorders of the liver and pancreatitis

Virtually any disease of the liver can occur in patients with congenital heart disease. This section discusses those encountered in perioperative cardiac patients. We have no data documenting their prevalence. Common neonatal conditions, such as jaundice related to ABO incompatibility, which have no notable association with congenital heart disease, are not covered.

Biliary atresia

Direct hyperbilirubinemia is common in a cardiac intensive care unit and observed in patients with long-standing reduced systemic perfusion and especially with parental nutrition (see below). Direct hyperbilirubinemia may indicate extrahepatic biliary atresia associated with the heterotaxy syndromes (especially polysplenia) [20,21]. In one study extrahepatic biliary atresia occurred in 10% of patients with left atrial isomerism (polysplenia) [22]. The relative hazard ratio for death was considerably higher for children with biliary atresia associated with cardiac malformations related to left atrial isomerism (2.76 [1.10–5.46]) than for patients without biliary atresia [22]. Biliary atresia has also been reported with hypoplastic left heart syndrome [23] and other cardiac lesions unassociated with heterotaxy. There is little information regarding the effect of biliary atresia on outcomes of cardiac surgery.

The impact of cardiac malformations on the outcomes of operations for biliary atresia or liver transplantation is also poorly defined. Davenport *et al.* [21] reported 56 children with biliary atresia associated with a splenic abnormality and noted that the 5-year *liver* survival was less favorable for patients with a splenic abnormality than for those with isolated biliary atresia. This reduction in survival was not related to congenital cardiac defect. Vazquez *et al.* [24] reported the results of *Kasai operation* in 11 patients with polysplenia syndrome, two of whom had a "cardiac malformation." One of the two patients with a "cardiac malformation" survived operation. Living donor *liver transplantation* for end-stage hepatic disease in children with a congenital cardiac defect can be undertaken with low mortality, although most of the reported patients had relatively mild heart disease [25,26].

Cirrhosis is an important risk factor in adults undergoing cardiac surgery utilizing cardiopulmonary bypass, with patients having Child–Turcotte–Pugh class C disease being at particularly high risk of postoperative complications and death [27]. Limited information is available for pediatric patients. Bacha *et al.* [28] reported open-heart operations involving four patients (aged 10 weeks–2 years) with end-stage liver disease; two had had the Kasai procedure for biliary atresia and two had Alagille's syndrome. One patient had Child's class A and three had Child's class B disease. One (Child's class B with Alagille's) died of refractory hypotension due to vasodilation postoperatively, and three were hospital survivors.

Acute liver failure

Ischemia can cause acute liver failure (ALF), the histological picture of which is confluent or multilobular necrosis [29]. Pre- and postoperative cardiac patients might be at risk for ischemic ALF because of reduced systemic oxygen delivery, systemic arterial hypotension, and increased central venous pressure, either alone or in combination. Mildly increased serum levels of liver enzymes and bilirubin are indeed common, although full-blown ALF (including hypoglycemia, clinically relevant coagulopathy, and encephalopathy) is very unusual. Postoperative Fontan patients seem more vulnerable to ALF than most, because they have acutely increased central venous pressure (2–5-fold greater than before operation), and some also have systemic arterial hypotension and reduced systemic oxygen delivery. Indeed, given the relatively high incidence of (at least transient) hypotension and low systemic oxygen delivery in most congenital cardiac patients after operation, with the very

low incidence of ALF, it seems likely that markedly increased systemic venous pressure (in concert with the other hemodynamic abnormalities) is often an important factor in the genesis of ALF.

Reports of ALF in pediatric cardiac patients are sparse [29–32]. It is difficult to know to what extent the patient's phenotype is shaped by the liver dysfunction as distinct from the coexisting severe hemodynamic disturbance. Indeed, for unknown reasons, ALF itself can reduce systemic vascular resistance and cause hypotension. Renal dysfunction often complicates nonischemic ALF [29]. It may be difficult to distinguish ALF-related encephalopathy and even cerebral edema from that caused by hemodynamic events. The effect of ALF on outcome is obscured by the fact that patients may die from a cardiac cause rather than liver disease. As the two reports [30,31] discussed below show, the Fontan procedure is associated with acute liver injury.

Jenkins *et al.* [30] reported 11 patients (aged 0.25–20 years) with ALF in the early postoperative period, six after Fontan palliation and the remainder after various reparative or palliative operations. Hepatic failure was apparent in the first or second postoperative day in seven, and between postoperative days 6 and 9 in the remainder. They had low cardiac output (cardiac index <2 l min m^{-2}), elevated central venous pressure (12–29 mmHg, mean 20 mmHg) and hepatic perfusion pressure from 29 to 56 mmHg (mean 42 mmHg). Mean systemic arterial pressure ranged from 50 to 85 mmHg at the onset of ALF, but the ages of the patients were not linked to the arterial pressure, limiting interpretation. Inotropic support (and aortic counterpulsation in two patients) was required. Acute renal failure developed in each, with seven requiring peritoneal dialysis. Six children died acutely, all of intractable cardiac failure, and two died later of their cardiac lesions; the authors did not attribute any of the deaths to hepatic failure *per se*.

In a retrospective review of early postoperative "liver dysfunction" after Fontan palliation [31], of 15 consecutive patients seven had elevated serum glutamic pyruvic transaminase (SGPT) >1000 U l^{-1} and total bilirubin and abnormal prothrombin time. Hepatic dysfunction correlated with cardiac index, urine output, systolic arterial pressure, and central venous pressure. Four of the 15 patients died before hospital discharge, but none of the deaths were attributed to liver dysfunction. The same group [32] subsequently reported that in Fontan patients, acute postoperative liver dysfunction (as measured by elevation of alanine aminotransferase and serum total bilirubin) was only weakly related to cardiac index, but strongly related to hepatic venous oxygen saturation; hepatic venous oxygen saturation less than a "critical value" of about 25% was strongly correlated with hepatic dysfunction.

Preventing ischemic ALF consists in maneuvers to maintain adequate systemic oxygen delivery and arterial pressure, while minimizing central venous pressure. Close attention should be paid to volume infusion and to judge, as best as

possible, when to switch from augmenting central venous pressure to inotropic and pressor agents to maintain adequate arterial pressure and systemic blood flow. *Therapy*, in addition to strategies to increase hepatic perfusion, is supportive: close monitoring and provision of blood glucose, monitoring and adjustment of serum electrolytes, replacement of coagulation factors as needed, lactulose to treat elevated ammonia, monitoring of central nervous system status, and responding with appropriate therapy.

Cholestasis

Any of the many causes of cholestasis can affect cardiac patients in an intensive care unit, but few occur with any frequency. Biliary atresia and acute liver failure, although very uncommon, are two causes discussed above. *Conjugated hyperbilirubinemia* is observed in neonates with chronically marginal systemic perfusion, especially if they are receiving total parenteral nutrition [33]. The cause of parenteral nutrition-related jaundice in neonates remains unknown [34].

Acute acalculous cholesystitis

Acute acalculous cholecystitis can rarely develop after cardiac surgery or cardiac catheterization [35]. Presenting signs and symptoms are fever, right upper quadrant pain, vomiting, jaundice, and right upper quadrant mass. Risk factors for acute acalculous cholecystitis include shock, sepsis, total parenteral nutrition, prolonged fasting, intravenous narcotics, and multiple transfusions – a list which explains why postoperative cardiac patients are at risk. Optimal therapy is unclear; antibiotics (only), drainage of the gallbladder, and cholecystectomy are the usual approaches [35].

Portal hypertension

Portal hypertension is very uncommon. It occurs occasionally in neonates with a cardiac lesion and umbilical venous cannulation causing portal venous thrombosis. The most common presenting signs and symptoms are splenomegaly and gastrointestinal bleeding [36].

Acute pancreatitis

Acute pancreatitis is well described in adults after cardiopulmonary bypass [37], and there are a few reports in pediatric patients after cardiotomy [38–41]. In adults, one retrospective study found that pancreatic cellular injury (hyperamylasemia with increased serum lipase or pancreatic isoamylase) occurred in 27% of post-bypass patients; 9% had abdominal signs or symptoms consistent with acute pancreatitis. Pancreatic cellular injury was associated with preoperative renal insufficiency, valve surgery, postoperative hypotension, and perioperative administration of calcium chloride.

In a report [40] of 349 patients (all >3 months old) having open-heart surgery, 46 had hyperamylasemia and 18 had "clinical pancreatitis." The "pancreatitis" was defined by increased serum amylase activity plus high output failure,

central nervous system changes, and hypocalcemia, rather than abdominal findings or pancreatic imaging. The mortality rate for patients with clinical pancreatitis was 49.2%. The patients had a variety of cardiac lesions and the inciting factor(s) for pancreatitis were unknown. A subsequent prospective study [40] from the same institution found that serum amylase was increased relative to preoperative values in 34% of patients after cardiac surgery (both closed and open); the incidence of clinical pancreatitis was not reported. In a report of four children with acute pancreatitis after open-heart surgery [38], all were hemodynamically unstable and receiving high doses of vasoactive drugs. The authors concluded that shock and pre-existing systemic disease are risk factors for this disease. In another study, acute pancreatitis occurred in four (of 40) patients soon after Fontan palliation, two of whom died in the early postoperative period [39]. *Preoperatively*, the patients with pancreatitis had a higher echocardiographic tau (suggesting decreased ventricular compliance) and lower systemic blood flow than patients who did not develop pancreatitis.

Acute Kidney Injury (AKI)

Patients with congenital heart disease have a wide range of circulatory alterations that can stress renal compensatory mechanisms and contribute to AKI. Potent physiologic derangements induced by palliative and reparative congenital heart surgery can further destabilize the cardiorenal axis. Although the responsible biologic mechanisms remain unclear, even subtle alterations in renal function are associated with increased hospitalization and mortality rates among a wide range of critically ill patients, including those recovering from heart surgery [42–45]. Hospitalization and mortality rates in children recovering from cardiac surgery increase with the severity of AKI and may approach 60% for those requiring dialysis [46–49].

Definition and diagnosis

The more than 30 definitions of AKI have hindered the epidemiologic understanding of this important postoperative complication. In 2004, the Acute Dialysis Quality Initiative developed a consensus definition and staging system for adult AKI (*RIFLE* classification) [50]. In 2007, the Acute Kidney Injury Network (*AKIN*) modified the *risk* category of the *RIFLE* classification to include patients with a serum creatinine increase of ≥0.3 mg dl⁻¹ (*AKIN* Stage 1) and eliminated the *loss* and *end-stage renal disease* categories [51]. This was based on the recognition that even a small increase in serum creatinine can be associated with hospitalization and mortality rates and that the *loss* and *end-stage renal disease* categories were outcomes of AKI, rather than descriptors [42]. In both staging systems, the criteria for AKI can be met by an increase in serum creatinine concentration or a specified degree of oliguria (Tables 15.1 and 15.2).

The *RIFLE* classification system and the closely related *AKIN* staging system have become the *de facto* definitions of AKI in critically ill adults, and are slowly becoming the standard in children also. Although creatinine concentration and urine output are the currently accepted clinical standards for assessing renal function in critically ill patients, they have limitations, including delay in the rise of the serum creatinine concentration after kidney injury, the potential uncoupling of serum creatinine and true renal function (i.e., glomerular filtration rate) related to tubular secretion of creatinine, and the dependence of creatinine on muscle mass [52,53].

There is an effort to find more accurate markers of AKI, assayable shortly after renal injury; these include measurement of cystatin c, kidney injury molecule-1, neutrophil gelatinase-associated lipocalin, interleukin-18 (IL-18), and *N*-acetyl-β-D-glucosaminidase [54]. These markers are not yet in widespread clinical use, but it appears that one (or several) will become so, forcing a change in the definition of AKI. Although the use of changes in creatinine concentration to define AKI has been more accepted in children, its use in neonates is limited. In the

Table 15.1 *RIFLE* acute kidney injury classification system.

RIFLE category	GFR criteriaª	Urine output criteriaª
Risk	Creatinine increase of 1.5 × or GFR decrease of >25%	UOP <0.5 ml kg⁻¹ h⁻¹ × 6 h
Injury	Creatinine increase of 2 × or GFR decrease of >50%	UOP <0.5 ml kg⁻¹ h⁻¹ × 12 h
Failure	Creatinine increase of 3 × or GFR decrease of >75%	UOP <0.3 ml kg⁻¹ h⁻¹ × 24 h or anuria × 12 h
Loss	Complete loss of renal function for >4 weeks	
End-stage renal disease	Need for renal replacement therapy for >3 months	

ªGFR, glomerular filtration rate; UOP, urine output.

Table 15.2 *AKIN* acute kidney injury staging system.

AKIN stage	GFR criteria[a]	Urine output criteria[a]
Stage 1	Creatinine increase of 1.5–2 × or creatinine increase ≥0.3 mg dl^{-1}	UOP <0.5 ml kg^{-1} h^{-1} × 6 h
Stage 2	Creatinine increase of >2–3 ×	UOP <0.5 ml kg^{-1} h^{-1} × 12 h
Stage 3	Creatinine increase of >3 × or need for renal replacement therapy	UOP <0.3 ml kg^{-1} h^{-1} × 24 h or anuria × 12 h

[a]GFR, glomerular filtration rate; UOP, urine output.

early neonatal period, serum creatinine concentration reflects maternal creatinine concentration, not glomerular filtration rate, rendering the diagnosis of AKI based on this measurement unreliable in this age group [55].

Incidence

Post hoc application of the *RIFLE* classification system to the limited available data regarding renal function after congenital heart surgery (CS-AKI) demonstrates an overall AKI prevalence of 20–37%. The prevalence of more than mild AKI, corresponding to the *Injury*, *Failure*, *Loss*, and *End Stage* categories, ranges from 12 to 19% [56,57]. Unpublished data from 321 patients from the Children's Hospital Boston suggest that the prevalence of any degree of AKI within 72 h of surgery is 33% (*n* = 107), with 15% (*n* = 48) in the *Injury*, *Failure*, *Loss*, and *End Stage* categories. Significant threshold variation makes the accurate determination of the prevalence of AKI severe enough to require dialysis difficult, with recently reported rates ranging from 2 to 12% [46,48].

Pathophysiology

The development of CS-AKI is the result of several complex processes that often begin well before operation. Focusing on the pre-, intra-, and postoperative periods facilitates understanding the pathophysiology of CS-AKI. Accumulating evidence suggests that pre-existing renal insufficiency is an important risk factor for AKI. The potential etiologies of preoperative renal insufficiency in pediatric patients include coexisting developmental kidney anomalies, shock-induced acute tubular necrosis in neonates with delayed recognition of ductal dependent heart disease, suboptimal hemodynamics resulting in lower renal perfusion pressure (mean arterial pressure – systemic venous pressure), cyanosis, exposure to nephrotoxic medications, diuretic-induced prerenal azotemia, and renal injury related to previous congenital heart surgery. The prevalence of preoperative renal insufficiency in children with congenital heart disease is unknown.

Several events during the operation contribute to CS-AKI by directly or indirectly causing cellular injury to the tubular epithelium, beginning with the induction of general endotracheal anesthesia. Induction can be associated with peripheral vasodilation, redistribution of blood flow away from vital organs, and occasionally hypotension causing a decrease in renal perfusion pressure and a period of relative renal ischemia. Most palliative and reparative procedures require cardiopulmonary bypass (CPB). The renal perfusion provided by CPB has complex and deleterious effects on the kidney that are likely proportional to the duration of bypass. The lack of pulsatile renal blood flow provided by both roller and centrifugal CPB disturbs kidney autoregulation and microcirculatory flow, both of which contribute to ischemia–reperfusion injury of the kidney. Mechanical hemolysis related to suction, autotransfusion, CPB cannulae, tubing, and pump trauma release iron and free hemoglobin, both of which cause renal oxidative stress injury. CPB also induces a potent and complex inflammatory response, partly by activating white blood cells and platelets, an increase in the ratio of pro-inflammatory interleukins and cytokines to anti-inflammatory proteins, and an upregulation of vascular adhesion molecules. The resultant kidney injury from this pro-inflammatory cascade is complex and incompletely understood, but likely involves direct tubular damage and acute tubular necrosis [58,59].

In almost all circumstances, congenital heart surgeons utilize some degree of hemodilution during CPB. Because of improved rheology and viscosity, hemodilution decreases blood exposure and improves perfusion through certain microvascular territories. Significant hemodilution during CPB (i.e., hematocrit <24%), however, is associated with AKI because of a reduced oxygen-carrying capacity to a level that induces renal ischemia [60–62]. The optimal degree of hemodilution to maximize clinical outcomes, including renal function, remains uncertain, but is likely above 25%.

Some degree of hypothermia is used in most on-pump congenital heart operations. The rationales for hypothermia include decreasing global tissue metabolic rate, thus allowing lower bypass flow rates, providing greater end-organ protection, and decreasing CPB-related systemic inflammation. The degree of hypothermia achieved on bypass may be associated with AKI as a result of renal cortical hypoperfusion during rewarming [63].

Cessation of CPB and a period of deep hypothermic circulatory arrest (DHCA) are often used during an operation where a completely bloodless surgical field is required (e.g., repair of obstructed total anomalous pulmonary venous connection) and in operations involving reconstruction of the aortic arch. This profoundly altered physiologic state (DHCA) has been associated with end-organ dysfunction, particularly when prolonged. Whereas most work has centered on the relationship of DHCA to neurologic injury, DHCA can be

associated with postoperative AKI, possibly from vascular endothelial dysfunction [64].

During complex congenital heart surgery, antifibrinolytics are often administered to decrease bleeding. One such medication, aprotinin, attracted much attention after a large study of adults undergoing coronary surgery demonstrated an association between aprotinin use and a twofold increase in AKI requiring dialysis. Because of the studies in adults demonstrating increased rates of both mortality and end-organ dysfunction, aprotinin is no longer marketed. The renal toxicity of aprotonin, however, remains controversial. Some clinical and basic studies support its role as a nephrotoxin, but others suggest that it may have nephro-protective effects [56,57,65,66].

Early postoperative period events are significant in AKI development because of the intraoperative stressors outlined above. Myocardial ischemia–reperfusion injury, direct myocardial injury and edema, CPB-induced systemic inflammatory response syndrome (SIRS), and residual cardiac lesions each contribute to the postoperative low cardiac output syndrome which results in decreased renal perfusion. The decrease in renal perfusion pressure can be compounded by renal afferent arteriolar vasoconstriction induced by inotropes and vasoconstrictors used to treat the low cardiac output. Furthermore, postoperative fluid overload and decreased myocardial compliance elevate central venous pressure and contribute to decreased renal perfusion pressure [58,59].

When severe, ascites resulting from a combination of capillary leak secondary to SIRS, accumulation of transudate secondary to high central venous pressure, and fluid overload related to volume administration can cause abdominal compartment syndrome, compromising kidney function [67]. Many components of the stress response to congenital heart surgery interfere with normal carbohydrate metabolism and cause hyperglycemia, an effect compounded by the frequent administration of glucocorticoids in the perioperative period during CPB. Renal mitochondrial dysfunction secondary to intracellular hyperglycemia has been suggested as a potential mechanism for hyperglycemia associated with AKI [68,69]. Finally, pre-renal states induced by diuretics and fluid restriction and the administration of directly nephrotoxic medications (e.g., nonsteroidal anti-inflammatory agents and aminoglycosides) exacerbate AKI [70].

Prevention and management

There have been many failed attempts at preventing or ameliorating CS-AKI, including the use of low-dose dopamine, diuretics, volume loading, dexamethasone, theophylline, natriuretic peptides, mannitol, calcium channel blockers, angiotensin-converting enzyme inhibitors, preoperative statin therapy, and *N*-acetylcysteine [59,71]. Two renal protection strategies, however, are promising: perioperative infusion of sodium bicarbonate (inhibits the production of oxygen radicals in the renal tubules) and infusing the

selective dopamine receptor agonist fenoldopam (renal vasodilator) [72,73].

Beyond optimizing hemodynamics to maintain renal perfusion pressure with appropriately selected vasoactive medications and minimizing residual cardiac defects surgically, two important strategies to preserve renal function are minimizing nephrotoxic medications and avoiding diuretic-induced prerenal azotemia. Both exacerbate or cause CS-AKI, particularly in a susceptible host. Evolving ascites-related abdominal compartment syndrome, characterized by abdominal distension, a fluid wave, worsening respiratory mechanics, and oliguria should be promptly recognized and relieved to avoid CS-AKI, intestinal ischemia, and progressive respiratory and hemodynamic compromise.

In patients with severe CS-AKI, renal replacement therapy (RRT) may be required, although mortality remains unacceptably high despite its use [46–48]. The common RRT modalities after congenital heart surgery are peritoneal dialysis for infants and continuous veno-venous hemofiltration for larger patients. The indications for RRT after cardiac surgery include anuria with hyperkalemia or metabolic acidosis, severe volume overload refractory to diuretics and fluid restriction, and uremic encephalopathy or platelet dysfunction. RRT has the potential to alter clinical outcomes and disease course for adults with CS-AKI. The timing, institution threshold, and intensity of RRT remain largely unresolved [74–76].

16 Fetal Treatment

Helena M. Gardiner

Imperial College, and Queen Charlotte's and Chelsea Hospital, Royal Brompton Hospital, London, UK

Introduction

Surgical procedures for major congenital heart disease (CHD) are performed in the first days to months after birth following the recognition that neonatal mortality is high in unoperated children and secondary myocardial damage (thought in part to be due a reduction in coronary angiogenesis) is common in children undergoing their first surgical procedure later in childhood [1]. It is likely that the substrate for damage occurs prenatally [2] and this has led to evaluation of the benefits of cardiac intervention for aortic and pulmonary stenosis in the fetus [3]. Relatively noninvasive fetal therapy for arrhythmia, with antiarrhythmic drugs given (in relatively high dosage) to the healthy mother to treat fetal tachycardia transplacentally, is already well established and usually successful [4,5]. More invasive fetal therapies include intrauterine blood transfusions for fetal anemia, insertion of pleural shunts for recurrent effusions, and laser photocoagulation of placental anastomoses to separate the circulation in monochorionic twins with twin-to-twin transfusion syndrome, and are performed by fetal medicine obstetricians [6,7]. Teams combining this fetal medicine expertise with their cardiologists have more recently introduced fetal cardiac interventional procedures: valvoplasty of the aortic and pulmonary valve, balloon atrial septostomy for restrictive or closed interatrial septum, and fetal pacing in complete heart block into this range of therapeutic options [8–10].

Assessment of therapeutic efficacy

In general, new fetal therapies are offered where the procedure is either life saving or may improve postnatal outcomes. The rapidity of progression of fetal aortic and critical pulmonary valve stenosis results in substantial ventricular damage, including impaired growth, and affected hearts are often considered to lie within the spectrum of hypoplastic left or right heart syndrome within weeks following diagnosis [3,11,12].

Several percutaneous fetal procedures, such as bladder shunting and opening of posterior urethral valves, have been evaluated and largely discarded as ineffective. Open fetal surgery for repair of diaphragmatic hernia and spina bifida has been the subject of randomized trials, [13,13a]. The approach for these procedures is more invasive and involves exteriorization of the fetus to perform surgery. Where the therapeutic efficacy of one treatment versus another, or one treatment versus no treatment, has not been established, a randomized trial is the ideal assessment tool. However, it may be difficult to obtain sufficient power for a randomized controlled trial for fetal cardiac disease for several reasons, including rarity of suitable patients, relatively poor detection rate at an early stage of the disease, compromising recruitment, and the wide diversity of cardiac morphology that may require further subgroup analysis and reduce power.

Detection of heart disease in pregnancy

The fetal heart is examined using ultrasound usually as part of a fetal anomaly scan at ~20 weeks' gestation (Videoclip 16.1). Antenatal screening tests in the first and second trimesters vary depending on health care systems and are undertaken by a variety of health professionals. Prenatal detection of cardiac defects remains disappointingly low in many countries, with only one in four affected babies detected in screening programs [14,15]. However, if fetal therapy is to be evaluated further, an improvement in antenatal detection is vital to detect fetuses with semilunar valve stenosis or

atresia in the early stages of the disease when valvoplasty is most likely to be effective by protecting the growth of the supporting ventricle and theoretically preventing the development of a hypoplastic left or right heart [11] (Videoclips 16.2 and 16.3).

History of human fetal cardiac intervention

Human fetal cardiac intervention was first attempted in the 1990s because surgical results for critical aortic stenosis in the neonate were poor and because aortic valve stenosis detected *in utero* often progressed rapidly to hypoplastic left heart syndrome, for which there was no widely available successful surgical strategy. The fetuses had advanced disease and technical success was only achieved in about half (defined as crossing the valve and achieving forward flow) and procedure-related deaths occurred in ~30% with only one long-term survivor [16,17]. Fetal valvoplasty was not developed further until more recently; the stimulus for this is not entirely clear but perhaps the development of fetal screening programs with more timely referral of cardiac malformations played a role. Early reports of technical success [8,9] stimulated others to try these techniques, but apart from one large center in the United States, there are no studies with sufficient power to evaluate efficacy. There are important criteria to consider when introducing a new therapy and any new interventional program must be able to demonstrate an improvement in outcome over current surgical techniques. Current in-hospital survival following the Norwood procedure for hypoplastic left heart syndrome or the borderline left heart size is ~70% with 2 year survival of 55% in most centers. Higher risk morphology has been identified and includes babies with an intact or restrictive interatrial septum who have only a 30% 1 month survival, even in high-volume centers, because of pulmonary lymphangiectasia and pulmonary venous damage [18,19].

Case selection, counseling, and timing

True outcomes for fetuses diagnosed with CHD are not as good as those reported in postnatal surgical series because such series do not represent the entirety of the disease. Fetuses may not be born either because of spontaneous demise or interruption of the pregnancy; babies may not be offered surgery because morphology or function are worse than anticipated from fetal scans, or because of important coexisting chromosomal defects or extracardiac malformations which occur in ~10% of patients with aortic and pulmonary stenosis or atresia [20].

Guidelines for selecting patients for left-sided procedures have been modified based on best-available but relatively

Table 16.1 Revised selection criteria and threshold score for fetal aortic valvoplasty[a].

Aortic valve	Stenosis – not atresia
LV size	LV length Z score ≥−2
Mitral valve annulus	Z score ≥−3
LV function	MR >15 or AS >10 mmHg
Threshold score ≥4 points	*(permits 100% sensitivity for BV outcome)*
LV length	Z score >0 = 1 point
LV width (short axis)	Z score >0 = 1 point
Aortic valve annulus	Z score ≥−3.5 = 1 point
Mitral valve annulus	Z score ≥−2 = 1 point
LV function	MR or AS >20 mmHg = 1 point

[a]AS, aortic stenosis; LV, left ventricular; MR, mitral regurgitation.

short-term experiences of outcome from one center (Table 16.1). Not surprisingly, the better the fetal anatomy at the time of procedure, the more likely a two-ventricle circulation is after birth. However, the ideal gestation for interventions remains unclear [8,21]. The fetus may not tolerate the procedure well below 20 gestational weeks, particularly if the procedure is lengthy or there is hydrops. There is a 10–20% risk of procedure-related death with a 5% risk of premature labor following the procedure [22]. We know that cardiac pathology worsens during pregnancy, but the risk of preterm delivery after fetal intervention must be weighed up when considering its timing as it is unlikely that the Norwood [23,24] or hybrid procedure [25] would be offered to a baby of <30 weeks gestation because of low birth weight, although radiofrequency perforation and dilatation of the pulmonary valve and surgery have been performed in low birth weight babies in some large centers [26]. As a consequence, in our interventional program we have elected not to offer emergency Cesarean section should persistent fetal bradycardia occur that is unresponsive to intracardiac atropine or adrenaline.

Patient selection

Aortic valve stenosis

Previous guidance based on one retrospective series suggested that the fetus should have a dilated left ventricle and reasonably sized mitral valve with a Z score better than −4 to be considered suitable for fetal intervention. The observation of reversed flow in the transverse aortic arch (Videoclip 16.4) was identified as an indicator of progression to hypoplastic left heart syndrome [11], but this center has subsequently revised outcomes, considering only those with the best morphology (Videoclip 16.5) to be suitable for intervention because it has become clear that a fetal intervention cannot

Table 16.2 Potential selection criteria for fetal pulmonary valvoplasty[a].

Pulmonary valve	Stenosis or membranous atresia
Tricuspid valve annulus and TV/MV ratio	Z score $\geq$−3.4; TV/MV >0.71 below 31 weeks
	Z score $\geq$−3.95; TV/MV >0.59 above 31 weeks
Predictive score[b] for BV	Selection could be based on scores worse than predictive for BV
<23 weeks (100% prediction BV; 80% UV)	TV Z score >−3.4 ; PV Z score >−1.0
<26 weeks (sensitivity 68%; specificity 72%)	Median TV Z score >−3.95
26–31 weeks (sensitivity 100%; specificity 100%)	(Median PV Z score >−2.8) + (median ratio TV/MV >0.71)
>31 weeks (AUC = 0.87)	(Median TV Z score >−3.9) + (median ratio TV/MV >0.59)
Right atrial pressure score	Tricuspid regurgitation + ductus venosus + oval foramen dynamics
	Values 0–2 per variable: score >3 predictive for BV circulation[b]
Tricuspid regurgitation	None/mild = 0; moderate = 1; severe = 2
Ductus venosus	Normal = 0; absent EDF = 1; reverse EDF = 2
Oval foramen dynamics	Normal = 0; tense $1-1.5\,m\,s^{-1}$ = 1; restrictive >$1.5\,m\,s^{-1}$ = 2

[a]AUC, area under the ROC curve; BV, biventricular circulation; EDF, end-diastolic flow; MV, mitral valve;
PV, pulmonary valve; TV, tricuspid valve; UV, univentricular circulation.

alter outcome from a univentricular circulation in more severely affected patients [22] (Table 16.1).

Restrictive interatrial septum

About 6–10% of patients with aortic stenosis and hypoplastic left heart syndrome have a restrictive interatrial septum and may be considered for balloon atrial septostomy to maximize the chances of developing a normal pulmonary bed (Videoclips 16.6 and 16.7). However, the stage at which this damage occurs and when it becomes irreversible are unknown [19]. Abnormalities of lymphatic development cause lymphangiectasia and poor function and this, coupled with pulmonary venous stenoses and occlusions, proves almost universally fatal in early life. Restrictive interatrial septum may also be recognized in fetuses with simple transposition of the great arteries (ventriculo-arterial discordance). The restriction reduces left-to-right shunting at the atrial level after delivery and may result in early pulmonary venous hypertension, acidosis, and pulmonary hemorrhage with significantly increased preoperative morbidity and perinatal mortality [27]. However, as restriction usually occurs towards the end of pregnancy, a planned delivery with ready access to facilities for septostomy or early surgery is the more usual management pathway.

Pulmonary atresia with intact interatrial septum

Fetuses with critical pulmonary stenosis or membranous pulmonary atresia have also been considered for prenatal intervention. The United Kingdom and Ireland study reported a 64% 10 year survival for live-born children with pulmonary atresia with intact ventricular septum (PAIVS). Moreover only about 50% of the survivors have a two-ventricle repair, the remainder having a univentricular

"Fontan" circulation or no final pathway [28,29]. There is a spectrum of morphology in this anomaly, and clearly fetuses with minute tricuspid valves, diminutive right ventricles, and large coronary fistulas will never be suitable candidates for fetal intervention as there is no prospect of achieving a two-ventricle circulation (Videoclip 16.8). Only fetuses with membranous pulmonary atresia with an adequate right ventricle (Videoclip 16.9) are suitable for fetal valvoplasty (Table 16.2), and as only a handful of procedures have been performed there is insufficient power to assess efficacy of outcome [9,30,31]. Some children initially designated to follow a biventricular surgical pathway eventually require conversion to a Fontan circulation several years after delivery because of right ventricular failure, often associated with pulmonary regurgitation [28]. The substrate for right ventricular failure probably has its roots in fetal life and it is this that theoretically may be altered by a fetal intervention because cardiomyocyte division and maturation are severely compromised under the increased pressure load and post-mortem histopathology reveals intense mineralization, calcification, and fibrosis [21].

Fetal pacing

Complete heart block is associated with complex structural heart disease in about half of the patients (usually isomerism of the left atrial appendages) (Videoclips 16.10–16.12) and in the remainder normally connected hearts have been damaged by the transplacental transfer of anti-Ro or anti-La antibodies leading to fibrosis of the conduction tissue, myocardial calcification, and sometimes diminished cardiac function. Their mothers may be asymptomatic or have signs of connective tissue disease such as systemic lupus erythematosis or Sjorgren's syndrome [32]. There is a spectrum of fetal

presentation, the worst presenting with complete heart block and hydrops in early gestation (Videoclip 16.13) when therapeutic options are limited, usually unsuccessful, and fetal demise is common. [33] Current therapeutic strategies have included prophylactic approaches [34] (intravenous γ-globulin and maternal plasmaphoresis) to reduce or remove the antibody load early in pregnancy, and those intended to prevent progression of atrioventricular block (high-dose steroids). There is no sufficiently powered trial of any of these therapies to test their efficacy [35]. When there is no hydrops, the intrauterine course is more stable, but if the ventricular rate falls below 55 beats per minute fetal hydrops may develop and carry a high risk of intrauterine demise. Sympathomimetic drugs have been used to increase the fetal heart rate, but not always successfully as tolerance develops and higher doses of the drug are not well tolerated by the pregnant woman [36]. Fetal pacing is an alternative potential therapy [10] and was first reported in 1986 where temporary pacing was achieved in a hydropic fetus, but not sustained [37,38]. As about 75% of babies will require pacing in the first year of life, it is not known whether fetal pacing rather than earlier delivery would theoretically improve long-term outcomes as important myocardial disease coexists in ~8% and is difficult to manage. Most cardiologists try to extend the intrauterine period for as long as possible and deliver the fetus as close to term as feasible.

Interventional techniques

Fetal valvoplasty is largely performed in the same way as it was in the early 1990s, despite animal work that has explored various methods of gaining vascular access in the fetus [39] and improved imaging using fetal trans-esophageal echocardiography. Although these techniques are very attractive, they remain experimental with only isolated reports in humans [40]. They are more invasive than current percutaneous methods and lengthen the procedural time, both of which put mother and fetus at increased risk and increase the likelihood of preterm delivery due to amnionitis or rupture or separation of membranes.

Since 2000, improvements in equipment, including ultrasound imaging and development of small coronary catheters that are suitable for fetal procedures, have encouraged a reappraisal of fetal therapy. However, the development of a successful fetal therapeutic program requires an experienced team approach with the fetal medicine obstetrician key to a technically successful procedure. Most procedures have used an ultrasound-guided percutaneous technique (Videoclip 16.14) performed under local or general anesthetic [8,9]. The invasive part of the cardiac procedure takes only a few minutes once fetal lie is optimal. General anesthesia gives some procedural advantages, such as easy manipulation of the fetus into a good position for intervention, but increases the potential dangers to a pregnant woman.

Equipment and protocol

The mother is given prophylactic intravenous antibiotics to prevent amnionitis and the procedure is performed under aseptic techniques using local or general anesthesia. A 15 cm needle with a flexible stylet is introduced percutaneously by the fetal medicine obstetrician through the maternal abdominal and uterine walls and into the fetal chest. Correct alignment of the needle along the right or left outflow tract is essential for technical success and is guided by ultrasound. There is a learning curve for this, but experienced fetal medicine obstetricians already have skills in percutaneous fetal cardiac access from performing feticide for serious anomalies beyond 22 weeks by intracardiac injection of potassium chloride prior to terminating pregnancy. The percutaneous technical success rate is high in most reports, although mini-laparotomy has been required by some to gain access to the fetal heart in the early stages of their experience [8,9].

Although debate exists as to whether the fetus has the neural circuitry and developmental processes to feel pain, fetal analgesia (usually fentanyl) is usually delivered using intramuscular, intravenous, or intracardiac routes either before or just after gaining access [41]. Atropine and adrenaline are often prepared to treat sustained fetal bradycardia and may be used prophylactically upon entry into the fetal chest. The use of a paralyzing agent is not usually necessary and may be counter-productive as the fetus may then lie in a fixed, unfavorable position. Following percutaneous access, an over-the-wire short coronary balloon is used. The balloon is usually slightly larger than the diameter of the valve. An 8 mm length is the shortest balloon commercially available. A high-pressure 4 mm balloon inflated to 18 atm pressure may be suitable for creating an interatrial communication. The balloon is inflated 2–3 times across the valve if tolerated by the fetus and all equipment is removed from the fetal heart and uterus in one movement to minimize the development of pericardial effusion. A similar technique is used to cross the interatrial septum and create a patent oval foramen, and a stent has been deployed across the defect to maintain its patency. This has proved challenging and a wide variety of balloons, stents, and radiofrequency catheters have been used to create a reasonably sized and persistent communication [42,43].

Post-procedural pregnancy management and support

Women who have undergone the procedure using local anesthetic can be managed as day patients and reviewed the following morning. Those who have had a general anesthetic

or a mini-laparotomy require a longer hospital stay. The risk of premature labor associated with this type of procedure is ~5% and cervical length is usually checked before discharge. The cardiologists review the baby's cardiac function and circulation immediately after the procedure and the following day, and plan for serial evaluation locally or at the referral center depending on available expertise and family convenience.

Altering the natural history of disease

The ideal study of any disease comprises a longitudinal series of observations beginning before birth [20]. Unfortunately, the anomalies for which percutaneous fetal cardiac therapy is currently suitable are relatively rare and data are limited, and a recent audit of success in the largest series has substantially revised the acceptance criteria for fetal valvoplasty.

It is difficult to envisage a single center, or indeed a European country, having enough patients to power a study adequately to test whether the natural history has been altered by a fetal intervention. The end points of a study should ideally include preservation of a two-ventricle circulation in the short term, normal pulmonary pressures, and, for those where this has proved impossible, whether they are better Fontan candidates and experience less heart failure later in childhood or adult life [44]. Thus real benefit may only be assessed 20 years later. Centers performing fetal valvoplasty should be supported by a surgical program that includes a surgical strategy for babies with critical aortic stenosis born with a borderline left ventricle, usually including aggressive resection of endocardial fibroelastosis from the left ventricle [45]. Interestingly, neither fetal or postnatal valvoplasty nor removal of endocardial fibroelastosis were statistically significant contributors to a successful biventricular circulation in this series [46].

Conclusions

It is tempting to conclude that there is little merit in fetal therapy as only those with the very best anatomy have achieved biventricular outcomes in the largest series and we do not know whether these fetuses would have achieved this without intervention. There is still insufficient power and a lack of a large contemporaneous natural history series to be sure of its potential. However, perhaps too much emphasis is placed on the achievement of a biventricular circulation at all costs [1]. We recognize that the early surgical pathway does not always predict the final circulation because of reduced right ventricular function and progressive valvar regurgitation in some. Perhaps the success of a fetal intervention should be judged on the medium- and long-term functional outcome of either the one- or two-ventricle

circulation, reflecting the optimization of the pulmonary and myocardial development that may be achievable following successful and timely fetal intervention.

Critical congenital heart disease: frequency of and necessity for early diagnosis

Neonates with critical congenital heart disease (CHD) frequently die within 30 days after birth if not correctly diagnosed and treated [1–3]. These diseases were documented in autopsy studies before 1960 in Toronto, Boston, and Baltimore, and are tabulated in Table 17.1. The frequency of critical CHD has not changed much since those studies [4,5].

Among those critical CHDs, hypoplastic left heart syndrome, complete transposition, and coarctation of the aorta are the most frequent conditions. They account for 60% of the neonatal deaths from critical CHD [1–3]. These neonates present in several ways: with cyanosis frequently due to a ductus-dependent pulmonary circulation, dyspnea and congestive cardiac failure due to excessive volume or pressure loads, a heart murmur, or shock with weak or absent pulses in the lower extremities or indeed in all extremities due to a ductus-dependent systemic circulation.

Advances in surgical techniques have substantially reduced the perioperative mortality for neonates with critical CHD, but early diagnosis is essential for a good surgical outcome. In the best centers, the in-hospital mortality for neonates who undergo the arterial switch operation early for simple complete transposition of the great arteries now approaches 1% [6]. In a report from Paris [6], all 68 prenatally diagnosed patients survived neonatal arterial switch operation, whereas 250 postnatally diagnosed patients had a 6% presurgical mortality and a 9% postsurgical mortality, respectively. The disadvantages of delayed diagnosis have been well described in other studies [7,8]. Delay of diagnosis is particularly serious in neonates with critical CHD. Many infants with missed or late diagnosis of critical CHD die [8–10], and most of these neonatal deaths are from hypoplastic left heart syndrome, coarctation of the aorta and interrupted arch, and transposition of the great arteries. Reports from the United Kingdom that 30–50% of neonates with critical CHD left hospital undiagnosed emphasize the need for neonatal screening [11,12].

Critical CHD: Presentations

Neonates with critical CHD are usually well nourished and developed at birth, because their cardiac malformations do not impair the circulation during fetal life [13]. In every neonate after birth, the respiration switches from the placenta to the lung, the ductus arteriosus and the foramen ovale close, and the right and the left ventricles, which worked in parallel prenatally, function in series postnatally. A neonate with critical CHD cannot adapt to the postnatal circulation brought about by these physiologic changes. Table 17.1 shows presentations of these forms of critical CHD.

In complete transposition of the great arteries, cyanosis persists after birth and increases because the parallel systemic and pulmonary circulations have little blood exchange between them [13]. The neonatal patent ductus arteriosus permits aorto-pulmonary shunting and increases pulmonary blood flow, which increases left-to-right atrial shunting and increases arterial oxygen saturation. Postnatal constriction of the ductus arteriosus increases aortic hypoxemia, which can be treated with prostaglandin E_1 (PGE_1), opening the ductus arteriosus [14–16].

In coarctation of the aorta, the aortic obstruction is mild prenatally, and increases with the constriction of the ductus arteriosus postnatally [13]. This occurs usually from 1 to 7 days after birth [13]. A careful early check may reveal

Table 17.1 Critical congenital heart disease in the neonate: frequencies (%, total 376 autopsy cases) [1–3], presentation, treatment with prostaglandin E$_1$ (PGE$_1$) [14–16], and surgical indication[a].

Critical congenital heart disease	Frequency (%)	Presentation	PGE$_1$	Surgery
Transposition of great arteries	18	Cyanosis	+	+
Ventricular septal defect	15	Murmur, dyspnea		+
Coarctation of the aorta	13	Absent pulses	+	+
Aortic and mitral atresia	13	Cyanosis, shock	+	+
Pulmonary atresia and stenosis	6	Cyanosis, murmur	+	+
Patent ductus arteriosus	5	Murmur, dyspnea		+
Tetralogy of Fallot	4	Cyanosis, murmur	+	+
Cor biloculare and triloculare	4	Cyanosis	+	+
Persistent truncus arteriosus	3	Cyanosis		+
Atrioventricularis commune	2	Murmur, dyspnea		+
Total anomalous pulmonary venous return	2	Cyanosis		+
Dextrocardia or levocardia	2	Cyanosis, murmur	+	+
Endocardial fibroelastosis	3	Dyspnea		
Miscellaneous	7	–		+

[a]Note that most of those with a ventricular septal defect died with, but not because of, the defect. Most infants with an isolated large ventricular septal defect do not develop congestive heart failure until 4–6 weeks after birth when the pulmonary vascular resistance has decreased enough to permit a large left-to-right shunt.

normal femoral pulses and right-to-left ductal shunting, resulting in low SpO$_2$ in the lower extremities but a normal SpO$_2$ in the right arm. A few days after birth, femoral pulses are no longer palpable and the SpO$_2$ is the same in the upper and lower extremities. PGE$_1$ infusion in these neonates is effective in lessening aortic obstruction and can be used as a bridge to emergency surgery [13]. Similar changes occur in the courses of neonates with interruption of the aortic arch. Some neonates with very severe coarctation or with severe aortic stenosis present with a clinical picture of shock.

In aortic and mitral atresia (hypoplastic left heart syndrome), the neonate deteriorates in the first week of life [13]. Cyanosis persists after birth because the entire systemic blood flow depends on the right ventricular output and blood flow through the ductus arteriosus [13]. Postnatal ductal constriction causes circulatory shock and death, which occurs between 3 and 7 days after birth in 70% of patients [2]. PGE$_1$ infusion [14–16] is used to dilate the ductus arteriosus as a bridge to emergency surgery.

In pulmonary atresia or severe pulmonary stenosis with intact ventricular septum, the pulmonary circulation depends entirely on the ductus arteriosus [13]. After birth, the ductus arteriosus constricts, pulmonary blood flow decreases, and cyanosis increases. A ductus-dependent pulmonary circulation is present in those critical CHDs associated with pulmonary atresia, including instances with tetralogy of Fallot, tricuspid atresia, transposition of the great arteries, or single ventricle. In such patients, cyanosis is usually mild at birth while the ductus is patent. Then cyanosis may increase progressively during the first 7–10 days, or may suddenly become severe if the ductus closes rapidly. Apart from the cyanosis, the neonate is usually asymptomatic. Only when hypoxia is severe, with arterial oxygen saturation below 45%, do symptoms, particularly tachypnea, appear [13]. Metabolic acidemia develops due to tissue hypoxia and stimulation of aortic chemoreceptors causes tachypnea and hyperpnea. Urgent treatment of the hypoxia is indicated, as discussed later in this chapter.

Diagnosis

Phenotypic signs of chromosomal anomalies [17] may be the first clue to congenital heart disease. Down syndrome is associated with CHD in 30–50% of patients, including atrioventricular septal defect and tetralogy of Fallot [17]. Chromosome 22q11.2 deletion syndrome (DiGeorge syndrome) may present with hypocalcemia in the neonate, and is associated with congenital heart disease in 80% of patients, with anomalies including tetralogy of Fallot, truncus arteriosus, and aortic arch interruption (type B) [18,19]. A heart murmur in a neonate may be the first clue to the disease [20]. It is present in valvar abnormalities, such as aortic stenosis and pulmonary stenosis, and is frequently

heard on the first day. It may be slight or absent with severe stenosis. A murmur of a small ventricular septal defect may be heard in the newborn nursery, but in a large ventricular septal defect the murmur appears some weeks later, following the decrease in pulmonary vascular resistance and the increase in shunting. An innocuous murmur [20] is frequently present in healthy neonates, and is often due to peripheral pulmonary artery stenosis, pulmonary blood flow, or a small or closing patent ductus arteriosus. The best way to determine the origin of these cardiac murmurs is from echocardiographic studies.

Peripheral pulses should be evaluated carefully. Tachycardia may be associated with heart failure. Easily palpable bounding pulses in all extremities occur in CHD associated with large aorta-to-pulmonary shunts, such as a patent ductus arteriosus and truncus arteriosus [21]. Weak or absent pulses in the lower extremities are associated with coarctation and interruption of the aortic arch.

Feeding difficulty, tachycardia, tachypnea, and peripheral cyanosis may be signs of cardiac failure.

Cyanosis is a serious sign in neonates, and one to be treated with respect. Generalized cyanosis occurring more than a few minutes after birth is associated with low cardiac output, polycythemia, methemoglobinemia, cyanotic congenital heart disease, and pulmonary diseases. When a neonate remains cyanotic after a period of oxygen therapy, the clinician must perform a rapid and systematic evaluation to determine whether a cardiac malformation is present so that potentially life-saving measures can be instituted and must determine if the patient is in an optimal hemodynamic and metabolic state to undergo an operation. Neonates suspected of cyanosis are best examined when they are quiet or sleeping under a white light, preferably daylight. Central cyanosis is noticed in the tongue, mucous membranes, and nail beds, and the extremities are usually warm. A comparison of the patient's nail beds with those of the examiner may clarify the presence or absence of cyanosis. In central cyanosis, the oxygen saturation of arterial blood is reduced.

Pulse oximetry

Pulse oximetry [8,10,22–25] measures arterial oxygen saturation and pulse rate. In the neonate, an oximeter probe is applied to the right hand and a foot. If an adequate pulse is not present, as in patients with poor perfusion due to shock, or obstruction to flow as in infants with aortic coarctation, the measurement may not be possible or may be unreliable. Measurement of arterial oxygen saturation by oximetry is more reliable at higher levels of saturation. Thus, at oxygen saturation levels >90% the saturation varies by ~2%, at levels of 70–90% the variation is 3–4%, whereas at levels <70% the variation may be 5% or even higher [13].

Normal neonatal oxygen saturation [13,23]

Every neonate is cyanotic at birth. The first breaths and increasing pulmonary circulation induce a rapid rise in pulse oximeter saturation (SpO_2). The mean preductal (right hand) and postductal (foot) SpO_2 of healthy newborns at the age of 2 min is 73% (range 44–95%) and 67% (34–93%), respectively. At 10 min of age, these values increase to 92% (65–99%) and 85% (62–99%), respectively, and both of these measurements reach 95% within 1 h except in ~5% of newborns with a delayed transitional circulation. Thereafter, the normal baseline SpO_2 is fairly stable at ~98%, except for short periods when it is lower, such as during feeding and apneic spells.

Abnormal oxygen saturation [13,22]

In complete transposition, cyanosis is associated either with a generally low level of SpO_2 (<88%) or a continuous preductal/postductal difference of at least 7%. Rarely with an associated large patent ductus arteriosus, the postductal saturation exceeds the preductal saturation. In critical CHD with a ductus-dependent pulmonary circulation such as tetralogy of Fallot with pulmonary atresia, cyanosis is associated with a generally low level of SpO_2 (<88%). In ductus-dependent obstructive left heart defects, such as coarctation of the aorta, the preductal–postductal SpO_2 difference is often at least 4–5%. In hypoplastic left heart syndrome [26] and total anomalous pulmonary venous return, mild cyanosis is associated with generally low levels of SpO_2 (<95%). A pure left-to-right shunt, such as a ventricular septal defect, does not affect systemic oxygenation and is not detectable by pulse oximetry.

Age at screening [25]

The first hour of life is not suitable for pulse oximetry screening owing to the large number of false-positive findings. Thereafter, infants can be screened at any age, but more reliably at ≥2 h. First-day screening identifies CHD and some other problems, whereas later screening is more specific for congenital heart disease. Most institutions screen between 6 and 48 h after birth [8,10,24,25].

First-day screening [22,25] is performed at ≥2 h. It is so early that even many acute or life-threatening noncardiac problems may still be asymptomatic. Many such diseases have been detected as false-positive findings during screening, most of these being respiratory problems and persistent pulmonary hypertension (discussed later). First-day screening uses a two-point cut-off to form three groups. Immediate echocardiography of all newborns with SpO_2 <90% is indicated. If the first measurement is >95%, no further action is needed [10]. Those within the 90–94% group are checked at 6-hourly intervals, including respiratory rate, heart rate, and feeding. Repeat measurements within 6 h show most of the asymptomatic newborns with an SpO_2

of 90–94% group as false positive. Later screening [22,24,25] is simple because a single measurement is sufficient but may delay diagnosis.

Probe site [22,25]

Newborns with transposition or various types of pulmonary atresia have reduced SpO_2 both pre- and postductally. Anomalies with a ductus-dependent systemic circulation exhibit higher pre- than postductal SpO_2 levels due to right-to-left shunting of unoxygenated blood to the lower body. Pulse oximetry screening is therefore most effective with postductal probe placement.

Signal quality and newborn behavior [13,24]

Technical errors are minimized by accepting only high-quality pulse oximetry signals, confirmed by a good pulse signal displayed simultaneously. The heart rate displayed by the oximeter should be within the range expected for a calm, regularly breathing newborn (~90–160 min^{-1}). The highest average stable SpO_2 value of the pulse oximetry is recorded.

Cut-off [24,25]

On the first day screening, a cut-off of 95% is adequate. On the second day or later, cut-offs of 95–96% appear high enough to make the measurement of pre- or postductal SpO_2 differences unnecessary.

Sensitivity of pulse oximetry screening [24,25]

The sensitivity of pulse oximetry screening in critical CHD is ~70%, and higher than that of clinical examination. Cyanotic CHDs can be detected by pulse oximetry more often than by the clinical examination. Defects in which murmurs are predominantly absent (total anomalous pulmonary venous connection, atrioventricular septal defect, and coarctation of the aorta) are missed clinically more often than by pulse oximetry. Pure left-to-right shunts such as ventricular septal defect or patent ductus arteriosus should not be detectable by pulse oximetry. Some of these shunts (5–17%) are screen positive, however, within the first 24 h of life, probably due to bidirectional shunting during early postnatal pulmonary hypertension.

Discharges with undiagnosed heart disease [8,10,22,24,25]

Pulse oximetry before discharge reduces the number of discharges with an unrecognized serious defect. For example, in one study six of the eight newborns in whom asymptomatic cyanotic CHD was not diagnosed on clinical examination (three with total anomalous pulmonary venous return and one each with pulmonary atresia, tricuspid atresia, and common arterial trunk), the anomaly was detected by late pulse oximetry screening.

Benefits [8,10,24,25]

Pulse oximetry screening enhances timely diagnosis of critical CHD and minimizes the risk and sequelae of delayed detection. Emergency transfer and surgery carry increased risk, not to mention parental anxiety.

Drawbacks [22,25]

Pulse oximetry does not detect left-to-right shunts or other CHDs not affecting oxygenation. Its sensitivity for most of the severe defects is good, but coarctation of the aorta is often missed. A recent study has suggested that the more accurate newest generation of oximeters reveals smaller ductal shunts than previously, allowing for more sensitive detection of coarctation of the aorta. Although false-positive results incur costs for follow-up echocardiography, they are less than those using clinical diagnosis alone, and are probably very low [26].

Further diagnosis

A full cardiac work-up usually includes blood pressure measurements (all limbs), electrocardiogram (ECG), X-rays, and oxygen tests, but only echocardiography is mandatory. B-type natriuretic peptide concentration reveals CHD causing volume or pressure overload, but its sensitivity is unknown, and neonatal reference values need to be refined.

Electrocardiography

In neonates with suspected cardiac anomalies, electrocardiography may show patterns specific to each congenital heart disease. A pattern of right ventricular hypertrophy and right axis deviation is present in normal neonates, and is indistinguishable from the pattern in neonates with critical CHD, including tetralogy of Fallot, aortic atresia, and complete transposition of the great arteries. In tricuspid atresia, left ventricular hypertrophy and left axis deviation are invariably present.

Chest radiography

In the neonate with cyanosis or dyspnea, chest radiography is essential to evaluate any pulmonary disease and also critical CHD. It may show a diaphragmatic hernia, agenesis or hypoplasia of the lungs, atelectasis, pneumonia, or other lung diseases.

Management: prostaglandin E$_1$ [14–16]

Many neonates with critical CHD become symptomatic as the ductus arteriosus closes. Four types of anomalies depend on ductal flow postnatally: (1) those in which the systemic flow is either totally through the ductus (HLHS) or partially (interruption of aortic arch); (2) those in which pulmonary blood flow depends on ductal flow (conditions with

pulmonary atresia); (3) those which depend upon ductal flow for admixture (complete transposition); and (4) those in which ductal closure makes manifest a coarctation.

Maintaining ductal patency with prostaglandin E_1 (PGE_1) is vital in preoperative management [27]. Although ductal closure is rarely immediate, nearly all infants have physiologic closure of the ductus by the fourth day of life; 20% of infants demonstrate functional ductal closure during the first day, and 80% of infants demonstrate ductal closure during the second day of life. For this reason, PGE_1 therapy [14–16] should be initiated immediately when HLHS or other ductal-dependent conditions are diagnosed or suspected. The patient's physiologic state directs initial PGE_1 dosing. For patients who present in shock with suspected ductal closure, initial doses range from 0.05 to 0.1 $\mu g\,kg^{-1}\,min^{-1}$. Once ductal patency is ensured, the infusion rate can be decreased to an effective dose of 0.01 $\mu g\,kg^{-1}\,min^{-1}$. Maintaining ductal patency with the lowest effective PGE_1 dose minimizes the most common dose-dependent side effects of PGE_1.

Hypotension associated with PGE1 necessitates volume resuscitation. The associated respiratory depression necessitates mechanical support. Intravenous caffeine or aminophylline can be used to prevent apnea. Caffeine's loading dose is 20 $mg\,kg^{-1}$ followed by a maintenance dose of 5 to 10 $mg\,kg^{-1}\,day^{-1}$. Aminophylline is given as a bolus dose of 6 $mg\,kg^{-1}$ before or during the initiation of PGE_1, and is continued at a dose of 2 $mg\,kg^{-1}$ every 8h. Patients who receive these have a decreased incidence of apnea and may not require intubation.

In complete transposition, intercirculatory mixing between the systemic and pulmonary circulations is essential for postnatal survival [13,28]. In complete transposition with intact ventricular septum, the ductus arteriosus is often widely patent after birth. At this time, when pulmonary vascular resistance is still high, there is bidirectional ductal flow. With a continuous fall in pulmonary vascular resistance, the shunt through the ductus is primarily from aorta to pulmonary artery, with an equal amount of shunted blood from the left to the right atrium [13,28]. Some patients present with a delayed fall in pulmonary vascular resistance that results in persistent pulmonary hypertension, trivial ductal shunting, and limited intercirculatory mixing. Urgent balloon septostomy will not improve the severe hypoxemia, and these neonates may need urgent support with early repair or extracorporeal membrane oxygenation [13,28]. During the brief perinatal transitional interval, there may be sufficient intercirculatory mixing to limit cyanosis and avoid severe hypoxemia. However, in most affected infants, the ductus soon constricts, with resulting increased hypoxia.

In neonates with transposition, PGE_1 infusion is instituted as a bridge to surgery as soon as feasible, including during transport to the cardiac surgical center, even before the diagnosis has been confirmed echocardiographically. If the PGE_1 infusion is not effective in improving hypoxemia, balloon atrial septostomy may be required urgently.

Pulmonary atresia and patent ductus arteriosus are associated either with an intact ventricular septum [29] or with various congenital heart diseases, including ventricular septal defect, complete transposition, single ventricle, and tricuspid atresia [30]. The pulmonary circulation depends completely on the patent ductus in most patients, but only partially in those patients associated with major aorto-pulmonary collateral arteries (MAPCAs) [30]. In those neonates with a ductus-dependent pulmonary circulation, mild cyanosis persists after birth. The timing of postnatal ductal constriction in these patients is variable, but in most patients it occurs during the first 7 days of life [2]. Infusion of PGE_1 is life-saving in such neonates, and is used as a bridge for surgery [14–16].

Constriction of the ductus arteriosus is important in the development of aortic obstruction in infants with coarctation or interruption of the aortic arch. PGE_1 is used effectively in lessening the aortic obstruction and improving left ventricular failure [13]. PGE_1 is usually effective within the first 7–10 days after birth, but has less effect later [14].

Persistent Pulmonary Hypertension of the Newborn (PPHN) [31]

This syndrome consists of persistent pulmonary hypertension leading to cyanosis and respiratory failure in a newborn [32,33]. The condition usually presents at or shortly after birth. The severity of PPHN can run the full spectrum from mild with transient respiratory distress to severe hypoxemia and cardiovascular instability requiring intensive care support. Current mortality is <10% at most tertiary care centers. Most PPHN patients have an associated pulmonary parenchymal disease, such as meconium aspiration syndrome (MAS) and respiratory distress syndrome (RDS). Some occurrences without known lung disease are termed, however, primary PPHN [32–34].

PPHN primarily affects full-term and near-term neonates with an incidence estimated to be two per 1000 live births. MAS is the most common underlining diagnosis of PPHN, followed by primary PPHN. Other diagnoses include RDS, pneumonia or sepsis, pulmonary vasoconstriction from asphyxia, and pulmonary hypoplasia secondary to congenital diaphragmatic hernia or oligohydramnios [35]. Perinatal stress, such as hemorrhage, hypoglycemia, aspiration, or hypoxia, may also cause PPHN [32].

Diagnosis [30]

PPHN should be suspected in a newborn with symptoms of respiratory distress complicated by labile oxygenation and hypoxia out of proportion to the degree of lung disease. Physical examination usually reveals tachypnea, intercostal retractions, grunting, and cyanosis. Abnormal cardiac sounds, such as a systolic murmur of tricuspid regurgitation or a prominent S_2, may be heard. The chest radiograph can be

normal in primary PPHN, but in PPHN secondary to parenchymal lung disease obvious changes are evident. An atypical course with a poor response to surfactant therapy and hypoxia that is out of proportion to the respiratory problem should lead the clinician to suspect cyanotic CHD or severe PPHN. A PaO_2 increase of >20 mmHg or a saturation increase of >10% in response to oxygen suggests that hypoxemia is secondary to lung disease or mild PPHN. Higher preductal PaO_2 and SaO_2 compared with postductal equivalents indicate a ductal right-to-left shunt which occurs in approximately half of the neonates with PPHN. Ductus-dependent critical left-sided CHDs are also associated with a right-to-left shunt at the PDA and lower postductal oxygen saturation. The response to inhaled nitric oxide (iNO) may help to differentiate PPHN from cyanotic CHD. Most neonates who have PPHN respond rapidly to iNO, with an increase in PaO_2 and SaO_2. On the other hand, neonates with severe PPHN and infants with cyanotic CHD may experience little or no increase in oxygenation with iNO. An echocardiogram is needed to make an accurate diagnosis and if ductus-dependent CHD is found then PGE_1 therapy is begun. In PPHN, echocardiography can also document right-to-left or bidirectional shunts at the level of the ductus or foramen ovale, and can estimate the pulmonary artery pressure from Doppler velocity measurement of the tricuspid regurgitation jet.

Management [31]

Neonates with PPHN require supportive care tailored to the degree of hypoxemia and physiologic instability. The approach should focus on restoring the cardiopulmonary adaptation while avoiding lung injury and adverse effects on systemic perfusion. Prolonged exposure to 100% oxygen and aggressive ventilation can be avoided by judicious application of newer therapies, such as iNO, surfactant replacement, and inotropic support. A normal PaO_2 of 60–90 mmHg is important for postnatal adaptation. There is no evidence that a PaO_2 of >100 mmHg causes a greater reduction in pulmonary vascular resistance [31].

Because PPHN is often associated with parenchymal lung disease or systemic illness, therapy should target the underlying disease. Neonates with mild and transient respiratory distress may respond well to supplemental oxygen alone or with added nasal continuous positive airway pressure. Neonates with moderate respiratory distress and hypoxemia may need ventilator support and monitoring of blood gases. Management of moderate to severe PPHN requires a comprehensive approach to optimize cardiac function and to achieve uniform lung expansion and pulmonary vasodilatation. Reversal of right-to-left extrapulmonary shunting requires a reduction in pulmonary artery pressure and maintenance of the systemic blood pressure. Sedation may be necessary to provide comfort and to decrease oxygen consumption from agitation in hypoxic neonates. Finally, neonates who fail to respond to

optimum medical management may require extracorporeal membrane oxygenation (ECMO).

Inhaled Nitric Oxide therapy (iNO) [31,34]

This is the most important therapy used as a vasodilator in PPHN. The improvement in oxygenation is usually evident within a few minutes of starting iNO. iNO improves oxygenation in ≥70% of neonates who have PPHN, with the best responses in idiopathic PPHN. The ideal starting dose for iNO is 20 ppm, with the effective dose being 5–20 ppm. Doses >20 ppm do not appear to increase efficacy and are associated with more adverse effects. iNO therapy can lead to three potential adverse events: methemoglobinemia generated by oxidation of hemoglobin by NO, exposure to nitrogen dioxide generated by reaction of NO and oxygen, and inhibition of platelet aggregation by NO. With the use of iNO at <20 ppm, these adverse effects are insignificant.

Alternatives to iNO [33,35]

These include inhibiting phosphodiesterase-5 by sildenafil to preserve cyclic GMP, activation of cyclic AMP by PGI_2, and phosphodiesterase-3 inhibition by milrinone. To date, these therapies have been tested in limited clinical trials in patients who did not respond to iNO or when iNO was not available. In the most severe PPHN, ECMO is utilized [36].

18 Noncardiac Problems of the Neonatal Period

James M. Greenberg

Cincinnati Children's Hospital Research Foundation,
University of Cincinnati College of Medicine, Cincinnati, OH, USA

Preterm birth and congenital malformations account for the vast majority of mortality and morbidity encountered during the neonatal period, typically defined as the first 28 days of postnatal life. This chapter focuses on noncardiac problems encountered by small preterm infants, problems that can have dramatic effects on approaches to the management of congenital heart disease and related problems.

Preterm birth

A preterm birth is defined as occurring prior to the 259th day (37 weeks) after the onset of the last menstrual period. More than 12% of all births in the United States are preterm, with rising rates over the past two decades. The preterm birth rate in the United States is substantially higher than those in most developed countries. Preterm birth is now considered a major public health problem and is a major contributor to the high infant mortality rates reported by the United States [1]. Although preterm birth is typically treated as a single entity in vital statistics reports, the problem is a consequence of a complex interplay among biologic, genetic, environmental, and socioeconomic factors that lead to delivery prior to 37 weeks' gestation [2]. Key factors associated with preterm birth are listed in Table 18.1.

Threshold of viability

Decisions regarding delivery room resuscitation and ongoing clinical care for extremely preterm infants remain extraordinarily challenging for parents and caregivers. Most developed countries identify gestational ages ranging from 22 to 26 weeks to define the threshold of viability [3].

Reported survival rates range from 15 to 30% among infants born at 23 weeks' gestation and rise to 30–55% among those born at 24 weeks' gestation [4,5]. At 25 weeks' gestation, 30–50% of survivors display moderate to severe long-term disabilities in the form of neurodevelopmental delay, cerebral palsy, blindness, and deafness [6]. However, even published data do not account for co-morbid conditions such as major malformations or genetic disorders. Accurate gestational age dating is imperative. Survival and outcomes improve when delivery takes place at a specialty perinatal center with on-site level III NICU facilities [7].

The late preterm infant

Infants born at 34–37 weeks' gestation are the largest proportion of preterm infants. These so-called late preterm infants may appear healthy at delivery and are frequently managed in low-acuity hospital nursery settings. Analysis of large data sets demonstrates that these newborns have a significantly higher mortality risk than their term counterparts [8]. Late preterm infants are also at higher risk for numerous complications of premature birth, including hypothermia, hypoglycemia, infection, hyperbilirubinemia, and respiratory distress requiring positive pressure ventilation (Table 18.2) [9]. Long-term follow-up studies suggest that late preterm infants are more likely to experience learning difficulties in school and attention deficit disorders [10,11].

Many maternity centers are implementing restrictions and guidelines for elective inductions and cesarean delivery with subsequent reductions in the proportion of late preterm delivery [12]. Infants with congenital malformations, including those with congenital heart disease, are more likely to experience poor outcomes when delivered prior to 39 weeks [13].

Table 18.1 Risk factors for preterm birth [2]: the complexity of preterm birth is underscored by the spectrum of risk factors – despite decades of research, the pathophysiologic mechanisms leading to premature delivery remain elusive.

Pregnancy-related conditions
Pre-eclampsia
Chorioamnionitis
Gestational diabetes
Short interpregnancy interval (<6 months)
Family history of preterm birth
Assisted reproductive technology
Polyhydramnios
Cervical dysfunction
Premature, preterm rupture of membranes

Maternal medical conditions
Asthma
Hypertensive diseases
Heart disease
Diabetes
Hyperthyroidism
Autoimmune disease
Proinflammatory states (bacterial vaginosis)

Fetal conditions
Aneuploidy
Multifetal gestation
Congenital malformations

Behavioral/psychosocial
Tobacco use
Alcohol/illicit drug use
Underweight/low BMI
Stress

Sociodemographic
African-American race
Mother <18 years old
Mother >35 years old
Low socioeconomic status
Environmental/toxin exposure
Elective delivery

Table 18.2 Common complications associated with late preterm infants: most of the problems encountered by late preterm infants resolve with timely diagnosis and treatment; however, the number of late preterm births has grown over the past two decades, and associated morbidities contribute substantially to the high aggregate cost of preterm birth.

Hypothermia/temperature instability
Respiratory distress
    Transient tachypnea
    Respiratory distress syndrome
Hypoglycemia
Feeding difficulties
Hyperbilirubinemia

Maternal considerations

Optimal neonatal management requires careful attention to maternal history. Complications of pregnancy have well-described consequences for neonatal outcomes. Diabetes during pregnancy is an excellent example. In addition to an increased risk for congenital heart disease, infants born to diabetic mothers at any gestational age have elevated risk for hypoglycemia, polycythemia, and electrolyte disturbances. Those born at or near term are often macrosomic, with an attendant risk for shoulder dystocia or birth injury.

Chorioamnionitis is associated with premature rupture of membranes and preterm delivery. Fetal exposure to proinflammatory cytokines may increase fetal susceptibility to neurologic injury [14]. Maternal chorioamnionitis may accelerate fetal lung maturation as measured by surfactant protein production, but also increase the risk for subsequent bronchopulmonary dysplasia [15–17]. Neonatal complications of pre-eclampsia include growth restriction, thrombocytopenia, neutropenia, polycythemia, and hypoglycemia. Maternal autoimmune disorders such as lupus may cause fetal heart block, and prompt early delivery.

Respiratory problems

The most common respiratory problem of preterm birth is *respiratory distress syndrome* (RDS), caused by pulmonary surfactant deficiency. Since 1990, the availability of exogenous surfactant treatment and advances in respiratory support have reduced the morbidity and mortality associated with this problem [18].

The classic risk factors for RDS include preterm delivery, maternal diabetes, perinatal asphyxia, cesarean delivery without labor, and genetic factors including male gender and surfactant protein gene deficiencies. Newborns with RDS typically present with respiratory distress characterized by retractions, tachypnea, and grunting respirations. The last symptom reflects an effort to increase end-expiratory pressure by exhalation against the resistance of a partially closed glottis.

The symptoms of RDS are due to increased surface tension within the terminal airspaces, with attendant small airway collapse and air trapping. The consequences are hypoxemia and hypercarbia that progress without treatment. The cornerstone of management of RDS is exogenous surfactant treatment. Prompt intratracheal administration reverses the surfactant deficiency and improves pulmonary compliance and gas exchange.

Some providers are now employing early continuous positive airway pressure (CPAP) support in the delivery room instead of early surfactant, with good results. Early CPAP safely distends distal airways without lung injury.

Either early surfactant administration or CPAP supports respiratory function until endogenous surfactant production suffices to reduce alveolar surface tension, usually by 2–3 days after birth [19].

Surfactant treatment is typically accompanied by positive pressure mechanical ventilation. Careful control of ventilator pressure and volumes minimizes lung injury from atelectasis or over-distension.

Bronchopulmonary dysplasia (BPD) is the most important pulmonary complication of preterm birth. Northway *et al.* first described this disorder as a complication of mechanical ventilation for RDS, resulting in chronic respiratory failure with associated characteristic chest radiographic findings of atelectasis and hyperinflation [20]. This manifestation of BPD is less common in the post-surfactant era. Instead, a "new" form of BPD is now encountered which is characterized by arrest or delay of alveolarization with subsequent progressive impairment of gas exchange [21]. Neonates born prior to 28 weeks' gestation represent the highest risk group.

The diagnostic criteria for BPD have evolved over the past three decades. The current diagnostic definition is based upon oxygen requirement at 28 days after birth and further designated as mild, moderate, or severe based upon oxygen requirement at 36 weeks' postmenstrual age. Clinical decision-making surrounding oxygen administration in the NICU remains variable and subject to interpretation [22].

Both forms of BPD can be complicated by pathologically high pulmonary artery pressures and persistent abnormalities of pulmonary function. It remains difficult to predict who will develop BPD among the at-risk population. In general, the risk of BPD varies inversely with gestational age. RDS, especially severe disease, may increase risk. Volutrauma (over-distension) from excessive tidal volume delivery during mechanical ventilation also clearly raises risk [23]. However, some preterm neonates with benign early neonatal clinical courses develop BPD.

Vitamin A treatment during the early neonatal period is the only intervention capable of reducing the risk of BPD. The effect is mild, with the number needed to treat calculated as 15 on the basis of a well-controlled clinical trial [24]. Several large clinical trials have examined early treatment with inhaled nitric oxide to prevent BPD [25,26]. None showed consistent benefit, although secondary analysis suggests other potential benefits, including reduction of neurologic morbidity and respiratory morbidity for certain subpopulations.

Treatment options for BPD are supportive and do not change important long-term outcomes such as length of stay or mortality [27]. Diuretic treatment remains popular, although only short-term improvements in pulmonary compliance and respiratory support occur. Long-term complications of BPD account for a large proportion of hospital readmissions for bronchiolitis and pneumonia in the at-risk population, even among those with mild disease. Abnormalities of pulmonary function persist throughout the first year of life and beyond. BPD is an independent predictor of poor neurodevelopmental outcome and poor somatic growth [28].

Pulmonary hypoplasia is usually a secondary phenomenon following premature preterm prolonged rupture of membranes (PPPROM) during pregnancy [29]. Other causes of decreased amniotic fluid production, such as bladder outlet obstruction and renal dysplasia, also lead to pulmonary hypoplasia. The resulting oligohydramnios blunts pulmonary development during the period of branching morphogenesis, leading to decreased surface area for gas exchange after delivery. The severity of pulmonary hypoplasia is directly related to the degree and duration of the oligohydramnios and also the extent of prematurity. Prenatal treatment with amnio-infusion accompanied by shunting procedures to relieve bladder outlet obstruction may improve outcomes [30]. Space-occupying lesions in the thorax can also cause pulmonary hypoplasia. These include congenital diaphragmatic hernia and congenital pulmonary adenomatoid malformations (CPAMs).

Whatever the precipitating cause, the clinical presentation of pulmonary hypoplasia varies as a function of severity. Subtle signs and symptoms include tachypnea and spontaneous pneumothorax. As severity increases, respiratory distress escalates, with oxygenation and ventilation affected. Elevated pulmonary vascular resistance and pulmonary hypertension complicate care, as there is usually a limited response to treatment with pulmonary vasodilators, such as nitric oxide. Many practitioners, however, offer these therapeutic interventions to reduce the potential for the development of fixed pulmonary hypertension.

Feeding and gastrointestinal problems

Difficulty with oral feedings is one of the most common problems encountered in the intensive care nursery [31]. Prematurity, congenital malformation, gastrointestinal disorders, and neurologic compromise all contribute to feeding dysfunction during the newborn period. Immature suck–swallow coordination and lower esophageal sphincter function in preterm infants resolve with maturation. Co-morbidities such as BPD with tracheomalacia invariably delay progression to oral feedings [32,33]. Chronic intubation and associated procedures such as suctioning further exacerbate the problem, with oral aversion a significant long-term issue that may persist for months to years.

Infants with congenital malformations are at particularly high risk for feeding difficulties. For example, the incidence of gastroesophageal reflux in patients with congenital diaphragmatic hernia is reported as ≥60% [34,35]. Most are refractory to therapy and require long-term gastrostomy feedings. Foregut malformations such as congenital tracheo-esophageal fistula frequently include a significant degree of

tracheomalacia and esophageal dysmotility. Careful introduction and advancement of oral feedings using cue-based strategies can optimize feeding outcomes. Experienced bedside providers working closely with NICU-based speech and occupational therapists best manage the transition to oral feedings for the at-risk population. Parents and other post-discharge caregivers should also be engaged in oral feedings to ensure a safe, timely discharge from the NICU.

Necrotizing enterocolitis (NEC) remains one of the most devastating gastrointestinal complications of the neonatal period (also see Chapter 15). The etiology of NEC remains unclear. Pathologic invasion of the intestinal mucosa by endogenous bacterial flora appears to be an important common mechanism. Affected individuals develop inflammation and, if severe, transmural necrosis of the bowel. The terminal ileum is preferentially affected, although any region of the large or small bowel may be involved.

Preterm infants are the primary at-risk population. The incidence of NEC decreases with increasing gestational age. Among very low birthweight infants (<1500 g) the incidence is ~7% [36]. The disease is occasionally encountered in term infants. Congenital heart disease or myocardial dysfunction is associated with increase risk of NEC in the late preterm and term neonatal population [37].

The presentation of NEC may be subtle or fulminant and is characterized by the acute onset of feeding intolerance, with tender abdominal distension and dysmotility. Severe disease displays hematochezia, septic shock, and respiratory

Figure 18.1 Radiographic findings in severe necrotizing enterocolitis. This plain film of the abdomen demonstrates many of the classic radiographic findings of severe, Bell stage IIIB, NEC (see Table 18.3 for a complete staging scheme). Of note there is pneumatosis intestinalis, portal venous gas, and pneumoperitoneum. Surgical intervention is indicated and may take the form of exploratory laparotomy with resection of necrotic bowel, or placement of a peritoneal drain. Mortality risk approaches 50% for stage IIIB disease.

Table 18.3 The modified Bell staging system [1,2] for necrotizing enterocolitis (NEC) guides management and provides a useful basis for clinical studies.

Stage	Systemic signs	Abdominal examination	Radiographic signs	Treatment
IA (suspected NEC)	Nonspecific temperature instability, apnea, lethargy, feeding intolerance	Normal or subtle distension	Normal or mild ileus	Bowel rest; 3 day antibiotic treatment
IB (suspected NEC)	As above with hematochezia	As above	As above	Bowel rest; decompression; 3–10 day antibiotic treatment
IIA (definite, mild disease)	As above	As above with tenderness or absent bowel sounds	Intestinal dilation, bowel wall thickening, and pneumatosis intestinalis	Bowel rest; decompression; 10 day antibiotic treatment
IIB (definite, moderate disease)	As above plus mild metabolic acidosis, thrombocytopenia	As above; tenderness more pronounced	As above; ascites may be evident	As above; may require correction of acid–base abnormalities and blood products
IIIA (severe disease with intact bowel)	As above with definite metabolic acidosis, thrombocytopenia, neutropenia, clotting abnormalities	As above with definite abdominal distension, peritonitis	As above	As above
IIIB (severe, with bowel perforation)	As above	As above	As above with pneumoperitoneum or portal venous gas	As above plus surgical intervention

failure exacerbated by compromised diaphragmatic excursion. Abdominal X-rays demonstrate distended bowel loops, bowel wall thickening, and pneumatosis intestinalis, a speckled pattern of intraluminal radiolucency caused by bacterial gas production (Figure 18.1). This X-ray finding is pathognomonic of NEC. A staging scheme described by Bell *et al.* remains useful for defining management and prognosis [38,39]. Those with Bell stage IIIB (Table 18.3) usually require surgical intervention in the form of peritoneal drain placement or exploratory laparotomy with resection of nonviable bowel. Medical management is supportive. Antibiotics, fluid resuscitation, bowel rest, and respiratory support with a focus on achieving acid–base balance are the norm. Bell stage III or IV disease has a high mortality risk approaching 40%. Long-term complications among survivors include stricture formation and complication of short bowel syndrome and also increased risk for developmental delay. Prevention strategies remain largely investigational. Pro- and prebiotics have shown promise in prospective trials [40]. Progress has been limited by variations in such preparations, availability, and safety concerns.

Hyperbilirubinemia is common in the early neonatal period, with >50% of preterm infants experiencing some degree of clinical jaundice [41,42]. Much of this is an exaggerated physiologic manifestation of the normal increase in unconjugated bilirubin levels that takes place after delivery. Bilirubin is a catabolic bile pigment byproduct of heme metabolism. Excess production from pathologic hemolysis or impaired catabolism due to hepatic dysfunction or immaturity represents a major source of elevated bilirubin levels. The overriding concern associated with hyperbilirubinemia is kernicterus, the irreversible death of central nervous system structures caused by toxic levels of unbound bilirubin crossing the blood–brain barrier.

Treatment of hyperbilirubinemia is directed towards eliminating the risk of kernicterus. In general, the risk of kernicterus increases with rising serum bilirubin levels. There is no single level of bilirubin that predicts kernicterus, especially in a preterm infant. Nomograms designed to predict peak bilirubin levels represent an important advance in clinical management [43]. In general, the rate of rise, duration of elevated levels, and etiology of bilirubin production are important variables to consider when developing a management strategy. The standard first-line treatment of hyperbilirubinemia is phototherapy, its effectiveness being a function of maximizing the area of exposed skin illuminated by an effective light source. Specialized banks of lights and fiber-optic phototherapy "blankets" are used to achieve this therapeutic goal. Recent studies demonstrate that immune-mediated hemolysis, such as that caused by ABO or rH incompatibility, also responds to reticuloendothelial blockade with intravenous immunoglobulin treatment [44]. If bilirubin levels do not decrease with phototherapy and intravenous immunoglobulin, double-volume exchange

Figure 18.2 Cranial ultrasound examinations demonstrating intraventricular hemorrhage and periventricular leukomalacia. The upper panels depict (A) coronal and (B) sagittal views of a severe, grade IV, intraventricular hemorrhage involving the right lateral ventricle. A large clot and hemorrhage extend into the surrounding brain parenchyma. There is also ventricular dilation. In (C), multiple small cystic lesions and excess echogenicity of periventricular white matter are seen over the posterior horn of the lateral ventricle. These lesions can occur without associated intraventricular hemorrhage and may not be apparent on ultrasound during the first 1–2 months after delivery. MRI imaging is more sensitive.

transfusion should be performed. This procedure carries substantially more risk than phototherapy and should be performed under careful observation by experienced providers.

Neurologic problems (also see Chapter 52)

The preterm infant is at risk for *intraventricular hemorrhage* (IVH) that arises in the germinal matrix and, in more severe forms, extends into the lateral ventricles. Staging of IVH is based upon anatomic location: grade I hemorrhage is limited to the germinal matrix, grade 2 bleeding involves the ventricle without dilatation, grade 3 IVH includes ventricular dilatation, and grade 4 IVH extends beyond the lateral ventricle into the adjacent parenchyma. The incidence of IVH has declined with more frequent transfer of high-risk mothers to specialty perinatal centers, antenatal steroid administration, and surfactant treatment for RDS.

The risk of severe (grade 3 or 4) IVH increases with decreasing gestational age, especially at <32 weeks. Most IVH occurs within the first 5 days after birth; it is very unusual to encounter new-onset IVH after 10 days of age [45]. Because IVH can be asymptomatic, at-risk infants should be screened by cranial ultrasound at 7–10 days of age (Figure 18.2). Treatment for IVH is supportive. Follow-up cranial ultrasounds should be provided for infants with IVH until the hemorrhagic process is deemed to be in the resolution stage. Obstructive hydrocephalus is the most common complication of severe IVH and may require neurosurgical intervention for intraventricular shunt placement [46].

Preterm infants are also at risk for periventricular white matter injury, also known as *periventricular leukomalacia* (PVL). Those with IVH or a history of cardiopulmonary instability are most likely to develop PVL [47,48]. Affected areas may be defined by focal necrosis (cystic PVL) or demyelination (Figure 18.2). The periventricular white matter in preterm infants is particularly sensitive to ischemia due to immature cerebrovascular pressure regulation and vascular distribution. The reported prevalence of PVL diagnosed by cranial ultrasound is estimated as 5–15% in at-risk populations. Improvements in access and protocols for MRI techniques, however, may reveal lesions in more patients, including those with congenital heart disease. Those who have undergone surgical correction appear to be at particularly high risk. The clinical and prognostic significance of PVL diagnosed by advanced imaging techniques remains an important area for future investigation. Long-term sequelae include cerebral palsy and developmental delay.

19 The Epidemiology of Cardiovascular Malformations

Christopher Wren

Freeman Hospital, Newcastle upon Tyne, UK

Introduction

Congenital malformations are the commonest cause of infant mortality in the Western world, and those affecting the cardiovascular system are the commonest type of major congenital anomaly [1,2]. Cardiovascular malformations are said to account for 6% of infant deaths and 30% of deaths due to malformation [3]. Study of the epidemiology of cardiovascular malformations is important for several reasons: we may gain insight into possible causes, we can measure the disease burden in the population, and we can use the data for planning health services and the training and provision of facilities for healthcare providers.

Definitions, inclusions, and exclusions

Most reports adopt the definition first proposed by Mitchell *et al.*: "a gross structural abnormality of the heart or intrathoracic great vessels that is actually or potentially of functional importance" [4]. Most also exclude isolated systemic venous anomalies, patent ductus arteriosus associated with prematurity, cardiomyopathies, isolated cardiac arrhythmias, and cardiac tumors. Bicuspid aortic valve without stenosis or regurgitation is another common exclusion. Its reported prevalence ranges from 0.4 to 2.25%, so it is more common than all other "congenital heart defects" [5,6].

Most congenital cardiovascular malformations are easy to define so that their clinical ascertainment should be complete. Three common exceptions to this are mild pulmonary valve stenosis, mild aortic valve stenosis, and atrial septal defect. Very few reports define Doppler velocities in valve stenosis. None defines atrial septal defect, which is a common normal finding in infancy. The frequent lack of a definition, and lack of consistency when there is one, means that there is likely to be considerable variation between studies and this leads to ascertainment bias.

In some reports, double outlet right ventricle is a relatively common diagnosis whereas in others it does not occur at all. Double outlet right ventricle defines one part of a malformation, which is important when contemplating surgical repair [7], but it does not have a constant definition [8,9] and does not define an anatomically or physiologically distinct group of malformations [8]. It includes diagnoses that may otherwise be described as transposition of the great arteries, tetralogy of Fallot, ventricular septal defect, and so on. There are other instances of methods of classification leading to apparent inconsistencies in birth prevalence of cardiovascular malformations. Pulmonary atresia with ventricular septal defect is sometimes considered as a variation of tetralogy of Fallot and is coded as such. This accounts for the apparent lack of patients having pulmonary atresia with ventricular septal defect in many US reports [10].

Description of complex malformations

Most malformations are easily described by a single term such as ventricular septal defect or coarctation of the aorta. Some common abnormalities, such as tetralogy of Fallot, are made up of more than one morphological abnormality but occur together so frequently that the pattern is universally recognized. Other malformations are complex and cannot be described by a single term or combination of terms [11]. If this occurs, sequential analysis is used to describe the total cardiac morphology and connections, beginning at the venous end of the heart and progressing to the great arteries [12].

Diagnostic hierarchy

Classification of patients with multiple cardiovascular malformations can be difficult, and most published reports have allocated each patient a single diagnosis based on the malformation which is judged to be most important. If patients with more than one diagnosis have to be given only one label, some type of hierarchy is required to decide in which category they fit best, but there is no consensus on how this is best achieved.

The main hierarchies which have been used can be described as anatomic, physiologic, embryologic, and functional, although many older series ignore the problem altogether. Many reports have adopted either the classification proposed in the New England Regional Infant Cardiac Program, which defined a hierarchy based mainly on anatomic severity [13], or that in the Baltimore–Washington Infant Study, in which priority was given to "the malformation components with the earliest embryonic disturbance" [10]. In practice, these two approaches, both of which use a broadly "anatomic" hierarchy, are similar. Reports which are institution based and which cannot define the denominator population usually adopt a "physiologic" hierarchy, taking as the most significant that abnormality which requires the earliest intervention or which causes the greatest hemodynamic disturbance.

Measures of disease frequency

The incidence of disease measures the number of new cases arising over a period of time in a population at risk. Prevalence is a measure of the disease burden in a population. Neither incidence nor prevalence in their classical definitions is directly applicable to descriptive studies of congenital malformations. Most congenital cardiovascular malformations are not immediately apparent at birth but come to notice over time. Hence the period of ascertainment has a significant effect on the measure of disease frequency.

Incidence or prevalence?

Hoffman and Kaplan have argued that the population frequency of cardiovascular malformations should be known as the incidence [6,14]. Both Ferencz and colleagues [10,15] and Daniels [16] favor the use of the term "prevalence at live birth." Because many diagnoses are made retrospectively (i.e., some time after birth), the prevalence would appear to increase with time, yet this is only due to increasing retrospective diagnosis. Open-ended ascertainment obviously gives the opportunity for further increase in the apparent

prevalence at live birth. Ferencz and colleagues therefore suggested that reported diagnoses should be made within 1 year from birth.

The definition of "prevalence at live birth" used here is *the number of patients with a cardiovascular malformation within the population present at birth and diagnosed within the first year of life*. Obviously this is not a true measure of disease occurrence or frequency. It does not consider cardiovascular malformations causing stillbirth or early fetal loss. The rates of cardiovascular malformations in stillbirths are many times higher than those in live births [17]. Prevalence at live birth also cannot take account of antenatally identified lesions that lead to termination of pregnancy, and such reports have to be made separately. This means that prevalence at live birth is the best measure we have but can never be a precise measure of total disease frequency. The total amount of disease is higher because of failure to consider cases causing death before birth, continued ascertainment in childhood and adult life, and the necessarily restrictive definition of cardiovascular malformation.

Prevalence at live birth of cardiovascular malformations

There have been many reports of the live birth prevalence of cardiovascular malformations in the last 50 years. Comparison of reports is hampered by the lack of a common method. Early studies included many unconfirmed clinical diagnoses (before ultrasound was widely available) and some more institution-based recent studies are limited by their inability to define the population from which their patients were derived. Comparisons between studies are also made more difficult by uncertainties over ascertainment and because of the different diagnostic categories and diagnostic hierarchies employed. The reported disease frequency varies considerably. Even if we limit assessment to studies which have a defined denominator population, exclude stillbirths and terminations of pregnancy, and limit ascertainment to the first year of life, there is no evidence of a significantly higher or lower number of malformations in any specific population [6]. The same applies to individual malformations.

The overall prevalence at live birth of cardiovascular malformations is around eight per 1000 live births [14]. The reported live birth prevalence has increased over time but this is probably entirely due to better ascertainment of minor malformations [18]. Figure 19.1a shows a plot of results in 84 population-based reports published in 1951–2005, and Figure 19.1b shows the relationship between smaller studies and higher reported live birth prevalence in the same 84 reports.

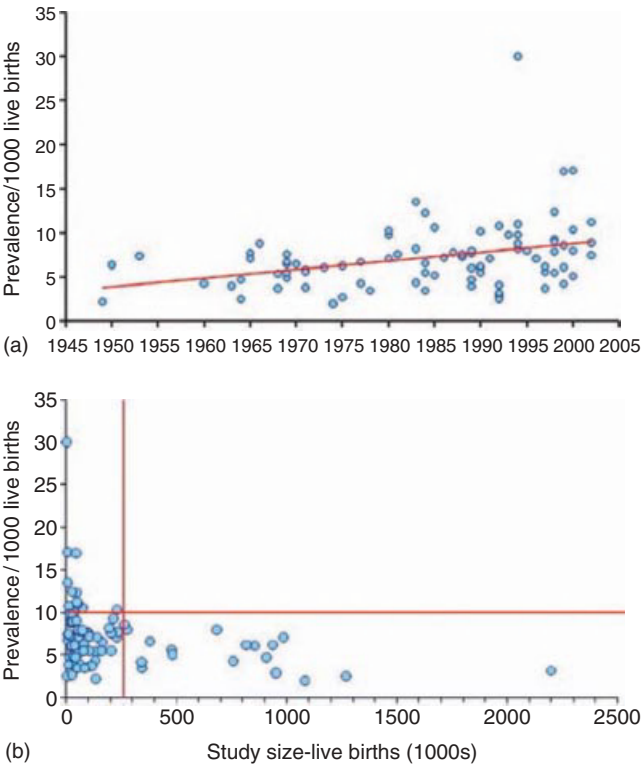
Ventricular septal defect is the commonest anomaly in all reports (Table 19.1), with a mean live birth prevalence of


Figure 19.1 (a) Relationship between final year of data collection and reported prevalence at live birth of cardiovascular malformations. Similar results are obtained by plotting middle year of study or year of publication. (b) Relationship between study size (denominator live births) and prevalence at live birth of cardiovascular malformations.

Table 19.1 Prevalence at live birth of cardiovascular malformations – all per 100 000 live births[a].

Cardiovascular malformation[b]	Hoffman and Kaplan, 2002 [14]: median	Papers with common method [41–55]: mean

[a]A summary of published data on the prevalence at live birth of the most common cardiovascular malformations. Data from Hoffman and Kaplan [14] are compared with a summary of data from papers [41–55] sharing a common method (having a defined birth cohort, confining ascertainment to the first year of life, excluding stillbirths and terminated pregnancies, and including only diagnoses confirmed by echocardiography, cardiac catheterization, surgery, or autopsy).

[b]AS, aortic valve stenosis; ASD, atrial septal defect; CAT, common arterial trunk; CTGA, congenitally corrected transposition of the great arteries; CAVSD, complete atrioventricular septal defect; CoA, coarctation of the aorta; DIV, double inlet ventricle; Ebstein, Ebstein's malformation of the tricuspid valve; HLH, hypoplastic left heart; PA, pulmonary atresia; PA/IVS, pulmonary atresia with intact ventricular septum; PA/VSD, pulmonary atresia with ventricular septal defect; PDA, persistent ductus arteriosus; PS, pulmonary valve stenosis; SV, single ventricle; TA, tricuspid atresia; TAPVC, total anomalous pulmonary venous connection; TGA, transposition of the great arteries; ToF, tetralogy of Fallot; UVH, univentricular heart; VSD, ventricular septal defect.

around 175 per 100 000 (but up to 5000 per 100 000 in studies which used early color Doppler echo to find very small defects). Coarctation of the aorta, complete atrioventricular septal defect, transposition of the great arteries, and tetralogy of Fallot all have a mean live birth prevalence of around 30–40 per 100,000 (Table 19.1). Data for other individual anomalies are also summarized in Table 19.1. The lack of a definition of malformations such as aortic stenosis, pulmonary stenosis, and atrial septal defect leads to marked variations in ascertainment.

Some cardiovascular malformations are more prone to ascertainment bias than other. Those, such as transposition of the great arteries and tetralogy of Fallot, have a widely accepted definition, usually occur as isolated anomalies, are little affected by prenatal diagnosis and termination of pregnancy, and almost always present in the first year of life. As expected, they have fairly constant reported birth prevalence with variations explained by sample size, that is, a wider confidence interval in smaller studies (see Figure 19.2a–d). Others, such as ventricular septal defect, atrial septal defect, coarctation of the aorta, and pulmonary valve stenosis, are affected by variable ascertainment and reporting due to

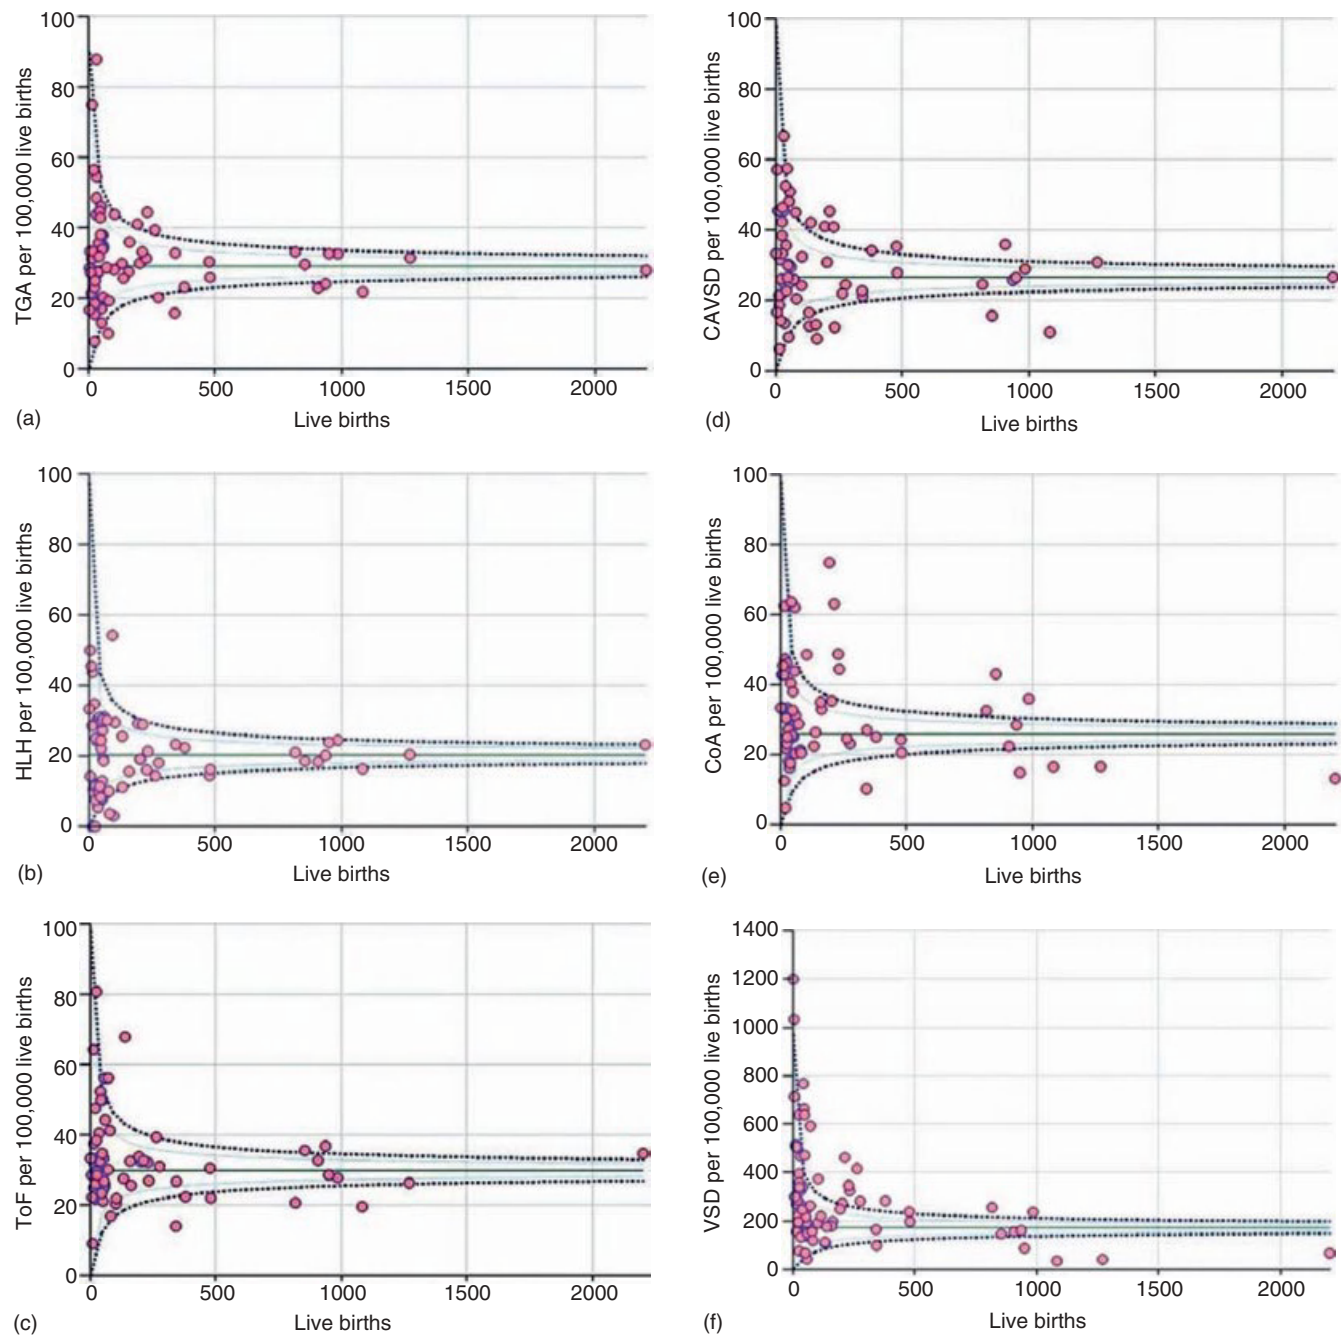
lack of a uniform definition, significant numbers being first diagnosed after infancy, variable ranking of diagnostic hierarchy in the presence of multiple malformations, and so on. This leads to significant skew when the data are plotted, as shown in Figure 19.2e and f.


Figure 19.2 Funnel plots of the variation in reported prevalence at live birth of six common cardiovascular malformations. Each funnel plot shows the relationship between study size (thousands of live births in the denominator population) on the *x*-axis and reported live birth prevalence on the *y*-axis. Each individual study is shown by a pink circle. The green line shows the mean, the pale blue lines show two standard deviations from the mean and the dashed dark blue lines show three standard deviations from the mean. As can be seen, the variation is much wider with smaller study size. In the absence of ascertainment bias, almost all data points will lie within three standard deviations from the mean – as shown here for transposition of the great arteries (TGA) in (a) and hypoplastic left heart (HLH) in (b). There is a little more variation for tetralogy of Fallot (ToF) in (c) and complete atrioventricular septal defect (CAVSD) in (d). The results for coarctation of the aorta (CoA) in (e) and ventricular septal defect (VSD) in (f) are notably skewed and more widely scattered, providing clear evidence of ascertainment bias – see text for further explanation.

Table 19.2 Estimates of population prevalence of cardiovascular malformations.

	UK	EU	USA
2005 population	60 266 000	491 875 000	281 422 000
2005 birth rate (per 1000 population)	12.0	10.4	14.1
2005 births	723 000	5 134 000	3 940 000
New cases of CVM[a] (at 10 per 1000 live births)	7000	51 000	39 000
Hoffman *et al.* all CVM 3.9	235 000	1 919 000	1 110 000

Marelli *et al.* all CVM 4.1	247 000	2 017 000	1 154 000
Severe CVM 0.38	23 000	187 000	107 000

[a]CVM, cardiovascular malformation.

Causes of cardiovascular malformations

About 10–15% of cardiovascular malformations have a chromosomal or genetic cause [19–22]. Rather fewer are known to be environmental in origin [23,24]. Most environmental causes of cardiovascular malformations occur within the fetal–placental–maternal "environment." Factors associated with increased risk include maternal illness and infection, maternal nutritional excesses and deficiencies, maternal drug exposure, and other environmental exposures.

The cause of most cardiovascular malformations remains unknown, although many more will probably be found to be caused by genetic factors. Epidemiologic studies have produced some interesting findings which offer intriguing clues. Cardiovascular malformations are more common in the offspring of diabetic mothers [25], in twins [26], and in preterm [27] and small-for-dates infants [28]. Some anomalies, such as transposition of the great arteries, hypoplastic left heart, and aortic valve stenosis, are more common in boys, whereas atrioventricular septal defects, atrial septal defects, and patent ductus arteriosus are more common in girls [29].

Population prevalence of cardiovascular malformations

The term "prevalence" measures the total disease burden in a population at any given time. Hoffman *et al.* estimated the total prevalence of cardiovascular malformations by modeling the survival of individual malformations with and without treatment over the period 1940–2002 [30]. They produced high and low estimates and predicted the range of malformations to be found within the total population. Rosamond *et al.* assumed that the true prevalence is two-thirds of the way between Hoffman *et al.*'s estimated

high and low ranges [31]. This leads to predictions that the total population prevalence of all cardiovascular malformations is 3.9 per 1000 (7.4 in children and 2.4 in adults) (Table 19.2).

Marelli *et al.* used a healthcare administration database to determine the population prevalence of severe and other cardiovascular malformations in Quebec [32]. The prevalence increased over time so that there are now more adults than children with cardiovascular malformations (Table 19.2).

The increasing number of children with cardiac malformations who now survive into adolescence and adulthood underscores the need for the healthcare community to prepare for the challenging and often complex needs of adults with congenital heart defects. The predicted number of patients graduating to adult follow-up each year is relatively small compared with the number of adults with heart disease. These patients, their families, and their cardiologists and surgeons, however, have already invested greatly in time, effort, and resources. Rapid recent advances have led to the emergence of adult congenital heart disease as a distinct subspecialty and it is important to be able to predict its future growth to ensure appropriate provision of medical manpower, facilities, and resources for the care of these patients [33–35,35a].

Predicting and measuring surgical workload

Rosamond *et al.* [31] used predictions from Moller [36] to suggest that cardiovascular malformations needing surgery or causing death in infancy occur in 2.3 per 1000 live births. The United Kingdom Central Cardiac Audit Database data for 2005–2006 showed that 2372 operations were performed in infancy – 3.3 per 1000 live births (another 1612 operations

(a) Infant deaths per 100,000 population

(b) Infant deaths per 100,000 live births
Figure 19.3 The contribution of individual diagnoses to infant mortality. (a) is redrawn from data in Boneva *et al.* [38] and shows the relative contribution of individual malformations *causing* infant mortality. (b) is redrawn from data in Wren and O'Sullivan [35] but includes malformations in all infant deaths, where the malformation was not necessarily the cause of death. This explains the much higher numbers of ventricular septal defects and atrioventricular septal defects, both strongly associated with fatal trisomies. AS, aortic valve stenosis; ASD, atrial septal defect; CAT, common arterial trunk; CAVSD, complete atrioventricular septal defect; CoA, coarctation of the aorta; DS, Down syndrome; HLH, hypoplastic left heart; PDA, patent ductus arteriosus; PS, pulmonary valve stensosis; TGA, transposition of the great arteries; ToF, tetralogy of Fallot; VSD, ventricular septal defect.

were performed in childhood) [37].There will have been more than one procedure per patient, so the number of infants requiring intervention is probably around 3–3.5 per 1000 live births. These data can be used to predict the surgical workload and show that around 2200–2500 infants per year will require intervention in the United Kingdom and 15 000–18 000 within the European Union. The prediction for the United States of 12 000–14 000 procedures is close to measured activity [31].

Cardiovascular malformations and mortality

Mortality associated with cardiovascular malformations has been assessed in several studies, although most include only surgical or postoperative deaths. Boneva *et al.* analyzed death certificate data to investigate trends in mortality associated with cardiovascular malformations in the United States in 1979–1997 [38]. Mortality decreased from 2.5 to 1.5 per 100 000 persons in the whole population. Mortality in infancy declined by 39%. In Western populations, it is estimated that 44% of all deaths from malformations are due to cardiovascular malformations [39] and that cardiovascular malformations cause around 10% of all infant deaths [40].

The contribution of individual malformations to total mortality can be derived from published data [38]. Figure 19.3a, adapted from Botto and Correa [39], shows that hypoplastic left heart made the highest individual contribution to mortality. Other data show a different picture (Figure 19.3b), with ventricular septal defect making the largest contribution to infant deaths [35].The discrepancy between these two findings is that the US study investigated the cause of death whereas the UK study looked at deaths in infants with a malformation. Most deaths in infants with a ventricular septal defects were not caused by the malformation itself but represent the total mortality in patients from associated severe noncardiac malformations or chromosomal and genetic problems, such as fatal trisomy.

20 Anatomy and Description of the Congenitally Malformed Heart

Robert H. Anderson[1], Anthony M. Hlavacek[1] & Jeffrey Smallhorn[2]
[1]Medical University of South Carolina, Charleston, SC, USA
[2]Stollery Children's Hospital, Edmonton, AB, Canada

Introduction

In the first edition of this book, the question was posed as to why a chapter needed to be devoted to the nomenclature of congenitally malformed hearts, because the lesions themselves had not changed since their initial descriptions. In fact, two chapters were included in the first edition in attempts to answer this question, as not all were agreed at that time on the best way to describe and catalog the manifold individual lesions that could coexist within the congenitally malformed heart. In this second edition, this is the only chapter specifically devoted to anatomy and nomenclature, albeit that accounts of salient anatomic features will be provided in the various chapters describing well-recognized individual lesions. The reasons why a single chapter is now considered sufficient are multiple. In the first place, it is now appreciated that many perceived differences between "schools of nomenclature" are more apparent than real. More importantly, the techniques used to demonstrate the anatomic features of the congenitally malformed heart are now sufficiently advanced that morphology can now be displayed with as much, if not more, accuracy during life as when we hold the autopsied hearts in our hands. In this chapter, therefore, we summarize the details of sequential segmental analysis, now universally accepted as the point of departure for clinical diagnosis. We show how the newly developed diagnostic techniques providing three-dimensional information during life have resolved many, if not most, of the previous controversies. We conclude the chapter with brief considerations of the morphology that underpins the understanding of septal deficiencies.

Sequential segmental analysis

All congenitally malformed hearts, like normal hearts, have three building blocks, namely the atrial chambers, the ventricular mass, and the arterial trunks (Figure 20.1). Initial approaches to description and categorization were based on the need to recognize the limited potential for variation in each of these so-called cardiac segments [1–4]. When some of us sought to modify these early approaches [5], our failure to recognize the fact that the terms concordance and discordance had been used to describe harmony or disharmony between the segments, rather than the fashion in which the components were joined, or not joined, together led to decades of ongoing controversy. The initial use of concordance and discordance to account for the relations between the topological arrangement of the segments [1,2] was reasonable, because at that time it was difficult to be sure of how, for example, the cavities of the atrial and ventricular chambers were joined across the atrioventricular junctions. The development of cross-sectional echocardiography changed all that. Thus, when the concept of sequential segmental analysis was promoted [5], attention was concentrated on the potential anatomic variations across the atrioventricular and ventriculoarterial junctions [5]. Junctional connections, of course, cannot be established without knowledge of segmental topology, so the arrangements within the segments remained the starting point for analysis.

As intimated above, the reason for subsequent dissent came because concordance and discordance were used specifically to define the feature now known as "connections," using these terms to distinguish these variants from other
Figure 20.1 The three primary cardiac segments are delineated anatomically by the discrete atrioventricular and ventriculoarterial junctions.

arrangements such as double inlet or double outlet [5]. Within the original concept, however, patients having double inlet left ventricle within the segmental combination codified as {S,D,D} were also described as exhibiting atrioventricular concordance [1,4]. One of the fundamental differences between the usual heart (Figure 20.2a) and the heart showing double inlet left ventricle (Figure 20.2b), nonetheless, lies in the way that the atrial cavities join the ventricular cavities across the atrioventricular junctions. We now overcome these conceptual difficulties between the segmental and sequential segmental approaches by avoiding the use of "concordance" and "discordance" to describe the fashion in which cavities are joined together across the atrioventricular and ventriculoarterial junctions. Instead, we specify the existence of concordant or discordant connections.

Sequential segmental analysis, therefore, has evolved with the passage of time [5,6]. Despite the changes, it continues to follow its initial basic and simple rules. Morphology, connections, and relations of the segmental components are recognized as three individual facets of the cardiac make-up. Clarity in describing these features is considered more important than brevity. It is the desire to achieve optimal clarity that has led to the changes in descriptions made during the process of evolution. No apologies are made for these changes [7], made in response to valid criticisms, which have eradicated initially illogical points from the system to its advantage [8]. Should further illogicalities become apparent, they will similarly be extirpated.

The morphological method

Segmental analysis depends on the ability to distinguish the morphology of the individual atrial and ventricular chambers, and to recognize the nature of the arterial trunks taking origin from the ventricular mass. This is not as straightforward

as it may seem, because when the heart is congenitally malformed, these chambers or arterial trunks may lack some of the morphologic features that most obviously characterize them in the normal heart. For example, the most obvious feature of the morphologically left atrium in the normal heart is its connection to the pulmonary veins. In hearts with totally anomalous pulmonary venous connection, these veins connect to extracardiac sites, yet it is still possible to recognize the remnant of the left atrium. It was considerations of this type that prompted the establishment of the concept now used to underpin the recognition of the cardiac chambers and great arteries, which is known as the morphologic method [9,10]. The principle states that cardiac structures should be recognized in terms of their intrinsic morphology, one part of the heart not being defined in terms of other structures that are themselves variable.

When applying this concept to the atrial chambers, the connections of the great veins are immediately disqualified as markers of morphological rightness or leftness, simply because the veins do not always connect to their expected atrial chamber. Septal morphology is of little help when the septum itself is absent, and the atrial vestibule is ruled out as a marker because it is usually lacking in hearts with atrioventricular valvar atresia. Fortunately, there is another component of the atrial chambers that is almost universally present, namely the appendage. When judged on the extent of its contained pectinate muscles, this feature always distinguishes between morphologically right and left atrial appendages [11]. The morphologically right appendage has the shape of a blunt triangle and joins over a broad junction with the remainder of the atrium. The junction is marked externally by the terminal groove and internally by the terminal crest, while the pectinate muscles lining the appendage extend all around the parietal atrioventricular junction (Figure 20.3a). The morphologically left appendage, in contrast, is much narrower and tubular. It has a narrow junction with the remainder of the atrium that is marked by neither terminal groove nor muscular crest. The pectinate muscles are confined within the morphologically left appendage, with the posterior aspect of the morphologically left vestibule being smooth-walled as it merges with the pulmonary venous component (Figure 20.3b).

The morphologic method also shows its value when it is applied to the ventricular mass, which extends from the atrioventricular to the ventriculoarterial junctions. Within the ventricular mass, as thus defined, there are almost always two ventricles. Description of ventricles, no matter how malformed they may be, is facilitated if they are analyzed as possessing an inlet, extending from the atrioventricular junction to the distal attachment of the atrioventricular valvar tension apparatus, an apical trabecular component, and an outlet component, the latter part supporting the leaflets of the arterial valve. Of these three components, it is the apical trabecular component that is most universally

(a)   (b)
Figure 20.2 Panel (a) shows how the normal heart has separated atrioventricular junctions for the right-sided and left-sided atrial and ventricular chambers. The cavities of the chambers are connected together across these junctions. Panel (b) shows double-inlet left ventricle. The essential feature is that both atrioventricular junctions are connected to a dominant left ventricle.
Figure 20.3 The computed tomographic reconstructions show the morphologic differences, based on the extent of the pectinate muscles, between the morphologically right (a) and the morphologically left atrial appendages (b). The pectinate muscles in the right atrium extend around the orifice of the tricuspid valve, while those in the left atrium are confined within the tubular appendage.

present in normal, and also in malformed and incomplete, ventricles. Furthermore, it is the pattern of the apical trabeculations that differentiates best the morphologically right from the left ventricle (compare Figure 20.4a and b). This remains true when the apical components exist as the basis of incomplete ventricles, which lack either an inlet or an outlet component, or sometimes both.

When the morphology of individual ventricles is identified according to the apical myocardium, all hearts with two ventricles can readily be analyzed according to the way that the inlet and outlet components are shared between the apical trabecular components. When describing the overall ventricular mass, it is also necessary to describe the way in which the two ventricles themselves are related to each other. There are two patterns, which are mirror images of

each other. They can be conceptualized in terms of the way that, figuratively speaking, the palmar surface of the hands can be placed on the septal surface of the morphologically right ventricle. In the morphologically right ventricle of the normal heart, irrespective of its position in space, it is the palmar surface of the right hand which can be placed on the septal surface such that the thumb occupies the inlet and the fingers fit into the outlet (Figure 20.5a). The palmar surface of the left hand then fits in comparable fashion within the morphologically left ventricle, but it is the right hand that is taken as the arbiter for the purposes of categorization. The usual pattern, therefore, can be described as right-hand ventricular topology [12]. The second pattern is then described as left-hand ventricular topology. It is seen in the mirror-imaged normal heart, or in the variant of

Figure 20.4 Computed tomograms showing the characteristic apical trabeculations that distinguish the morphologically right ventricle (a) from its left ventricular partner (b). Both ventricles, nonetheless, have obvious inlet and outlet components in addition to the apical component.
Figure 20.5 Ventricular topology is conceptualized in terms of the way in which the right (a) and left hands (b) can be placed on the septal surface of the morphologically right ventricle. All hearts with biventricular atrioventricular connections have either right-hand or left-hand topology. Panel (a) shows the normal heart and (b) shows the left-sided right ventricle in the heart from a patient with usual atrial arrangement and congenitally corrected transposition.
congenitally corrected transposition found with usual atrial arrangement (Figure 20.5b). With this pattern, it is the palmar surface of the left hand that fits on the septal surface of the morphologically right ventricle with the thumb in the inlet and the fingers in the outlet.

When determining the identity of the arterial trunks, there are no intrinsic features that enable an aorta to be distinguished from a pulmonary trunk, or from a common or solitary arterial trunk. The branching pattern of the trunks themselves, nonetheless, is sufficiently characteristic to permit these distinctions (Figure 20.6). Thus, the aorta gives rise to at least one coronary artery and the bulk of the systemic arteries. The pulmonary trunk gives rise directly to both, or one or other, of the pulmonary arteries. A common trunk directly supplies the coronary, systemic, and pulmonary arteries. A solitary arterial trunk exists in the absence of the intrapericardial pulmonary
Figure 20.6 The arterial trunks can be divided into four patterns according to the nature of their branching. The solitary trunk exists in the complete absence of any intrapericardial pulmonary arteries.

Figure 20.7 The four possible arrangements of the atrial chambers based on the extent of the pectinate muscles relative to the atrioventricular junctions.

arteries. In such circumstances, it is impossible to state with certainty whether the persisting trunk is common or aortic, hence it is best described as being solitary.

Basic analysis

The system depends first on the establishment of the arrangement of the atrial chambers, or atrial situs. Next, attention is concentrated on the anatomic nature of the junctions between the atrial myocardium and the ventricular myocardial mass. This feature, which is described as a type of connection, is separate from the additional feature of the morphology of the valve or valves that guard the junctions. There are two atrioventricular valves in the normally constructed heart, each guarding a separate atrioventricular junction (Figure 20.2a), but the junction can be a common structure, guarded by a common valve, without changing the overall fashion in which the atrial myocardium is connected to the ventricular mass. Proper analysis of the atrioventricular junctions also requires identification of the structure, topology, and relationships of the chambers within the ventricular mass. When the atrioventricular junctions have been dealt with in this fashion, the ventriculoarterial junctions are similarly analyzed in terms of the arrangement of the connections of ventricles with arterial trunks, and the morphology of the arterial valves guarding them. Separate attention is directed to the morphology of the outflow tracts, and to the relationships of the great arterial trunks. A catalog is then made of all associated cardiac and, when pertinent, noncardiac, malformations. This should include such features as the location of the heart, and the arrangement of the other thoracic and abdominal organs. Each system is analyzed in its own right, and is not designated according to changes observed in other systems. When analyzed and described in this fashion, there is obviously no such thing as "situs ambiguous."

Atrial arrangement

Analysis of atrial arrangement cannot be done on the basis of venoatrial connections, because this would be a direct abrogation of the morphologic method. In the current era,
there is no problem in analyzing atrial arrangement according to the morphology of the junction of the appendages with the rest of the atrial chambers (Figure 20.3). Assessment on the basis of this myocardial morphology reveals that there are four possible patterns of arrangement. This is because all hearts have two atrial appendages, each of which can only be of morphologically right or left type (Figure 20.7). With the usual and mirror-imaged arrangements, the appendages are lateralized, the morphologically right appendage being to one side of the heart and the morphologically left appendage to the other. The two other arrangements show isomerism of the atrial appendages. Ideally, this feature should also be recognized by direct examination of the extent of the pectinate muscles around the vestibules, now possible with use of cross-sectional echocardiography, particularly in its three-dimensional format. Morphology of the appendages is also accurately displayed with magnetic resonance imaging or computed tomography (Figure 20.2).

In most clinical situations, however, it is rarely necessary to rely only on direct identification. This is because, almost always, the morphology of the appendages is in harmony with the arrangements of the thoracic and abdominal organs. In patients with usual and mirror-imaged arrangements, it is exceedingly rare for there to be disharmony between the location of the thoracic and abdominal organs. When the appendages are isomeric, there is usually so-called visceral heterotaxy. In this setting, the lungs and bronchial tree are almost always symmetric, and it is rare for the bronchial arrangement to be disharmonious with the morphology of the appendages. In suspicious circumstances, therefore, isomerism can almost always be inferred from the bronchial anatomy. The morphologically left bronchus is long, and

branches only after it has been crossed by a branch pulmonary artery, making the bronchus hyparterial. In contrast, the morphologically right bronchus is short, and is crossed by a pulmonary artery supplying the lower lobe only after it has branched, giving an eparterial pattern of branching.

Inferences similar to those provided from bronchial arrangement can also usually be obtained noninvasively by using cross-sectional ultrasonography to image the abdominal great vessels [13]. The relation of these vessels to each other, and to the spine, generally reflects bodily arrangement, although not as accurately as does bronchial anatomy. When the atrial appendages are lateralized, the inferior caval vein and aorta lie to opposite sides of the spine, with the caval vein on the side of the morphologically right appendage. When there is right isomerism, the great vessels usually lie to the same side of the spine, with the caval vein anterior. The finding of an azygos vein carrying the inferior caval venous blood on the same side, and posterior to, the abdominal aorta is a good indicator of left isomerism, albeit not always differentiating the isomeric variant from usual or mirror-imaged arrangement with interrupted inferior caval vein. Generally, right isomerism is associated with absence of the spleen, whereas left isomerism is associated with multiple spleens. Because of this association, patients with isomerism of the atrial appendages have traditionally been grouped together, from the cardiac standpoint, under the banner of the "splenic syndromes." This approach is much less accurate than describing the syndromes directly in terms of isomerism of either the right or left atrial appendages [14,15]. In reality, it is necessary to describe both the state of the spleen and the morphology of the appendages, but it is the latter feature that serves to concentrate attention on the heart.

Atrioventricular junctions

In the normal heart, the atrial myocardium is contiguous with the ventricular mass around the orifices of both the mitral and tricuspid valves (Figure 20.2a). Electrical insulation is provided at these junctions by the fibrofatty atrioventricular grooves, other than at the site of the penetration of the bundle of His. In abnormal hearts, in order to analyze the morphology of the atrioventricular junctions accurately, it is first necessary to know the atrial arrangement. Equally, it is necessary to know the morphology of the ventricular mass to establish which atrium is connected to which ventricle. With this information, it is then possible to define the pattern of the atrioventricular connections and to determine the morphology of the valves that guard the junctions.

In every heart, because there are two atrial chambers, there is the possibility for two atrioventricular connections, which will be right-sided and left-sided. This is irrespective of whether the connections are guarded by two valves or a common valve. One of the connections as thus defined may be blocked by an imperforate valvar membrane, but this does not alter the fact that, in such a setting, there are still two atrioventricular connections present. In some hearts, in contrast, this possibility is not fulfilled because one of the connections is completely absent. Then, the atrial myocardium on that side has no connection with the underlying ventricular myocardium, being separated from the ventricular mass by the fibrofatty tissues of the atrioventricular groove. This arrangement is the most common pattern producing atrioventricular valvar atresia.

When atrioventricular connections are defined in this way, all hearts fit into one of three groups. In the first group, by far the most common, each atrial chamber is connected actually or potentially, but separately, to an underlying ventricle. In the second group, only one of the ventricles, if indeed two are present, has connections with the atrial chambers. In the third, and rarest, group, one atrioventricular connection is absent, the solitary atrioventricular junction being connected to two ventricles by a straddling valve. This arrangement is uniatrial but biventricular [16].

There are three possible types of biventricular atrioventricular connections, concordant, discordant, and biventricular and mixed. The last arrangement is found in hearts with isomeric appendages, whether they are of right or left morphology. Because of the isomeric nature of the appendages, this third arrangement cannot be described accurately in terms of concordant or discordant connections. It is a discrete biventricular pattern in its own right. The mixed variant is independent of ventricular relationships and atrioventricular valvar morphologies, but requires specification of ventricular topology to make the description complete.

There are also three possible junctional arrangements that produce univentricular atrioventricular connections [17]. The first is when the cavities of right-sided and left-sided atrial chambers are connected directly to the same ventricle (Figure 20.2b). This is double-inlet atrioventricular connection, irrespective of whether the right-sided and left-sided atrioventricular junctions are guarded by two atrioventricular valves or a common valve. The other two arrangements exist when one atrioventricular connection is absent, giving absent right-sided or absent left-sided atrioventricular connections. The group of univentricular atrioventricular connections is different from the group of biventricular connections, being independent not only of ventricular relationships and valvar morphology, but also of atrial and ventricular morphologies. Hearts with concordant or discordant atrioventricular connections can exist only when usually arranged or mirror-imaged atrial chambers are each connected to separate ventricles. A heart with biventricular and mixed connections can be found only when each of two atrial chambers having isomeric appendages is connected to a separate ventricle. In contrast, double-inlet, absent right-sided, or absent left-sided atrioventricular connection can be found in the settings of usually arranged, mirror-imaged, or isomeric atrial appendages. Each type of univentricular atrioventricular connection can also be found with the atrial

chambers connected to a dominant left ventricle (Figure 20.2b), a dominant right ventricle, or a morphologically indeterminate ventricle. Hence it is always necessary to describe ventricular morphology in hearts with univentricular atrioventricular connections [8].

In the hearts with univentricular atrioventricular connections, although only one ventricle is connected to the atrial chambers, most possess a second ventricle. This second ventricle, of necessity, is incomplete, lacking at least its inlet component. It is of complementary trabecular pattern to the dominant ventricle. Most frequently, the dominant ventricle is morphologically left, and the incomplete ventricle possesses right ventricular apical trabeculations. More rarely, the dominant ventricle is morphologically right and the incomplete ventricle is morphologically left. Even more rarely, hearts will be found with a solitary ventricular chamber of indeterminate morphology, albeit that, in clinical practice, it can be difficult to distinguish the truly solitary ventricle from apparently solitary left or right ventricles in which the incomplete ventricle is too small to be demonstrated.

Description of the type of atrioventricular connection accounts only for the way in which the atrial musculature is joined to the ventricular mass. The morphology of the valves guarding the overall atrioventricular junctional area, within the constraints imposed by the connections themselves, is an independent feature. Thus, when the cavities of both atrial chambers communicate directly to the ventricular mass, the right-sided and left-sided atrioventricular connections may be guarded by two patent valves, by one patent valve and one imperforate valve, by a common valve, or by straddling and overriding valves. These arrangements can all be found with the concordant, discordant, mixed, or double-inlet types of connection. Either the right-sided or left-sided valve may be imperforate, producing atresia, but in the setting of a potential as opposed to an absent atrioventricular connection. A common valve guards both right-sided and left-sided atrioventricular connections, irrespective of its morphology. A valve straddles when its tension apparatus is attached to both sides of a septum within the ventricular mass. It overrides when its annulus is connected to ventricles on both sides of a septal structure. A right-sided valve, a left-sided valve, or a common valve can straddle, can override, or can straddle and override. Rarely, both right-sided and left-sided valves may straddle or override in the same heart. When one atrioventricular connection is absent, however, the possible modes of connection are greatly reduced. This is because there is a solitary atrioventricular valve, which is usually committed in its entirety to one ventricle. More rarely, it may straddle, override, or straddle and override. These patterns produce the extremely rare group of uniatrial but biventricular connections [16].

An atrioventricular valve that overrides has an additional influence on description, as the degree of commitment of the overriding atrioventricular junction determines the precise nature of the atrioventricular connections. Hearts with overriding valves are anatomically intermediate between those with, on the one hand, biventricular and, on the other hand, univentricular atrioventricular connections. There are two ways of describing such hearts. One is to consider the hearts as representing a special type of atrioventricular connection. The other is to recognize their intermediate nature, and to split the series depending on the precise connection of the overriding junction. Our preference is for the second option. When most of an overriding junction is connected to a ventricle that already receives the other atrioventricular connection, we designate the connection as being double inlet. If the overriding junction is connected mostly to a ventricle not itself connected to the other atrium, each atrium is categorized as though connected to its own ventricle.

When describing the atrioventricular valves, the adjectives "mitral" and "tricuspid" are strictly accurate only in hearts with biventricular atrioventricular connections having separate junctions, each guarded by its own valve. The tricuspid valve is then always found in the morphologically right ventricle, and the mitral valve in the morphologically left ventricle. In hearts with biventricular atrioventricular connections but with a common junction, in contrast, the common valve lacks mitral and tricuspid components, even when it is divided into right and left components. The essence of the left-sided component in this setting is its trifoliate, rather than bifoliate, configuration (Figure 20.8). In hearts with double inlet connection (Figure 20.2b), the two valves are again better considered right-sided and left-sided, rather than mitral or tricuspid. Similarly, when one connection is absent, although it is usually possible to deduce the presumed nature of the remaining solitary valve from concepts of morphogenesis, this is not always practical or helpful. The valve can always accurately be described as being right-sided or left-sided.

Ventricular topology and relationships

Even in the normal heart, the ventricular spatial relationships are complex. The inlet portions are more or less to the right and left, with the posteroinferior part of the muscular ventricular septum lying in an approximately sagittal plane. The outlet portions are more or less anteroposteriorly related, with the septum between them in an approximately frontal plane. The trabecular portions extend between these two components, with the apical muscular septum spiraling between the inlet and outlet components. If a short-hand term is needed to account for these complex spatial arrangements, it is provided for by the concept of ventricular topology (Figure 20.5). In persons with usually arranged atrial chambers and discordant atrioventricular connections, for example, the left ventricular mass almost always shows left-hand topologic pattern (Figure 20.5b), whereas right-hand ventricular topology is usually found with the combination of mirror-imaged atrial chambers and discordant atrioventricular
Figure 20.8 The left side of the common atrioventricular valve seen in association with atrioventricular septal defects (a) is a trifoliate structure, and bears scant resemblance to the bifoliate morphologically mitral valve (b).

connections. These topological arrangements can be modified by rotation or twisting, accounting for so-called "criss-cross" and "upstairs–downstairs" hearts. In noting such unexpected ventricular relationships as a feature independent of topology, it may be necessary to account for right–left, anterior–posterior, and superior–inferior coordinates. Should it be necessary, the position of the three ventricular components may be described separately, and relative to each other. Description of ventricular topology is also essential when accounting for the combination of isomeric appendages with mixed and biventricular atrioventricular connections. It is equally important to describe both the position and relationships of incomplete ventricles in hearts with univentricular atrioventricular connections. Here, the relationships are independent of both the connections and the ventricular morphology. For example, while the incomplete right ventricle is usually anterior and right-sided in classical tricuspid atresia, it can be anterior and left-sided without in any way altering the clinical presentation and hemodynamic findings. Similarly, in hearts with double-inlet ventricle, the position of the incomplete ventricle plays only a minor role in determining the clinical presentation. Although an argument can be made for interpreting such hearts with univentricular atrioventricular connections on the basis of presumed morphogenesis in the settings of right-hand or left-hand topologies, there are sufficient exceptions to make this approach unsuitable in the clinical setting. In accounting for the position of incomplete ventricles, therefore, it is best simply to account for their location relative to the dominant ventricle, taking note, when necessary, of right–left, anterior–posterior, and superior–inferior coordinates.

Ventriculoarterial junctions

Most previous polemics concerning the ventriculoarterial junctions have reflected the failure to distinguish between connections, relations, and infundibular morphology. It is the prerogative of those who choose to define transposition in terms of an anterior aorta to speak rightly of "double outlet with transposition." For those choosing this approach, "posterior transposition" is an impossibility. This is not so when transposition is defined on the basis of discordant ventriculoarterial connections. Such problems in the qualification of transposition, however, are dispelled when the term is not used as a descriptor for any single facet of the ventriculoarterial junctions, but rather as a combination of connections at atrioventricular and ventriculoarterial junctions, as in regular transposition or the congenitally corrected variant. It is possible also to defuse controversies concerning the role of the "bilateral conus" in the diagnosis of double-outlet right ventricle when assessing connections independently from infundibular morphology. Whenever connections, infundibular morphology, and arterial relationships are described independently, with mutually exclusive terms, there is no confusion.

There are four types of ventriculoarterial connections, specifically concordant, discordant, double outlet, and single outlet. A single outlet may take one of four forms. A common trunk exists when both ventricles are connected by a common arterial valve to one trunk that gives rise directly to the coronary arteries, at least one pulmonary artery, and the majority of the systemic circulation. A solitary arterial trunk exists when it is not possible to identify any remnant of an atretic pulmonary trunk within the pericardial cavity (Figure 20.6). The other forms of single outlet are single pulmonary trunk with aortic atresia and single aortic trunk with pulmonary atresia. These two categories are used only to describe those arrangements in which, by use of clinical techniques, it is not possible to establish the precise connection of the atretic arterial trunk to a ventricular cavity. If its connection can be established, but is found to be imperforate, the appropriate connection is described, and the imperforate valve is then categorized separately. It is also necessary in hearts with
Figure 20.9 Overriding arterial valves are assigned to the ventricle supporting their greater circumference as judged relative to the cord subtended by the ventricular septum on the valvar orifice. In the examples shown in (a), a circle, representing the aortic valve, is superimposed on the normal heart as viewed from the apex in short axis. The red circle shows an aorta predominantly supported by the left ventricle, and the green circle shows an aorta supported mostly by the right ventricle. Panel (b) shows how this decision can now be made on the basis of three-dimensional echocardiography.

single outlet to describe the ventricular connection of the arterial trunk. This may be exclusively from a right or a left ventricle, but more usually the trunk overrides the septum, being connected to both ventricles.

There are fewer modes of connection at the ventriculoarterial than at the atrioventricular junctions. A common arterial valve exists only with a common arterial trunk. Straddling of an arterial valve is impossible because it has no tension apparatus. Hence the potentially variable modes of connection are two perforate valves, one or both of which may override, and one perforate and one imperforate valve. The degree of override of an arterial valve determines the precise ventriculoarterial connections. For this purpose, we allocate the overriding valve to the ventricle supporting the greater part of its circumference. For example, if more than half of an overriding pulmonary valve is connected to a right ventricle, the aorta being connected to a left ventricle, the ventriculoarterial connections are appropriately described as concordant. In contrast, if more than half the overriding aortic valve is connected to the right ventricle in this situation, there are double-outlet ventriculoarterial connections. When making this arbitration, it is best to assess the connection of the valve in its short axis, determining the proportions of the overriding junction supported by the right as opposed to the left ventricle (Figure 20.9a). This approach, now readily achievable using three-dimensional techniques for clinical diagnosis (Figure 20.9b), again avoids the need for intermediate categories.

The infundibular regions are no more and no less than the outlet components of the ventricular mass. When recognized in this fashion, and their morphology described as such, they also provide no problems in recognition and description. The morphology of the ventricular outlet portions is variable for any heart. Potentially, each ventricle can possess a complete muscular funnel as its outlet portion, and then each arterial valve can be said to have a complete infundibulum. Considered as a whole, the outlet portions of the ventricular mass in the setting of bilateral infundibulums have three discrete parts (Figure 20.10). Two of the parts form the anterior and posterior halves of the funnels of muscle supporting the arterial valves. The anterior parietal part is the free anterior ventricular wall. The posterior part is the inner heart curvature, or ventriculo-infundibular fold, which separates the leaflets of the arterial from those of the atrioventricular valves. The third part is the muscular or fibrous septum that separates the two subarterial outlets, the outlet or infundibular septum. In most hearts, some part of the infundibular musculature is effaced so that fibrous continuity occurs between the leaflets of one of the arterial valves and the atrioventricular valves. Most frequently, it is the morphologically left ventricular part of the ventriculo-infundibular fold that is attenuated, so there is fibrous continuity between the leaflets of the mitral valve and the arterial valve supported by the left ventricle. When both arterial trunks are connected to the morphologically right ventricle, the ventriculo-infundibular fold often persists in its entirety, and there is bilateral atrioventricular-arterial valvar discontinuity (Figure 20.10a). Many hearts in which both arterial valves are connected unequivocally to the right
Figure 20.10 A morphologic specimen (a) and a comparable three-dimensional echocardiogram (b) revealing the location of the ventriculo-infundibular fold (star) and the muscular outlet septum in the setting of double outlet from the right ventricle when the interventricular communication is in the subaortic position and there are bilateral infundibulums. Panel (c) shows how the arterial trunks can arise exclusively from the right ventricle in this setting even when there is fibrous continuity between the leaflets of the aortic and mitral valves in the roof of the interventricular communication.

ventricle, nonetheless, have atrioventricular–arterial valvar continuity (Figure 20.10c). Such hearts unequivocally possess a double-outlet ventriculoarterial connection. The ventriculo-infundibular fold, therefore, does not need to be intact bilaterally to justify the diagnosis of double-outlet right ventricle (Figure 20.10c).

The final feature of the ventriculoarterial junctions requiring description is the relationships of the great arteries and their valves. Arterial valvar relationships are best described in terms of right–left and anterior–posterior coordinates. The positions of the arterial trunks are also important. The pulmonary trunk either spirals around the aorta as it ascends, or else the two trunks ascend in parallel. Spiraling trunks are usually associated with concordant ventriculoarterial connections, and parallel trunks with discordant or double-outlet connections, but there is no predictive value in these relationships. The arcane conditions of "anatomically corrected malposition" and "isolated ventricular discordance" are greatly simplified when it is realized that these are no more than concordant ventriculoarterial connections, but with parallel rather than spiraling arterial trunks [18]. The aortic arch itself crosses superiorly to the bifurcation of the pulmonary arteries. The side of the aortic arch is then determined by whether it passes to the right or left of the trachea, with the position of the descending aorta defined relative to the vertebral column.

Associated malformations

Most patients seen with congenital heart disease have normal intersegmental connections together with normal morphology and relations. In such settings, the associated malformation will be the major anomaly. The body of this book is concerned with describing the specific morphologic and clinical features of these anomalies. Certain anatomic principles, nonetheless, pertain to the description of all these lesions, and will be discussed briefly below. Consideration must also be given to the position within the chest of the heart itself, and of the cardiac apex, or, for that matter, identification of a heart positioned outside the thoracic cavity, so-called ectopia cordis. An abnormal position of the heart within the chest is best considered as an associated malformation, and the cardiac malposition should not be promoted as a prime diagnosis. This is not to decry the importance of cardiac malposition, if only to interpret an electrocardiogram, but knowing that the heart is malpositioned gives no information concerning its internal architecture. Full sequential segmental analysis is needed to determine this analysis, not the other way around.

Septal morphology

A majority of congenitally malformed hearts exhibit the potential for shunting through holes between the cardiac chambers or arterial trunks. Such holes are usually termed septal defects, yet not all are found within the septal components of the normal heart. Understanding of septal defects, therefore, requires an appreciation of the extent of the normal septal structures, and knowledge of the mechanisms that permit shunting outside the confines of these normal components. In the normal heart, it is possible to recognize atrial, atrioventricular, and ventricular septums. There are then additional parts of the cardiac walls that interpose
Figure 20.11 Not all of the walls that separate adjacent chambers can be removed without trespassing on extracardiac space. Four-chamber sections through the walls separating the atrial chambers (a and b) show that the superior rim of the oval fossa is a deep fold (a), whereas the extension of the atrial muscle into the vestibule of the tricuspid valve is the superior fold of an atrioventricular muscular sandwich [double-headed arrow in (b)]. A further four-chamber section (c) reveals that the only true atrioventricular septum in the normal heart is that part of the membranous septum superior to the hinge of the septal leaflet of the tricuspid valve (yellow double-headed arrow). The parasternal long axis section (d) then reveals that the "septal" aspect of the subpulmonary infundibulum is separated by a fibrofatty tissue plane from the sinuses of the aortic root.

between chambers, but in the form of folds or sandwiches, rather than as solitary walls that can be removed without compromising the pericardial space [19]. When the structures interposing between the atrial chambers are analyzed in this fashion, it is the floor of the oval fossa, and its muscular anteroinferior buttress, that qualify as septal structures (Figure 20.11a). The extensive superior rim, although often described as the "septum secundum," is the deep infolding between the attachments of the superior caval vein to the right atrium and the right pulmonary veins to the left atrium. Even though a large part of the anteroinferior buttress is also a septal structure, when this atrial musculature is traced into the septal vestibule of the tricuspid valve, it overlies the crest of the muscular septum. It is then possible to place needles through this area, the floor of the triangle of Koch, and to enter the base of the left ventricle. This area is seemingly an atrioventricular muscular septum. More rigorous analysis, however, shows that a layer of the inferior atrioventricular groove, containing extracardiac fat, interposes between the atrial and ventricular musculatures. The area, therefore, is an atrioventricular muscular sandwich, rather than a septum (Figure 20.11b). The only true atrioventricular septum in the normal heart is the small part of the fibrous septum

that interposes between the cavity of the right atrium and the subaortic outflow tract (Figure 20.11c). Part of this so-called membranous septum also interposes between the ventricular cavities. The greater part of the ventricular septum, nonetheless, is muscular. Not all of the apparently septal surface of the right ventricle, however, separated the cavities of the right and left ventricles. The apparently septal surface of the subpulmonary outlet is part of the free-standing muscular sleeve that lifts the leaflets of the pulmonary valve away from the base of the ventricular mass (Figure 20.11d). It is this feature that permits the surgeon to remove the pulmonary valve as a free-standing structure, and to use it as a prosthesis in the Ross procedure [20]. All of these anatomic features are also key to understanding the structure of the so-called septal defects.

Interatrial communications

There are several lesions that permit shunting between the atrial chambers. Not all are correctly described as septal defects, at least not when the septal structures are defined as suggested above. Only the holes within the confines of the oval fossa, so-called "secundum" defects, and the rare holes found within the substance of the anteroinferior buttress,
Figure 20.12 The images show features of so-called "septal defects," albeit that not all are true septal deficiencies. In (a), the so-called sinus venosus defect is seen to be a veno-venous collateral channel. Panel (b) shows the common atrioventricular junction, which is the pathognomic feature of the "ostium primum" defect, thus revealing it to be an atrioventricular rather than an atrial septal defect. Panel (c) shows the aortic valve overriding the crest of the muscular ventricular septum in the setting of tetralogy of Fallot, creating problems as to whether the right ventricular aspect of the cone of space subtended from the valvar leaflets to the crest of the septum (red line) is the ventricular septal defect, or whether this is the superior continuation of the plane of the muscular ventricular septum (blue arrow and line). The latter blue line is certainly the interventricular communication.

are true septal deficiencies. The essence of the sinus venosus defects is that they are found outside the confines of the oval fossa. These holes exist because one of more of the right pulmonary veins achieves a connection to either the superior or the inferior caval vein while retaining the expected connection with the left atrium. The lesions are veno-venous collateral channels (Figure 20.12a) rather than septal defects, albeit that they unequivocally permit interatrial shunting of blood. Shunting between the atrial chambers can also exist through the mouth of the coronary sinus when the walls that normally interpose between the cavities of the coronary sinus and left atrium are either fenestrated or absent. The so-called ostium primum defect also permits interatrial shunting, but in these instances through an atrioventricular rather than an atrial septal defect.

Atrioventricular septal defects

These holes are true septal defects, but their pathognomonic feature is the common atrioventricular junction (Figure 20.12b). It is the level of shunting across the atrioventricular septal that accounts for the variability within the lesion. In the so-called "complete" variant, defined on the basis of a common atrioventricular valvar orifice, the bridging leaflets float to varying degrees so that shunting is possible at both atrial and ventricular levels. The ostium primum defect is usually considered a "partial" form of the lesion, albeit that the atrioventricular junction is just as common as when there is a common atrioventricular valvar orifice [21]. The feature of the ostium primum defect is that a tongue of valvar tissue joins together the bridging leaflets so that there are dual valvar orifices within the

common atrioventricular junction. In most instances, the bridging leaflets, along with the connecting tongue, are firmly fused to the scooped-out crest of the muscular ventricular septum, this feature serving to confine shunting across the septal defect at atrial level. In some instances, however, there can be additional minimal shunting at ventricular level through intercordal spaces on the ventricular aspect of the bridging leaflets. Rarely, the bridging leaflets can be attached to the leading edge of the atrial septum, thus serving to confine shunting at ventricular level. It is this lesion that is the true ventricular septal defect of atrioventricular canal type. Even more rarely, although now recognized with increasing frequency, the atrioventricular septal defect itself can undergo spontaneous closure, so that there is no shunting even though there is a common atrioventricular junction [22].

Ventricular septal defects

Holes between the ventricles are the commonest congenital cardiac malformations, and form part of many other lesions, such as common arterial trunk, tetralogy of Fallot, and double-outlet right ventricle. In countries where the vernacular language is derived from Latin, these holes are often described as interventricular communications, which is in many ways a better descriptor, since as with holes between the atriums, not all the so-called ventricular septal defects are found within the confines of the normal ventricular septum. Problems also exist in defining the plane of space best defined as representing the interventricular communication, raising questions as to whether the interventricular communication is necessarily the same thing as the

ventricular septal defect. Consider the situation in the setting of tetralogy of Fallot, where one of the anatomic features is overriding of the orifice of the aortic valve (Figure 20.12c). The plane of space that is blocked by the surgeon when closing the "ventricular septal defect" is the right ventricular aspect of the cone of space subtended from the attachments of the overriding valve. The interventricular communication, in contrast, is the plane of space marked by the superior continuation of the plane of the muscular ventricular septum. Also, in double-outlet right ventricle, the interventricular communication is the hole between the ventricles, albeit that this hole is never closed by the surgeon during an operative repair, but rather is tunneled to one or other of the subarterial outlets. In most instances, nonetheless, it is the right ventricular border over which the surgeon places a patch that is considered to represent the "ventricular septal defect," and this plane is usually considered as being synonymous with the interventricular communication. Different systems still exist for describing the different types of "ventricular septal defect" as thus defined, but the differences reflect the feature used for the purposes of categorization. Unity can again be achieved if note is taken of all the pertinent clinical features. These include the size of the hole, the anatomic nature of its borders as seen from the right ventricle, the direction in which the hole opens into the right ventricle, and the additional presence of malalignment of the septal components. If all of these features are described, there should be no room for disagreement on nomenclature [23].

Conclusion

The techniques now available for the clinical diagnosis of congenitally malformed hearts are now so sophisticated that all the features of normal and abnormal cardiac anatomy can be seen with greater facility during life than in the autopsy room, with the added advantage that serial studies will now permit the establishment of the natural and unnatural history of the various lesions. It is hoped that the lessons being learned from the applications of these new techniques will resolve all of the controversies that have bedeviled pediatric cardiologists and pediatric cardiac surgeons over recent decades.

21 Atrial Level Shunts Including Partial Anomalous Pulmonary Venous Connection and Scimitar Syndrome

Carlos A. C. Pedra & Simone R. Fontes Pedra

Instituto Dante Pazzanese de Cardiologia, São Paulo, SP, Brazil

Introduction

An atrial septal defect (ASD) is an opening between the atria due to a deficiency of one or more components of the interatrial septum (IAS) [1]. The most common type of ASD is the secundum defect located in the region of the fossa ovalis [1]. It is usually single but multiple fenestrations may also be encountered. A patent foramen ovale (PFO) should not be considered an abnormal finding *per se* and occasionally may coexist with an ASD. Because of its association with paradoxical embolization, it is briefly discussed. Partial anomalous pulmonary venous connection (PAPVC) to the systemic venous circulation shares physiologic similarities with ASD and is often associated with it, and is also discussed. Defects in the inferior portion of the atrial septum, the so-called primum ASDs, represent a form of endocardial cushion defect and are discussed in Chapter 22.

An ASD of the secundum or fossa ovalis type is a common congenital heart defect (CHD), with an incidence of around 568 per million live births [2]. The true incidence may be even higher because many patients have a smaller defect that is not diagnosed until adulthood. It affects 5–10% of patients with CHD and is usually considered the fourth or fifth most common type of cardiac malformation [3]. Additionally, up to 50% of children with CHD have an associated ASD. Females are affected approximately 2–3 times more often than males. Although most secundum ASD occurs sporadically, an autosomal dominant inheritance has been reported in some families [4]. When it is associated with atrioventricular conduction defects there may be a mutation of the *NKX*-2.5 gene [4]. Also, an ASD is associated with abnormalities of the radius or radial portion of the hand (Holt–Oram syndrome). Because of its relative lack of symptoms and at times inconspicuous physical signs in childhood, it is one of the most frequent forms of CHD initially recognized in adults [1].

Anatomy

The IAS is a complex structure that develops from two separate primitive septal ridges (*septum primum* and *septum secundum*) that must migrate, coalesce with the endocardial cushions and sinus venosus, and partially reabsorb to function normally in fetal and postnatal life [5]. The septum primum appears first, growing superiorly from the junction between the inferior vena cava (IVC) and the right atrium (RA) towards the septum secundum. It normally forms the inferior portion of the atrial septum and the flap-like valve of the foramen ovale. The septum secundum is a crescent-shaped muscular ridge that invaginates from the postero-superior portion of the developing atria. It forms the anterior and posterior rims of the limbus of the fossa ovalis, which demarcates the foramen ovale, and much of the superior portion of the IAS [5]. The smooth-walled posterolateral portion of the RA is the remnant of the right horn of the sinus venosus. Abnormal incorporation of this structure into the RA produces a sinus venosus defect near the orifice of the superior vana cava (SVC) or the IVC. The AV canal septum is formed, at least in part, by the endocardial cushions and septates the outlet portion of the atria and the inlet portion of the ventricles. The normal development of the IAS results in formation of the fossa ovalis, which is bounded superiorly by the septum secundum and inferiorly by the muscular AV canal septum [5]. The superior portion of the septum primum attaches to the left atrial aspect of the septum secundum (Figure 21.1).
Figure 21.1 Diagram of the interatrial septum viewed from the right atrium. The locations of the different types of atrial septal defects (secundum, sinus venosus, coronary sinus and primum defects) are displayed in different colors.

A secundum ASD occurs in the region of the septum primum, which is also called the valve of the fossa ovalis (Figure 21.1) [5]. It can result from an abnormally short valve, an unusually large foramen ovale that is incompletely covered by a normal valve, fenestrations in the valve, or a combination of these factors [5]. It is by far the most common type of ASD.

The foramen ovale is an opening in the septum secundum that is covered on its left atrial side with a flap of tissue derived from the septum primum. This flap valve allows right-to-left atrial shunting during fetal life. After birth, when left atrial exceeds right atrial pressure, the flap usually seals the defect and separates the atria. However, persistent patency of the foramen ovale from incomplete fusion of the valve of the foramen ovale to the septum secundum may occur and can be found in 30% of adults at autopsy or by echocardiography [6,7]. Usually unassociated with a significant left-to-right shunt, it is considered a normal finding rather than a pathologic defect. To avoid considering a PFO as an ASD, some investigators define an ASD as having an opening of >5–6 mm in diameter associated with a dilated RA and right ventricle. On the other hand, variable degrees of right-to-left shunting may occur through the PFO and result in paradoxical embolization and neurologic events in an occasional patient. Both ASDs and PFOs may be associated with aneurysms of the atrial septum (ASA), although an ASA may occur with an intact atrial septum [1].

Sinus venosus defects comprises 3–10% of all ASDs [1,5]. They are located in the smooth-walled region of the atrium posterior to the fossa ovalis (Figure 21.1). They usually occur superiorly near the orifice of the SVC, but an inferior sinus venosus defect may also be found near the orifice of the IVC. Some 80–90% of patients with a superior sinus venosus defect also have PAPVC of the right pulmonary veins to either the RA or SVC [8,9].

PAPVC is a connection between one or more (but not all) pulmonary vein(s) with a systemic vein, right atrium, or coronary sinus. This anomaly is associated with a sinus venosus ASD in >85% of patients [9] but can also occur with an intact IAS [8]. There are several anatomic variations, with the most common types being the left upper pulmonary vein connecting to the left innominate vein [10] and one or more right-sided veins connecting to the SVC at its junction with the RA [9]. Anomalous connection of the inferior or all right pulmonary veins to the IVC is known as Scimitar syndrome [11], other features of which include hypoplasia or even absence of the right pulmonary artery, hypoplasia of right lung with secondary dextrocardia, anomalous systemic arterial supply to the right lung through collaterals usually arising from the descending aorta, pulmonary artery stenoses, and bronchial abnormalities. About 70% of these patients also have an ASD [11].

A coronary sinus septal defect is a rare type of ASD in which the coronary sinus is partially or completely unroofed, allowing communication between the coronary sinus and the left atrium (LA) with left-to-right shunt through the coronary sinus orifice [5]. When this defect is associated with a persistent left superior vena cava it is termed Raghib syndrome [12] (see Chapter 37).

Finally, a most uncommon type of ASD may be occasionally encountered especially in patients with isomerism of the right atrial appendages or heterotaxy syndrome. Due to leftward malposition of the septum primum, one or more of the right pulmonary veins may functionally drain into the RA despite being normally connected to the LA [5]. Closure of the defect eliminates the left-to-right shunt.

Associated lesions may be encountered with an ASD [13]. Occasionally, an unusually large Eustachian valve may be found with an ASD or PFO and may contribute to significant right-to-left shunting across the IAS when the patient stands up (platypnea–orthodeoxia syndrome) [14,15]. Functional abnormalities and prolapse of the mitral valve are commonly present in patients with an ASD [16–18]. It is unknown whether the prolapse is secondary to deformation of the mitral apparatus by an enlarged right ventricle, an inherent abnormality of mitral valve tissue, or reduced left ventricular volume [13]. Although it is common to record a flow-related gradient across the pulmonary valve, anatomic pulmonary valvar stenosis is found in only 5% of patients with an ASD [13]. Despite the posterior displacement and compression of the left ventricle (LV), left ventricular systolic function is

usually normal. Left ventricular diastolic distensibility, however, is often decreased, especially in older patients, and may complicate closure of the defect [19]. The right ventricle (RV) is dilated with larger shunts, but functions well [13]. Significant tricuspid regurgitation may develop with marked dilatation, especially if pulmonary hypertension coexists. Pulmonary regurgitation occurs late in patients with severe pulmonary hypertension.

Pathophysiology

The amount of shunting through an ASD depends on the relative right and left ventricular compliances [1,5,13,20]. Early after birth, flows in the pulmonary and systemic circulations equalize with expansion of the lungs and removal of the placenta from the circulation. In the neonate, compliance of the left and right ventricles is similar, atrial pressures are relatively equal, and flow through an ASD may be bidirectional with little net left-to-right or right-to-left shunt. During infancy, the RV gradually becomes more compliant than the LV because of the markedly lower pressure and resistance in the pulmonary circulation compared with the systemic circuit. Because the increasingly compliant RV more readily accepts excess volume, more blood is diverted from the LA to the RA through the ASD. Pulmonary blood flow, consisting of systemic venous return plus the volume of blood that shunts from the LA to the RA, is thus increased. The pulmonary-to-systemic flow ratio usually exceeds 1.5:1 and atrial level left-to-right flow enlarges the RA and RV after infancy. Under normal circumstances, flow through an ASD is nearly all left-to-right, but there is a phasic variation, with a small and transient right-to-left shunt occurring near the end of the QRS.

Because the volume and direction of shunting through an ASD largely depend on the relative distensibility of the right and left ventricles, patients with right ventricular hypertrophy secondary to conditions such as pulmonary stenosis or pulmonary hypertension have a smaller left-to-right shunt [1,5,13,20]. Severe right ventricular hypertrophy with an ASD or a PFO results in a net right-to-left shunt and cyanosis. In contrast, reduced left ventricular distensibility due to aging, ischemic heart disease, diabetes and systemic arterial hypertension, may cause left ventricular hypertrophy and an increase in left-to-right shunting in late adulthood.

Congestive cardiac failure in an ASD might be thought to affect only the overloaded RV, but the cardiac failure is atypical in that both ventricles have equally raised diastolic pressures, even though the LV is not dilated. The raised left ventricular diastolic pressure has been ascribed to compression of the LV by a hugely dilated RV, much as ventricular diastolic pressures are raised by pericardial tamponade [13].

With PAPVC, the degree of volume overload to the RV depends on how much of the pulmonary venous drainage in diverted to the right atrium [8]. If only one lobe drains to the right atrium, the left-to-right shunt is small (Qp/Qs < 1.5) with little or no dilation of the RV. In contrast, if two or more pulmonary lobes are draining anomalously to the RA, the left-to-right shunt is significant (Qp/Qs > 2) and produces RV enlargement. There is more flow to an anomalously connected pulmonary vein to the RA than through a similarly sized vein connected to the LA because the pressure drop across the low-resistance pulmonary vascular bed is slightly greater to the RA than to the LA [8]. Conversely, little flow passes through a pulmonary lobe if a significant stenosis is present in the anomalous pulmonary vein draining that lobe.

In patients with Scimitar syndrome, the deleterious hemodynamic effects depend on many factors, including associated complex cardiac defects, especially in infants; size of the right pulmonary artery and the amount of flow through it; possible stenoses in either or both pulmonary arteries; size, number, and possible obstruction of the anomalous pulmonary veins draining into the IVC; and the amount of flow through the collateral supply to the lung [11]. Bronchial abnormalities may be responsible for respiratory symptoms. Pulmonary arterial hypertension often occurs in infants, even without associated lesions, usually because of a large systemic-to-pulmonary flow through the collateral supply and a decreased size of the right pulmonary arterial bed. Pulmonary venous obstruction may also play a role [11].

Natural history

The deleterious effects of an ASD depend mainly on the magnitude of the left-to-right shunt. Small shunts through defects <5–6 mm in diameter produce no symptoms and few, if any, abnormal physical signs [1,5,13]. Larger shunts may cause fatigue on exertion, frequent pulmonary infections, and with increasing age pulmonary vascular disease, congestive heart failure, and atrial arrhythmias. Infective endocarditis is rare in the absence of other cardiovascular abnormalities such as mitral insufficiency [1].

Depending on its size and the age of the patient, a secundum ASD may become smaller and close spontaneously [21–28]. An echocardiographic study has suggested that a secundum ASD <3 mm in diameter in the first 3 months of life nearly always closes, and those >8 mm in diameter are unlikely to close [27]. Closure of small defects occurs frequently within the first or second year of life, with closure rates reaching 74–100% [21–28]. Although closure is much more likely with a small defect, it can also occur in patients with a relatively large ASD (>10 mm), and even in patients with congestive heart failure. Some larger defects become smaller but do not close completely. There is no substantial rate of spontaneous closure above 6 years of age. On the

other hand, an ASD can also increase in size over time [25,26,29]. The causes of this increase in size and rate of increase are unknown.

Patients with an isolated secundum ASD are generally asymptomatic through infancy and childhood. Rarely, symptoms of pulmonary overcirculation, frequent respiratory infections, and overt congestive heart failure are seen in small infants with very large defects who have no other identified cardiac abnormality [30–32]. However, associated extracardiac anomalies, chromosomal abnormalities and chronic lung disease associated with prematurity are common in such symptomatic infants and may contribute to the underlying status [33]. Patients diagnosed later in childhood often come to the cardiologist's attention because of a relatively inconspicuous murmur. Although they do not have overt symptoms, they may appear asthenic [13]. Symptoms become progressively more common after the age of 20 years and include dyspnea on exertion, fatigue, palpitations, and arrhythmias, with 90% of untreated patients having one or more of these "minor" symptoms by the age of 40 years [13]. More debilitating symptoms due to complications, such as congestive cardiac failure, pulmonary arterial hypertension, and recurrent arrhythmias develop in ~35% of the patients older than 40 years [13]. Usually pregnancy is well tolerated in untreated women but congestive heart failure may occasionally occur [1].

Mild-to-moderate pulmonary hypertension occurs in <10% of children with an ASD [1]. Although pulmonary vascular disease may occasionally be seen in young children with a large defect [34], in a few patients with a (coincidental) small ASD, pulmonary vascular resistance remains high from birth and resembles idiopathic pulmonary hypertension [13]. Pulmonary artery pressure does gradually increase with age in patients with an ASD. Approximately half of patients older than 30 years have a pulmonary artery mean pressure greater than 20 mmHg but only mild elevation of pulmonary arterial resistance [35–37]. Advanced histologic changes of the small pulmonary arteries are much less frequent and take longer to develop with an ASD than with other types of CHD with a large left-to-right shunt. As such, markedly increased pulmonary vascular resistance is uncommon in patients under the age of 20 years. Patients living at high altitudes may have pulmonary hypertension at an earlier age and progress more rapidly [38]. It is debatable whether symptoms and pulmonary hypertension are found more often and earlier with sinus venosus than with secundum ASDs [39]. Another rare cause of severe pulmonary hypertension in a patient with a large ASD is thrombosis of the large pulmonary arteries [40,41].

Atrial arrhythmias become increasingly common with advancing age. More than half of patients >45 years old have intermittent or chronic atrial fibrillation or flutter [42–49]. The onset of atrial fibrillation or flutter is a common cause of relatively rapid deterioration in a previously minimally symptomatic adult. These atrial arrhythmias are probably due to the stretched right atrium, but a distended left atrium and mitral regurgitation are contributory. A few may present with severe paroxysmal supraventricular tachycardia. Although an ASD is a potential pathway for paradoxical embolization, >90% of strokes in adult ASD patients occur in those who have atrial fibrillation [50]. In addition to these overt abnormalities in adults, many children with an ASD may have subclinical sinus node dysfunction and atrioventricular conduction abnormalities [51]. It seems that patients with sinus venosus defects do not have an increased incidence of arrhythmias preoperatively [1].

Survival of patients with a clinically detectable ASD into adulthood is expected, with >75% of patients surviving into their 30s. Campbell et al., however, estimated that ~75% of patients do not survive past the age of 50 years, and only 10% survive past the age of 60 years [52]. Because Campbell et al.'s patients were identified before the widespread availability of current sensitive diagnostic tests, these estimates may be overly pessimistic and apply accurately only to patients with a large, easily detectable ASD. There are numerous reports of patients with an ASD surviving past the age of 80 years [13].

Finally, an ASD or a PFO also allows possible paradoxical embolization of thrombus, air, or other material to the systemic circulation, resulting in stroke or ischemic damage to the extremities or major organs [53–55]. The risk of paradoxical embolization may be increased with pregnancy, especially in the peripartum period. Paradoxical embolism was inferred originally from autopsies that showed typical venous thrombi in an artery [53,54]. Several case–control studies of adults with cerebral vascular events showed that those without any known risk factors were more likely to have a PFO or an ASA that is often associated with a PFO [1,56]. Venous thrombi have also been observed straddling the foramen ovale at autopsy or on echocardiography [57]. Right-to-left shunting through these defects detected by echocardiography can occur during transient pressure reversal during the cardiac cycle or with release of a Valsalva maneuver [55]. An extensive meta-analysis of the relationship of PFO and ASA concluded that under 55 years of age both lesions were associated with ischemic strokes in patients without other likely predisposing causes [1,56]. More recently, this association has been shown to be valid in patients over 55 years of age [58]. However, in prospective, longitudinal, and observational studies in the general population, PFOs were not found to be independently associated with ischemic strokes [59,60]. As such, any form of preventive treatment in asymptomatic patients with PFOs detected incidentally appears unjustified at present [1]. Additionally, PFOs have also been associated with migraine, especially with aura, increased mortality in patients with pulmonary embolism, and central nervous system lesions in divers [1,55,61–65].

Diagnosis

Clinical history and physical examination

Because of the lack of both symptoms and an easily audible murmur, the diagnosis of an ASD is usually delayed and only made at the preschool/school age, and sometimes later in adolescence or adulthood [1,5,13]. The clinical history in most children is usually unremarkable. It may be possible to elucidate a minor difference in exercise tolerance or growth compared with siblings, but it is unusual to have failure to thrive or clearly reduced exercise tolerance. In adult patients, symptoms of overt congestive cardiac failure are more common [1,5,13]. Palpitations are a frequent complaint, and the onset of atrial fibrillation or flutter may precipitate the definitive evaluation and diagnosis. A small percentage of patients may be found to have an ASD or PFO on cardiac evaluation after a stroke [13].

The physical findings of an ASD may be relatively subtle, especially to a noncardiologist. Mild left chest prominence or bulge on inspection and a right ventricular lift or heave on palpation can be detected in patients with large left-to-right shunts. The first heart sound is usually loud at the left lower sternal border. The second heart sound at the left upper sternal border is characteristically widely split and the respiratory variation is greatly reduced, leading to the perception of fixed splitting [13]. A large, nonrestrictive ASD equalizes the respiratory influence on both right and ventricular output, with the wide split resulting from delayed emptying of the enlarged RV. The intensity of the pulmonary component is usually normal, reflecting normal pulmonary artery pressures. There is usually a grade 3 (or less) soft systolic ejection murmur at the mid-to-upper left sternal border due to the increased blood flow passing through the pulmonary valve (flow-related "relative" pulmonary stenosis). The murmur radiates to the lung fields posteriorly. Patients with a large left-to-right shunt (Qp/Qs >2:1) often have along the lower left sternal border a mid-diastolic flow rumble due to the increased diastolic flow through the tricuspid valve [3,15]. Pulmonary hypertension may accentuate the pulmonary component of the second heart sound and also normalize its respiratory variation. With severe pulmonary hypertension, murmurs of pulmonary regurgitation and tricuspid regurgitation may appear [13].

Electrocardiography

The normal regression of right ventricular dominance with age usually does not occur and a typical pattern of persistent right-axis deviation and right ventricular enlargement becomes identifiable in early childhood [5,13]. The QRS duration is at the upper limit of normal or mildly prolonged, with an rSr′ or rsR′ pattern seen in the right precordial leads in ~90% of patients. Crochetage, a notch near the apex of the R wave in inferior limb leads, occurs in ~75% of patients

with an ASD, especially if large, but in <10% of normal subjects or patients with other forms of CHD. In the occasional patient with severe pulmonary hypertension or significant pulmonary valve stenosis associated with an ASD, the electrocardiographic pattern may be more typical of pure pressure overload with an rR or tall monophasic R wave preceded by a small Q wave in lead V_1 [13].

Conduction abnormalities and arrhythmias become increasingly apparent with age [13]. Usually the PR interval is normal, in contrast with the prolonged interval found in patients with atrioventricular septal (endocardial cushion ostium primum) defects [5]. The P waves frequently become tall, peaked and slightly prolonged as the right atrium enlarges. An advanced first-degree atrioventricular block progressing to a second-degree block or a complete atrioventricular block may be seen in a familial pattern associated with secundum ASDs. Atrial fibrillation (most commonly), atrial flutter, and supraventricular tachycardia can also develop at older ages, with more than half of patients having atrial fibrillation after the fourth decade [42–49].

Chest radiography

The typical appearance is of cardiac enlargement, including the RA, RV, and MPA with a small-appearing ascending aorta. The SVC shadow is often absent in the posteroanterior view due to RA enlargement and clockwise rotation of the heart [5]. Right ventricular enlargement may be better appreciated in the lateral view with reduction in the normal retrosternal clear space. Pulmonary vascularity is increased, in proportion to the amount of shunting. With pulmonary hypertension, the peripheral pulmonary vascularity may gradually become decreased along with increasing size of the central pulmonary arteries. In adult patients with congestive cardiac failure, especially associated with atrial fibrillation or flutter, the pulmonary veins may be prominent and the left atrium may become enlarged [13]. In the occasional patient with Scimitar syndrome, the heart shadow is shifted to the right hemithorax and the right lung is hypoplastic with diminished pulmonary vascularity (also known as hypertranslucent lung). The anomalously connected right pulmonary veins form a curved line in the right lower lung field, giving an appearance of a scimitar [5].

Echocardiography

Echocardiography is the primary method of diagnosis and evaluation of ASDs. Transthoracic two-dimensional echocardiography (TTE) using standard views demonstrates the size and location of an ASD, the systemic and pulmonary venous connections, and also the expected secondary changes of right atrial and right ventricular enlargement [5,13]. Estimates of the pulmonary-to-systemic flow ratio may be obtained, although their accuracy and reproducibility are uncertain [5]. The parasternal views typically demonstrate enlargement of the RV with flattening of the left ventricle

Figure 21.3 Two-dimensional transesophageal echocardiogram of a patient with a sinus venosus ASD. (a) Modified four-chamber view shows a superior sinus venosus defect and an enlarged right upper pulmonary vein connected to the superior vena cava–right atrium junction. (b) Color flow mapping in bicaval view shows left-to-right shunting across the superiorly located defect.

in the long-axis view. Short-axis views are helpful in demonstrating that the intraventricular septum typically maintains a normal rounded contour in systole but is flattened or even concave in diastole because of the right ventricular volume overload. Secundum ASDs are seen in the central portion of the atrial septum and may extend anteriorly to the aortic root. The best views to visualize and measure an ASD are from the subxiphoid or subcostal location because the atrial septum is nearly perpendicular to the imaging axis [5,13], and measurements of the defect are most accurate and correlate with the transesophageal echocardiography (TEE) findings (Figure 21.2a and b). In contrast, a false drop-out in the middle of the septum is relatively common in the apical view because the ultrasound beam is parallel to the septum. The apical view, however, is excellent to evaluate the relative size of the right and left atria and right and left ventricles. Sinus

venosus ASDs are typically more difficult to image than secundum ASDs due to their location in the superior atrial septum near the orifice of the SVC. The finding of a sinus venosus ASD should prompt thorough evaluation of the right-sided pulmonary veins because partial anomalous drainage of one or more right-sided pulmonary veins is seen in 90% of affected patients. Complete delineation of the anatomy in such patients may be better appreciated by TEE or magnetic resonance imaging (Figure 21.3a and b). Color Doppler echocardiography is helpful in confirming flow through an apparent ASD on two-dimensional echocardiography (Figure 21.2b). Normally left-to-right flow is relatively laminar and can be easily seen. In patients with a small and restrictive ASD, the left-to-right flow may be identified as a higher velocity turbulent jet extending from the atrial septum into the right atrium. In patients with right ventricular hypertrophy from pulmonary

stenosis or pulmonary hypertension, there may be little left-to-right flow, and right-to-left flow may predominate. Contrast echocardiography using agitated saline can help to demonstrate right-to-left shunting across the inter-atrium septum at baseline and/or after a Valsalva maneuver in patients with suspected PFOs and paradoxical embolization [5]. Also, it can demonstrate the rapid appearance of contrast in the LA after injection into the left arm in patients with unroofed coronary sinus and Raghib syndrome [5].

In younger patients with good windows and une-quivocal delineation of the underlying anatomy, transtho-racic echocardiography usually suffices for management planning. However, in patients with suboptimal trans-thoracic echocardiographic windows, especially in obese adolescents and adults, TEE may be needed [1,5,13]. It is also better for patients with a sinus venosus defect and anomalies of the pulmonary veins (Figure 21.3a and b). TEE has been used frequently for screening patients who are candidates for transcatheter closure of secundum ASDs [66–68]. It provides an excellent window to assess the size and location of the defect, number of defects, septal rims, pliability and total length of the IAS, and other important nearby cardiac structures (Figure 21.4a). It also guides the procedure for balloon sizing of the defect (stretched diameter), proper device placement and assessment of residual leaks [66–69]. Some centers use intracardiac echocardiography (ICE) for these purposes with excellent imaging views and results (Videoclips 21.1 and 21.2). This technique provides better imaging of the posteroinferior portion of the IAS near the IVC and obviates the need for general anesthesia [70–73]. Whether it is associated with cost reduction is debatable [74]. The choice between ICE and TEE to guide the transcatheter procedure depends on local issues such as availability of equipment and anesthesiology, costs, and familiarity of the operators with the techniques. Recently, real-time three-dimensional TEE has been used as a new imaging tool to better understand the anatomy of the interatrial septum and secundum ASDs [75] (Videoclips 21.3 and 21.4). Although it provides superb pictures, it is debatable whether its use results in better outcomes after transcatheter treatment of the secundum ASD (Figure 21.4b). TEE has also been employed intraoperatively to assess surgical results, especially after correcting sinus venosus or other complex defects [5].

Magnetic Resonance Imaging (MRI)

Magnetic resonance imaging (MRI) is another noninvasive modality that may be useful in selected patients with a known or suspected ASD, especially adolescents and adults who have inconclusive clinical and echocardi-ographic findings due to suboptimal echocardiographic imaging windows [76]. It is an alternative to transesophageal

(a)
(b)

Figure 21.4 Two-dimensional transesophageal echocardiogram of a patient with a secundum atrial septal defect and an atrial septal aneurysm who underwent percutaneous closure of the defect. (a) Short-axis view shows an anterior defect and an aneurysm of the posterior portion of the interatrial septum. The septum bulges into the right atrium. Also, there is an additional and very small posterior defect. (b) Real-time three-dimensional transesophageal echocardiogram. After percutaneous closure of the defect, the left disc of the device is seen on the left side of the picture. Its anterior portion is splayed around the aorta, which was cut longitudinally.

echocardiography and diagnostic catheterization. MRI can demonstrate the size and location of the ASD and its suitability for transcatheter versus surgical closure [5]. MRI is particularly helpful in older patients with sinus venosus defect and anomalous connections of the pulmonary veins [77]. Functional assessment can also be performed to estimate the pulmonary-to-systemic flow ratio [78] and RV size and function.

Diagnostic cardiac catheterization and angiography

Diagnostic cardiac catheterization and angiography are no longer indicated in most patients with typical clinical and echocardiographic features of an ASD [5]. Catheterization may sometimes be needed to evaluate associated abnormalities such as pulmonary valvar stenosis, pulmonary hypertension, or exact sites of connection of the pulmonary veins. In older adult patients, catheterization is indicated preoperatively to exclude concomitant coronary artery disease [13].

The hemodynamic burden of an ASD can be evaluated in the cardiac catheterization laboratory [20]. Oximetry is useful in estimating the relative pulmonary/systemic blood flows (Qp/Qs) by the Fick principle, but the inability to obtain a true mixed venous saturation introduces a significant source of error in the calculations [5,13]. With a large shunt, there is considerable reflux of highly saturated blood to the SVC coming from the LA and RA. Therefore, saturations should be obtained in the high SVC or even in the proximal innominate vein. This is particularly true if there is suspicion of an anomalous connection of the right or left pulmonary vein to the normal right SVC. When there is anomalous connection of one or more left pulmonary veins to the distal innominate vein through a left vertical vein, blood samples should be taken in the left internal jugular vein or left subclavian vein. An increase in saturation of ~8–10% is found in the area of left-to-right shunting of pulmonary venous blood [20]. The estimated Qp/Qs frequently exceeds 2:1, but values as small as 1.5:1 may be associated with right atrial and right ventricular enlargement. Systemic arterial saturation is generally normal (occasionally slightly diminished), as is systemic cardiac output measured by the Fick method. Estimation of the cardiac output by thermodilution is misleading due to intracardiac shunting [5]. Right and left atrial pressures are usually similar in patients with unrestrictive moderate or large defects. Patients with significant pulmonary arterial hypertension should be assessed with regard to pressure and resistance response to vasodilators such as oxygen and nitric oxide [5]. In such patients, if the catheterization data suggest that the defect can still be closed, temporary test occlusion with a balloon or a device may be advisable [5]. When appropriate, a pulmonary arteriogram delineates the sites of pulmonary venous connection if the pulmonary veins are not entered directly or the oxygen saturation values are inconsistent [13]. In patients with severe pulmonary hypertension and vascular obstructive disease, selective pulmonary angiography with a wedge catheter typically shows enlarged proximal vessels with abrupt distal tapering. The distal vessels are tortuous and small in number. If it is necessary to delineate the secundum ASD angiographically, the catheter can generally be passed through it in the midportion of the atrial septum and an injection of contrast agent in the right upper pulmonary vein in a left anterior oblique with cranial angulation projection profiles the defect because flow from the vein is directed along the atrial septum. If there is a sinus venosus defect, the catheter passes into the left atrium near the base of the superior vena cava.

Management

Secundum ASDs

The main reasons for closing a secundum ASD (and all ASDs) is to prevent late pulmonary vascular disease, arrhythmias, and heart failure, all rare at <20 years of age [1]. Because the optimal timing for treatment has yet to be defined, the management strategy of a patient with a secundum ASD is based on multiple factors including the size and natural history of the defect, magnitude of the shunt and hemodynamic burden to the RV, age of the patient, and symptoms and/or co-morbid diseases [1,5,13]. Asymptomatic infants with a secundum ASD <8 mm in diameter should be observed expectantly [21–28]. Endocarditis prophylaxis precautions are not necessary. More than 75% of such secundum ASDs, particularly those <3–4 mm, close spontaneously before 18 months of age [21–28]. Spontaneous closure can also occur in infancy, even among patients who have signs of congestive cardiac failure [27]. If medical management fails, closure of the defect may be warranted even in children younger than 1 year [30,33]. Similarly, infants with associated co-morbid diseases, such as genetic syndromes, prematurity, diaphragmatic hernia, tracheoesophageal fistula, and chronic lung disease, may benefit from earlier closure [32,33]. Defects that are >8 mm in diameter in infancy are unlikely to close spontaneously and may even become larger with time [27]. If an infant with such a defect is asymptomatic and thriving well, closure may be deferred and carried out at 3–5 years of age, [13] provided that close surveillance is assured. Studies have shown no long-term benefit to earlier closure [79]. In older children and young adults, elective closure is recommended shortly after diagnosis if there is evidence of right ventricular enlargement. The management of an older adult patient with a secundum ASD is more controversial because of the lack of carefully conducted clinical trials on a large number of patients [1]. Despite some discussions about which patients need to have defect closure, the limited studies suggest that closure of an ASD in the older patients is warranted if the shunt is large and pulmonary vascular disease is not severe [1]. Although older patients may have a higher operative risk (especially if they have significant pulmonary hypertension with indexed PVR >7 Wood units m^{-2}, it seems that outcomes after surgery are better than those patients who are treated medically [44–50,80]. Theoretically, transcatheter treatment should further improve the beneficial effects of closure in this older age group. If the defect and

shunt are small and the right heart is not dilated, the patients can be followed, although a few will develop a larger shunt or symptoms and require closure of the defect [81].

A patient with an ASD associated with severe pulmonary hypertension and severely elevated pulmonary vascular resistance must be evaluated carefully. Operative risk is substantially increased by increased pulmonary vascular resistance (>7 Wood units m^{-2}) and is contraindicated if pulmonary vascular resistance is >15 Wood units m^{-2} [82–84]. In the latter, the ASD is probably an associated defect in conjunction with idiopathic pulmonary hypertension rather than Eisenmenger's reaction. Patients with severe idiopathic pulmonary hypertension may survive longer and have better exercise tolerance if a small ASD is present, and creation of a small ASD has even been used as a form of palliation in this situation [13,85]. Patients with a pulmonary resistance between 10 and 15 Wood units m^{-2} need expert investigation of pulmonary vascular reactivity or even lung biopsy [82–84]. Patients in this group whose defects are closed usually benefit symptomatically [82].

Closure of a secundum ASD can be performed surgically or by transcatheter means. Due to its less invasive nature, short hospital stay, no scar formation, and no need to use blood products, transcatheter closure of ASDs is indeed more appealing and has become the preferred method of treatment for selected patients in the last 5 years. Although no randomized trial has been conducted to compare both management strategies (catheter versus surgery), recent studies with contemporaneous cohorts of patients demonstrated that transcatheter closure of ASDs using either Amplatzer or Helex devices is as effective as surgery and results in less morbidity [86,87]. These studies resulted in approval of the Amplatzer and Helex devices for clinical use in the United States. Generally, 80–85% of all patients with secundum ASDs are suitable for transcatheter closure [88]. Due to evolving techniques, feasibility and indications for device implantation have expanded and now include the small child (<15 kg), those a with large defect, two or more isolated defects, a fenestrated IAS and an ASA, or only one insufficient rim (usually the retroaortic) [88–95]. Although device closure of secundum ASDs in the small child (<10–15 kg) is feasible, safe, and effective, higher rates of implantation failure, complications, and residual leaks are observed in this age group when compared with older patients [92,93]. Therefore, the indications for device closure in an asymptomatic small child who is thriving well and has no associated co-morbid conditions should be more strict and individualized. On the other side of the age spectrum, the elderly adult probably benefits the most from transcatheter closure due to anesthetic and thoracotomy issues, and other associated ailments that substantially increase the operative risks [1,95]. An occasional patient judged unsuitable for device closure may have a very large defect (>35–40 mm), defects with more than one inadequate rim,

too large a defect for the size of the patient (usually in children <10–15 kg), or a combination of these factors. These patients and those with all other types of ASDs, when indicated, should undergo surgical repair. Obviously, device closure is not indicated when a secundum ASD is associated with other cardiac lesions that require surgical correction. Although several devices have been used worldwide with varied results, only the Amplatzer septal occluder (AGA Medical, Golden Valley, MN, USA) and the Helex device (W. L. Gore and Associates, Flagstaff, AZ, USA) are approved for clinical use in the United States. In terms of costs, device closure has generally been less costly than [96,97] or similar to surgery [98], except in underdeveloped countries where the price of the devices may exceed hospital and professional costs [99].

PFOs, paradoxical embolization, and stroke

Because longitudinal studies in the general population fail to demonstrate that a PFO is a risk factor for ischemic strokes [59,60], any form of preventive treatment in asymptomatic patients with PFOs detected incidentally is unjustified at present. Therefore, patients with a PFO or a small ASD unassociated with right ventricular and right atrial enlargement do not generally require closure unless there is a high risk of paradoxical embolization with potentially life-threatening consequences (e.g., professional scuba divers) [65,100]. In this setting, the rationale of PFO closure is primary prophylaxis. On the other hand, in uncontrolled studies, percutaneous closure of the PFO in patients who had a cryptogenic stroke (i.e., unknown cause) due to presumed paradoxical embolization has abolished or markedly reduced the risk of repeat cerebral embolism (secondary prophylaxis) [55,56,101–103]. This is in contrast to the 8–16% recurrence rate in a 3–5 year follow-up in patients treated medically with antiplatelet medications or anticoagulants [104,105]. There are ongoing prospective and randomized clinical trials comparing both treatment strategies (device closure versus medical treatment) to determine whether device closure should be applied to all or some patients with a PFO with a single cryptogenic stroke. At present, most authorities and published guidelines agree that the PFO should be closed percutaneously only in cryptogenic stroke patients who had a second event while on medical treatment [106]. There are insufficient data to justify routine percutaneous closure of the PFO for such patients after the first cerebral event. Platelet antiaggregants (aspirin) are as effective as anticoagulants for secondary prevention and are associated with less bleeding [104]. Anticoagulants are indicated for recurrence prevention only if there is evidence of deep venous thrombosis or a coagulopathy [106]. Some offer transcatheter closure after the first cryptogenic stroke to patients who have unique PFOs with anatomic and/or functional characteristics considered at a higher risk for recurrences. These characteristics include large openings

(>4 mm), much mobility and redundancy of the interatrial septum, an atrial septal aneurysm, a right-to-left shunt at rest, massive right-to-left shunting after Valsalva maneuver, or a prominent Eustachian valve [102]. Probably a coagulopathy should also be included in the decision to treat [1]. Until the results of the prospective trials become available, many experts consider the issue of the best treatment strategy to be unsolved [1]. Interestingly, many studies in which the PFO or a small ASD was closed to prevent cerebral embolization reported a marked decrease in the incidence of migraine, especially migraine with an aura [61,63,64, 107–110]. Conversely, case–control studies failed to show such beneficial effect [111]. Therefore, at present, owing to the lack of well-conducted prospective and randomized trials, PFO device closure cannot be indicated as a well-established form of prophylactic treatment for patients with migraines unresponsive to medical treatment.

Sinus venosus defects

These patients have clinical findings similar to those with secundum ASDs. Essentially, all patients are referred to surgery because they usually have a significant left-to-right shunt through the defect and the commonly associated PAPVC [5,8,13]. The SVC type of sinus venosus defect should be closed using a prosthetic patch. The patch usually needs to be directed to the orifice of the SVC because of the PAPVC to this area. In some patients, the SVC needs to be enlarged with a patch or transected and relocated to the roof of the RA to ensure unobstructed drainage [5]. The rarer form of the IVC type of sinus venosus defect should also be repaired using a patch to close the defect and redirect the anomalously connected right lower pulmonary vein to the LA.

Partial Anomalous Venous Connections (PAPVCs)

These relatively common lesions have a wide anatomic variation. Usually there is an associated ASD [9]. Surgical indications and techniques should be tailored individually, considering the likelihood of operative success, expected technical difficulties, possible postoperative stenoses, and debatable benefits in an individual patient [5,8,9]. Because it does not result in a significant left-to-right shunt, PAPVC of a single small pulmonary vein does not require an operation [5]. On the other hand, PAPVC of all left pulmonary veins into a left vertical vein and then to the inomminate vein usually results in right ventricular volume overload and does require surgical treatment [5]. In this anomaly, the vertical vein is usually large and long enough to be detached from the innominate vein and anastomosed to the LA [5]. In neonates and infants, anastomosis of the small anomalous pulmonary veins to the LA may be complicated by postoperative stenosis and complete occlusion [5]. The incidental finding of a single anomalous pulmonary vein or multiple small anomalous pulmonary veins at a cardiac operation can be dealt with by simply leaving them alone [5].

Unroofed coronary sinus defects

The management strategy should be tailored to the underlying anatomy. If the mouth of the coronary sinus on the right side is small with no right ventricular enlargement, the ASD is left alone. If it is large, it should be patch closed with little practical consequence if the coronary venous blood cannot be redirected to the RA [5]. If a left SVC connected to the LA is present, it can be redirected and baffled to the RA or simply ligated if an adequate innominate vein is present [5].

Scimitar syndrome

This rare entity can be readily diagnosed based on the chest X-ray findings. Surgical treatment should be tailored based on the age of the patient, associated lesions, the amount of flow going across the right lung, and the amount of flow through the collateral supply to the lung [11]. The adult form of this disease has a more benign presentation and limited symptoms. Surgical correction is debatable because the amount of left-to-right flow shunting through the hypoplastic right lung is usually small [5]. However, if the shunt is large and results in RV enlargement, surgical redirection of the anomalous vein to the LA should be undertaken. In contrast, infants are usually more symptomatic from pulmonary hypertension and pulmonary sequestration [11]. Although the anomalous right pulmonary veins can be surgically redirected to the LA, postoperative obstruction is common at this age, causing reduction or abolition of flow to the right lung. Alternatively, the right pulmonary veins are left alone and the large aortopulmonary collaterals supplying the right lung are closed percutaneously, ameliorating symptoms and decreasing the pulmonary artery pressures [11]. Left pulmonary artery stenoses, if present, can also be dilated in the catheterization laboratory. Lobectomy or pneumonectomy may be indicated for patients with repeated pulmonary infections or hemorrhage due to abnormal bronchi [11].

Platypnea–orthodeoxia syndrome

Platypnea–orthodeoxia is a rare and poorly understood syndrome of postural hypoxemia accompanied by breathlessness [14]. The predominant symptom, dyspnea induced by upright posture, can be striking and debilitating. The precise cause of the syndrome is unclear, but patients develop right-to-left intracardiac shunting across a PFO, a small ASD, or a fenestrated septal aneurysm despite normal right-sided cardiac pressures. A persistent and unusually large Eustachian valve may be seen in some, but not all, patients. Hypothetically, standing upright could stretch the interatrial communication, thus allowing more streaming of venous blood from IVC through the defect, whether or not a persistent Eustachian valve coexists. This redirection of flow caused by an anatomic distortion of the atrial septum might also result from a variety of conditions, including cardiac

(pericardial effusion), pulmonary (emphysema, arteriovenous malformation, pneumonectomy, amiodarone toxicity), abdominal (cirrhosis of the liver or ileus), and vascular (aortic aneurysm, aortic elongation) diseases [14]. Catheter closure of the interatrial communication results in dramatic symptomatic and hemodynamic improvement [15].

Outcomes after treatment

The prognosis for patients with an ASD is generally very good, especially if the diagnosis is made early and the defect is closed [112]. Young patients who undergo uneventful ASD closure have an excellent outlook for survival for the next 30 years, but should be evaluated periodically.

Outcomes after surgery for secundum ASDs

Operative closure is accomplished by either direct suture closure or placement of a prosthetic patch over the defect with use of cardiopulmonary bypass. Direct suture is usually preferred if the defect is not too large because of concern about the possibility of thrombus formation on patch material, but no clear data exist regarding the superiority of one technique over the other [13]. Surgical techniques have improved and the use of a ministernotomy has become widespread. Other approaches, such as the submammary incision in women, lateral thoracotomy or right axillary incision, can also be used because of the potentially better cosmetic result [113–123]. More recently, techniques for video-assisted closure [124], robotic-assisted closure [125,126], and off-pump closure [127,128] have also been applied. In the modern era, the operative mortality risk in younger patients should approach zero and even in patients >30–40 years old, hospital mortality rates are usually <6.5% and indeed are often zero [43–50,79,112,129–138]. On the other hand, significant transient complications that delay discharge may occur in up to 25% of patients, including incomplete defect closure, bleeding, wound or patch dehiscence, wound infection, transient arrhythmia (including sinus node dysfunction and atrial fibrillation), pneumonia, pulmonary embolism, pleural effusion, superior vena cava obstruction, and postpericardiotomy syndrome requiring pericardiocentesis [43–50,79,112,129–138]. Despite these in-hospital complications, the average time of hospitalization for ASD closure has been reduced to 3–4 days in some institutions.

Long-term survival after operation is usually very good in children and good even in older adults [43–50,79,112, 129–138]. All the survival curves are better than the natural history curve derived from autopsy data and comparable to the population survival for the younger patients [1]. Patients under 20 years of age at the time of surgery show little decreased survival with age over a 20–30 year period, with their survival curves paralleling those for the normal population [1]. Survival curves for patients over 30 years of age at the time of operation show slightly more fall-off with age [1]. This does not mean, however, that such patients should not undergo closure of their ASD. Late operative closure may or may not lengthen survival in an individual patient but clearly results in improvement of symptoms [43–50]. In this regard, symptoms associated with a large left-to-right shunt are generally reversible even if operation is undertaken after the age of 60 years [46,139]. Children and adults who previously did not admit to symptoms often report that they can undertake more activity after the surgery. Even in those in heart failure before surgery, symptoms usually disappear [43–50,79,129–138]. Women who had surgery before becoming pregnant had a lower incidence of miscarriage, preterm delivery, and cardiac symptoms during pregnancy [140]. Exercise capacity increases in most patients, no matter the age at operation, but does not always return to normal [141–145]. Better performance has been found when defects were closed at <5 years of age [144].

Late complications and cardiovascular events may occur after surgical repair and are generally more common when the operation is performed at an older age. These include right ventricular dysfunction, residual pulmonary hypertension, symptomatic arrhythmias, need for pacemaker implantation, endocarditis, and mitral or tricuspid regurgitation requiring valvar surgery [13]. Cerebral embolism is also a threat, especially in older patients with atrial fibrillation [13]. Incomplete closure of the defect is rare and any residual defect is seldom large enough to cause problems [5].

Surgical closure of an ASD usually leads to a progressive decrease in size of the RV, usually taking 6–12 months (or even more) to attain normal dimensions [1,146–148]. In some patients, however, especially those with higher pulmonary blood flows and operated at older ages, the RV remains enlarged [1,79,146–148]. Although this residual dilatation has been termed cardiomyopathy of volume loading [1], its clinical effect on exercise performance is limited [146–149]. The left ventricular volume increases due to the shift of the septum towards the decompressed right ventricle and this plays a major role in the improved exercise response [1]. Echocardiography, computed tomography, and functional studies have shown better RV improvement in younger than older patients and those undergoing closure by interventional catheterization rather than by surgery [150–162]. Pulmonary arterial pressure usually decreases but resistance does not always return to normal [163–165]. Some may show increase in pulmonary arterial pressures during exercise [166].

Management of postoperative arrhythmias is an important issue in patients with an ASD. Persistent or newly developed arrhythmias may occur after surgical repair [1]. In general, those who already had arrhythmias before operation tended to have them postoperatively [167]. Also, the incidence of postoperative atrial arrhythmias has correlated with

increasing age of the patient, the left-to-right shunt size, and the degree of pulmonary hypertension [168]. A recent study suggested that arrhythmias are less frequent after interventional device than surgical closure [169]. In children, postoperative arrhythmias were reported in usually <10% after surgery, with most being sinus node dysfunction manifested by ectopic atrial rhythms, bradycardia, or sick sinus syndrome [1]. Relatively few had paroxysmal or sustained atrial fibrillation or needed pacemakers. In adults, however, paroxysmal or sustained supraventricular tachycardia, atrial fibrillation, or flutter are reported in up to 20–40% of patients after surgery, being increasingly frequent with aging [1,43–50,79,129–138]. The appearance of atrial fibrillation is serious because it may result in symptomatic deterioration and greatly increases the risk of stroke, which can occur late after surgery. In general, the risk of embolization is very low if the patients are <40 years of age and have normal pulmonary arterial pressures, sinus rhythm, and no history of preoperative emboli [13,43–50,79,129–138]. Although operative closure of an ASD in an older patient does not significantly reduce the incidence of late strokes because the incidence of atrial fibrillation is not reduced, this should not influence the decision to close the defect [13]. Therefore, patients should be monitored for the onset of atrial fibrillation, and if sinus rhythm does not return, anticoagulation therapy should be considered strongly [13]. On the other hand, some patients with atrial flutter revert to sinus rhythm after surgery [170]. Alternatively, surgical treatment of arrhythmias (Maze procedure) or radiofrequency ablation of atrial flutter or fibrillation have been performed successfully at the time of closing an ASD [171–174].

Outcomes after device closure of secundum ASDs

The technical aspects, feasibility of implantation, safety, and efficacy of device closure of the secundum ASD should be evaluated for each device available on the market. Because of the plethora of devices, this is beyond the scope of this chapter. The discussion is focused on the Amplatzer septal occluder (AGA Medical) and the Helex device (W. L. Gore and Associates). In short, the Amplatzer septal occluder, the most often used device worldwide, is constructed of a weave of relatively fine nitinol (nickel–titanium alloy) wire filled with thrombogenic fabric. The device can be withdrawn into a delivery catheter and resumes its intended shape as it is extruded from the catheter. The shape is that of two relatively flat, round disks connected by a central portion of large diameter that provides self-centering and stenting to maintain the device in position. It can be easily withdrawn and repositioned before release [86]. The Helex device is a non-self-centering double disk device consisting of a nitinol wire frame on which is bonded a curtain of hydrophilic ePTFE (Goretex; W. L. Gore and Associates). The nitinol is wound as two opposing spirals such that when the device is positioned it configures in two planar parallel discs that sit

on either side of the IAS. It is also repositionable and retrievable before release and even after it [87]. The success rate of implantation of such devices depends on the operator. Due to its design and easier-to-use system, the Amplatzer device results in higher rates of successful implantation, approaching 99% in experienced hands [86,88–95,175–179] (Figure 21.4b) (Videoclips 21.1–21.2). Reasons for failure include larger defects, multiple defects, inadequate rims of septal tissue, an atrial septal aneurysm, or a combination of these factors [86,88–95,175–179]. Whereas the Amplatzer septal occluder can close a broad range of ASD dimensions including the very large ones, the Helex device should be used only for the small to moderate ASD (<18 mm stretched diameter) [87,89,180,181].

Complication rates decrease with operator experience. Mortality is virtually zero. Occasionally the device embolizes immediately after release but can usually be retrieved in the catheterization laboratory and replaced. The Helex device is the easiest device to retrieve using transcatheter techniques. Sometimes surgery is needed to remove the embolized device, especially if it is stuck in the RV. Late (1 day–6 years) embolization is very unusual [182]. Occasionally there are supraventricular arrhythmias or atrioventricular block after closure, but no more than after surgical closure [183]. Older patients and oversizing of the device may be risk factors for arrhythmias. Thrombus formation on the left atrial side of all available devices has occasionally been detected immediately after placement or in the first 6 months of follow-up, and ironically may occur after closure of a patent foramen ovale to prevent paradoxical embolism [184]. The prevalence of thrombus formation is 2–3%, with the Amplatzer device being the least affected [1,184]. Treatment includes medical lysis or sometimes surgical removal. Cerebral embolism, however, is rare, perhaps no more frequent than after surgical closure of the defect. Fracture of the wire frame of the Helex device with no untoward clinical effect has been described with the larger diameter devices [185]. Probably the most feared complication is early or late erosion into the aortic root with subsequent pericardial tamponade and very rarely death or production of a fistula between the aorta and left or the right atrium [186]. This has been described with the Amplatzer device with an incidence of 0.1% [186], and also with other devices [187]. Owing to its design, flexibility, and softer characteristics, the Helex device has not resulted in perforations or erosions. Oversizing of the Amplatzer device and a higher ASD location in the IAS are risk factors for this complication [186]. Rarely, infective endocarditis occurs after device placement [188,189].

Complete closure of the defect depends on the type of device, size of the defect, and timing of evaluation. An immediate residual shunt may be seen in up to 10–30% of patients immediately after device release [86–95,175–181]. With progressive endothelialization of the devices, closure rates reach 92–99% after 1 year of follow-up, being higher

for the Amplatzer device and smaller defects [86–95, 175–181]. Because of its non-self-centering mechanism, a residual leak is more frequently observed with the Helex device [87,180,181]. Most, if not all, of these residual leaks seen with either device are trivial or small (<3–4 mm) and do not result in any hemodynamic burden to the RV. Therefore, clinical cure is achieved in virtually 100% of patients.

As with surgery, closure of the defect with a device decreases the size of the right ventricle, increases the size of the left ventricle, and improves cardiac function and exercise capacity. Improvement has occurred in children and adults without any notable age-related differences, with remodeling and cardiac function being slightly better after device closure than surgical repair [150–162,190–193].

Outcomes after surgical repair of other types of ASDs and PAPVC

Operative mortality for correcting a PAPVC with or without a sinus venosus defect is <3% [8]. After surgery, patients become asymptomatic or less symptomatic and exercise tolerance increases. Late complications such as reoperation, vena cava obstruction, pulmonary vein obstruction, and pacemaker implantation are uncommon [9]. Occasionally, the technique of repair may stenose the SVC and require balloon dilation and stent implantation [5]. Significant postoperative arrhythmias are also uncommon, although an occasional patient may show late sinus node dysfuntion due to surgical damage to the sinoatrial node [8,9].

Symptomatic infants with the Scimitar syndrome have a more guarded prognosis. Pulmonary arterial hypertension is a risk factor for operative mortality and may persist in those patients undergoing transcatheter closure of the collateral arterial supply to the right lung [11]. If surgical reimplantation of the anomalous pulmonary veins is undertaken, postoperative obstruction is common [5]. In contrast, the outcomes after surgical treatment of the adult form of this disease are much better [11]. If the right pulmonary artery and the right lung are not significantly hypoplastic, redirection of the anomalous veins to the left atrium results in symptomatic improvement and reduction of RV size. However, postoperative pulmonary vein stenosis is more common than for other types of PAPVC [11].

Future directions

In the next 10 years, we will witness the application of new technologies for the imaging, diagnosis, and treatment of ASDs. Evolving imaging technology will be applied not only for the accurate diagnosis of all types of ASDs but also for the guidance of transcatheter closure of the secundum ASD. Real-time three-dimensional intracardiac echocardiography will probably be helpful in this regard.

MRI-guided intervention is an exciting field that may have an effect on abolishing the need for radiation exposure in the catheterization laboratory for ASD closure. MRI-compatible catheters and devices should be developed to achieve this goal. Closure devices with reabsorbable materials have already been employed in clinical practice with good short-term outcomes [194–197]. Their main advantage is to allow free transseptal access to the left atrium in the future. With the rapid development of new devices to close the left atrial appendage in high-risk elderly patients with atrial fibrillation and to repair functional mitral valve insufficiency percutaneously, this is of paramount importance. Surgical approaches will also evolve and the application of less invasive, video-guided robotic surgery through small thoracic ports will be available for selected patients with ASDs.

22 Atrioventricular Septal Defects

Stuart Berger, Peter J. Bartz, David E. Saudek, John T. Hambrook & James S. Tweddell
Medical College of Wisconsin, Milwaukee, WI, USA

Introduction

Atrioventricular septal defects (AVSDs) are common and can be associated with morbidity and mortality in the fetus, neonates, and young infants. The anatomic defects relate to abnormalities in the embryologic development of the endocardial cushions including the atrioventricular valves, persistence of the atrial ostium primum, and associated ventricular septal openings.

Up to 17% of fetuses undergoing echocardiographic examination have a form of AVSD [1]. The fetal mortality associated with AVSDs can be shown by the much lower frequency of AVSDs diagnosed after birth, with most studies documenting an incidence of AVSDs in the 3–5% range [2,3].

AVSDs are strongly associated with genetic syndromes, such as Down syndrome. About 40% of children with Down syndrome have a congenital cardiac abnormality of which 40% have AVSDs. The association of syndromes with AVSDs suggests a very strong genetic influence, including the localization of these abnormalities to specific genes.

Finally, in general, the prognosis is excellent for most infants with AVSDs as surgical outcomes are outstanding. The good outcomes for infants with complete, balanced AVSDs implies early surgical intervention to avoid and prevent severe congestive heart failure or pulmonary vascular obstructive disease.

Pathologic anatomy

Currently, AVSD is the most widely used term to describe the spectrum of congenital heart malformations characterized by a common atrioventricular junction coexisting with deficient atrioventricular septation [4]. Many general and specific terms have been applied to this lesion, including endocardial cushion defect, atrioventricular canal defect, ostium primum defect, and common atrioventricular orifice. Terms to categorize AVSDs further have included partial, transitional, intermediate, and complete. Unfortunately, many of these terms can be interpreted as having a similar meaning or referring to a distinct entity, depending upon the individual users of the terms. For this reason, understanding and communicating about the anatomy are best achieved by describing the atrioventricular valve morphology and extent of atrial and ventricular septation.

In a normal heart, the tricuspid valve annulus is displaced apically with respect to the mitral valve annulus, so that separate left and right atrioventricular junctions result. In contrast, the morphological hallmark of AVSD is a common atrioventricular junction. In ASVD, the ventricular septum adjacent to the atrium is "scooped out." The lower attachment of the left atrioventricular valve annulus decreases the inlet length, as measured from the annulus to the left ventricle apex. Conversely, the outlet length measured from the left ventricular apex to the aortic valve is elongated (Figure 22.1) [5]. Thus, the aorta is not wedged between the mitral and tricuspid valves as in a normal heart (Figure 22.2). With the aorta "sprung" anterosuperiorly in AVSD, the left ventricular outflow tract is elongated and frequently narrowed, producing the so-called "gooseneck" deformity.

The leaflet morphology in AVSD bears little resemblance to the normal tricuspid and mitral valves. In AVSD, the valve guarding the common atrioventricular junction consists of five leaflets. Typically there is a left mural (or lateral) leaflet and a right mural leaflet that are positioned over the respective ventricles. Occasionally, a mural leaflet can be severely hypoplastic, which complicates achieving adequate surgical repair. The inferior (or posterior) bridging leaflet is

Figure 22.1 Left ventricular aspect of the septum in hearts with normal (a) and deficient (b) atrioventricular septation. (Reproduced from Anderson *et al.*, *Cardiol Young* 1991;1:290, with permission from Cambridge University Press.)
Figure 22.2 (a) Diagram depicting the relationship of the mitral and tricuspid valves to the aortic valve in a normal heart. The aortic valve sits wedged between the two atrioventricular valves. (b) The same view is depicted in this diagram of common atrioventricular septal defect. The superior and inferior bridging leaflets are demonstrated with the "cleft" where the two bridging leaflets come together at the ventricular septum. The aortic valve is unwedged anteriorly as a result of the superior bridging leaflet.

inferiorly positioned and crosses the ventricular septum with extensive chordal attachments to the crest of the septum. The superior (or anterior) bridging leaflet is positioned superiorly. The superior bridging leaflet can be considered variably divided, such as described by Rastelli *et al.* [6]. Alternatively, the superior portion of the valve can be considered to be composed of the superior bridging leaflet and the right anterosuperior (or accessory) leaflet, each of
Figure 22.3 Arrangement of the atrioventricular valve leaflets in complete atrioventricular septal defect as seen from the apex looking towards the base.

variable size, resulting in the common valve being composed of five leaflets (Figure 22.3).

In a normal heart, the left-sided papillary muscles are obliquely situated in the posteromedial and anterolateral position. In AVSD, the left-sided papillary muscles are rotated to a superior and inferior position. The muscles are usually equal in size and support the commissures between the bridging leaflets and left mural leaflet. Other left atrioventricular valve abnormalities exist in ~10% of AVSDs. Most frequently, accessory mitral valve tissue connects the superior and inferior leaflets to create a double-orifice left atrioventricular valve. Less frequently, a single papillary muscle creates a parachute configuration. Such valve abnormalities may complicate surgical repair, with possible residual left atrioventricular valve regurgitation, stenosis, or both [7]. Two or three papillary muscles are found in the right ventricle, including a fairly consistent anterior and posterior papillary muscle and variably present and positioned medial papillary muscle.

In AVSD, the posterior position of the atrial and ventricular septal defects interfere with the development of the normal conduction pathways. The atrioventricular node is displaced posteroinferiorly from the apex of the triangle of Koch, the usual anatomic location [8]. The conduction system then courses posterior to the ventricular septal defect, and the left bundle is also displaced posteroinferiorly. This anatomic variation probably accounts for the typical electrocardiographic finding of left axis deviation because depolarization of the left bundle proceeds from right inferior to left superior. This course also has important implications for operative repair. In some hearts, both an anomalous anterolateral node and a "regular" posteroinferior node give rise to penetrating bundles and atrioventricular bundles to form a sling of conduction tissues. When AVSD is associated with atrial isomerism, dual atrioventricular nodes with conduction tissue sling are also found [9].

Partial AVSD

The differentiation of partial from complete AVSD is based largely on the common atrioventricular valve being divided by a bridge of tissue between the superior bridging leaflet and the inferior bridging leaflet, creating two separate orifices. Usually the bridging tissue adheres to the crest of the ventricular septum, allowing no ventricular level shunting. The atrial septal defect is frequently termed a primum defect and is anteroinferior to the fossa ovalis and immediately adjacent to the atrioventricular valve. The defect size varies, but is usually fairly large, allowing for significant atrial shunting. A patent foramen ovale or a secundum defect may coexist. Rarely, secundum and primum defects coalesce, producing, in effect, a common atrium.

Although the left atrioventricular valve is referred to as cleft, it may also be considered as failure of fusion of the superior and inferior bridging leaflets. Regurgitation occurs through this defect. Because the valvar defect can extend medially towards the ventricular septum, a regurgitant jet can be directed through the primum atrial septal defect, effectively passing from the left ventricle to the right atrium. Abnormalities of the right-sided atrioventricular valve can also occur. These include a "cleft" in the septal leaflet or even a gap at the commissure, resulting in valve incompetence. The term transitional or intermediate form of AVSD has been applied when there are two valve orifices and a variably sized ventricular septal defect.

Complete AVSD

In complete AVSD, there is both a large inlet ventricular septal defect with the characteristic "scooped" appearance of the ventricular septum and a primum atrial septal defect. The common atrioventricular valve has a single orifice spanning the ventricular septal defect. The superior and inferior leaflets are not connected by the bridge of tissue, as in partial AVSD.

As discussed previously, the common atrioventricular valve is generally described as having five leaflets: (1) left mural, (2) right mural, (3) right anterosuperior, (4) inferior bridging leaflet, and (5) superior bridging leaflet (Figure 22.3). Rastelli et al. [6] devised a widely used classification for complete AVSD based on superior bridging leaflet morphology and the resultant attachment to the ventricular septum (Table 22.1). In this classification, the superior bridging leaflet is considered to be divided or "cleft" without the existence of the right anterosuperior leaflet.

Unbalanced AVSD

In most patients with AVSD, the common atrioventricular valve is shared equally between the right and left ventricles,

Table 22.1 Rastelli classification of complete AVSD.

Type	Description
A	The superior bridging leaflet is divided into two relatively equal portions, both attached medially to the muscular septum. The membranous septum has formed, and the interventricular communication does not extend to the region adjacent to the aortic cusps
B	The superior bridging leaflet is divided into two relatively unequal portions, unattached to the septum, but both portions are attached medially to a papillary muscle in the right ventricle adjacent to the ventricular septum
C	The superior bridging leaflet is undivided and unattached to the septum, floating freely above it. The interventricular communication is complete under the common superior leaflet and extends to the region adjacent to the aortic cusps

Figure 22.4 (a) Diagram showing double-outlet right atrium with malalignment of the atrial septum towards the left atrium. (b) Diagram showing double-outlet left atrium with malalignment of the atrial septum towards the right atrium. (c) Diagram showing unbalanced common atrioventricular septal defect (AVSD) to the right with concomitant left ventricular hypoplasia. (d) Diagram showing unbalanced AVSD to the left with concomitant right ventricular hypoplasia. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

creating a "balanced" defect. In the unbalanced form of AVSD, the relationship of the atrial or ventricular septum to the common atrioventricular valve is shifted either leftwards or rightwards with unequal sharing of the common valve orifice (Figure 22.4). With leftward shifting of the ventricular septum, the right ventricle is dominant and the left ventricle hypoplastic. Less commonly, the ventricular septum is shifted rightwards, creating left ventricular dominance and a hypoplastic right ventricle. Rarely, the atrial septum is unbalanced or malaligned, creating a double-outlet atrium. When the atrial septum is deviated leftwards, a double-outlet right atrium exists. Conversely, when the atrial septum is deviated rightwards, a double-outlet left atrium is created.

An unbalanced AV canal occurs in ~10% of patients with complete AV canal. Commonly, the ventricle receiving the smaller amount of blood flow is hypoplastic to some extent. In the extreme, one ventricle (usually the left) is severely hypoplastic and requires single ventricle palliation. With a mild hypoplasia, decisions between single-ventricle palliation and two-ventricle repair may be difficult. In a moderately unbalanced AV canal, ductal-dependent circulation, large VSD, and small ventricular volumes raise concern about the adequacy of the underdeveloped ventricle. A complete, unbalanced AV canal adds risk for patients undergoing the Norwood procedure.

Associated abnormalities

Atrioventricular septal defect and tetralogy of fallot

AVSD may be associated with tetralogy of Fallot. Surgical series report the association in 2.7–10% of atrioventricular septal repairs and 1–6.5% of tetralogy of Fallot repairs [10].

Trisomy 21 has been found in ~77% of patients with AVSD-TOF [11]. This combination of anomalies is not typically seen with heterotaxy syndrome, but the association of AVSD and double-outlet right ventricle commonly is [12].

In AVSD with tetralogy of Fallot, the inlet ventricular septal defect extends into the outlet septum and underneath the inferior bridging leaflet. Usually the atrioventricular valve morphology is Rastelli type C [11,13]. Significant atrioventricular valve regurgitation is not common [13]. The usual features of tetralogy of Fallot are seen. Rarely the pulmonary valve is atretic. The pulmonary arteries may be variably hypoplastic [10]. Details of this anatomy can be demonstrated echocardiographically.

Other associated defects

Almost any other form of congenital heart disease may be associated with complete AVSD, including abnormalities of venous connections, additional ASDs and VSDs, outflow
Figure 22.5 Sections through the heart at 4.5, 5 and 6 weeks of age. (a) The common atrioventricular canal has shifted to the midline. (b, c) Fusion of the endocardial cushions gives rise to the mitral and tricuspid orifices. The course of the circulation is noted in the figures in the lower row. Ao, aorta; ventral AV cushion, superior endocardial cushion; dorsal AV cushion, inferior endocardial cushion; DA, ductus arteriosus; IVS, intraventricular septum; M, mitral orifice; Pry IVF, primary intraventricular foramen; PT, pulmonary trunk; RV, right ventricle; T, tricuspid orifice.

tract obstruction of either ventricle, patent ductus arteriosus, and coarctation of the aorta. AVSD is common in patients with *heterotaxy syndrome* (see Chapter 50).

Embryology

During the fourth and fifth weeks of human embryo development, two swellings of mesenchymal tissue protrude from the superior and inferior portions of the atrioventricular junction of the primitive heart. These endocardial cushions fuse to form the supporting structure and precursor tissue for the atrioventricular valves. Following fusion of these endocardial cushions, cells overlying the future valve structures delaminate, differentiate and migrate to form mature valve structures by the sixth week. The embryologic events noted above are depicted in Figures 22.5 and 22.6.

AVSD forms from inadequate fusion of the endocardial cushions [14]. This process is guided and influenced by a number of undetermined pathways. Genetic influences on endocardial cushion development are an area of intense research focus. Because of the association between trisomy 21 and AVSD, a major genetic locus for AVSD would be suspected on chromosome 21, but linkage studies have not shown this. Linkage studies have pointed towards a mutation in CRELD1 for AVSD associated with trisomy 21 and also in isolation [15].

Hemodynamics

The hemodynamics of AVSD vary with the specific defect anatomy and physiology. Within the same anatomic subsets there may be differences in physiology.

An uncomplicated balanced AVSD typically has the physiology of a left-to-right shunt lesion influenced by the degree of atrioventricular (AV) valve regurgitation and the degree of pulmonary hypertension. The pulmonary artery pressure is at systemic level and if the resistance is not unduly elevated, the patient has left ventricular volume overload from the left-to-right ventricular level shunt. The left ventricular volume overload is accentuated by the AV valve regurgitation. Symptoms of heart failure occur as a result of both left ventricular volume overload and pulmonary overcirculation.

Patients with Down syndrome may develop elevated pulmonary vascular resistance early in infancy. As a result, heart failure may be attenuated or may not develop because of the limitation of left-to-right shunting. Surgical intervention early in infancy is warranted, even if symptoms of heart failure are not present, to prevent irreversible pulmonary hypertension.

In patients with a primum atrial septal defect and cleft mitral valve, the hemodynamics are typical of a large ASD. These findings include left-to-right shunt at the atrial
Figure 22.6 Embryo at 33 days of age showing inferior, right, and left endocardial cushions. The superior and inferior cushions have yet to fuse and divide the AV orifice in two. The right and left endocardial cushions contribute to AV valve formation.

level with accompanying right ventricular volume overload. Additionally, mitral regurgitation through the mitral valve cleft is associated with a varying degree of left ventricular volume overload. Despite these hemodynamics, this variant rarely results in significant symptoms in infancy or early childhood.

Patients with pulmonary outflow obstruction and AVSD present with a clinical picture of tetralogy of Fallot. Patients with Down syndrome are overly represented in this group. The degree of desaturation from diminished pulmonary blood flow varies and tends to progress.

The hemodynamics of the more complex forms of AVSD also vary. The left dominant form of AVSD presents like the patient with AVSD and tetralogy of Fallot described above. The right dominant form of AVSD presents with hypoplasia of the left ventricle and ascending aorta much like the infant with hypoplastic left heart syndrome. The AVSD variants associated with heterotaxy syndromes are influenced by the specific associated anatomic conditions.

Natural history

Survival with an unrepaired AVSD is extremely poor. About 60–80% of non-terminated pregnancies with AVSD are born live [16]. If left unrepaired after birth, survival at 6 months is 54%, at 12 months 35%, at 24 months 15%, and at 5 years 4% [17].

Many infants with unrepaired AVSD experience profound heart failure. Deaths before 24 months of age are primarily from severe congestive heart failure. Unfortunately, patients who do not die from heart failure at a young age have elevated pulmonary vascular resistance, which becomes irreversible if the defect remains unrepaired. As these patients age, pulmonary vascular resistance increases until they become cyanotic and eventually die from complications from pulmonary vascular disease. This process is seemingly accelerated in patients with Down syndrome, most likely as a result of accompanying airway, lung, and inherent pulmonary vascular issues. Hence surgical repair of complete AVSD should occur before 6 months of age, before the development of pulmonary vascular obstructive disease.

The development of pulmonary vascular disease in infants with complete AVSD is more severe than in those with an isolated VSD and is related to a cellular intimal proliferation that appears to develop earlier in life for unknown reasons. One possible factor is the obligatory left ventricular to right atrial shunt that delays or prevents the decrease in pulmonary vascular resistance. Because severe medial hypertrophy and intimal proliferation have been described as early as 6 months of life, intervention should occur in the first 6 months of life. If left untreated or unrecognized, or if the patient has arrived from a developing country without tertiary care, cardiac shunting may be minimal and right- and left-sided resistances are balanced. The time when this occurs varies. In later childhood and adolescence, it is not

uncommon for the shunt to reverse, with the patient becoming cyanotic and developing polycythemia, clubbing, and complications of fixed pulmonary vascular obstructive disease.

Finally, if there is associated pulmonary stenosis or atresia, the course and natural history (both treated and untreated) resemble tetralogy of Fallot. With an AVSD, the course parallels that of a single ventricle in both the treated and untreated forms.

History and physical examination

The history and physical examination vary depending on the specific anatomy and physiology of the endocardial cushion defect. Although the history and physical examination are targeted towards the cardiopulmonary systems, a general evaluation seeking information about an associated genetic condition should be performed.

Patients with an ostium primum AVSD are asymptomatic and do not develop symptoms of heart failure in childhood. Rarely, subtle respiratory symptoms and slow growth may occur with significant mitral regurgitation. The cardiac findings typically include an active right ventricle, a fixed, widely split second heart sound in the pulmonic area and a pulmonary ejection murmur, usually grade ≤3/6. With a large left-to-right atrial shunt, a grade 1–2/4 mid-diastolic flow rumble is heard at the mid-left sternal border from increased flow across the tricuspid valve. With a cleft in the anterior leaflet of the mitral valve and associated mitral regurgitation, a high-pitched, apical, pan-systolic murmur radiates to the left lower sternal border and axilla. If the regurgitant volume is large, an apical thrust and an apical mid-diastolic murmur are found.

In patients with complete AVSD, shunting occurs at both the atrial and ventricular level and is accompanied by variable severity of regurgitation of the common AV valve. Most patients develop symptoms in infancy, especially as the pulmonary vascular resistance decreases. Left ventricular volume overload results from the left-to-right shunt across the VSD and the mitral regurgitation [18]. Excess pulmonary blood flow and pulmonary hypertension at the systemic level are present. As a result, the typical symptoms include failure to thrive, frequent respiratory tract infections, and heart failure. If symptoms of heart failure are not present or resolve spontaneously, significant elevation of pulmonary vascular resistance is present.

On cardiac examination, typically the precordium is hyperactive, the second heart sound is narrowly split and P_2 is loud, and there may be an S_3 gallop. An apical holosystolic murmur is heard with mitral regurgitation and a more widely heard holosystolic murmur from the VSD. A mid-diastolic murmur is present at the left lower sternal border and apex from increased flow across the AV valves. Mild

cyanosis and a generalized diminution of pulses may be found. Decreased lower extremity pulses may indicate an associated coarctation of the aorta. Cyanosis associated with a loud, harsh pulmonic murmur suggests right ventricular outflow tract obstruction [19].

Electrocardiography

Related to the posteroinferior displacement of the AV node and left bundle [20], complete AVSDs have a "northwest axis," typically between –90° and –150° in the frontal plane. This is accompanied by left, right, or bi-ventricular hypertrophy reflecting the hemodynamics. A prolonged PR interval is common (see Figure 22.7). Patients with a primum ASD and cleft mitral valve also have a superior leftward axis, but not to the degree of a complete canal. Incomplete right bundle branch block (rSR′ in the right precordial leads), a widened or bifid P wave indicative of left atrial enlargement (dependent upon the degree of mitral valve regurgitation [21]), a tall P wave indicating right atrial enlargement, and electrocardiographic signs of right ventricular hypertrophy are typical.

Echocardiography

Transthoracic echocardiography
Transthoracic echocardiography is the primary tool for diagnosis and postoperative follow-up of AVSD. Important information can be obtained about both morphologic features of the defect and physiologic alterations that affect surgical planning. Initial evaluation should assess the AV valve morphology, atrial and ventricular septal defects, and relative ventricular size. Associated anomalies should be sought. Following repair, echocardiography is used to assess residual lesions.

Atrioventricular valve
The echocardiogram should differentiate between a partitioned or common AV valve orifice. This differentiation depends on the presence or absence of a tongue of tissue connecting the superior and inferior bridging leaflets that divides the valve into two separate orifices [22]. The subcostal and parasternal short axis views are useful for visualization of the AV valve orifice *en face*. Rotating the transducer 30–45° clockwise from the subcostal four-chamber view allows visualization of the AV valve *en face*. When the plane of sound is aligned with the fibrous annulus, the nature of the bridging tissue can be detected [23]. Although partial AVSD commonly lacks a VSD, the presence or absence of a VSD is not sufficient to differentiate complete from partial AV canal. Both partial AVSD with a large VSD and complete AVSD without a ventricular level shunt have been described [22].

Figure 22.7 12-lead ECG of a 3-month-old child depicting a sinus rhythm, northwest axis, and combined ventricular hypertrophy.

Rastelli *et al*. described division of the superior bridging leaflet in complete forms of AVSD, as described previously [24] (Figure 22.8). When the AV valve is viewed *en face* from the subcostal short-axis view, the division of the superior bridging leaflet and the status of septal attachments to the ventricular septum can be clearly seen [22,24,25]. Attachments of the superior bridging leaflet can also be demonstrated by sweeping superiorly from the apical four-chamber view [25].

The left ventricular papillary muscle configuration may affect surgical repair. Spacing of the papillary muscles can be clearly defined from the parasternal short-axis or subcostal short-axis views [26]. When the papillary muscles are closely spaced, the left mural leaflet may be small. A single left-sided papillary muscle results in absence of the left mural leaflet. Closure of the commissure between the superior and inferior bridging leaflets with a deficient left mural leaflet may result in left AV valve stenosis. Double-orifice left AV valve can be identified from both the parasternal and subcostal

short-axis views. Double-orifice left AV valve is more common in partial than complete AVSD, and the accessory orifice is more commonly associated with the posteromedial papillary muscle [27].

Atrioventricular valve regurgitation should be assessed with color Doppler. It is important to define the amount and location of regurgitation. Sweeps through the AV valve should be performed and the valve interrogated from orthogonal planes. Coaptation of leaflets may be complex and regurgitation may be underestimated from a single imaging plane.

Atrial and ventricular septal defects

The presence and size of atrial and ventricular septal defects should be determined. A primum atrial septal defect is characterized by deficient atrial septal tissue at the crux of the heart (Figure 22.9). These defects are typically well visualized from the apical and subcostal four-chamber views (Figure 22.10). Tilting posterior from the four-chamber view,
Figure 22.8 Subcostal imaging is helpful in determining the atrioventricular valve morphology. (a) During systole, the AV valve is closed. In Rastelli type A, attachments of the anterior bridging leaflet (yellow arrows) to the interventricular septum (white arrow) can be seen. (b) During diastole the valve is open and the anterior bridging leaflet is tented by the attachments to the ventricular septum. (c) With Rastelli type C, the anterior bridging leaflet is free floating without attachments to the interventricular septum (red arrow).
Figure 22.9 Transesophageal echocardiogram of a partial AV canal defect. The primum atrial septal defect is seen at the crux of the heart. The inlet ventricular septum is intact. Note that the left and right AV valves are at the same level, in contrast to the normal slight apical displacement of the tricuspid valve relative to the mitral valve. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

(a) The single atrioventricular valve opens into both ventricles during diastole.
The valve is mildly unbalanced to the right. (b) During systole the primum
atrial septal defect and inlet ventricular septal defects (arrows) are visualized.
LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

the imaging plane enters the coronary sinus, which may erroneously appear to be a primum ASD, particularly when the coronary sinus is dilated from receiving a left superior vena cava. Subcostal imaging may further delineate the size of the primum ASD. In an isolated primum ASD, the common AV valve is often divided (partial AVSD) and the bridging leaflets are adherent to the interventricular septum [25]. Additional ASDs should also be noted. Occasionally, the atrial septum is virtually absent, resulting in a common atrium. Rarely, the atrial septum is intact.

The inlet VSD is well visualized from the apical four-chamber view, and its size should be noted. Sweeping anteriorly from the four-chamber view may demonstrate outlet extension of the defect. From a subcostal short-axis view, a ventricular shunt may be demonstrated below the bridging leaflets. The inferior bridging leaflet often has dense attachments to the crest of the interventricular septum limiting shunting. Commonly, the shunt occurs beneath the superior bridging leaflet [22]. Extension of the defect into

the trabecular muscular septum or outlet septum should also be assessed. Additional muscular VSDs should be sought.

Ventricular size

Usually the atrioventricular valve is aligned equally over the ventricles. When the AVSD is unbalanced and there is a greater commitment of the atrioventricular valve to one ventricle, the ventricle receiving lesser inflow may be hypoplastic. The degree of hypoplasia varies from mildly but adequate to support systemic circulation to severely hypoplastic. The relative proportion of the atrioventricular valve inflow committed to each ventricle can be measured by planimetry of the valves *en face* [28]. Estimating left ventricular volume has also been performed when making decisions regarding suitability for two ventricle repair, although echocardiography underestimates left ventricular volumes in this setting [29].

Left ventricular outflow

In the normal heart, the aorta is wedged in the space anterior to the junction of the tricuspid and mitral valves. When the atrioventricular valves fail to divide, the aorta is unable to assume its usual wedged position and is displaced anteriorly, increasing the distance from the left ventricular apex to the aortic valve. This increased outflow length may contribute to late development of outflow tract obstruction. Additionally, left atrioventricular valve chordal attachments may cross the outflow tract, increasing the risk of obstruction [22]. A significant gradient is rarely found through the left ventricular outflow tract at the time of initial repair, but may develop later.

Associated lesions

A complete assessment of cardiac anatomy is important in all patients with AVSD to detect associated defects.

Left ventricular outflow tract obstruction may be caused by a number of mechanisms, and may be progressive [27]. Left ventricular outflow elongation often results in tunnel-like narrowing, although a gradient is not always present. Chordal attachments originating from the superior bridging leaflet of the left atrioventricular valve may cross the left ventricular outflow tract, resulting in obstruction that is more common with partial AVSD or Rastelli type A complete AVSD due to the dense chordal attachments to the crest of the septum [30]. A discrete fibromuscular ridge may cause obstruction, most commonly becoming apparent several years following initial repair [22]. Because left ventricular outflow tract obstruction often becomes apparent during late follow-up, serial assessment after repair is important [27].

Transesophageal echocardiogram

An intraoperative transesophageal echocardiogram helps guide surgical repair. Details of intracardiac anatomy can be confirmed, although in most patients transthoracic echocardiography clearly delineates the anatomy preoperatively.

Figure 22.11 Fetal four-chamber image of a complete AV canal defect in a patient with heterotaxy syndrome. There is a single common AV valve with large atrial and ventricular septal components to the AV canal. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

The four-chamber view allows assessment of atrial and ventricular level shunts. The common atrioventricular valve can also be inspected from this view for morphology and regurgitation. The long-axis view is useful for assessing the left ventricular outflow tract. The AV valve can be viewed *en face* from the transgastric view. Any bridging tissue connecting the anterior and posterior bridging leaflets and also division of the superior bridging leaflet (Rastelli classification) can be seen from this view. Both left and right ventricular outflow tracts can also be interrogated from the transgastric view [31].

Fetal echocardiography

Complete AVSD is one of the more common lesions detected prenatally, but antenatal detection rates vary between centers [32] (Figure 22.11). Common reasons for referral for sub-specialty evaluation of fetuses with AVSD include abnormal four-chamber view, fetal bradycardia, hydrops, and concerns about trisomy 21 [33]. AVSD detected prenatally raises concerns about other abnormalities that may affect the prognosis. Heterotaxy syndrome, with or without complete heart block, and ventricular hypoplasia are commonly seen in the fetus diagnosed with AVSD [34]. These lesions are likely over-represented in fetal series because these more severe forms of atrioventricular septal defects are more easily detected during the obstetric screening. The relative risk of the fetus having an abnormal karyotype (trisomy 21 in particular, but also trisomy 13 and 18) is significantly increased with AVSD in the absence of heterotaxy syndrome [35]. Finding an AVSD in a fetus should prompt discussion about amniocentesis. Extracardiac anomalies have been reported in 15% of fetuses found to have AVSD [36].

Antenatal detection of AVSD provides the opportunity for counseling the family regarding the expected prenatal course, delivery plan, and postnatal outcome. The risk of hydrops or fetal demise in the fetus with complete AVSD is increased [36]. Risk factors *in utero* include development of complete heart block (often associated with heterotaxy syndrome) and significant AV valve regurgitation. Fetuses with left atrial isomerism appear to have a particularly poor prognosis [37]. Signs of significant fetal distress or concern about ductal-dependent lesions should prompt delivery at a center familiar with the evaluation and management of neonates with significant heart disease.

Radiography

The chest X-ray characteristics depend largely on the degree of pulmonary over-circulation and the amount of valvar regurgitation. With increased pulmonary blood flow, the chest X-ray demonstrates cardiomegaly, prominent pulmonary vasculature, and a large main pulmonary artery. With significant valvar regurgitation, the cardiac size is larger than expected for the amount of increased pulmonary vasculature.

Cardiac catheterization

Cardiac catheterization is rarely necessary for patients with AVSD, because. echocardiography delineates the anatomic and hemodynamic features so well. When echocardiography is unable to delineate complex associated anatomic abnormalities, cardiac magnetic resonance imaging (CMRI) may be useful. If the clinical information and echocardiographic findings cannot determine suitability for surgery because of concerns about elevated pulmonary vascular resistance (PVR), cardiac catheterization and measurement of PVR with acute pulmonary vasodilator testing may be useful. An elevation of PVR >10 units m^{-2}, in the absence of AV valve insufficiency, and despite provocative pulmonary vasodilator testing, is considered to deem the patient inoperable.

Cardiac magnetic resonance imaging

CMRI serves a complementary role to echocardiography in answering specific clinical issues, including quantification of right and left ventricular volume, function, pulmonary to systemic flow ratio, and valvar regurgitation. Details of intracardiac anatomy are also well demonstrated [38]. Volume measurements are typically performed in contiguous short-axis images through the ventricles from the apex to base of the heart using gradient echo cine imaging. The volumes of slices through the ventricles are summed, yielding

the ventricular volumes, which may be indexed to body surface area. Ventricular volume measurements at end-diastole and end-systole allow the calculation of the ejection fraction for both the left and right ventricles. Flow assessment can be used to quantify anterograde and retrograde flow through the atrioventricular valves. In the absence of an intra-cardiac shunt or significant semilunar valve regurgitation, comparison of stroke volumes from short-axis imaging can also be used to calculate valvar regurgitation. With borderline left ventricular size, ventricular volumes measured on CMRI can help with decisions about left ventricular adequacy. Left ventricular volume obtained by this method may underestimate the potential volume due to shifting of septal position towards the left ventricular cavity.

Medical management

In today's era of complete neonatal surgical repair, the preoperative management of AVSD involves managing pulmonary over-circulation until operation. Anticongestive medical therapy reduces preload, enhances cardiac contractility, reduces afterload, improves oxygen delivery, and enhances nutrition. Diuretic therapy is the mainstay of medical management. Other medications include digoxin and ACE inhibitors. Most infants with an AVSD have normal ventricular function, so there is little rationale for the use of digoxin. Ventricular volume overloading is the rationale for using ACE inhibitors, but data on its efficacy are lacking. Nutrition should be optimized. Medical management is maintained until surgical repair. Few data are available about the ideal size for surgical repair, with decisions varying between institutions. Excellent outcomes have been reported for repair of complete AVSD even in neonates. Pulmonary artery banding is rarely performed other than in premature or very sick infants or infants with complex anatomy.

After repair, patients typically require no more than routine follow-up. Medications are usually not needed after discharge from the hospital except for AV valve regurgitation when diuretics and/or afterload reduction may be necessary. Large residual septal defects are uncommon and would typically be addressed prior to hospital discharge.

Surgical repair of AVSD

The first successful repair of AVSD was reported by Lillehei and colleagues at the University of Minnesota in the mid-1950s [39,40]. They initially used cross-circulation for cardiopulmonary bypass and the complete AVSD was repaired by directly suturing the rim of the atrial septal defect (ASD) to the crest of the ventricular septal defect (VSD) [Editor's note – This patient is doing well and has not needed a reoperation in the 55 years since the operation. J.H.M.].

Within 2 years they transitioned to a heart–lung machine and along with other pioneering heart surgeons of 1950s, such as John Kirklin, Dwight McGoon and Denton Cooley, began to incorporate patch material into the repair of AVSD [41,42]. Mortality remained high in part because the patients were older and at risk for complications from elevated pulmonary vascular resistance. Improvements in the techniques of surgery and cardiopulmonary bypass paralleled the transition to earlier age at repair.

Operative techniques

Cardiopulmonary bypass is used for repair of AVSD. In general, mild to moderate hypothermia (25–32 °C), aortic cross-clamping, and cardioplegia are used. The conduction system is vulnerable along the inferior–posterior edge of the defect and the sutures are placed to the right side of the interventricular septum to avoid heart block (Figure 22.12) [43–45]. Regardless of the specific form of AVSD or the specific operative technique, the cleft in the left sided AV valve should be closed except when it would lead to stenosis. Following closure, valve competence is tested to identify important insufficiency [46], which is managed by commissuroplasty sutures (Figure 22.13) [47,48].

Transesophageal echocardiography is performed at the end of the operation to identify major residual lesions. Postoperatively, transesophageal echocardiography (TEE) can provide the surgeon with information about residual lesions that need to be addressed prior to sternal closure [31]. Important details of the postoperative TEE include residual atrial or ventricular level shunts, AV valve function, ventricular function, and outflow tract obstruction. Atrioventricular valves should be closely inspected for either regurgitation or stenosis. The degree of AV valve regurgitation seen on intraoperative TEE may not correspond to that on follow-up transthoracic echocardiography. Multiple variables, including level of sedation, inotropic support, ventricular function, and filling pressure, may lead to discrepancies in the assessment of AV valve function in the operating room and at follow-up [49]. Right ventricular pressure may be estimated by measuring the velocity of either tricuspid valve regurgitation or residual VSD gradient. If increased pulmonary vascular resistance is suspected, this information may help guide postoperative management.

Partial AVSD (Primum Atrial Septal Defect)

In this form of AVSD, the ventricular septal defect component is absent [50]. The morphology of the AV valve varies. In some, an annular fibrous ridge separates the left- and right-sided components of the AV valve. In others, the bridging leaflets of the common AV valve attach to the ventricular septum, obliterating any ventricular level communication but the fibrous separation between the left and right-sided components is indistinct. Patients with a partial AVSD are unlikely to have congestive heart failure unless there is
Figure 22.12 The conduction system in AVSD. (a) The conduction system in partial AVSD. Note the position of the atrioventricular node (N) in the atrium inferior to the coronary sinus ostium (CS) and the course of the penetrating bundle (PB) along the posterior inferior margin of the ASD. (b) The conduction system in complete AVSD. The atrioventricular node (N) is in the same position as in the partial AVSD. The course of the penetrating bundle (PB) is along the posterior inferior margin of the ventricular septal defect (CAVO). op, partial AVSD; L, limbus; BB, branching AV bundle; RA, right atrium; RBB, right bundle branch; RV, right ventricle. Figure 22.13 Achieving left AV valve competence is essential for successful repair of any form of AVSD. After closure of the cleft, which should be possible in most patients, the valve is assessed for competence and additional reparative procedures performed. In this example, commissuroplasty sutures are shown. (Reproduced with permission from Karl, *Semin Thorac Cardiovasc Surg* 1997;**9**:26–34.)

significant left AV valve insufficiency. It has been common to delay repair until preschool age, but surgery from 3 to 18 months of age is associated with a lower risk of residual left-sided AV valve regurgitation [51]. Repair includes closure of the left-sided AV valve cleft and patch closure of the defect (Figure 22.14) [44]. The conduction system in AVSD is exposed along the inferior end of the defect and care is taken to place sutures to the right side in this area [51]. Some place the coronary sinus ostium on the left side of the patch to decrease further conduction system injury.

Transitional and intermediate AVSD

Transitional and intermediate forms of AVSD have distinct left- and right-sided AV orifices, an ASD, and a VSD below the AV valves [50]. With a transitional AVSD, the ventricular component is restrictive and frequently at the level of the cleft. Repair includes closure of the cleft and suture closure of the VSD component by passing pledget-supported horizontal mattress sutures from the right side of the interventricular septum through the area of division of the common AV valve and then through the bottom of a separate pericardial or Gore-Tex patch. With a restrictive VSD, it is not necessary to repair in early infancy, but delay past 4 years of age is associated with worse long-term left-sided AV valve function [52]. The VSD can be nonrestrictive, associated with heart failure, and at risk for early development of pulmonary vascular disease [52]. Larger ventricular septal defects may require a separate VSD patch. The conduction system occupies the same position as with a complete AVSD.

Complete AVSD

Elective repair of AVSD is undertaken at between 2 and 4 months of age to avoid the development of elevated pulmonary vascular resistance. Currently there are three

techniques used to repair AVSDs: the single-patch technique initially described by Maloney *et al.* in 1962 [53], the two-patch technique first reported by McGoon *et al.* at the Mayo Clinic in 1959 [42] and reintroduced by Trusler in Toronto in 1976 [54], and the modified one-patch technique originally described by Wilcox *et al.* in 1977 [55] and subsequently by Nicholson *et al.* in 1999 [56].

The one-patch technique

In this technique, the single AV valve is separated into left (mitral) and right (tricuspid) halves by incising the superior and inferior bridging leaflets back to the annulus. A single patch of pericardium, Dacron, or Gore-Tex, is sutured to the right side of the crest of the interventricular septum. The valve leaflets are then resuspended to this patch. The cleft in the left side of the valve is closed using interrupted sutures and then the atrial component of the defect is closed by suturing the upper portion of this patch to the native atrial septum using continuous suture.(Figure 22.15) The largest series of classic single-patch technique are summarized in Table 22.2. The classic one-patch technique provides excellent exposure of the interventricular septal crest and may decrease the risk of a residual VSD. This technique is well suited to repair of AVSD with tetralogy of Fallot because incising the anterior bridging leaflet provides excellent exposure to the outlet component of the VSD. Its suitability in neonates and very small infants is questionable because their valve tissue is very thin and flimsy. Division and reapproximation of the delicate valve tissue are difficult without producing insufficiency.

The two-patch repair

In this technique, the VSD component of the AVSD is repaired with a separate patch of either pericardium, Dacron, or Gore-Tex. This sickle-shaped shallow VSD patch is sutured to the right side of the interventricular septum. Sutures are then passed from the top of the VSD patch through the appropriate dividing line of the superior and inferior bridging

leaflets and then through the bottom of a separate ASD patch. The cleft in the left-sided AV valve is approximated with suture and the ASD is then closed by suturing the atrial patch to the edge of the defect. The two-patch technique is illustrated in Figure 22.16. The two patch repair preserves AV valve integrity. Most patients before surgery have a competent and non-stenotic common AV valve [57]. With the two-patch technique, the valve is not incised but rather the VSD patch is placed underneath the intact valve. A disadvantage of this approach is more difficult VSD exposure than in the classic one-patch technique. The two-patch repair of tetralogy of Fallot with AV canal is challenging because even after retracting the anterior bridging leaflet, exposure of the large outlet extension of the VSD is difficult. The two-patch technique may be better in neonates and small infants than the one-patch repair but the patch itself can distort the common AV valve and additional valvoplasty may be necessary to achieve competence. Experience with the two-patch repair is summarized in Table 22.3.

The modified one-patch technique

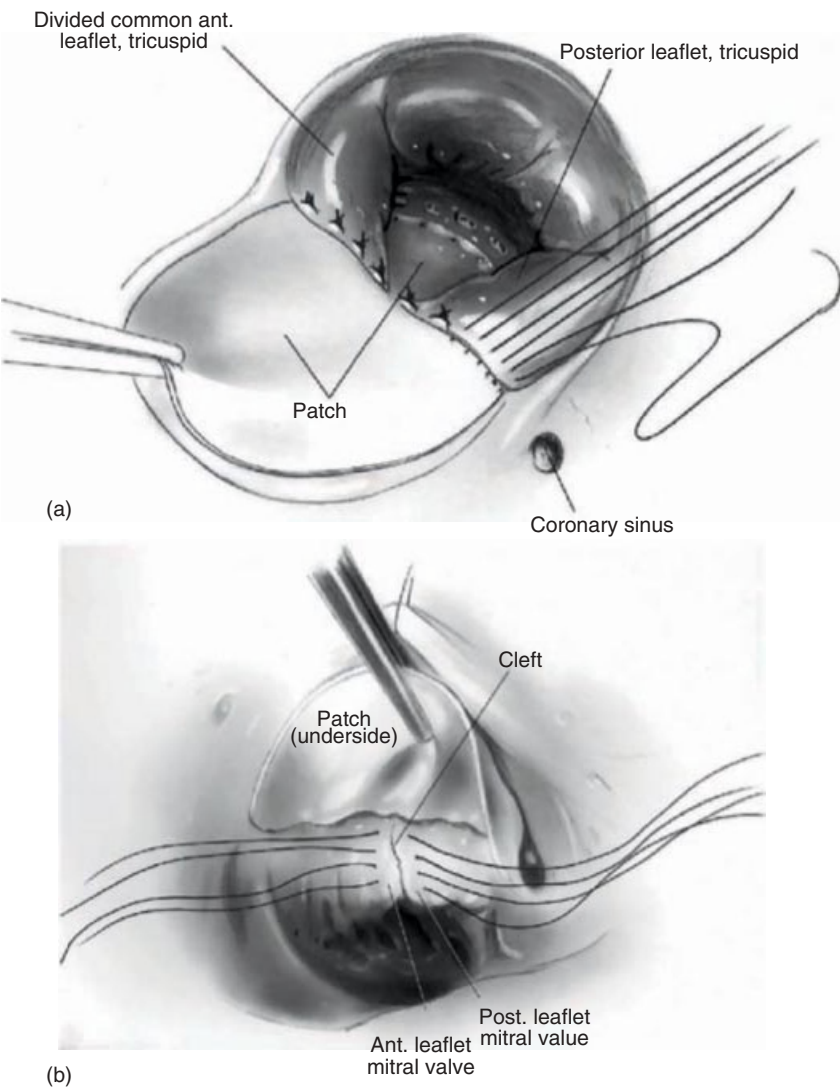
In this technique, a series of sutures are placed along the right side of the interventricular septum and then passed directly through the appropriate dividing line of the superior and inferior bridging leaflets of the common AV valve. These sutures are then passed through the bottom of a single patch, which is generally pericardium. The VSD is closed by suturing the leaflets of the common AV valve directly on to the crest of the interventricular septum. The atrial component of the defect is closed by approximating the edge of the patch to the remaining edge of the atrial septum (Figure 22.17). Valve integrity is maintained because no incisions are made in the common AV valve. The exposure of the VSD is less important because the technique does not require a separate VSD patch. It is suitable for neonates and small infants because there is minimal manipulation of the delicate leaflets. It is not suitable for repair of AVSD with tetralogy of Fallot or a large VSD. Direct approximation of the valve leaflets to the


Figure 22.15 The one-patch repair. (a) A single patch is used to close both the ventricular and atrial components of the defect. crest of the septum could predispose to left ventricular outflow tract obstruction. Polimenakos *et al*. reported the development of left ventricular outflow tract obstruction with modified one-patch repair, and with longer follow-up this complication may prove to be more common [58]. Outcomes of the modified one-patch technique are summarized in Table 22.4. In comparison with the tables summarizing the results of the two-patch and classic single-patch techniques, the series reporting outcomes of the modified single-patch technique are more recent, and mortality is lower and mitral valve reoperations are fewer because of the more recent era and shorter follow-up.

Special circumstances

Palliative procedures

Palliation with a pulmonary band is rarely used today but may be indicated in an infant with congestive heart failure and a contraindication to cardiopulmonary bypass such as intracranial hemorrhage or necrotizing enterocolitis. With tetralogy of Fallot and complete AVSD, the right ventricular outflow tract obstruction reduces pulmonary blood flow and heart failure. This initially amelierative effect on the pathophysiology may complicate subsequent repair. The decreased pulmonary blood flow results in less flow across the common atrioventricular valve and therefore a smaller common AV valve annulus and decreased biventricular volumes. [46] The smaller common AV valve area demands precise partitioning and the acceptable margin of error is decreased. Furthermore, the

smaller annulus limits annuloplasty techniques to deal with residual left AV valve regurgitation. Although excellent results with repair of tetralogy of Fallot and complete AVSD in infancy can be obtained, in a small cyanotic infant, systemic to pulmonary artery shunting or right ventricular outflow tract stenting provides suitable palliation and allows repair when the patient is larger and reparative techniques are more easily applied [59,60].

Double-orifice left av valve

Double-orifice left AV valve complicates 5% of AVSD [61]. Double-orifice left AV valve almost always consists of abnormal holes in essentially normal leaflets, rather than abnormal fibrous bridges or adhesions across commissures between leaflets [61]. The accessory orifice is not the result

of fusion or adhesion between leaflets. Therefore, division of the bridging tissue between the accessory orifice and the major orifice must be avoided as it will result in left AV valve regurgitation. Because the abnormal subvalvar apparatus with accessory papillary muscle and crossing chordae tendineae can result in inflow obstruction, limited cleft closure may be necessary to avoid stenosis of the reconstructed LAV valve. Avoiding division of the bridging leaflet tissue and selective partial cleft closure achieves results comparable to those for uncomplicated AVSD [62,63].

Postoperative status

In patients with coexistent AVSD and tetralogy of Fallot, recovery from surgical repair may be more complicated than with either anomaly alone. Residual right ventricular outflow tract obstruction or pulmonary insufficiency may exacerbate right AV valve insufficiency, increasing right ventricular work load [11]. Left AV valve insufficiency can increase pulmonary artery pressure, causing pulmonary insufficiency. Surgical results have improved, and excellent operative survival has been reported [13]. The need for late intervention for residual ventricular level shunting or left AV valve insufficiency is not unusual. In contrast to isolated complete AVSD, or partial AVSD, left ventricular outflow tract obstruction is rare [11]. Following repair of AVSD, residual lesions should be defined and followed serially. The most common reasons for reintervention are left AV valve insufficiency or left ventricular outflow tract obstruction [27]. Residual atrial and ventricular shunts should be sought.

AV valve function may be abnormal following repair. Left AV valve dysfunction is less well tolerated. Residual cleft between the superior and inferior bridging leaflets may result in residual left AV valve regurgitation. Two-dimensional imaging from the parasternal short-axis or subcostal sagittal view best demonstrates a residual cleft. Color Doppler may quantify and localize the regurgitation using orthogonal planes, as the regurgitant jet may have an irregular contour. Chamber dilation suggests significant regurgitation. The AV valves should also be interrogated for stenosis. Left AV valve stenosis should be considered with closely spaced papillary muscles, single papillary muscle, or double-orifice left AV valve. Continuous-wave Doppler from the apical four-chamber view can determine the mean gradient.

(a)   (b)

Figure 22.17 The modified one-patch repair. (a) Sutures are placed along the right side of the interventricular septum and then passed directly through the appropriate dividing line of the anterior and posterior bridging leaflets of the common AV valve. These same sutures are then passed through the bottom of a single patch, which is generally pericardium. (b) These interrupted sutures are then tied down and this closes the VSD by placing the leaflets of the common AV valve directly onto the crest of the interventricular septum. The left sided AV cleft is approximated with interrupted suture. The atrial component of the defect is then closed by approximating the edge of the patch to the remaining edge of the atrial septum (Reproduced with permission from Silverman et al. Int J Cardiol 1986;**13**:309–31.)

Summary and conclusions

A variety of operative techniques are used for repair of AVSD, and surgeons have reported excellent outcomes with all three approaches [54–75]. All of them achieve the goal of separating the VSD component, dividing the common AV valve into left- and right-sided components, and closing the ASD. In most patients, a durable left-sided AV valve is constructed with a low risk of late incompetence. The outcomes depend more on a surgeon's experience than the particular technique used. Indeed, most of the large series presented are dominated by a single surgeon author with a strong interest and experience in this lesion and whose experience over time is isolated to generally one technique.

Table 22.4 Results of "modified" one-patch repair.

Nunn [75]	1983–2005	128	7.3 years	1.6	0	2.3	0
Jonas [48]	1997–2002	34	N/A	0	N/A	0	1
Backer et al. [65]	2001–2006	26	1.8 years	3.8	0	3.8	0

The dramatic improvements are likely due to many factors, but most importantly an earlier age at operation. The younger age of repair has generally eliminated the "pulmonary hypertensive crisis," previously a common postoperative occurrence. Transesophageal echocardiography has helped identify residual lesions, particularly mitral regurgitation, permitting early reintervention for significant left-sided AV valve regurgitation. Improvements in postoperative control of pulmonary hypertension have also contributed to improved results. Currently, a baby with AVSD is likely to have a successful early repair, an uncomplicated postoperative course, and a low likelihood of reintervention on the left-sided AV valve.

Prognosis after surgery

The outcomes after surgical repair of AVSD are excellent. Left AV valve regurgitation is the most common indication for reoperation, occurring in 5–15% of patients [74,76–80]. Typically, this is caused by incomplete closure of the zone of apposition between the inferior and superior bridging leaflets. Stenosis occurs less frequently, particularly when associated with parachute choral apparatus. Late left ventricular outflow tract obstruction necessitating intervention occurs in both forms of AVSDs, but is more frequent in partial AVSD.

23 Ventricular Septal Defect

Daniel J. Penny

Texas Children's Hospital and Baylor College of Medicine, Houston, TX, USA

Introduction and historical background

Anatomists and pathologists have documented defects in the ventricular septum for centuries. Defects associated with more major malformations have been described or referred to in numerous publications during the last 200 years – especially in association with right ventricular outflow tract obstruction (pulmonary stenosis or atresia) [1,2]. During the latter part of the nineteenth century, two widely different and notable publications drew attention to some of the clinical consequences of ventricular septal defect (VSD). First, the characteristic harsh and strikingly loud systolic murmur present in many affected patients was described, and the remarkable absence of symptoms experienced by such individuals was recognized [3]. Since this publication appeared, the term *maladie de Roger* has been widely used to imply a small asymptomatic VSD. The second was a report in 1897 by Eisenmenger, who described a patient who died at the age of 32 years, having suffered with cyanosis from early childhood [4]. At autopsy, he was found to have a ventricular septal defect with an overriding aorta and pulmonary arterial sclerosis. The development of cyanosis in adult life was attributed to the overriding aorta and so the defect described in this publication (large VSD with aortic override) came to be known as *Eisenmenger's anomaly*, and when cyanosis appeared in adolescence or adult life, the combination has been referred to as *Eisenmenger's complex* by Abbott. In the twentieth century, it was the detailed physiological assessments by Paul Wood [5] in the 1950s and the pathological studies of Heath and co-workers [6,7] which highlighted the role of the pulmonary vasculature in the development of cyanosis in this setting, the condition to which we now refer as *Eisenmenger syndrome*.

During the second half of the twentieth century, two schools of thought regarding the hemodynamic significance of a VSD emerged. The first was based on Roger's premise that most patients were asymptomatic and Eisenmenger's observations that unrepaired defects resulted in late cyanosis or death. Thus, until the 1970s, the strongly held view of many pediatric cardiologists was that most VSDs would if unrepaired, inevitably lead to pulmonary hypertension and the Eisenmenger syndrome [8]. More recent epidemiological studies, however, led to a very different, and more benign, view of most defects, suggesting that more than 70% are small and clinically asymptomatic and that a large proportion close spontaneously during infancy or early childhood [9,10]. This perspective is further supported by echocardiographic studies using color flow mapping, which have shown a high incidence of extremely small defects in the fetal and neonatal period or later in infancy. These are usually clinically silent and would in the past have gone undetected, often closing spontaneously in the first weeks or months of life [11,12].

Incidence and genetics

According to published population-based series, VSD accounts for up to 40% of congenital cardiac malformations. Of 4390 infants with congenital heart disease in the Baltimore–Washington Study, 1411 (32.1%) had VSD. Of these, 895 were reported to be perimembranous, 429 to be muscular, and 22 to be doubly committed [13]. A significant number of VSDs close spontaneously. According to Hoffman, ~85–95% of tiny muscular defects close spontaneously in the first year after birth and about 70% of small defects close during childhood [14]. Of the 10–25% of defects considered to be large, ~10–15% close spontaneously. The quoted incidence, or prevalence, of VSD within populations therefore varies according to the age of the population studied and to the method of diagnosis. Clinical studies of children born in

Bohemia [15] and Merseyside [16] demonstrated a prevalence of 2.56 and 2.74 per 1000 live births, respectively. More recent studies using echocardiography rather than clinical examination or postmortem have reported a higher prevalence. The true point prevalence of VSD at birth is higher still, as reported in a prospective echocardiographic study of 1053 prospective newborns, of whom 56 had a VSD at birth, (53.2 per 1000), but nearly 90% of these had closed within 10 months [17].

The genetic origins of VSD are complex and in most patients are probably multifactorial. Thus, an underlying genetic predisposition to CHD acts in synergy with other influences, including somatic mutations early in development, epigenetic factors, environmental influences, and purely stochastic effects to produce cardiac anomalies [18]. Family aggregation studies strongly suggest that genetic factors play an important role in the development of CHD, because the relative risk of having an affected child is increased when a first-degree relative also has a cardiac malformation [19]. The multifactorial origin of the majority of congenital cardiac defects, including VSD, is probably best supported by the observation that even identical twins display a relatively low concordance rate for congenital cardiovascular malformations, usually below 10% [20,21].

In some families, monogenic influences contribute to the pathogenesis of congenital cardiovascular malformations, including VSD [22]. The characterization of these has facilitated the identification of important components of the signaling pathways that regulate cardiac development and septation [23–25]. The roles of mutations in the T-box transcription factor gene *TBX5*, the zinc finger transcription factor gene *GATA4*, and the *NKX2.5* homeobox transcription factor in abnormal cardiac septation, have received particular attention. *GATA4* and *TBX5* are co-expressed in the heart and their interaction is critical for cardiac septation [26]. In addition to being expressed in the heart, *TBX5* is expressed in the upper limb buds and the eyes and the most often-reported mutation is associated with the autosomal dominant Holt–Oram syndrome [27,28], characterized by abnormalities of the forelimbs and also a number of cardiac abnormalities, including atrial septal defect, VSD, and tetralogy of Fallot. Recently, a *TBX5* polymorphism has been shown to be strongly associated with isolated VSD in a population of Chinese Han [29]. Recent reports have also identified *GATA4* sequence variants in familial septal defects (particularly atrial), although they have also been found in some patients with sporadic VSD [30–32].

Even in families with cardiac defects that have been linked to monogenetic mutations, pleiotropy and incomplete penetrance are typically seen.

Environmental influences, such as teratogens, including maternal alcohol and drugs, maternal infections, and untreated maternal metabolic illnesses have all been associated with VSD [33]. Lastly, many patients with VSD have no known predisposing risk factor, so that stochastic events or factors may play an important role in their development.

Embryology

The interventricular septum has distinct mesenchymal and muscular components [34]. The mesenchymal component faces the arterial valves and separates the ventricular inflow and outflow tracts, and appears to originate mainly from fusion of the conotruncal and atrioventricular endocardial cushions. The processes underlying the development of the muscular septum are less well defined, and at least two hypotheses have been proposed for this. Studies of human embryos [35,36] suggested that the muscular interventricular septum forms from the coalescence of the component of the ventricular wall that is interposed between the enlarging free walls of the developing right and left ventricles. Thus, as the ventricular cavities become deeper, the septum grows passively inwards. Observations, particularly in chick embryos, however, using *in vivo* labeling did not fully support this concept [37,38], and instead suggest that the muscular septum originates from a cluster of cells, the so-called "primitive interventricular septum" which grows actively towards the cushions of the AV canal [38].

Defects of the ventricular septum are likely to develop as a consequence of several factors. Failure of complete formation of the primary septum may contribute to trabecular defects, and many muscular defects in the trabecular septum likely result from excessive undermining beneath and between trabeculae, during formation of the trabecular part of the septum. Failure of fusion of the atrioventricular cushions, with each other or with the primary septum, may result in an inlet VSD, either in the context of an atrioventricular septal defect or as an isolated defect. Malalignment or poor development of the outlet cushions contributes to outlet defects, and finally, failure of complete closure of the area that forms the membranous septum leaves a perimembranous defect. Defects in this area are much larger than the normal membranous septum and are likely to result from incomplete development of one or other components of the muscular septum. This leaves a communication of such a substantial size that the normal mechanism for formation of the membranous septum is unable to effect complete closure.

Pathologic anatomy

VSD, in many respects, is considered to be one of the simpler congenital cardiac malformations, so it is ironic that there is still no universal consensus for its classification [39]. Some defects are completely surrounded by muscle (muscular
Figure 23.1 Cartoon demonstrating the position of ventricular septal defects from the right side of the ventricular septum. The positions of perimembranous, doubly committed, and muscular defects are shown.

defects) and classified according to their location within the muscular septum (inlet, apex or outlet). Defects at the margins of the muscular septum can be related to the hinge-points of the leaflets of the atrioventricular valves (perimembranous), those of the arterial valves (juxta-arterial), or both (Figure 23.1).

Muscular defects are located within the muscular septum. They are surrounded exclusively by muscular rims and, when viewed from the cavity of the right ventricle, may open into its inlet, its outlet, or its apex.

Perimembranous defects: the membranous septum is the smallest component of the ventricular septum, lying close to the central fibrous body. It delineates a small part of the left ventricle, immediately below the aortic valve, and is related to the commissure between its right coronary and noncoronary leaflets, and the part of the right ventricle adjacent to the septal commissure of the tricuspid valve. Defects in this area are termed *perimembranous VSDs*. They open into the right ventricle where the subpulmonary outflow tract turns superiorly relative to the atrioventricular junction, and are characterized by fibrous continuity between the leaflets of the tricuspid and the aortic valves, which form their postero-inferior margin. When a perimembranous VSD extends anterosuperiorly, it tends to lie in an immediately "subaortic" position, and may be referred to as a *subaortic VSD*. This type of defect usually excavates the outlet septum to a degree and may be called a *perimembranous outlet VSD*. When the aorta overrides such a defect, as in tetralogy of Fallot, the term *malalignment VSD* is some-

times applied. A perimembranous VSD may, alternatively, excavate the inlet septum (see inlet VSD) and then lie below the septal leaflet of the tricuspid valve, sometimes being associated with overriding or straddling of the tricuspid valve. A large perimembranous VSD may excavate into all three of the muscular parts of the septum, and this may be referred to as a *confluent defect.*

Part of the membranous septum separates the left ventricular outflow tract, adjacent to the commissure between the right and noncoronary leaflets of the aortic valve, from an area in the right atrium just above the annulus of the tricuspid valve, which is close to its septal commissure. This curious feature results from the fact that the anterior part of the annulus of the septal tricuspid leaflet is actually attached across the middle of the membranous septum, thus separating it into atrioventricular and interventricular components. Further posteriorly, behind the membranous septum, the annulus of the septal tricuspid leaflet is also attached at the inferior margin of the atrial septum, and is at a lower level than the mitral valve on the opposite side. This results in the characteristic offsetting of the septal leaflets of the mitral and tricuspid valves, readily seen on echocardiography in the four-chamber view. Such offsetting depends on an intact ventricular septum in this area, and a perimembranous VSD extending into the inlet septum (inlet perimembranous defect) is usually associated with loss of normal offsetting.

Gerbode defects refer to a spectrum of VSDs which are associated with a shunt directly from the left ventricle to the right atrium. This can occur with a VSD involving the atrioventricular component of the membranous septum, which allows direct communication between the left ventricle and the right atrium, a typical Gerbode VSD. There are other situations when a shunt from the left ventricle to the right atrium may occur through a VSD. Most commonly, the shunt through a perimembranous VSD that is directly related to the septal commissure of the tricuspid valve may flow through the commissure, from the left ventricle into the right atrium. Alternatively, there may be a defect in the septal leaflet at the area of the membranous septum, with lack of the normal annular attachment across the septum at this point, allowing the left ventricle to communicate with both the right atrium and the right ventricle.

Doubly committed and juxta-arterial defects are found in an area which in the normal heart constitutes a free-standing tube of muscular tissue – the muscular infundibulum – which supports the pulmonary valve. A defect in this region is characteristically associated with continuity between the aortic and pulmonary valves. Usually, these defects have a postero-inferior rim of muscle. If such defects extend into the perimembranous zone, then there is also fibrous continuity with the tricuspid valve, the so-called "doubly committed *and* juxta-arterial *and* perimembranous VSD."

Relation between conduction axis and ventricular septal defects

An understanding of the location of the cardiac conduction system is essential for a cardiac surgeon if damage to this pathway is to be avoided during surgical repair of VSD. The position of the cardiac conduction system in relation to VSDs is easily understood when the site of the defect is viewed in relation to anatomic landmarks. Those defects that directly abut the area of the membranous septum and central fibrous body (perimembranous defects) always have the conducting tissue at the posteroinferior margin of the VSD and related to the crest of the trabecular part of the ventricular septum. With an inlet perimembranous VSD, the atrioventricular node and His bundle are posteriorly displaced, and the bundle pursues a longer than normal course on the crest of the ventricular septum (as occurs with atrioventricular septal defects). With other types of perimembranous defects, the position of the His bundle tends to be more nearly normal, with a short course for the bundle before bifurcation immediately below the aortic valve on the left side of the crest of the trabecular septum.

The relationships between muscular VSDs and the atrioventricular conduction axis are more variable. Inlet defects lie consistently below and behind the conducting pathways. Trabecular defects usually open into the right ventricle anterior to the right bundle branch and into the left ventricle at a variable point, often with the radiations of the left bundle branch running around the anterior and the posterior margins of the defect. Most of these defects are distant from the bundle of His, although those that are close to the atrioventricular junction may have only a thin rim of muscle separating the defect from the bundle, and may therefore be vulnerable during repair. Outlet defects (muscular or doubly committed) are usually separated from the area of the membranous septum, although some may have only a slender muscle bar between the defect and the membranous septum. In most hearts with a doubly committed juxta-arterial defect, the conduction axis is protected by the muscular postero-inferior rim. However, in those juxta-arterial defects which extend into the perimembranous region, in which this muscular rim is deficient, the conduction axis will be contained within the postero-inferior rim of the defect, as occurs in other forms of perimembranous defect.

In general, perimembranous defects with their conducting system are likely to lie at the postero-inferior margin and are the most vulnerable to intraoperative damage. This is much less likely for muscular VSDs, as the bundle of His generally lies in the antero-superior rim of the defect with inlet defects and most commonly posterior to or inferior to most trabecular and outlet defects, and as such are less likely to be damaged.

Associated anomalies

In addition to existing in isolation, VSDs are present in a wide range of more complex cardiac malformations, including tetralogy of Fallot, tricuspid atresia, and transposition of the great arteries. These complex malformations are discussed elsewhere in this book. VSD is also commonly associated with atrial septal defect or persistent ductus arteriosus. In these settings, the clinical signs and symptoms are typically related to the VSD, rather than the other defects. On the other hand, when VSD is associated with aortic arch obstruction (coarctation or interruption), the clinical features related to arch obstruction usually predominate, particularly during the early neonatal period.

Association of VSDs with significant left ventricular outflow tract obstruction, either valvar or subvalvar aortic stenosis, may compound the clinical presentation, and add to the complexity of management. Other obstructive lesions of the left side of the heart, such as subaortic, mitral, or supramitral stenosis, may also coexist with VSD. The extent to which they aggravate the clinical symptoms depends on the severity of the associated obstruction.

By contrast, associated right ventricular outflow tract obstruction (valvar pulmonary stenosis or infundibular stenosis) may be well tolerated and often diminishes the effects of the VSD, especially if the septal defect is large. The development of increasing infundibular obstruction, which occurs in ~5% of patients with VSD, is probably related to progressive hypertrophy of anomalous muscle bundles in the right ventricle. Although different in its embryonic origins, this hypertrophy may progress during the first months of life, leading to tight infundibular stenosis, closely resembling that associated with tetralogy of Fallot.

Important but uncommon associated anomalies include those in which the mitral or the tricuspid valve overrides or straddles the VSD, because of malalignment between the atrial and the ventricular septums.

So-called aneurysms of the membranous septum are found in a high proportion of patients with a perimembranous defect, in which a fibrous sack around the right ventricular side of the VSD may partially occlude even a moderately large communication. These "aneurysms" are usually derived from tricuspid leaflet tissue, either of the septal leaflet or from accessory leaflet material, which becomes adherent to the rim of the VSD. The process of adhesion to the edge of the defect often progresses over months or years, leading to spontaneous diminution in size or closure in many patients.

Aortic valve prolapse may be found in patients with defects close to the aortic valve. This phenomenon is particularly characteristic of doubly committed defects, in which the prolapsing leaflet (the right coronary leaflet) may partially occlude the VSD, creating the impression clinically that the defect is small. Some perimembranous defects are associated

with prolapse of the noncoronary or the right coronary leaflet. Over time, if untreated, prolapse leads to progressively increasing aortic incompetence.

Pathophysiology

The key features that dictate the hemodynamic impact and clinical effects of a VSD are *the amount and direction of interventricular shunting*, *the degree of volume loading* to the cardiac chambers, and the presence of *secondary phenomena*, including prolapse or regurgitation of the aortic valve and obstruction to either the pulmonary or systemic outflow tract.

The amount of interventricular flow is determined first by the size of the defect and second by the relative resistances of the pulmonary and systemic vasculature. The amount of flow through a small, restrictive defect depends primarily on its size and, in the absence of other abnormalities, will usually be from the left to the right ventricle. The magnitude of flow through a larger nonrestrictive defect is determined by the relative resistances of the systemic and pulmonary vascular beds and may vary considerably during the clinical course and over time. Thus, with an elevated pulmonary vascular resistance during the early neonatal period, the magnitude of shunting, even through a very large defect, may be minimal. Consequently, many infants with an undiagnosed large VSD are discharged from the maternity hospital asymptomatic, with no appreciable murmur, only to develop an increase in the amount of left-to-right shunting and symptoms of pulmonary overcirculation as pulmonary vascular resistance falls during subsequent weeks. In a minority, the normal postnatal fall in pulmonary vascular resistance may be delayed or arrested, such that they never develop symptoms of excessive pulmonary blood flow and unfortunately only present later with signs of pulmonary vascular disease.

If a large VSD is unoperated, the pulmonary vascular bed remains exposed to a chronic elevation of pulmonary pressure and flow. These patients develop pulmonary vascular disease [40]. Pulmonary vascular resistance increases, reducing the amount of left-to-right shunting. Ultimately, as pulmonary vascular resistance increases further and exceeds systemic resistance, right-to-left interventricular shunting ensues, resulting in cyanosis and the so-called "Eisenmenger syndrome." The mechanisms for these changes are now well described. Characteristic histologic changes have been demonstrated in the pulmonary microvasculature with hypertrophy of the medial smooth muscle, migration of smooth muscle distally into normally nonmuscularized small vessels, deposition of interstitial elements within the media, migration of smooth muscle cells through a disrupted internal elastic lamina, and ultimately severe destruction of the normal vascular architecture and the so-called "plexiform

lesion" [41]. Studies in humans and animal models show that the endothelium plays a central role in the genesis of pulmonary vascular disease. Endothelial-derived vasoactive messengers whose synthesis is deranged in pulmonary vascular disease contribute both to the alterations in the function of vascular smooth muscle and to the structural changes characteristic of this condition [40,42,43] (see Chapter 5).

An increase in volume loading of the left atrium and ventricle typically results from the excessive pulmonary flow and, in turn, the increased pulmonary venous return associated with a moderate or large VSD. This volume loading dilates the left atrium and particularly the left ventricle. In response to the increase in wall stress, left ventricular hypertrophy may ensue. Significant longstanding pulmonary hypertension may result in right ventricular hypertrophy and dilation, which then predominate as a patient enters the terminal stages of severe Eisenmenger syndrome.

Secondary structural cardiac abnormalities may contribute significantly to the course of patients with VSD. Defects located near the aortic valve may be complicated by the later association with aortic valve prolapse. It appears that prolapse occurs secondary to the generation of Venturi forces in which the high-velocity jet across a restrictive VSD "sucks" the aortic leaflet into the defect [44]. Anatomic factors including a lack of structural support for the valvar leaflet (for example, in the setting of a doubly committed defect) or abnormal commissural suspension may also predispose particular patients to this complication. The type of VSD in which aortic prolapse occurs is usually the doubly committed subarterial ventricular septal defect, but a perimembranous defect may be involved if the VSD lies immediately adjacent to the aortic valve, without an intervening septal remnant. With a doubly committed defect, the right coronary sinus is involved; with a perimembranous defect, either the right or the noncoronary sinus is affected (or rarely both are). The consequence of aortic prolapse over time is the development of aortic regurgitation, which, if left untreated, may worsen the degree of left ventricular dilation.

The development of mid-cavity obstruction of the right ventricle due to hypertrophy of muscle bands creates the entity known as double-chambered right ventricle. This occurs in ~3%, according to the Joint Studies on the Natural History of Congenital Heart Disease [45,46], but may be higher [47]. The key pathophysiologic characteristic of this condition, which may represent accentuated septoparietal trabeculations [48], is the creation of a proximal "high-pressure" chamber and a distal "low-pressure" chamber within the cavity of the right ventricle. There is a well-recognized association between double-chambered right ventricle and membranous subaortic stenosis [49]. In a study of 21 patients with double-chambered right ventricle and VSD, the defect was perimembranous in 18, muscular in two and doubly committed in one. The defect was proximal to the muscle bundle in 13 and distal in eight

[50]. A right aortic arch [51] or a more horizontal pulmonary outflow tract [52] may be a risk factor for acquired right ventricular outflow tract obstruction.

Clinical features

Clinical history

Many infants with a VSD are asymptomatic at the time of presentation and come to notice when a murmur is detected on auscultation, either in the neonatal period or later. At least 75% of affected patients have a defect that is small with a hemodynamically insignificant left-to-right shunt, remain asymptomatic, and continue to feed and thrive normally. If careful assessment of such patients confirms that the shunt is small and that the heart is not subjected to significant volume loading, or associated anomalies of the outflow tracts or valvar dysfunction, there is little likelihood of symptoms developing, and the family may be reassured accordingly. Most infants with a larger VSD (except those in whom pulmonary resistance never falls) typically become symptomatic at between 2 and 6 weeks of age [53]. At this time, pulmonary resistance falls, and the increased pulmonary blood flow and venous return to the left atrium lead to the onset of pulmonary venous congestion with tachypnea, dyspnea, and feeding difficulties. The increased caloric demands resulting from the combination of high cardiac output and increased respiratory effort are further compounded by the difficulty in feeding. These infants typically fail to thrive.

Associated abnormalities may alter the clinical symptoms substantially. For instance, coexisting coarctation of the aorta usually leads to an earlier clinical presentation, often as the ductus closes in the first days of life. These infants typically present with dyspnea, poor feeding, and rapid progression to severe manifestations of systemic hypoperfusion and respiratory failure.

Physical examination

The typical murmur associated with VSD is described as a high-pitched murmur which usually occupies most, or all, of systole (pansystolic). In the early neonatal period, a small, restrictive defect may not always produce a typical murmur, and instead the murmur may be of medium frequency and occur in early to mid systole. The murmur generally becomes more characteristic over the next few weeks. There are usually few if any other abnormal findings on clinical examination of patients with a small defect. A thrill is present when the murmur is sufficiently loud. The murmur and thrill are usually most evident along the left sternal border, although the site of maximal intensity varies. An apical VSD may produce a murmur that is best heard toward the apex and may be mistaken for the murmur of mitral regurgitation.

With a larger VSD, the clinical findings are often different. In the early neonatal period and for several weeks, there may be no murmur or only a soft, nonspecific ejection murmur. As the shunt increases with gradual fall in pulmonary vascular resistance, the murmur becomes louder, often longer, and occupying more of systole. At the same time, with the increasing size of the left-to-right shunt, the heart becomes increasingly hyperdynamic. This is associated with a palpable systolic impulse at the left sternal edge due to the dilated and hypertensive right ventricle. At the apex, a mid-diastolic murmur due to high flow across the mitral valve becomes audible. With pulmonary hypertension, the pulmonic component of the second sound is accentuated. During this time, most infants become increasingly dyspneic and tachypneic and may manifest marked intercostal and subcostal retractions. Chronic dyspnea may result in the appearance of bilateral Harrison's sulci (horizontal depression across the lower thorax corresponding to insertion of diaphragm). These infants typically fail to thrive, falling away from their height and weight curves on a growth chart, and even occasionally from the curve of head circumference, and feed poorly, becoming sweaty on minimal exertion or on feeding.

Electrocardiographic features

The electrocardiogram (ECG) reflects the effect of the VSD on the cardiac chambers and pulmonary vasculature. With a small defect, the ECG may be normal. Left axis deviation occurs in a few patients and may reflect abnormal distribution of the left bundle branch [54]. Without other electrocardiographic abnormalities, it is usually of no sinister significance, but if partial or complete right bundle branch block coexists with a superior QRS axis, an atrioventricular septal defect or VSD of atrioventricular septal defect type should be excluded.

If the VSD is associated with a moderate or large shunt, the ECG manifests evidence of combined ventricular hypertrophy with increased left ventricular voltages along with prominent right ventricular forces or large combined voltages (R + S) in the mid-chest leads (V3, V4) (Katz–Wachtel phenomenon). Left atrial enlargement is also found in some patients. Left ventricular hypertrophy on voltage criteria may occur, especially in later childhood, usually indicating a significant shunt but nearly normal pulmonary resistance. Isolated right ventricular hypertrophy is a feature of infants with associated infundibular stenosis (similar to tetralogy of Fallot) or of patients with severe established pulmonary vascular disease (Eisenmenger's syndrome).

Chest X-ray

The chest radiograph reflects the hemodynamic disturbance associated with a VSD. Normal cardiac size and normally pulmonary vascular markings suggest only a minor left-to-right shunt and as such a hemodynamically unimportant defect.

(a)   (b)
Figure 23.2 Echocardiograms from a patient with a muscular (a) and a perimembranous defect (b) taken from an apical and subcostal window. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle

An increase in the transverse cardiac diameter usually indicates a significant shunt. The left ventricular apex is displaced laterally and inferiorly. The left atrium may be enlarged, producing flattening (upward displacement) of the left main bronchus and sometimes a double shadow over the right atrium. Increased pulmonary blood flow indicated by pulmonary arterial markings is evident as cross-sections of hilar vessels, which are distinctly larger than their accompanying bronchi. Prominent vessels are usually seen well out into the middle and upper zones of the lung, whereas such markings are seen only in the lower zones (particularly on the right side) in a normal chest radiograph. Hyperinflation is frequently seen in an infant with a large shunt and probably reflects altered airway resistance and compliance. Pulmonary congestion with interstitial edema may appear, and infective changes may be superimposed.

As pulmonary vascular obstructive disease develops, there may be a reduction in cardiac size toward normal, but the central pulmonary vascular markings become prominent and the peripheral pulmonary vascularity (beyond the hilar areas) become reduced ("pruned").

Echocardiography

A comprehensive echocardiogram is the mainstay of the diagnosis in most cardiac units. The goals of the echocardiographic examination, which would be part of a full segmental, sequential study, are to provide information about
• the location, size, and numbers of defects, whether they are restrictive and whether there are any indicators of their likelihood to close spontaneously
• the pulmonary-to-systemic flow ratio and the right ventricular systolic pressure

• the degree of volume loading of the left heart and left ventricular size
• the presence of aortic valvar prolapse, double-chambered right ventricle or straddling of an atrioventricular valve
• associated subpulmonary, or subaortic (with or without arch) obstruction.

The echocardiographer should be able to conceptualize the shape of the ventricular septum by integrating the multiple cross-sectional images to delineate the size of the defects and their relationship with surrounding structures. The newer technique of three-dimensional echocardiography may facilitate this integration [55,56].

The location of the defect can be determined from cross-sectional imaging. Depending on the location of the defect within the septum, this may be from subcostal, apical, or parasternal windows (Figure 23.2) (Videoclips 23.1 and 23.2). Small defects may only be detected on color Doppler, and finding one muscular defect should prompt the search for more, as these are commonly multiple. The parasternal short-axis projection is particularly important for demonstrating fibrous continuity between the tricuspid and aortic valves to distinguish a perimembranous defect from a muscular defect. This projection is also the best for demonstrating fibrous continuity between the aortic and pulmonary valves in a doubly committed defect, and for demonstrating a deviated outlet septum in defects with outlet extension.

VSDs are rarely circular and, in assessing the size of the defect, its dimensions should be examined in multiple projections. The cross-sectional area of the defect can be related to that of the aorta or to the body surface area [57]. In patients with a perimembranous VSD, it is worth noting whether the defect is related to aneurysmal tissue, which, with time, will tend to close it. This may be demonstrated using either a parasternal short-axis view or an apical four-chamber view. The apical projection is also used to

determine the degree of offsetting of the atrioventricular valves which will be deficient in patients with defects that extend into the inlet septum. Under these circumstances, it is particularly important to examine the morphology of the left atrioventricular valve to distinguish a ventricular septal defect with inlet extension from an atrioventricular septal defect, the latter characterized by a trifoliate left atrioventricular valve.

The accurate assessment of the pulmonary-to-systemic flow ratio by echocardiography would be welcomed by clinicians. It is theoretically possible to do this by examining the flow velocity profiles through the aortic and pulmonary valves, combined with an estimate of their cross-sectional areas. In general, however, the confidence limits around these estimates are wide and, as a result, they are rarely used routinely in clinical decision making. Continuous-wave Doppler interrogation of the flow velocity across a VSD, in the parasternal long- or short-axis projections, or sometimes a subcostal view, allows determination of the pressure drop across the defect. With a left-to-right shunt, higher velocities between left and right ventricles indicate a lower right ventricular systolic pressure. Where possible, this assessment should be combined with an examination of peak velocity of the tricuspid regurgitation jet, so that an estimate of right ventricular systolic pressure can be obtained and the relationship between the ventricular pressures can be clarified.

The degree of volume loading of the left atrium and ventricle can be assessed from parasternal windows and from M-mode measurement of the left ventricular dimensions on the short-axis projection. The left ventricular end-diastolic dimension is usually normalized to the body surface area and a Z-score derived.

In patients with VSD, associated aortic valve prolapse or regurgitation can be assessed using apical and parasternal projections. These views can also be used to detect obstruction within the cavity of the right ventricle (double-chambered right ventricle) or straddling of either the tricuspid or mitral valve. Where straddling exists, it is particularly important to measure the orifices of both atrioventricular valves.

Anterior deviation of the outlet septum may be associated with subpulmonary obstruction; whereas posterior deviation beneath the aortic valve may result in muscular subaortic stenosis (Videoclip 23.3) Parasternal short- and long-axis views can be used to confirm or exclude these important associations. In patients with posterior deviation of the outlet septum and subaortic obstruction, it is imperative to examine the aortic arch carefully, to exclude coexisting coarctation or interruption. With a large VSD, the velocity of flow across the aortic valve cannot provide an accurate estimate of the degree of its obstruction.

Intraoperative transesophageal echocardiography is widely used during surgical closure of VSD to locate defects, assess the surgical result, and detect residual defects. A recent study of 690 patients undergoing VSD closure revealed residual defects using transesophageal echocardiography in 260. Most were trivial, however, and closed spontaneously on follow-up. Reoperation was rarely needed [58]. Transesophageal echocardiography is considered essential by many operators in guiding transcatheter closure of VSDs.

Cardiac catheterization and angiography

Diagnostic cardiac catheterization is now rarely performed before VSD surgery, as echocardiography can provide accurate and detailed anatomic information. Nonetheless, there remain some patients for whom preoperative cardiac catheterization might be considered reasonable for both hemodynamic assessment and occasionally for additional profiling – particularly in those with multiple defects or associated abnormalities. Cardiac catheterization is occasionally performed to assess children in whom it is otherwise difficult to determine the severity of the hemodynamic disturbance. An example is an asymptomatic child with mild cardiomegaly and pulmonary plethora on chest X-ray, or with electrocardiographic changes. In this setting, cardiac catheterization helps decide whether it is safe to postpone an operation in the hope that the defect may become smaller or spontaneously close. Cardiac catheterization may also be indicated in patients with suspected pulmonary vascular disease, in order to decide about operability or for initiating medical therapy to manage this. Finally, cardiac catheterization may be therapeutic, with the intention of performing transcatheter closure of a defect (see below).

Hemodynamics

Hemodynamic measurements in a catheter study include oxygen saturations to assess the magnitude of the left-to-right shunt, or pulmonary-to-systemic flow ratio (Qp/Qs). Therefore, blood samples must be taken from the caval veins, a pulmonary vein (or left atrium, if it can be entered through a patent foramen or atrial septal defect), aorta, and pulmonary artery, including the main and branch pulmonary arteries.

Assessing pulmonary vascular resistance requires phasic and mean pressure measurements in the right atrium, left atrium (and pulmonary artery wedge pressure), main pulmonary artery, and aorta. In addition, phasic pressures in the left and right ventricles should be measured. Oxygen consumption should be measured in patients when calculating pulmonary resistance. Although assumed oxygen consumption values are commonly used, measured oxygen consumption in children may be very different from assumed values, resulting in significant errors in pulmonary resistance calculation [59].

In patients with elevated pulmonary vascular resistance, pulmonary vascular lability should be tested. In our laboratory, we do this by first ventilating the patient under conditions aimed at optimizing pulmonary vascular resistance–with 100% oxygen and 20 ppm of inhaled nitric oxide for at least 10 min, and then repeating the hemodynamic measurements. Decisions about suitability for repair with an elevated pulmonary resistance depend on the level of resting resistance, the evidence of lability or reversibility, and the patient's age. We consider that resistances $>8 \, U \, m^2$ $(mmHg \, l^{-1} \, min^{-1} \, m^{-2})$ under optimal conditions strongly indicate irreversible pulmonary vascular disease after the first year of life. Significant lability, with the level falling to $<6 \, U m^2$ in 100% oxygen, or with inhaled nitric oxide, and young age, however, are features that in otherwise borderline patients might favor operation.

Angiography

The anatomy and three-dimensional orientation of the ventricular septum and associated defects are complex. Thus, the effective angiographic demonstration of a VSD requires operators to have a detailed understanding of the anatomy of the ventricular septum in a normal heart and in a range of cardiac malformations. Using axial oblique views to profile the different parts of the ventricular septum accurately is now routine. The radiographic projection used must be aligned with the ventricular septum at the site of the defect, so that contrast medium passing across the defect is seen in profile. It is usually possible to identify the site or sites of VSDs with echocardiography before cardiac catheterization, thus making the choice of projection simpler.

Defects close to the membranous septum are best demonstrated by a left anterior oblique projection (40–45° from lateral) with moderate craniocaudal tilt (20°). This is not the conventional long-axial projection recommended for demonstrating a perimembranous VSD. The conventional projection (30° left anterior oblique with 15° craniocaudal tilt) is more useful for showing trabecular muscular, anterior muscular, or outlet muscular defects.

The so-called four-chamber view (16° left anterior oblique with 30° craniocaudal tilt) is used for profiling inlet defects and is particularly useful for demonstrating atrioventricular septal defects. A right anterior oblique projection is usually necessary to demonstrate doubly committed subarterial VSDs. When biplane angiography is used, the second plane produces a right oblique projection when the first plane is recorded in a long-axial, four-chamber, or intermediate projection. Thus, if an appropriate projection is obtained to exclude defects in the midmuscular, anterior muscular, outlet muscular, or perimembranous areas, the second projection will usually demonstrate a doubly committed subarterial defect.

The main requirement for angiography of a VSD is the need to identify multiple defects. Such defects can present a substantial challenge, both to the echocardiographer and to the cardiologist performing angiography. Multiple small muscular defects in the trabecular septum ("Swiss cheese" defects) are usually well demonstrated in a long-axial view. In some patients, however, several large defects are located at relatively distant sites within the septum. A moderate or large perimembranous defect may be accompanied by muscular defects at the apex or in the anterior muscular septum. Multiple axial oblique projections may be required to demonstrate all the defects adequately. A limiting factor, which may be difficult to surmount, is the equalization of ventricular pressures, so that shunting across the several defects may not be sufficient to outline each defect satisfactorily.

The angiographic study should always include attention to coexisting cardiovascular abnormalities that may require angiographic demonstration. Coexisting conditions, such as aortic coarctation or aortic regurgitation, may necessitate an aortogram, which will also help to confirm aortic valve prolapse and exclude an associated patent arterial duct. Right ventricular outflow obstruction or abnormalities of the pulmonary arteries, such as branch pulmonary artery stenosis, may necessitate a right ventricular angiogram or pulmonary arteriogram.

Other imaging modalities

Although comprehensive diagnostic information is provided by echocardiography in most patients, magnetic resonance imaging (MRI) may complete the diagnosis under some circumstances [60]. In an adult with a VSD, in whom echocardiographic imaging may be limited by suboptimal windows, MRI or computed tomography (CT) may improve the anatomic definition of the defect [61]. MRI and CT are useful adjunctive tools in the diagnosis of double-chambered right ventricle in an adult [62,63]. Associated extracardiac defects, such as aortic coarctation of the aorta or pulmonary artery stenosis, which may be difficult to demonstrate by echocardiography in older patients, can be demonstrated by these techniques. When the need for VSD closure is in question, MRI may provide an accurate assessment of the pulmonary-to-systemic flow ratio [64,65].

Management

Cardiac operation, generally by 3 months of age, is usually recommended for symptomatic infants with pulmonary hypertension, breathlessness, poor feeding, and failure to thrive. While awaiting surgery, improvement may result from low doses of diuretics with or without angiotensin-converting enzyme inhibitors. Digoxin is widely used, although we do not use it. The evidence base for these therapies is scanty. Blood pressure and renal function should be carefully monitored, because hypotension and renal failure are associated with medical therapy.

Frequently, patients with a VSD present with evidence of a volume-loaded left ventricle, from increased pulmonary flow, but without evidence of pulmonary hypertension. Many recommend surgical or transcatheter closure of these defects to avoid left ventricular dysfunction in the long term. In such patients without intervention over a follow-up period of 8 years, left ventricular end-diastolic dimension returned to normal levels in most [66]. The authors concluded that a conservative approach, with regular follow-up, might be appropriate for asymptomatic patients with a pressure-restrictive defects even with left ventricular dilation.

The outcome of asymptomatic patients without pulmonary hypertension or increased left ventricular volume loading treated conservatively is excellent. In patients with a VSD considered "not to require surgical closure during childhood" at mean age of 30 years, the mortality was zero, 94.6% remained symptom free and left ventricular size was normal or borderline in 99% [67]. The incidence of endocarditis was 1.8%.

Many small defects close or become smaller. One study of patients demonstrated that 68% of small or moderate muscular defects closed spontaneously, compared with 34% of perimembranous defects. Muscular defects closed spontaneously up to 88 months of age, but no perimembranous defect closed after the age of 62 months [68]. Muscular defects often close by ingrowth of muscle at the margins. Some perimembranous defects diminish in size, as discussed above. This process often produces a pouch of fibrous/leaflet tissue (aneurysm of the membranous septum), which can be seen by echocardiography or angiography, This is a favorable sign that spontaneous diminution in size or closure of the VSD is likely to occur.

Certain VSDs, however small, are unlikely to diminish in size or close spontaneously. These include defects in which semilunar leaflets of the aortic or pulmonary valve form the basal margin of the VSD, as occurs with many malalignment defects and doubly committed subarterial defects. Defects of the latter type may appear to be partially closed (and may be clinically small or trivial) by the distorted aortic sinus (usually the right coronary sinus) or semilunar leaflet tissue, which is entrapped in and partially occludes the septal defect.

A consensus has emerged regarding the management of patients with, or at risk of, aortic valve prolapse or regurgitation. We recommend that surgery not be delayed until the regurgitation becomes moderate or severe, as this will likely result in suboptimal repair and a higher likelihood of reoperation [69]. We recommend repair for patients with more than trivial aortic regurgitation. This recommendation applies particularly for patients with a juxta-arterial defect because of their high risk of aortic regurgitation and low rate of closing spontaneously.

Until recently, the treatment of patients with Eisenmenger syndrome was only supportive [70]. These patients should avoid dehydration and exposure to high altitudes, as this compounds the pre-existing hyperviscosity and arterial hypoxemia. Venesection to reduce the effects of polycythemia has been routine in many centers, but this may worsen exercise intolerance and iron deficiency and increase the risk of stroke [71]. Anticoagulation has been used in these patients, although the evidence is lacking about its application and the bleeding risk may be considerable [72]. Female patients must be made aware that pregnancy is associated with substantial maternal and fetal risk (see below).

The recognition of the contribution of endothelial dysfunction to the pathogenesis of Eisenmenger's syndrome has offered new therapeutic options and has revolutionized the pharmacological approach to their management [40]. Endothelial-based "advanced therapies" are being increasingly used to improve symptoms, quality of life, and survival in this condition. Two groups of pulmonary vasodilators are being used to treat patients with Eisenmenger's syndrome: inhibitors of the endothelial-derived vasoconstrictor endothelin-1, and drugs that enhance the nitric oxide–cyclic GMP pathway. The Breathe-5 study demonstrated that bosentan, an endothelin receptor antagonist, improved 6 min walk distances in a randomized placebo-controlled trial over 16 weeks [73] and this effect was continued in a subsequent open-label extension study [74,75]. Similarly, improvements in quality of life and functional capacity have been demonstrated in patients with Eisenmenger syndrome, in response to the oral phosphodiesterase-5 inhibitor sildenafil [76]. Advanced endothelial-based therapies enhance survival in these patients [77] (see Chapter 51).

These advances, combined with the observation that many patients with Eisenmenger syndrome respond to vasodilators in the catheterization laboratory [78], raise the possibility that aggressive treatment with endothelial-based therapies may make it possible to close a VSD in a previously inoperable patient. Despite favorable reports, systematic studies are lacking [79].

Surgery

Surgical closure is the mainstay of definitive treatment for an uncomplicated VSD. Surgery is performed through a midline sternotomy, generally with mild or moderately hypothermic cardiopulmonary bypass, with cardioplegic arrest. Bicaval cannulation allows direct visualization of the defect through the right atrium, facilitated by temporary detachment of the septal tricuspid valve leaflet [80]. The defect can be closed with a patch (generally autologous pericardium) or, if small, using interrupted or continuous sutures. Closure through one of the great arteries, particularly the pulmonary artery (a transpulmonary repair), is also fairly common. In patients with doubly committed defect with aortic regurgitation, a transaortic approach is used to close the defect and repair the aortic valve. Defects in the lower trabecular septum are sometimes approached through a short "fish-mouth" incision at the left ventricle apex. Closure through the right ventricle is rarely necessary. In

general, ventriculotomy is avoided as this increases the risk of ventricular dysfunction and arrhythmia.

The aim of surgical management is complete closure of the defect without damaging adjacent structures. The relationship between the conduction axis and the VSD is of particular importance. For muscular defects, the conduction axis is usually separated from the margin of the defect by a muscle bar, so that it is generally safe to place sutures around the margin of the defect without risk. For some muscular defects, however, this muscle bar might be fairly thin, placing the conduction axis at risk. The branching bundles of the conduction system can be close to the posterior and inferior margins of a perimembranous VSD. Suturing should be approached from the right ventricular side of the defect and away from its posteroinferior margin. Under some circumstances it might be possible to place very superficial sutures on the free margin of the defect [81]. Where a perimembranous defect is surrounded by fibrous tissue, it can usually be used to anchor the patch [81].

In patients previously considered inoperable due to elevated pulmonary vascular resistance, conventional patch closure can cause significant morbidity and mortality from intractable elevations in pulmonary arterial and right ventricular pressure, which result in right ventricular failure. A modified surgical technique with the creation of a "valved" patch which allows unidirectional right-to-left shunting across the residual shunt can be performed with low operative mortality [82]. The benefits of these methods over conventional closure have been questioned [83].

The postoperative course of most children after VSD closure is relatively uncomplicated, and mortality is exceedingly low. The postoperative period may be complicated by pulmonary hypertension – particularly in infants with very high preoperative pulmonary blood flow, with trisomy 21, or older infants with a large defect. Inhaled nitric oxide is commonly used to treat postoperative pulmonary hypertension [84], although there are few data supporting its use early after cardiac surgery [85]. Postoperative disturbances of rhythm affect a minority of patients early after surgery. A small proportion of patients require temporary pacing for postoperative atrioventricular conduction block. Failure to return to sinus rhythm within 7–10 days should prompt consideration of a permanent pacing system [86]. The long-term outlook for most children after surgery is excellent and quality of life is similar to that of age-matched controls. Behavioral and school performance problems may be increased in early childhood [87].

Banding of the pulmonary artery was previously performed as an initial palliative procedure to reduce pulmonary blood flow, particularly in small infants. This is now rarely performed except for patients with multiple or apical defects, in whom surgical access to the VSD(s) is difficult or impossible. There has been a recent trend to apply either absorbable or balloon-dilatable bands in patients with multiple muscular defects, possibly avoiding the necessity for band removal if the defects reduce in size or close spontaneously [88,89].

Transcatheter closure

Transcatheter techniques for VSD closure have been developed over the past decade. These are particularly useful for achieving closure of muscular defects which are difficult to access surgically. A variety of devices have been employed. Initially, double umbrellas, originally designed for closure of patent ductus arteriosus or atrial septal defects, were used [90,91]. More recently, specific septal occluders have been developed [92,93]. We always recommend the concomitant use of transesophageal echocardiography to guide the transcatheter closure. Right ventricular trabeculations can make crossing a muscular defect from its right ventricular side very challenging. Hence a double catheter technique is usually employed. A curved end-hole catheter is advanced through the defect from its left ventricular side via the femoral artery and aorta. A wire is passed through the catheter and the VSD to the right ventricle and pulmonary artery, where it is snared and exteriorized out of the internal jugular or femoral vein. This provides a stable "rail" along which a long delivery sheath can be advanced across the defect (Videoclip 23.4).

There has been considerable interest in transcatheter approaches for closure of perimembranous defects. Currently this approach is not used in most centers because of the unacceptable rate of post-procedure heart block associated with available devices (Figure 23.3). Of particular concern is that this risk does not appear to subside or decrease with time, with late-onset heart block being relatively prevalent [94,95]. It is possible that this approach may be reintroduced in the future as softer devices are developed.

Hybrid techniques

In smaller patients with muscular VSDs, in whom both transcatheter and standard surgical approaches are difficult, a hybrid technique combining surgery and transcatheter interventional methods has been introduced [96,97]. A sternotomy or a subxiphoid incision is performed. Under fluoroscopic and transesophageal guidance, the free wall of the right ventricle is punctured and a wire passed across the defect. An introducer sheath is passed over the wire with its tip placed in the left ventricle and the device is introduced through the sheath and deployed across the defect [96].

Long-term issues in treated and untreated adults

Exercise

Patients with a small defect and normal left ventricular function and pulmonary arterial pressure, without associated lesions, should have a normal exercise tolerance and
Figure 23.3 Ambulatory electrocardiogram from a patient who presented with new-onset syncope, 2 years after transcatheter closure of a perimembranous VSD, demonstrating complete heart block.

exercise restrictions are unnecessary. Patients with elevated pulmonary arterial pressure may have impaired exercise tolerance, and generally self-restrict their exercise levels. Exercise studies in adults showed that in those with Eisenmenger syndrome the peak levels of oxygen consumption were among the lowest of all patients. The relative reduction in peak oxygen consumption correlated with their long-term outcome [98].

Endocarditis

Traditionally, antibiotic prophylaxis was recommended to prevent procedure-associated endocarditis in patients with VSD. However, more recent evidence indicates that endocarditis is more likely to result from chronically poor oral hygiene. Moreover, there is very little evidence to support the efficacy of prophylactic antibiotics in patients with congenital heart disease. Recent guidelines for prophylaxis do not recommend that patients with a VSD receive antibiotic prophylaxis [99]. The primary prevention of dental infections, with careful daily dental hygiene and regular dental review, should be emphasized. Antibiotic prophylaxis for dental and other procedures is still recommended for 6 months after complete surgical or transcatheter closure of a VSD and indefinitely for a residual defect related to patch material which may inhibit endothelialization.

Pregnancy

Women with a small VSD and normal left ventricular function and pulmonary arterial pressures appear not to be at increased cardiovascular risk during pregnancy. Those with a moderate defect may experience symptoms related to increased pulmonary flow because of the increased circulatory volume during pregnancy. This may be compensated partially by the associated reduction in systemic vascular resistance. In women with Eisenmenger syndrome, pregnancy has an extremely high risk of maternal and fetal death and of premature delivery [100]. In one series of 17 ongoing pregnancies in 10 women with Eisenmenger syndrome, there was one maternal death, and in another patient there was severe maternal deterioration necessitating high-level intensive care. Four pregnancies resulted in spontaneous abortions, and there was one stillbirth. Ten of the 12 deliveries of live infants occurred prematurely [101]. As a result, women with Eisenmenger syndrome should be strongly counseled to avoid pregnancy and should be referred to a specialist for contraception advice [102]. Sterilization may be deemed appropriate for some, although this should be undertaken in a specialist center for the care of adults with congenital heart disease, as any surgical procedure requiring an anesthetic poses additional risk on these patients.

Aortopulmonary Shunts: Patent Ductus Arteriosus, Aortopulmonary Window, Aortic Origin of a Pulmonary Artery

Jie Shen[1] & D. Woodrow Benson[2]

[1]Shanghai Jiaotong University and Children's Hospital of Shanghai, Shanghai, China
[2]University of Cincinnati School of Medicine and Cincinnati's Children's Hospital Medical Center, Cincinnati, OH, USA

Anatomic connections between the aorta and the main or branch pulmonary artery usually cause aortopulmonary left-to-right shunts, although occasionally severe pulmonary arterial hypertension causes a right-to-left shunt. The connections from aorta to the main pulmonary artery are the patent ductus arteriosus (common) and the aortopulmonary window (rare). The connections between the aorta and a branch pulmonary artery are anomalous connection of one pulmonary artery to the aorta (rare) and multiple aortopulmonary collaterals; the latter is discussed in Chapter 41.

Patent ductus arteriosus

Introduction and historical background

The ductus arteriosus (DA) is a muscular artery connecting the left pulmonary artery to the aorta during intrauterine life. The DA is essential to the fetus, but normally it closes shortly after birth and is remodeled to form the ligamentum arteriosum. A defect in the closure mechanism leads to a clinical condition called patent ductus arteriosus (PDA). PDA usually occurs as an isolated cardiovascular malformation (CVM), but it may be associated with other CVMs. Based on distinctive auscultatory findings, PDA is easily diagnosed by physical examination; the precise diagnostic values of the physical findings may explain why PDA was one of the first congenital CVMs to be successfully treated by surgery over 70 years ago [1]. Although PDA occurring in preterm infants often closes spontaneously, immaturity of ductal closure mechanisms may lead to its persistence; some of these patients require PDA closure.

Epidemiology

Incidence

The incidence of PDA varies with gestational age and the age of subjects at the time of study. PDA incidence is ~1/2000 in term neonates, but ~8/1000 in premature infants, with the highest incidence in the youngest patients. The incidence in females is 2–3-fold higher than in males. PDA accounts for 5–10% of all CVMs [2].

Genetics

PDA typically has not been regarded as a genetic disorder because it most often occurs sporadically. Occasionally it is associated with cytogenetic abnormalities, for example, trisomy 21 and 4q-syndrome [3]. The idea that single genes can influence PDA has been demonstrated by a mouse model resulting from disruption of the prostaglandin E_2 receptor [4] and by rare syndromic forms of PDA, such as Char syndrome, an autosomal dominant disorder caused by mutations in the transcription factor TFAP2B, and familial thoracic aortic aneurysm with PDA due to mutations in MYH11 [3,5]. PDA recurrence risk is 1–5% [6], but family clustering of isolated PDA and PDA with bicuspid aortic valve has been reported [3]. In addition, Mani *et al.* [7] found a recurrence risk of 5% in a population with parental consanguinity and, using genome-wide linkage analysis, identified a locus on chromosome 12q24. Uncommon familial occurrence and infrequent association with genetic syndromes or cytogenetic abnormalities suggest that inheritance of PDA is complex.

Environmental factors

Prematurity increases the incidence of PDA, probably due to physiological factors related to prematurity, such as excess sensitivity to vasodilator prostaglandins and nitric oxide, decreased production of vasoconstrictor prostaglandins, response to inflammatory mediators, and relative resistance to local hypoxia–ischemia, rather than an inherent abnormality of the DA [8,9]. Hypoxia in newborns, and also altitude-related hypoxia, can also lead to failure of normal DA closure [10]. Maternal rubella infection during the first trimester of pregnancy is associated with a high incidence of PDA and peripheral pulmonary artery stenosis [11]. In congenital rubella syndrome, DA histopathology resembles that of a very immature ductus.

Embryology and development of DA

In normal cardiovascular development, the proximal portions of the sixth pair of embryonic aortic arches persist as the proximal branch pulmonary arteries, and the distal portion of the left sixth arch persists as the ductus arteriosus, connecting the left pulmonary artery with the left dorsal aorta. This arch transformation is complete by 8 weeks of human fetal life. In the past decade, our knowledge of the role of neural crest cells and the transcriptional networks that regulate smooth muscle development in the DA have provided new insights into patency and closure of the DA [12,13].

Pathophysiology

Normal postnatal closure of DA

In the fetus, the blood oxygen level is relatively low and the oxygen–hemoglobin dissociation curve is shifted to the left, enabling fetal blood to release oxygen in low-oxygen conditions. In addition, circulating prostaglandin levels are elevated. The placenta is the major site of prostaglandin production, whereas the fetal lung is the major site of prostaglandin degradation. As blood flow in fetal lungs is limited, the resulting high levels of prostaglandins in the fetus keep the DA open. After birth, prostaglandin synthesis is reduced due to separation from the placenta, and degradation is increased due to increased pulmonary blood flow [9,14]. The increased neonatal blood oxygen saturation associated with lung ventilation and elevated blood oxygen levels rapidly result in contraction of spiral and circular smooth muscle cells in the DA and thickening and shortening of the DA walls, leading to occlusion of the DA lumen. Usually, the DA is functionally closed within 12 h after birth. The nutrient blood vessels within the DA wall are then disrupted, and the cells undergo aseptic necrosis. Proliferating fibrous tissues then replace these cells, and the DA ultimately forms the ligamentum arteriosum. Thus, the combination of increased blood oxygen content and the decline of the prostaglandin levels that occur after birth are the main causes of postnatal DA closure [9,14]. In some premature infants, mechanisms other than prostaglandins appear to operate; these involve decreased expression of calcium and potassium channel genes, and also phosphodiesterase genes that modulate cAMP/cGMP signaling [15].

Anatomy of PDA

The DA lies between the pulmonary artery anteriorly and the descending aorta posteriorly. PDAs vary with regard to size, morphology, and orientation [16,17] (Figure 24.1). Usually, the PDA is vertical and is wider on the aortic side and narrower and cone-shaped on the pulmonary artery side. The opening on the aortic side may be dilated in a horn or funnel shape. The PDA can also connect from the right aortic arch to the right pulmonary artery or from the left subclavian artery to the left pulmonary artery.

For patients with congenital pulmonary artery atresia or severe pulmonary artery stenosis, the PDA tends to be very narrow and twisted. This causes the site at which it joins the aorta to shift towards the concave side of the aortic arch, most likely because the direction of blood flow in the DA is reversed from the aorta to the pulmonary artery. However, the structure of the PDA remains normal in these patients, and it can normally close after birth, thereby leading to a dramatic decline in pulmonary blood flow, exacerbating cyanosis [18]. Occasionally the PDA is right-sided or even bilateral.

Left-to-right shunting in the PDA

Normally, flow through the PDA is continuous because of the systolic and diastolic pressure gradients between the aorta and the pulmonary artery (left-to-right shunt). The arterial blood shunted from the aorta and the venous blood that comes from the right ventricle are mixed in the pulmonary artery, enter the pulmonary circulation, and then return to the left atrium and left ventricle. However, the size of the shunt and severity of symptoms vary between affected individuals, and are determined in part by the dimensions and morphology of PDA and pulmonary vascular resistance [19,20]. With a large shunt, left ventricular stroke volume is significantly increased. When the blood flow enters the aorta during systole, the systolic pressure in the aorta increases. During diastole, blood flow is shunted to the pulmonary artery, which has low resistance during diastole because the aortic valve is closed, thereby decreasing the diastolic pressure and widening the pulse pressure. As a result, these patients develop increased peripheral vascular pulsations, characterized by a rapidly rising and then rapidly decaying pulse (collapsing pulse) with an increased pulse pressure. The blood ejected from the left ventricle is partially diverted to the PDA and recirculates through the lungs to the left atrium. Therefore, blood volume must increase correspondingly to meet the requirements of the systemic circulation. Large shunts lead to left ventricular enlargement, elevated left ventricular end-diastolic pressure, and left atrial enlargement. The resulting pulmonary venous hypertension may cause pulmonary edema.
Figure 24.1 Diagrammatic representation of PDA configuration as demonstrated on the lateral angiogram as described by Krichenko *et al.* [16]. (a) A conical duct with well-defined aortic ampulla and constriction near the pulmonary artery end. (b) A large duct with window-like structure, which is very short in length. (c) A tubular duct without any constriction. (d) A complex duct with multiple constrictions. (e) An elongated duct with constriction remote from the edge of the trachea as viewed on lateral angiography. Right-to-left shunting in the PDA

Flow from the pulmonary artery to aorta (right-to-left shunt) results in the non-oxygenated blood within the pulmonary artery being shunted to the descending aorta. This may result

in differential cyanosis. Right-to-left PDA shunting may occur in obstructed pulmonary venous return to left atrium, cor triatriatum, mitral stenosis, or elevated pulmonary vascular resistance [21]. When the pulmonary vascular resistance is suprasystemic, blood flow can be shunted from the pulmonary artery to the aorta via a PDA. When this occurs, pulmonary arterial blood flows into the descending aorta, causing differential cyanosis, in which cyanosis is present only in the lower half of the body and not the upper half [20].

If communication between the systemic and pulmonary circulation relies on the PDA alone, such as in complete transposition of the great arteries (TGA) without a septal communication, desaturated blood from the aorta is shunted into the pulmonary circulation via the PDA. If TGA is associated with coarctation of the aorta and a PDA, the lower body is perfused with saturated blood from the left ventricle. The upper extremities exhibit cyanosis, but because the lower body has high levels of oxygenated blood, it is not cyanotic [20].

Eisenmenger syndrome

All CVMs increasing the flow of blood to the lungs, or increasing transmission of pressure to the pulmonary artery, tend to develop pulmonary vascular disease. The likelihood and rate of development of vascular abnormalities are determined by several variables, including the amount of left-to-right shunting, the nature of the underlying defect, and the duration of exposure of the pulmonary vascular bed to increased flow and pressure. Exposure of the pulmonary circulation to increased blood flow impairs endothelially mediated relaxation and increases vasomotor tone, and produces intimal proliferation and fibrosis, and eventual obliteration of pulmonary arterioles and capillaries (see Chapters 5 and 51). As a result, pulmonary vascular resistance increases progressively. When pulmonary vascular resistance approaches and exceeds systemic vascular resistance, shunting reverses and becomes right-to-left [22].

Clinical manifestations

Clinical history

The clinical history varies from those who are completely asymptomatic to those with severe congestive heart failure or Eisenmenger syndrome. Many patients are referred for evaluation of an asymptomatic heart murmur. In others, PDA may be an incidental finding on echocardiogram. Parents of an infant with heart failure may report poor feeding and tachypnea. Although most patients with PDA compensate well even with a moderate left-to-right shunt and remain asymptomatic during childhood, many years of chronic volume overload may lead to symptoms of congestive heart failure in adulthood. In these adults, symptoms may begin with onset of atrial fibrillation resulting from chronic left atrial enlargement. Also in the adult, a previously well-tolerated PDA may become clinically significant when its effects are

combined with acquired lesions such as ischemic heart disease, essential hypertension, or calcific aortic stenosis.

Physical examination

The pulmonary artery pressure remains elevated for several days after birth, so the PDA shunt may be small with no audible murmur. When pulmonary vascular resistance decreases, left-to-right shunting occurs and loud murmurs may be audible. The hallmark physical finding is a continuous murmur, located at the upper left sternal border, referred to as a "machinery" murmur [3,23]. The murmur often radiates down the left side of the sternum and into the back, and a thrill may be palpable. Occasionally a diastolic rumble is audible at the cardiac apex in patients with moderate or large ductal shunts. With elevation of pulmonary artery pressure, the pulmonic component of the second heart sound is accentuated. If the shunt is moderate or large, the left ventricular impulse may be prominent, and the pulse pressure increased. The peripheral pulses may be prominent, bounding, or sometimes collapsing. In premature infants with a large shunt, arterial pulsation is felt in the thenar eminence and the digital arteries. The bounding pulses are due both to rapid run-off from aorta to pulmonary artery and also because increased distension of the aortic baroreceptors by the large stroke volume inhibits sympathetic vasoconstriction and causes increased peripheral run-off. This can be shown readily by Quincke's pulse, a pulsatile blanching of the nail bed when it is compressed slightly. Two points should be noted. First, with a large VSD, the left ventricle has to eject a large stroke volume rapidly, so that the aortic pressure rises quickly. Because, however, most of the stroke volume is ejected through the VSD into the right ventricle, the actual pulse pressure is not increased as it would be in a PDA with a similar stroke volume; this is sometimes called the small bounding pulse of a big VSD. Second, with severe congestive heart failure, the resultant sympathetic vasoconstriction reduces peripheral run-off, abolishes the typical bounding pulses, and confuses the diagnosis.

Except in older patients with congestive heart failure, rales are uncommon even with a large shunt.

The most characteristic sign of a PDA is a continuous murmur. Continuous does not mean that the murmur occurs during the whole of systole and diastole, but rather that the systolic murmur obscures the second heart sound and continues beyond it. No murmur is present during early systole or late diastole. A typical continuous murmur is usually easily heard and the systolic component is usually louder. During diastole, the only source of an audible murmur is the vibration of blood coming from PDA shunt. The diastolic pressure gradient is usually smaller than the systolic gradient; therefore, the shunt decreases, and the murmur becomes softer immediately following the second sound. The murmur is heard clearly in the first and second intercostal spaces at the left sternal border.

Patients with Eisenmenger syndrome are cyanotic and may have differential cyanosis (cyanosis and clubbing of the toes but not the fingers because the right-to-left ductal shunting is distal to the subclavian arteries). Cyanosis may be more profound when systemic vascular resistance is decreased, such as in hot weather or after exercise. There may be no murmur during systole or diastole, because shunting may be minimal. Auscultation may reveal a high-frequency diastolic decrescendo murmur indicative of pulmonary regurgitation, and/or a holosystolic murmur suggesting tricuspid valve regurgitation. The intensity of the pulmonic component of the second heart sound may be increased and its closure earlier, leading to a loud and single S2. Peripheral edema may be present late in the course of disease when right ventricular dysfunction is present.

If the PDA does not close promptly after birth, it may close later via a mechanism that has not been fully elucidated, called delayed closure of the DA [10,24]. However, once a patient has reached 3 months of age, the chance of spontaneous closure is low [25]. Others, however, believe that the incidence of spontaneous closure is appreciable [26,27], and the issue remains to be resolved. The natural disappearance of murmur can indicate spontaneous closure, but may also be caused by pulmonary hypertension due to progressive increase in pulmonary vascular resistance. The symptoms of PDA-induced pulmonary hypertension include exertional shortness of breath without other symptoms of heart failure. In severe pulmonary hypertension, dilation of pulmonary arteries may compress the recurrent laryngeal nerve, causing hoarseness.

Newborns may have no murmur, as their pulmonary artery pressure has not yet dropped. Infants may only have systolic murmurs as the pressure difference between the aorta and the pulmonary artery is not significant during diastole. If the shunt volume is large and pulmonary hypertension occurs in older children, the diastolic pressure in the pulmonary arteries increases significantly and is close to that of the aorta. This means that the diastolic component of the murmur disappears first. With the continued increase in pulmonary artery pressure, the systolic pressures of the pulmonary artery and aorta become more similar, causing the systolic component of the murmur to become softer and shorter and finally disappear. Patients with a large shunt can be identified by diastolic murmurs at the apex of the heart or even opening snaps of the relatively narrow mitral valve due to the large inflow of blood that occurs. To-and-fro murmurs can be heard in the anterior fontanelle in infant patients with a large shunt. This murmur is due to the excessive inflow of blood in the intracranial blood vessels during systole and the increased flow of blood returning to the low-resistance pulmonary arteries during diastole.

Electrocardiographic (ECG) features

The ECG changes observed in patients with PDA depend on the degree of volume overload of the left ventricle and the pressure overload of the right ventricle. Patients with a small PDA may have a completely normal ECG. Patients with moderate to large PDA may exhibit left ventricular hypertrophy and/or left atrial enlargement. The ECG may show enlargement of both ventricles when pulmonary artery pressure is elevated. Patients with Eisenmenger syndrome may exhibit right ventricular hypertrophy [28].

Chest X-ray

Heart size in PDA patients is directly related to the shunt volume. Infants with heart failure symptoms have enlarged hearts with a cardiothoracic ratio >0.6. In most asymptomatic patients, heart size is normal to mildly enlarged. The configuration of the heart shadow is usually normal; however, left atrial and left and right ventricular enlargement may be seen when the shunt is large, and a pulmonary artery bulge is present due to high pulmonary artery pressures. The ascending aorta is usually normal in infancy but may gradually dilate with enlargement of the aortic knob with patient growth. This may distinguish PDA from findings observed in other left-to-right shunts.

Infants usually have enlargement of both ventricles and the left atrium. All four chambers of the heart enlarge if the pulmonary artery pressure increases, the left-to-right shunt remains unchanged, and heart failure occurs. It is not a good sign if a previously seen enlarged cardiac silhouette decreases, as this means that the shunt has decreased because of pulmonary hypertension.

Echocardiography

The echocardiogram has emerged as the procedure of choice to confirm the diagnosis and to assess the functional significance of PDA (Figure 24.2). Combined with clinical information, the echocardiogram may be used to classify the PDA as silent, small, moderate, or large. The echocardiogram also identifies and assesses the presence of other CVMs, for example, ventricular septal defect (VSD) and/or aortopulmonary septal defect. M-mode echocardiography can detect enlargement of the left atrium and left ventricle caused by volume overload. When the PDA is small, chamber sizes are usually normal. Moderate or large PDA enlarges the left atrium and ventricle. Two-dimensional imaging reveals the geometry of the PDA, and color Doppler, a very sensitive modality, is frequently used to estimate the degree of ductal shunting. Even an extremely tiny (silent) PDA can be detected by a color flow signal entering the pulmonary artery near the origin of the left pulmonary artery. In patients with high pulmonary vascular resistance, the low velocity or right-to-left flow in the PDA may be difficult to demonstrate with color flow Doppler, even if the PDA is large. Echocardiographic findings such as septal flattening,
Figure 24.2 Echocardiographic study demonstrating PDA. (a) Two-dimensional image of a PDA as seen in a high parasternal shortaxis view. DAO, descending aorta; MPA, main pulmonary artery. (b) Color Doppler image in a similar view shows left-to-right shunting through the PDA. (c) Spectral Doppler profile of continuous left-to-right ductal flow. unexplained right ventricular hypertrophy, and high-velocity pulmonary regurgitation should prompt a thorough investigation for a PDA.

Cardiac catheterization and angiography

Typical PDA patients do not need diagnostic cardiac catheterization and angiography. However, therapeutic catheterization is currently the treatment of choice for PDA. Complete hemodynamic assessment before transcatheter closure is important in adults and in patients with elevated pulmonary artery pressure; assessment of pulmonary vascular resistance and its response to pharmacologic agents may help in determining the advisability of PDA closure. Assessing hemodynamics during transient occlusion with a balloon catheter may also provide information regarding the advisability of PDA closure. Angiography defines the anatomy of the ductus arteriosus; detailed assessment is essential before

transcatheter closure so that the proper device and device size can be chosen for the intervention [16,29].

Differential diagnosis

PDA is characterized by a continuous murmur. It is not difficult to detect in typical patients; however, there are other conditions that can result in murmurs that sound similar to that produced by PDA:

1 Ventricular septal defect (VSD) in infants. Heart failure caused by a large PDA is similar to that caused by VSD in infants. VSD generally only causes a systolic murmur, but mid-diastolic filling sounds due to increased transmitral flow are common when the shunt is large. The combination may be confused with a continuous murmur. Unless a patient has severe heart failure, a palpable pulse can be detected in the patient's peripheral arteries. Echocardiographic examination can easily differentiate these two conditions [3].

2 Aortic sinus (sinus of Valsalva) rupture into the right heart [30]. Aortic sinus rupture into the right atrium or ventricle can cause a continuous murmur. During the rupture, the patient may develop a sudden shock-like syndrome. The murmur, usually very prominent, is loudest in the precordial region. Again, ultrasound examination can distinguish these possibilities.

3 Arteriovenous fistula [31]. If a fistula is connected to veins near the coronary artery, intercostal artery, or internal thoracic artery, a continuous murmur, similar to that caused by a PDA, will be heard. However, the source of the sound is superficial and may seem to be generated outside the heart [31,32]. A continuous murmur from arteriovenous fistulas in the lungs can be heard in unusual places on the torso. If blood flow is large enough to generate audible murmurs, patients will have cyanosis. Other conditions, such as origination of pulmonary artery branch from the aorta [32,33] and branch pulmonary artery stenosis, can also generate continuous murmurs that mimic some aspects of PDA (see below).

4 Anomalies such as a VSD with aortic regurgitation and congenital absence of the pulmonary valve can also generate systolic and diastolic murmurs; however, the murmurs are to-and-fro, not continuous [34].

5 Total anomalous pulmonary venous connection [35]. Some types of anomalous pulmonary veins converge into the left innominate vein through the vertical vein. If there is no obstruction, a continuous murmur that is louder in diastole can be heard because there is a large amount of blood flow present and the vessels turn sharply. This condition can be differentiated from PDA by ECG, X-ray, and/or echocardiogram.

6 Venous murmur (venous hum). When blood returns to the subclavian vein from the jugular vein, a "woop, woop" sound may be auscultated in normal healthy children. This sound is affected by the turning of the head and neck, body position, and respiration. Compression of the jugular vein or having the patient lie down can cause the murmur to disappear.

7 Aortopulmonary septal defect (aortopulmonary window). See below.

Complications

Patients are usually diagnosed by the incidental finding of a heart murmur. Most patients have no complications, but complications may occur at any age.

Congestive heart failure

The decrease in pulmonary vascular resistance that occurs normally after birth, and the resultant increased shunt, can cause congestive heart failure, similar to a large VSD. The initial decompensation in heart function that occurs in these patients is due to pulmonary congestion induced by left ventricular failure. After a long time, because of the burden of continued volume overload, right ventricular failure also occurs, and can induce hepatomegaly and subcutaneous edema. When the DA is closed by interventional or surgical means, this complication can be reversed [36]. Older patients with long-standing volume overload of the left atrium and ventricle may develop atrial flutter and fibrillation.

Endocarditis

Prior to the availability of surgical and antibiotic therapy, endocarditis was the main cause of death of patients with a PDA [37]. Fortunately, endocarditis rarely leads to death in these patients in the modern era. If a pulmonic valve vegetation detaches and enters the pulmonary circulation, pneumonia-like symptoms will occur. Aggressive antibiotic therapy will be required for treatment until further surgical or interventional cardiology procedures are performed to close the PDA.

Pulmonary vascular lesions

Large DAs ultimately lead to obstructive pulmonary vascular disease. In a few rare instances of pulmonary hypertension, the pulmonary artery wall structure does not mature after birth and develop the typical characteristics that allow it to transform into a thin-walled structure with a wide lumen. These patients retain the fetal-type pulmonary artery characteristics, specifically a thick-walled pulmonary artery with a narrow lumen, leading to a right-to-left shunt and lower body cyanosis [16].

Treatment

Gross performed the first successful surgical ligation of PDA in 1938 [1]. Surgery has a very low mortality and offers definitive therapy and excellent long-term outcomes [38]. In adults, the PDA may be calcified and friable, and occasionally closure is best performed with cardiopulmonary bypass.

Interventional catheterization procedures are just as safe, and have become the most common method for PDA closure in recent years (Figure 24.3). Coils are used for a small PDA and an Amplatzer ductal occluder or similar device for a larger PDA. There is about a 10% procedural failure rate,
Figure 24.3 Gianturco coil occlusion of PDA. (a) Views of a Gianturco coil in its stretched out configuration (top) and in its natural coiled configuration (bottom). Note the attached Dacron fibers, which promote thrombosis, along its length. (b)–(d) Lateral angiograms demonstrating closure of a PDA with a single 0.038 in diameter Gianturco coil. (Reproduced from Schneider DJ, Moore JW. *Circulation* 2006;**114**:1873–82, with permission from Wolters Kluwer Health.)

and there are rare complications such as device embolization or hemolysis due to a high-velocity jet through a small residual PDA [39]. All patients should therefore receive treatment before they reach school age to maintain good health and to prevent complications.

In patients with pulmonary hypertension, the safety and risks of surgery or intervention must be assessed. Closure can be performed if cardiac catheterization examination shows that the patient's pulmonary vascular resistance responds to vasodilators, and is <10 Wood units m^{-2} body surface area, especially if <2 years of age. If there is little or no response to vasodilators, a balloon catheter can be inserted to occlude the PDA. If the pulmonary vascular resistance decreases following balloon insertion, then ductal closure can be undertaken. Another technique that can be utilized to assess pulmonary vascular responsiveness is tightening the PDA through a thoracotomy and observing the changes in pulmonary artery pressure to determine if ductal ligation will be safe and tolerated. Although some children have a slow initial reaction, their pulmonary artery pressure decreases day by day after PDA ligation. Some patients may have continued pulmonary hypertension even in this setting. Surgery should not be performed on patients with pulmonary vascular resistance >15 Wood units m^{-2} or differential cyanosis caused by right-to-left shunting [40,41].

Treatment of other congenital heart diseases associated with PDA

Patients with congenital heart diseases with left-to-right shunts, such as VSD and atrial septal defect, may also have PDA, which increases the size of their shunts. Therefore,

these lesions should be treated simultaneously, or in a staged operation. If a PDA is associated with other severe cardiovascular malformations, this shunt may be beneficial, and physicians should think carefully before closing the PDA. If patients have pulmonary atresia or aortic atresia, the pulmonary or systemic circulation depends upon a PDA so that blood can be transferred from one great artery to the other great artery. In these lesions, the PDA is a lifeline and should not be closed. Oxygenation should be considered carefully in these patients , because an increase in blood oxygen in newborns can promote the closure of PDA [42]. All measures that maintain DA patency are good for these patients. Drip infusions of prostaglandin E$_1$ can maintain the patency of the DA and provide infants with good preoperative conditions. Other anomalies where the DA should be kept open include tetralogy of Fallot, tricuspid atresia, coarctation of the aorta, and aorta arch interruption. In fact, a systemic–pulmonary artery shunt operation in patients with cyanotic congenital heart disease with decreased pulmonary blood flow is like a physiologically created PDA [43].

Treatment of PDA in premature infants

In premature babies, the DA does not close by the usual time after birth because the structures that close the DA are immature, and premature babies react weakly to the most important stimulation for DA closure, increases in blood oxygen levels after breathing is initiated. Furthermore, the smooth muscle layer of the pulmonary artery is not fully developed in premature babies, so the resistance is small and the shunt is large. Therefore, patients are prone to heart failure and even death [44]. Once the diagnosis is confirmed, if conservative medical treatment fails, closure should be performed immediately [45].

Even though the shunt in the PDA of premature babies is small, it can reduce the blood supply of the systemic circulation and lower systemic blood pressure. Therefore, it causes hypoperfusion in many organs, and produces clinical symptoms. The decreased blood supply to the brain and the widened pulse pressure in patients with PDA increase the risk of intracranial hemorrhage. Renal function may also be affected, as is the myocardium, especially the subendocardium, due to lack of an adequate blood supply. One cause of necrotizing enterocolitis in premature babies is thought to be intestinal ischemia; therefore, abdominal circumferences and gastric residual volumes should be measured before feeding premature babies with PDA. The mortality rate of these premature babies can be reduced if their DAs are closed early, and should be performed early for abdominal distension, increased gastric residuals volumes before feeding, bloody stool, diminished peristaltic sounds, and/or pneumatosis intestinalis [24,46].

Patients with anemia should be treated to increase their hematocrit to above 45%. The increase in the oxygen-carrying capacity of the blood can improve cardiac function. The fetal

oxygen–hemoglobin dissociation curve is shifted to the left, which is advantageous for oxygen uptake under low oxygen conditions but disadvantageous for oxygen release into tissues. Therefore, repeated transfusion of small amounts of adult blood can facilitate the release of oxygen from the blood release into the tissues. Electrolytes, glucose, and nutrition should be supplemented in a timely manner. If necessary, intravenous hyperalimentation can be used, and patients' intake of sodium and water should be controlled [47,48]. Generally, digitalis should not be used as it has little effect on premature babies.

The first choice of medication to close the DA is oral or intravenous indomethacin. This can inhibit the synthesis of prostaglandins, thereby promoting closure of the PDA. The best time to initiate this medication is within 10 days of birth. The typical initial dosage is $0.2\,mg\,kg^{-1}$, administered orally or intravenously. If an intravenous injection is used, the dosages vary according to age. If the medication is given within 48 h, the next two doses should be $0.1\,mg\,kg^{-1}$. Patients' urine output should also be observed. If their urine output decreases over 12–24 h, the medication should be delayed or stopped. If the murmur reappears, a second course of treatment should be given. The contraindications to medical therapy include decreased renal function (creatinine $>1.6\,mg\,dl^{-1}$ or blood urea nitrogen $>20\,mg\,dl^{-1}$), bleeding, shock, necrotizing enterocolitis, or evidence of myocardial ischemia on ECG. The most important side effect is renal; therefore, the dosage should be closely monitored. Anuria can happen if overly aggressive water restriction occurs while the medication is being administered; however, most incidents of low blood sodium and oliguria are transient, with no significant sequelae. If a patient's body weight is <1000 g and symptoms appear within 72 h after birth, treatment should be initiated immediately [49–52]. If medical therapy does not control heart failure symptoms after 48–72 h, surgical ligation should be performed.

Although there are good theoretical reasons for closing a large PDA in premature infants, and some anecdotal evidence of dramatic improvement in some of these infants, some authorities believe that there is as yet no evidence that closure is beneficial in reducing mortality, complications such as bronchopulmonary dysplasia, and the duration of intubation or hospital stay [53].

Aortopulmonary window

This is a rare anomaly involving absence of the septum between the ascending aorta and the main pulmonary artery but with two distinct semilunar valve rings.

Embryology
The anomaly is due to incomplete separation of the primitive truncus by the aortopulmonary septum.

Anatomy and pathology
As a rule the window is large, and round or oval. There are three anatomically distinct types. Type I is a proximal defect between the semilunar valve and pulmonary artery bifurcation, type II is a distal defect that is usually accompanied by an anomalous origin of the right pulmonary artery from aorta, and type III is a large defect seen in combination with type I and II defects [33,54,55]. PDA frequently coexists (~70%), and >50% of patients have associated anomalies. Aortic arch abnormalities are common, including type A and type B aortic arch interruption and coarctation of the aorta. Associated intracardiac abnormalities include tetralogy of Fallot and transposition of the great arteries [34,54–56].

Pathophysiology
Because the aortopulmonary communication is usually large, a large left-to-right shunt occurs when pulmonary vascular resistance decreases. Early congestive heart failure develops, and if the patient survives pulmonary vascular disease supervenes.

Natural history
If untreated, most of these patients die in infancy and few survive beyond 10 years of age [57].

Clinical features
Typically patients present early in life with heart failure with a nonspecific history. The physical findings resemble those of a PDA but the diastolic component of the murmur is often absent because of the high pulmonary arterial pressure. The murmur is often more retrosternal than under the left clavicle, and at times it resembles the murmur of an VSD rather than a PDA.

Electrocardiogram and chest X-ray
There are no distinguishing ECG or chest X-ray findings, although in older patients the ascending aorta is not enlarged, unlike a PDA.

Echocardiography
The anomaly is usually discovered during echocardiographic examination used for detecting other anomalies such as PDA and VSD.

Other imaging modalities such as MRI have been used.

Cardiac catheterization
This is needed only if pulmonary vascular reactivity needs to be assessed.

Management
Medical treatment is only supportive until closure can be performed. The defects are closed either through the aorta or pulmonary trunk, with an autologous tissue patch in the former and a synthetic patch in the latter [56,58–60]. The

occasional smaller defect can be closed by an occluder introduced via a cardiac catheter. Late results appear to be good in the absence of associated anomalies.

Anomalous pulmonary artery from aorta

In this rare anomaly, erroneously referred to as "hemitruncus," one branch pulmonary artery arises from the aorta.

Embryology

The proximal form (see below) is considered to be an anomaly of truncal septation or a migration defect of the sixth aortic arch. The distal form has been attributed to abnormal persistence of parts of the fifth or sixth aortic arches [32].

Pathological anatomy

An anomalous right is more common than an anomalous left pulmonary artery. Usually the right pulmonary artery arises from the posterior aspect of the ascending aorta just above the aortic valve, but it may arise more distally near the innominate artery. The anomalous pulmonary artery is wide, but may have a stenotic origin. About 50% have an associated PDA, and others are associated with tetralogy of Fallot, VSD, aortopulmonary window, coarctation of the aorta, or interrupted aortic arch [61–64].

If isolated, an anomalous left pulmonary artery almost always arises from a right aortic arch. More than 50%, however, are associated with tetralogy of Fallot and a left aortic arch.

Pathophysiology

This is identical with that of a large PDA, with the same risks of congestive heart failure or pulmonary vascular disease. Pressures in the anomalous artery are systemic. Some, especially with distal connections, may have ductus tissue that contracts and stenoses the orifice, and then pressures are low. The pressure in the normally connected pulmonary artery is usually systemic, probably because the total cardiac output has to pass through one lung. Pulmonary vascular disease begins early and can occur in both lungs unless one lung is protected by a stenosis at its origin.

Natural history

Most untreated patients die before 1 year of age from congestive heart failure [57].

Clinical features

These are similar to those of a PDA or aortopulmonary window, as are the ECG and chest X-ray. If the anomalous artery has a stenotic origin, pulmonary vascular markings may be decreased on that side. Definitive diagnosis is made by echocardiography, angiography, or other imaging modalities.

Cardiac catheterization may be needed to define the anatomy and assess pulmonary vascular resistance. In those with tetralogy of Fallot, the latter anomaly dominates the clinical features.

Management

Unless there is pulmonary vascular disease, the anomalous artery can be detached and reimplanted with or without an interposition graft. Mortality can be high, especially because of pulmonary hypertensive crises [62–64]. Hospital survivors usually have a benign long-term course, although occasionally the reconnected anastomosis may become too small from scarring or with growth and need replacement.

25 Sinus of Valsalva Fistula

Alpay Çeliker & Seden Erten Çelik

Acıbadem University Medical Faculty, Acıbadem Maslak Hospital, Maslak, Istanbul, Turkey

Sinus of Valsalva aneurysm (SVA) is a rare cardiac anomaly first described by Hope in 1839 [1]. Lack of differentiation or fusion abnormality between the aortic media and aortic valve fibrous ring or failure of normal elastic tissue or abnormal development of bulbus cordis are the postulated mechanisms [2,3]. This weakened area may progress to aneurysm formation over time when subjected to high aortic pressure. Aneurysm progression at its apex may lead to rupture, causing shunting from the aorta to a cardiac chamber(s) [4,5].

Incidence and genetics

SVA may be congenital or acquired, comprises 0.1–3.5% of congenital heart defects (CHDs), and accounts for 0.14% of open heart operations for CHD [5]. The exact frequency of the SVA is unknown because they are often silent, although an autopsy study revealed 0.09% prevalence in the general population [6]. It is seldom familial.

Pathologic anatomy

Congenital SVA usually involves the right sinus (65–85%) of Valsalva, and less frequently the noncoronary sinus (10–30%) and left coronary sinus (1–5%) [4,5]. The most common associated cardiac anomalies are ventricular septal defect and aortic regurgitation, but associated bicuspid aortic valve, subaortic membranous stenosis, aortic coarctation, atrial septal defect, patent ductus arteriosus, and tetralogy of Fallot have been described [4,7,8]. Diagnosis in infancy is rare [9]. SVA is typically a single defect [10]. There is a male preponderance with a ratio of 4:1. SVA is less frequent in Western than Eastern countries [11], and the associated VSD

is supracristal, also more common in Eastern countries [12]. Occasionally, giant aneurysms 5–10 cm in diameter occur.

Acquired SVAs are rare compared with congenital forms. They may be caused by degeneration of the aortic wall from cystic medial necrosis, infections, or trauma [13,14]. The rounded and symmetrical shapes of the acquired aneurysms differ from the congenital form of the disease. SVA also differs from the diffusely dilated aortic sinuses characteristic of patients with Marfan and Ehlers–Danlos syndrome [15,16]. SVA also occurs in patients with Takayasu arteritis and Behçet syndrome [17,18]. Acquired aneurysms frequently occur after infective endocarditis and tend to extend superiorly. Left aortic sinus aneurysm is generally involved with acquired causes. Rupture of acquired SVA is usually extracardiac [15].

Natural history and clinical features

SVA is usually diagnosed by the third or fourth decade, most often secondary to complications [5]. Before rupture, most patients are asymptomatic, and the aneurysm remains undetected, although palpitations, fatigue, effort dyspnea, angina, swallowing problems, and dizziness may be presenting symptoms. Syncope may occur secondary to left or right ventricular outflow tract obstruction. Several reports describe rhythm problems, symptoms of myocardial ischemia from coronary artery compression by the SVA, or atrioventricular block secondary to pressure of SVA on the AV node or His–Purkinje system. Stroke occurs infrequently from a thromboembolic event in large aneurysms with thrombus formation [19,20]. Aortic regurgitation may be from prolapse of a cusp into a ventricular septal defect, distortion of the aortic valve ring, a bicuspid valve, or infective endocarditis.

Figure 25.1 Right coronary sinus to right ventricle fistula with two-dimensional (a) and color Doppler echocardiographic (b) views. Panel (a) in diastole, panel (b) in late diastole. The color shows regurgitant flow from the aorta into the aneurysm. An, aneurysm; Ao, aorta; LA, left atrium; LV, left ventricle; P LX, long axis; RV, right ventricle.
Figure 25.2 Aortic root angiogram showing right coronary sinus to right ventricle contrast filling via fistula (a) and severe aortic regurgitation (b). The patient has a subarterial-type ventricular septal defect.

SVA rupture typically occurs between 20 and 40 years of age [5] and is rare in infancy or childhood. The rupture occurs suddenly and may develop after heavy exercise, trauma, or during pregnancy. Right coronary sinus aneurysms usually rupture into the right ventricle, whereas aneurysms of the noncoronary sinus and left coronary sinus rupture into the right atrium and left atrium, respectively [5]. The interventricular septum is seldom affected by the rupture. The consequence of a rupture depends on the rupture speed, the rupture orifice size, and the chamber entered. The rupture may cause sudden deterioration, heart failure, acute cardiac tamponade, and death. There is left ventricular volume overload due to shunting through the aneurysmal tract. Ruptures with a small opening progress

insidiously, and patients become symptomatic only after months or years [21].

The first symptoms of rupture are acute chest or upper quadrant pain, followed by acute dyspnea or exercise intolerance. Progressive cough, dyspnea, edema, and oliguria are seen later after the acute rupture [5,21]. There are pulsatile peripheral pulses, a continuous murmur prominent in diastole, and a thrill at left or right sternal borders [22].

Laboratory investigations

The ECG may be normal or reveal evidence of biventricular hypertrophy. Findings secondary to myocardial ischemia or conduction problems may be seen in patients with compression

of coronary arteries or His–Purkinje system. Following rupture, the chest X-ray may show cardiomegaly and signs of pulmonary congestion [22]. Transthoracic echocardiography is very important for diagnosis and for demonstrating the extent of the aneurysm. The anatomic location of aneurysm, compressed cardiac structures, the rupture site, and associated abnormalities can be demonstrated by echocardiographic examination (Figure 25.1). The parasternal short-axis view is the most useful. Transesophageal echocardiography is mandatory in patients with SVA or where there is suspicion of aneurysm. Three-dimensional echocardiography may delineate the spatial relationships of complex abnormalities [23].

A computed tomographic scan is a very rapid diagnostic tool to obtain more data regarding the aneurysm size and location and site of rupture and also the coronary artery anatomy and its relation to the aneurysm [24]. Cardiac MRI examination may be used in patients for functional evaluation in a nonemergency setting [25]. Cardiac catheterization and angiography are needed some patients before surgery (Figure 25.2).

Management

Unrepaired SVA may cause death in months to years. The treatment for ruptured SVA is usually surgical. Early diagnosis may prevent endocarditis or further enlargement of the fistula, which might complicate surgical repair [5]. Depending on the SVA anatomy and related cardiac anomalies, primary or patch closure is the usual surgical approach. A combined approach through the involved chamber and aortic root is satisfactory. Patch closure of the aneurysm is preferred in most centers and gives excellent results, with a mortality of <5%. With severe distortion, aortic root replacement or the Ross procedure may be needed. Progressive aortic regurgitation is the crucial factor influencing prognosis [26–28], and aortic valve replacement may be required. The prognosis of small aneurysms is unclear and indications for operation in an asymptomatic patient with unruptured aneurysms are not defined. Progressive enlargement of the SVA on serial evaluation may be an indication.

Percutaneous closure of ruptured aneurysms has been reported [29,30]. Kerkar et al. [30] described successful results in 18 of 20 patients using an Amplatzer duct occluder. The results of this treatment modality, however, will have to be compared with surgery to evaluate its safety and efficacy.

Systemic Arteriovenous Fistula

Ahmad I. Alomari

Children's Hospital Boston, Harvard Medical School, Boston, MA, USA

Introduction and background

The widely used classification of vascular anomalies was proposed by Mulliken and Glowacki in 1982 [1]. This classification, based upon clinical, histologic, histochemical, biochemical, and imaging features, divides vascular anomalies into two major categories: tumors and vascular malformations (Table 26.1). Vascular malformations are divided into two major types: the slow-flow (e.g., venous malformation, lymphatic malformation) and fast-flow malformations [namely, arteriovenous malformation (AVM) and arteriovenous fistula (AVF)].

An arteriovenous shunt implies direct communication between the arteries and veins without passing through a capillary bed. In AVFs, the shunt is a simple direct communication between an artery and a vein, whereas in AVMs, the shunt is via a complex network of feeding arteries and draining veins. This distinction has major clinical, prognostic, and therapeutic implications. This chapter focuses on the clinical, imaging, and management aspects of systemic arteriovenous fistulas excluding the heart and lungs (see chapters 46 and 48).

Incidence

Congenital AVFs are much less common than acquired AVFs, and are rarely seen even at specialized vascular anomalies centers. Congenital fast-flow lesions are the least common types of vascular malformations.

The distinction between different types of vascular malformation has often been unclear in the literature. For example, Knudson and Alden reviewed 156 infants (<6 months old) with high flow lesions, of whom 81 had lesions in the CNS, 61 in the liver, and 14 in the lung [2]. The incidence of heart failure was 48–67% with a very high mortality (43–64%). Many of the patients with liver "high-flow" lesions probably had liver hemangiomas (as evident by a mass) rather than a true AV shunt. In one review of patients with AVFs, only 10% of the AVFs were in the head and neck area and none were visceral AVFs [3]. Nevertheless, accumulated experience with these lesions suggests a different distribution, with cerebrofacial fast-flow lesions being more frequent than in other locations [4].

Acquired AVFs are usually iatrogenic, particularly after percutaneous or surgical vascular interventions. Of >13 000 femoral arterial accesses for cardiac catheterization, iatrogenic AVFs were found in 0.11% [5]. Risk factors are periprocedural anti-coagulation, hypertension, and female gender [6]. The incidence is also higher with complex procedures using larger vascular sheaths. Other examples of acquired AFVs are shunts placed for dialysis and those created between and axillary artery and vein to enhance pulmonary blood flow in a patient with a Glenn anastomosis. Other causes are iatrogenic (surgery, biopsy), trauma (war injuries, fractures and stab wounds) [7], infection, and tumors.

Etiology and genetics

Formation of the vascular network in the embryo primarily includes two distinct mechanisms: vasculogenesis and angiogenesis [8–10]. Vasculogenesis *in situ* concerns differentiation and growth of blood vessels from mesodermal-derived hemangioblasts giving rise to the heart and the first primitive vascular plexus, and angiogenesis remodels and expands this network [10]. Both the arterial and venous lineages arise from this common plexus with complex network of communications between them. Nevertheless,

Table 26.1 Classification of vascular anomalies (Reproduced with permission from Mulliken JB, Glowacki J. *Plast Reconstr Surg* 1982;**69**:412–22.)

Vascular anomalies	
Tumors	**Malformations**
A. Benign (hemangiomas):	Low flow:
1. Infantile hemangioma (IH)	1. Capillary malformation (CM)
2. Rapidly involuting congenital hemangioma (RICH)	2. Venous malformation (VM)
3. Non-involuting congenital hemangioma (NICH)	3. Lymphatic malformation (LM)
	High flow:
	Arteriovenous malformations (AVMs) and fistulas (AVFs)
B. Borderline malignant: kaposiform hemangioendothelioma (KHE)/tufted angioma (TA), epithelioid hemangioendothelioma	Combined and syndromic
C. Other rare tumors, e.g., angiosarcoma	

there is an essential and early developmental distinction between arteries and veins, later exaggerated by blood pressure [11]. Molecular differences between arterial and venous channels, which accompany or even contribute to functional and morphologic differences, begin before the establishment of the circulation with several genes specifying the arterial–venous distinction (e.g., ephrinB2, EphB4. Notch1, Notch4, Dll4, and Jagged1, NRP1, CXCR4, connexin-37, connexin-40, CD44, Bmx, and Alk1) [12,13].

Primitive fetal arteriovenous connections are eventually obliterated. Congenital AVFs likely result from persistent embryonic connections between the primordia of arteries and veins originating from a common mesenchymal tissue between the fourth and eighth weeks of embryonic life [14–16].

Congenital AFVs are typically solitary and sporadic (i.e., unassociated with syndromes or known genetic defects). Several complex and overgrowth syndromes are associated with fast-flow vascular anomalies. Examples include hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu syndrome), CLOVES syndrome, PTEN hamartoma syndromes, and capillary malformation–arteriovenous malformation (CM–AVM). AVFs have also been reported in Noonan syndrome [17], Ehlers–Danlos syndrome [18,19], VACTERL association and fibromuscular dysplasia [20], and liver hemangioma [21], among others. Infantile hemangioma and rapidly involuting congenital hemangioma (RICH) are probably the most vascular pediatric tumors and can occasionally be associated with arteriovenous shunts. Hepatic RICH is typically a large, solitary mass and might be associated with various types of transhepatic vascular shunts and high-output heart failure [22].

Hereditary hemorrhagic telangiectasia (HHT), or Osler–Weber–Rendu syndrome, is an autosomal dominant disease characterized by epistaxis, mucocutaneous and gastrointestinal telangiectasia, and arteriovenous malformations in the lungs, CNS, and liver [23]. The two most common genetic mutations affect endoglin (ENG) (type 1) and ALK1 (type 2). HHT gene mutations lead to the development of abnormal vascular structures, which range from dilated microvessels to large AVFs [24]. The resulting disorganized cytoskeleton and failure to form cord-like structures are common characteristics of endothelial cells in HHT patients and disrupted abnormal angiogenesis [25].

Capillary malformation–arteriovenous malformation (CM–AVM) is an autosomal dominant disease caused by RASA1 gene mutation. Clinically, patients develop multiple capillary malformations without overgrowth [26]. Arteriovenous malformation occurs in about 12% of patients and may involve the CNS.

Bannayan–Riley–Ruvalcaba syndrome, caused by mutation in PTEN gene, is characterized by macrocephaly, lipomatosis, pigmented penile macules, vascular malformations, mental/developmental delay, Hashimoto's thyroiditis, and assorted tumors [27]. A spectrum of vascular anomalies, including paraspinal AVM, occur in >50% of these patients [28].

CLOVES syndrome (congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and skeletal/scoliosis/spinal anomalies), recently described, is a complex overgrowth disorder of vessels [29,30]. Fast-flow spinal–paraspinal vascular lesions, including AVMs and AFVs, are frequently encountered in this syndrome and cause debilitating spinal myelopathy [29,31].

Arteriovenous fistula can also be associated with persistent embryonal vessels such as the primitive olfactory [32,33] and sciatic arteries [34].

Klippel–Trenaunay syndrome (KTS) and Parkes–Weber syndrome (PWS) are two overgrowth syndromes of the extremities with complex vascular anomalies. Although they may share some clinical features, they are separate clinical entities with different pathogenesis and natural history. The designation "Klippel–Trenaunay–Weber syndrome" for a patient is misleading. KTS is a rare limb overgrowth disorder with slow-flow vascular anomalies including capillary, venous, and lymphatic malformations. KTS is not associated with fast-flow lesions [35,36] and the reported association between KTS and AVMs (particularly in the spinal region) is erroneous [37]. PWS is characterized by hypervascular (fast-flow) anomalies and capillary malformation in an overgrown limb (Figure 26.1). The capillary stain is pink, multiple, and diffuse. The symptoms are related to distal ischemia and high-output heart failure. PWS is not simply KTS with an AVM, as posited in some references. Improper assessment of patients can lead to the wrong diagnosis, mistreatment, and misdirected research efforts [38].
Figure 26.1 Parkes–Weber syndrome. (a) Diffuse faint capillary stain of the warmer hypertrophied right lower extremity. (b) The angiogram of the calf shows a diffuse increase in the arterial flow to the soft tissue with dense blush and no definite arteriovenous fistulas.

Pathologic anatomy

The two main types of fast-flow vascular malformations are AVMs and AVFs. Occasionally they are combined.. AVMs are abnormal communications between enlarged feeding arteries and draining veins via a smaller complex network of channels (nidus). AVFs are direct end-to-end communications between an artery and vein, and are classified as simple (supplied by one feeding artery) or complex (receiving blood supply from two or more feeding arteries) [39].

Based on the angioarchitectural pattern, arteriovenous shunts can be classified into three main categories: (1) arteriovenous (a few arterial feeders reaching a single draining vein which represents the initial venous compartment), (2) arteriolovenous (several small feeding arteries draining into a single vein which constitutes the initial venous compartment), and (3) arteriolovenulous (plexiform pattern of several small feeding arteries shunting into small corresponding small veins) [40]. The advantages of this classification are simplicity, accuracy, and the ability to predict the endovascular approach of treatment (arteriolovenulous lesions should be treated via the arterial route only, whereas arteriovenous and arteriolovenous shunt fistulas can be treated via transarterial or transvenous approaches). Although this classification was originally proposed for cerebral AVMs, it can be applied to other locations.

The histopathologic changes within the AVF pedicle include heterogeneity in vessel size and wall thickness, an increase in collagen deposition, splitting of the elastic lamina, multiple layers in the endothelium, and immature features of endothelial cells [41].

Pathophysiology

Shunting of arterial blood into a low-resistance draining vein causes several pathophysiologic changes. Both feeding artery and draining veins progressively dilate with increasing rate of left-to-right shunting. To compensate for the blood volume diverted via the shunt, both the blood volume and cardiac output increase. The sequential hemodynamic and structural changes resemble a large left-to-right shunt such as a PDA, including elevated arterial systolic pressure with normal/low diastolic pressure (widened pulse pressure), cardiomegaly (from enlargement of both ventricles), and high output failure [42]. Both fetal and postnatal AVFs are associated with persistent pulmonary hypertension (as are large AV shunts) with both functional and structural alteration of the pulmonary vasculature [43,44]. Following shunt closure, pulmonary hypertension subsided dramatically [45]. Significant AV shunting produces systemic vasoconstriction with decreased renal blood flow and activation of vasodilating systems [46–48].

Local hemodynamic and tissue disturbances can be attributed to the changes in the arterial and venous sides of the fistula. The capillary pressure is higher in tissue sharing the same feeding arterial pedicle as the AVF than in the draining vein. Blood preferentially flows away from the normal tissue, which eventually becomes chronically ischemic (steal phenomenon). The direct flow of arterial blood into the draining vein causes venous hypertension, which may become clinically evident particularly in the lower extremities.

Nicoladoni–Branham sign (bradycardia induced by temporary compression of large AVFs) is caused by arterial baroreceptor activation, which leads to decreased sympathetic nerve traffic, and increased arterial baroreflex sensitivity decreases heart rate [49].

Anatomic locations of AVFS

AV shunts have a predilection for the cerebrofacial region. Intracranial AV shunts are far more common than extracranial lesions, followed in frequency by the limbs, trunk, and viscera. Specific types and anatomic locations of AVFs are discussed below.

Intracranial AVFs
Intracranial fast-flow shunts can be broadly categorized as pial (parenchymal) and dural. They can be classified according to the angioarchitecture and the developmental etiology [50], and divided into single (AVM or AVF), multiple non-familial (metameric or nonmetameric), and multiple familial (systemic and nonsystemic).

Intracranial dural AVFs are shunts between the dural arteries and dural veins and sinuses. Although intracranial fistulas are

Table 26.2 Cognard classification of dural AVFs (Reproduced with permission from Alvarez H, Garcia Monaco R, Rodesch G, *et al. Neuroimaging Clin N Am* 2007;**17**:189–206.)

Type	Drainage
I	Normal anterograde flow into a dural sinus
IIa	Drainage into a sinus with retrograde flow
IIb	Drainage into a sinus with retrograde cortical flow
III	Drainage into cortical veins
IV	Drainage into ectatic cortical vein

typically considered to be congenital in children (e.g., vein of Galen aneurysmal malformation), dural AVFs in adults are typically acquired [50]. Several classifications [such as proposed by Cognard] (Table 26.2) and subclassifications of these lesions have been proposed, based primarily on their venous drainage [51,52], although a recent modified classification was based on the natural history of the disease and the risk of intracerebral hemorrhage or nonhemorrhagic neurologic deficits [53]. The venous drainage of dural AVFs is also responsible for the clinical presentations, including hemorrhage, progressive neurologic deficit, and intractable tinnitus. Leptomeningeal or cortical venous drainage is associated with a worse clinical presentation and requires prompt management [54].

The arterial supply of dural AVFs varies but is typically from branches of the external carotid artery, such as the middle meningeal, accessory meningeal, internal maxillary, occipital, and ascending pharyngeal arteries. Pial supply is rare [50]. The venous drainage can be into any dural sinus.

Dural AVFs with minor symptoms and no retrograde flow in the sinus or cortical vein can be managed conservatively. Endovascular therapy is preferred for most dural AVFs, although certain locations warrant neurosurgical or combined techniques (Figure 26.2) [55].

Cerebral (Pial or Parenchymal) AVMs

These are shunts from branches of the internal carotid or vertebral arteries and usually affect the cerebral hemispheres, including cortical locations, deep nuclei, and corpus callosum. Although congenital, they present in adults with variable symptoms depending on the location of the AVM and other factors. Bleeding, neurologic deficits, seizures, and headaches are common presentations. The risk factors predicting subsequent hemorrhage with cerebral AVMs are young age, previous rupture, deep and infratentorial locations, exclusively deep venous drainage, and large size [56]. The approach to treatment of cerebral AVMs should be managed by an interdisciplinary team. Therapeutic modalities include embolization, surgery, and radiotherapy. A combination of these is often used. About 10–40% of patients are completely cured by embolization.
Figure 26.2 Dural AVF. (a) Axial T2 MR image of the brain depicting the dilated torcula herophili and intracranial, orbital, and scalp vessels. External carotid angiography demonstrated the fistulas to the dilated torcular herophili (b) which was successfully embolized utilizing microcoils and Onyx (ethylene–vinyl alcohol copolymer) (ev3 Neurovascular, Irvine, CA, USA), as shown in (c) and (d).

Vein of Galen Aneurysmal Malformations (VGAMs)

VGAMs are fistulous communications between the choroidal and quadrigeminal arteries and the embryonic median prosencephalic vein (the precursor of vein of Galen) [57]; the use of "vein of Galen" to refer to these malformations is a misnomer. Although rare, VGAMs represent approximately one-third of the infantile cerebral vascular anomalies [58].

Two main angioarchitectural types of VGAM are recognized: choroidal and mural [59]. The arterial supply of VGAMs is typically complex. In the choroidal type, multiple arteries (e.g., choroidal, subforniceal, pericallosal, thalamoperforating) fistulate into the anterior end of the vein, whereas the mural type has an AVF located in the inferolateral wall of the draining vein [60].

The clinical presentation depends on the patient's age: neonates typically present with high-output cardiac and respiratory difficulty, infants and older children with hydrocephalus, mental retardation, seizures and headache [58–66].
Figure 26.3 Vein of Galen aneurysmal malformation. Axial (a) and coronal (b) T2 MR images of the brain show the aneurysmally dilated median prosencephalic vein (the precursor of vein of Galen) with numerous surrounding flow voids representing arterial feeders. Internal carotid angiography in the frontal (c) and lateral (d) projections demonstrates numerous fistulas via small branches. Note the persistence of the limbic arch. Successfully transarterial embolization with Onyx was performed [frontal projection (e)] with excellent control of the malformation (f).

The optimal treatment of VGAMs is endovascular therapy at a tertiary care center with a multidisciplinary team experienced in these challenging malformations (Figure 26.3) [60]. Patients who may benefit from the endovascular treatment must be carefully selected using a systematic evaluation protocol performed within an optimal therapeutic window. The objective of therapy is normal development in a child without neurologic deficit [66].

Embolization of VGAMs via the arterial approach is widely used, but both transvenous and direct injection into the

confluence of dural sinuses have also been described [58], although the latter was associated with higher mortality. The percutaneous transvenous approach is sometimes used to treat complex, multipedicular VGAMs [58].

The outcome of embolization treatment of VGAMs at a tertiary center of 317 patients, of whom 233 were treated with transarterial embolization, revealed that 23 children (10.6%) died despite or because of the embolization; 143 of 193 surviving patients (74%) were neurologically normal, 30 (15.6%) were moderately retarded, and 20 (10.4%) were severely retarded [66].

Spinal dural AVFs

These account for 80–85% of high-flow shunts [67]. Spinal shunts are classified into four main categories: type I, dural arteriovenous fistulas (AVFs); type II, intramedullary glomus AVMs; type III, juvenile or combined AVMs; and type IV, intradural perimedullary AVFs [68]. These lesions lead to progressive neurologic impairment such as sensory, motor, and sphincter dysfunction [69,70]. Dural AVFs can be successfully treated with endovascular or surgical therapy [71]. Due to the complex angioarchitecture of these AV shunts and the presence of adjacent vital areas, super-selective angiographic techniques are used for cerebral and spinal shunts to define the site of the shunt precisely without disturbing associated structures [72].

Cervicofacial AVFs: Carotid-jugular fistulas

These are likely to be between the external carotid (rather than the internal carotid) and the jugular vein. These rare lesions may present early after birth with heart failure [73] or during the first decade of life [74]. In older children and adults, these lesions may present with pain, pulsatile mass, tinnitus, cardiac failure, bleeding, or local regional ischemia [75–82]. External carotid artery ligation has no role in the current management of carotid–jugular fistulas [80]. Ligation proximal to the AV shunt is eventually bypassed by collateral feeders that are smaller and more complex than the original feeding arteries. It also eliminates future transarterial access to the lesion. Embolization is the preferred management of external carotid–jugular fistulas [75].

Vertebrovertebral AVFs

These are connections between the extracranial vertebral artery or one of its branches to the adjacent veins. Most of these fistulas are iatrogenic and may occlude spontaneously neighboring veins [83]. They also can be congenital or associated with fibromuscular dysplasia and neurofibromatosis [84,85]. Symptoms are from arterial steal, spinal venous hypertension, and compression causing neurologic deficits, hemorrhage, and cardiac failure in neonates and infants, A local bruit is often the first sign [83,86]. Embolization, alone or in combination with surgical repair, is feasible, safe, and highly effective, with low morbidity and mortality
Figure 26.4 Simple arterioportal fistula. Aortography in the frontal (a) projection and selective injection (b) shows an enlarged hepatic artery with a fistula to an aneurysmal portion of the portal vein. (c) Angiographically and clinically successful occlusion of the fistula with coils.

[83,86]. Mandibular AVFs may present severe hemorrhage requiring urgent treatment [79–88].

Abdominal AVFs

Acquired renal AVFs are more common than congenital lesions and usually result from penetrating trauma, percutaneous biopsy, surgery, malignancy, or inflammation [89,90]. Spontaneous renal AVFs can be bilateral and often occur in females and on the right kidney. Significant morbidity with hypertension, hematuria, proteinuria, congestive heart failure, and rupture of the fistula may occur [91]. Renal AVF may present either in infancy [92] or later in life, particularly during pregnancy [93].

Treatment options include embolization [75], surgical ligation of the feeding artery [75], or total or partial nephrectomy [94–96]. Embolization should be the initial treatment because of its decreasing morbidity and increasing efficacy and the potential complications and loss of normal renal parenchyma from other treatment methods [96].

Arterioportal fistulas

Arterioportal fistulas can be either intra- or extrahepatic and either congenital or acquired (secondary to cirrhosis, tumors, trauma, rupture of hepatic artery aneurysm, and iatrogenic causes) [97–104]. Most congenital arterioportal shunts are sporadic. Rarely, these fistulas are associated with other disorders such as Down syndrome, hereditary hemorrhagic telangiectasia, Ehlers–Danlos syndrome, and biliary atresia [98,105–107]. Congenital arterioportal shunts present early in infancy, although symptoms may not present until childhood or adulthood. The signs and symptoms can be nonspecific, and include those of portal hypertension (ascites, malabsorption, gastrointestinal bleeding, and abdominal pain), bowel ischemia, and high-output cardiac failure [106,108,109].

The angioarchitecture of congenital arterioportal fistulas can be simple (end-to-side connection between an arterial feeder and the portal vein) (Figure 26.4) or complex with numerous small feeders from mesenteric (e.g., the hepatic, gastroduodenal, and superior mesenteric) and non-mesenteric (e.g., phrenic and internal mammary) arteries. Aortography typically depicts a dilated aorta proximal to the origin of the celiac artery and distal tapering. The portal vein is dilated or focally aneurysmal (portal varix) at the site of the fistula. The hepatic artery may have no or little supply to the liver parenchyma [98].

These lesions have been stratified into three major categories: type 1 is a small peripheral intrahepatic fistula (typically secondary to needle biopsy), type 2 is a large central fistula, and type 3 is a congenital lesion [110]. Type 1 usually

resolves spontaneously whereas type 2 and 3 cause portal hypertension and hepatic parenchymal changes and should be treated. Because portal hypertension develops, even asymptomatic arterioportal fistulas should be treated [110]. Embolization of congenital lesions allows definitive closure of most shunts, and surgical ligation is typically reserved for the rare failure of endovascular treatment [100,101,111,112]. Minimally invasive embolization techniques allow faster recovery, have fewer complications, and can be safely repeated [98]. Following embolization, the patient should be monitored for acute portal vein thrombosis, particularly if the portal vein is aneurysmally dilated. Liver transplantation may be considered in some patients in whom both embolization and surgical ligation of the fistulas fail [102,103].

The increased flow and pressure within the portal venous system from the arterioportal fistula may be decompressed via a patent ductus venosus. Acute presentation of arterioportal AVF with gastrointestinal bleeding could possibly be precipitated by spontaneous closure of the ductus venosus. Hence we believe that the ductus venosus should not be closed during the embolization treatment of the arterioportal AVF because, once obliterated, the ductus venosus spontaneously closes [98].

For acquired arterioportal fistulas, some authors consider surgical repair to be the procedure of choice for the extrahepatic type, whereas embolization is optimal for intrahepatic fistulas and for patients whose associated co-morbidity prohibits surgical treatment [110].

Portosystemic Fistulas (PSFs)

PSFs, although the shunt in a PSF connects two separate venous systems, have many similarities to AVFs. The normal pressure gradient between the portomesenteric and systemic veins always directs the flow toward the latter. PSFs divert portal and mesenteric venous blood into the systemic veins, via either intra- or extrahepatic channels, bypassing the liver. These rare shunts can be sporadic or associated with other disorders (e.g., Down syndrome, congenital heart disease, heterotaxy, Goldenhar syndrome, biliary atresia, mental retardation, and genitourinary malformations) [97,98,113]. Intrahepatic portosystemic shunts are connections between the portal vein and hepatic vein or IVC and can be divided into four main types: (1) single fistula between the right portal vein and the IVC, the most common form, (2) localized fistula within a hepatic segment, (3) fistula through a varix, and (4) multiple fistulas between peripheral portal and hepatic veins [114,115]. Extrahepatic portosystemic shunts were first described by Abernethy and later classified by Morgan and Superina into complete (type 1 or end-to-side) and partial (type 2 or side-to-side) portosystemic diversion, in addition to other less common forms [116,117]. In type I, the portal vein is believed to be absent; thus the mesenteric venous return is diverted into the IVC. Portosystemic fistulas should be differentiated from persistent ductus venosus-related rare hepatic metabolic disorders (e.g., neonatal hemochromatosis leading to hepatic failure, portal hypertension, and coagulopathy) in which closing the ductus venosus is contraindicated [118].

Symptomatic portosystemic shunts present with cardiopulmonary dysfunction, hepatic encephalopathy, metabolic abnormalities (hyperammonemia and galactosemia), coagulopathy, and failure to thrive [119–122]. There is an increased risk of developing hepatic tumors (such as focal nodular hyperplasia, nodular regenerative hyperplasia, adenoma, hepatoblastoma, and hepatocellular cancer) [123–126] and hepatopulmonary syndrome [127].

Children seem relatively less prone to develop hepatic encephalopathy. Nevertheless, some authors believe that a shunt ratio >60% should be corrected because of the risk of encephalopathy and liver dysfunction [98,121,122]. Some low-flow shunts regress spontaneously during infancy [98,119]. Both embolization and surgical banding have successfully obliterated these fistulas [98,119,123]. Closure of type 1 (complete) extrahepatic portosystemic shunts is contraindicated because the fistula is believed to be the sole drainage of the splanchnic venous system. For this rare subset of patients, liver transplantation has been successfully performed [128–133].

In a literature review of 91 reported patients with splenic AVFs, 44% were from a ruptured splenic artery aneurysm, 20% were congenital and 13% were sequelae of splenectomy [134].

Females are more commonly affected than males, and pregnancy and multiparity are considered predisposing conditions [135]. Splenic AVFs present with signs and symptoms of portal hypertension, including variceal gastrointestinal bleeding, ascites, abdominal pain, and bruit [136–140]. Post-traumatic splenic AVFs may spontaneously regress [141]. Because of the fistula's location, adhesions, and extensive portal collateral vessels, surgical repair of the fistula can be challenging [142]. As embolization is safe and efficacious [143–150], it should be the first line of management for these shunts.

Congenital uterine AV shunts are very rare and fed by extrauterine arterial branches [151]. Acquired lesions typically occur after pregnancy-related procedures, such as an abortion or Cesarean section [152]. The treatment of uterine AV shunts should consider the patient's future fertility. Thus, embolizing the uterine artery is indicated in patients who plan future pregnancies, whereas hysterectomy can be considered for recurrent bleeding after embolization in patients not planning future pregnancies [153,154].

AVFs of the extremities

The lower extremity is the most commonly affected site [22]. Besides trauma, iatrogenic causes are not uncommon and follow surgical and interventional procedures [5,6]. For instance, postcatheterization femoral artery AVFs are
Figure 26.5 Extensive arteriovenous malformation of the left lower extremity and hemipelvis. The angioarchitecture as shown in the arterial phase (a) shows numerous dilated arteries from the internal iliac and profunda femoris arteries communicating directly with huge draining veins with some venous aneurysmal changes (b). Both fistulas and nidal types shunts are present. (c) The draining veins were embolized percutaneously with a marked reduction of the AV shunting.

frequently encountered at busy cardiac catheterization units. Nevertheless, they typically have a benign natural history and most (81%) resolve spontaneously [155,156]. Persistent femoral AVFs are typically repaired surgically.

Congenital AV shunts are typically complex with a nidal angioarchitecture supplied by numerous branches. The lesions typically affect the soft tissue component of the limb (Figures 26.1 and Figure 26.5), although some are centered within and around the bone. Extremity AV shunts can be extensive and have a large hemodynamic effect with potential high-output heart failure [157,158]. They present with diffuse, progressive overgrowth of the extremity (Figure 26.6). Distal to the shunt, signs of ischemia (e.g., skin atrophy, hair loss) become evident with time. In advanced disease, ischemia may also cause ulceration, bleeding, and pain [159–161]. Pain is the most common presenting symptom and hemorrhage is the rarest but most serious complication. Venous hypertension may cause marked cutaneous changes such as dark hyperpigmentation, skin thickening, and venous ulcers (Figure 26.7). Painful reddish violet cutaneous plaques (occasionally referred to as pseudo-Kaposi's sarcoma or Stewart–Bluefarb syndrome) may be associated with high-flow lesions of the extremities (Figure 26.7). The etiology of this phenomenon is not known, but possibly related to local venous flow disturbance [160,161].

Subclavian AVFs

Subclavian AVFs are exceedingly rare and may present in infancy with congestive heart failure, stridor, facial and neck swelling, and venous hypertension [162–165]. Popliteal AVFs

Figure 26.6 Arteriovenous malformation of the left foot with overgrowth.

Figure 26.7 (a) Sequelae of long-standing venous hypertension associated with AV shunt of the leg including swelling, hyperpigmentation, thickened, indurated leathery skin, and venous ulceration. (b) Early brownish–reddish macular changes in association with high-flow lesion of the foot (Stewart–Bluefarb syndrome).

are typically caused by trauma and have a high morbidity from high cardiac output and leg amputation [166–168].

Treatment of complex extremity AV shunts requires an interdisciplinary team [157,159], including interventional radiology, cardiology and plastic and orthopedic surgery.

Clinical features and natural history of AVFs

AVFs may present at birth or during childhood or adulthood. Occasionally, AVFs are diagnosed incidentally. The signs of AVFs depend primarily on the volume of blood shunted through the fistula (i.e., the number and size of the fistulas) and the anatomic location. Peculiar signs and symptoms can be specific to certain affected organs or areas.

Typically, in AVFs not located in a body cavity, the affected area is warm and overgrown with thrill or bruit. The overlying skin may demonstrate dilated veins, telangiectasia, capillary stain or, rarely, signs of ischemia. High-flow shunts may cause pain, bleeding, heart failure, ulceration, and tissue loss [169]. Associated tissue overgrowth can lead to disfigurement and compression of adjacent structures. Congenital shunts are a rare cause of congestive cardiac failure in newborns and, except for intracranial and intrahepatic AVFs, the onset of failure is usually later in life [170]. Neonates and young children may exhibit poor physical development and nonspecific symptoms of stress. For large AVFs, upon manual compression or temporary occlusion of the fistula (e.g., by an endoluminal balloon), the heart rate drops (Nicoladoni–Branham sign) [49].

Peripheral AVFs usually follow a progressive course with worsening symptoms. Increased blood flow over time leads to incorporation of more arterial feeders and draining veins, thickening and dilatation of the vessels, aneurysm formation, and weakening of the mucocutaneous coverage [169]. Chronic AVFs may be difficult to differentiate angiographically from nidal-type AVMs; this differentiation has important therapeutic implications [171].

Diagnostic imaging

Findings on plain radiographs are nonspecific and usually reflect secondary changes of the AV shunting. Chest radiographs may show cardiomegaly, increased fluid in the alveolar and septal walls, and pleural effusion (Figure 26.8). Soft tissue and bony overgrowth, altered opacity, atrophy, and opaque embolic agents can also be depicted on plain films. Other findings on plain radiographs include bone thinning and deformity, pathologic fractures, and enlarged vascular foramina of the long bones.

Compared with other vascular anomalies, destructive intraosseous changes are more commonly noted in the arterial or high-flow lesions, possibly related to altered skeletal growth from mechanical, physiologic, and developmental processes [172]. Ultrasonography with color Doppler interrogation is a simple and widely available diagnostic tool for the diagnosis of AVFs [173]. The main sonographic findings are dilated, tortuous feeding arteries and draining veins, lack of soft tissue mass, and thickening/overgrowth of the surrounding tissue. Arterialized veins may mimic arteries with low-resistance pulsatile flow (Figure 26.9). The distinction between vascular masses (e.g., infantile hemangioma) and AV shunts is critical, because their prognosis and treatment are different [175]. Aneurysmally dilated vessels

Figure 26.8 Chest radiograph. High-output heart failure secondary to a massive AV shunt. Note cardiomegaly, septal thickening, and small pleural effusions.

demonstrate turbulence of flow on both gray-scale and color Doppler images.

Computed tomography (CT) scanning provides less tissue contrast than MRI and is infrequently used for diagnosing soft tissue AVFs, but is invaluable for visualizing the bony changes. Both MR angiography (MRA) and CT angiography (CTA) can be used to depict the AVF's spatial anatomy and relations with the surrounding tissue (Figure 26.10).

Angiography is infrequently needed for the diagnosis of AVFs. Nevertheless, some chronic AVFs may mimic AVMs on clinical and sonographic examinations and must be differentiated. The typical angiographic features of infantile hemangiomas include a soft tissue mass with multiple, enlarged feeding arteries, well-circumscribed contrast blush in the tissue/capillary phase, and lack of immediate AV shunting. In addition, the closely packed proximal feeding arteries form an "equatorial" network at the periphery of the hemangioma, sending smaller feeding arteries into the lesion at right-angles to the peripheral vessels with large draining veins at the base of the mass [174].

Management

Management of arteriovenous fistulas is simpler than that of the nidus-type AVMs. The latter is one of the most challenging interventional procedures and requires extensive experience
Figure 26.9 Ultrasound of an extensive AV shunt of the lower extremity. Note the abnormally superficial, tortuous arterial branch within the subcutaneous tissue. The spectral wave demonstrates a high diastolic component (low resistance pattern).

in performing superselective angiography using various types of embolic agents.

Proximal embolization of AV shunts by focal obliteration of a feeding vessel leaves some distal collateral flow. Proximal embolization is equivalent to proximal surgical ligation and should be avoided.

There are different approaches to close simple AVFs. The fistula can be closed transarterially or transvenously. Direct percutaneous access to some accessible fistulas sometimes offers a good alternative [175]. In some patients, a combination of accesses is warranted. Regardless of the approach, the fistula should be closed as close as technically possible to the direct communication between the artery and the vein.
Figure 26.10 (a) Frontal abdominal aortogram of large renal AVF demonstrates the enlarged, single renal artery (large black arrow) with direct fistulas to the renal vein (lower white arrow) and dilated inferior vena cava (upper white arrow). Note the small aneurysm of the proximal segment of the splenic artery. (b) Coronal maximum intensity projections (MIP) and (c) volume rendering (VR) display of the AVF. The dilated draining renal artery, vein (lower thick arrow), dilated IVC (upper thick arrow) and multiple aneurysms of the splenic artery (thin white arrows) are clearly demonstrated in both techniques.

For complex AVFs with multiple feeding arteries and one dominant vein, obliterating the draining vein can achieve excellent control of the shunt without the need to embolize multiple or numerous feeding arteries.

Some AVFs, commonly arterioportal shunts, present with aneurysmal dilatation of the immediate segment of the draining vein, which can be large. These are treated by embolization transarterially without obliterating the venous aneurysm. There is a risk of post-embolization thrombosis of the venous aneurysm and, for some large aneurysms, post-embolization prophylactic anticoagulation is warranted. This is particularly important for arterioportal fistulas.

Sacrifice of the feeding artery is rarely needed for complex AVFs. The technique is still frequently used for caratico-cavernous fistulas and life-threatening cervicofacial hemorrhage from a carotid artery [176–180].

Proper management of AVFs requires an interdisciplinary group of interventional, surgical, and medical specialists.

Clinical and imaging follow-up is preferably performed or supervised by the individual who performed the procedure. Imaging studies should be simple and safe, particularly in children, and complex studies should be used only if essential. Minimizing the radiation in pediatric diagnosis and interventions can be achieved by standardizing workflow and encouraging team responsibility [181]. For instance, instead of repeating the angiographic or CT studies after embolizing a portovenous fistula, adequate diagnostic information can be obtained with ultrasonography.

Left Ventricular Inflow Obstruction: Pulmonary Vein Stenosis, Cor Triatriatum, Supravalvar Mitral Ring, Mitral Valve Stenosis

Walter H. Johnson, Jr & James K. Kirklin
University of Alabama at Birmingham, Birmingham, AL, USA

Introduction

In this chapter, obstructions to left heart inflow are considered in three broad categories: pulmonary vein obstruction, left atrial-level obstruction (cor triatriatum, and supravalvar mitral ring), and left ventricular (LV) inflow obstruction (mitral stenosis and hypoplasia). All have similar hemodynamic and clinical consequences: elevated pulmonary vascular resistance and limitation of left heart output, with signs and symptoms of heart failure, accompanied by pulmonary hypertension and/or edema [1] (Figure 27.1). Except for acquired mitral stenosis resulting from rheumatic fever, congenital forms of LV inflow obstruction are rare, with most occurring with other cardiac malformations. Isolated forms of LV inflow obstruction are very rare.

Left ventricular inflow obstructions are among the most challenging cardiovascular conditions to recognize, evaluate, and manage, and despite great advances in diagnosis and treatment, they remain very significant sources of morbidity and mortality for patients.

Pulmonary vein atresia, hypoplasia, and stenosis

Pulmonary vein stenosis (PVS) is rare, occurring more often (80%) with other severe cardiac malformations than as an isolated condition [2]. Congenital PVS has a reported incidence of 0.4% of congenital heart defects in an autopsy series [3] and with an incidence of 0.03% in children undergoing interventional procedures or surgery for congenital heart disease [4]. It has been estimated to occur in approximately two children per 100 000 [5].

Primary pulmonary vein atresia occurs in the setting of pulmonary agenesis [6] yet the term is most often used to describe the complete obliteration of an existing pulmonary vein following a period of progressive stenosis [7,8].

Pathophysiology
Obstruction to pulmonary venous return increases pulmonary vascular resistance, at a post-capillary level, with attendant pulmonary edema, pulmonary hypertension, and limited cardiac reserve. Infants who appear minimally symptomatic at rest may be unable to increase cardiac output appropriately during any increase in cardiac demand (such as occurs during feeding, or acute illness, particularly with fever) and may develop marked increase in symptoms.

Natural history
Although PVS and even obliteration have been reported with increasing frequency in adults, usually as an iatrogenic complication of radiofrequency ablation procedures for atrial arrhythmias, congenital forms have been recognized, very rarely, in adolescents and adults [9–13]. Otherwise, most congenital PVS is diagnosed in infancy, likely because of the progressive nature of the stenoses and the severe hemodynamic derangements that accompany it. However, neonatal PVS can present clinically as persistent pulmonary hypertension of the newborn (PPHN) [14,15]. The disease has been associated with high mortality [2,4] and is often refractory to medical, catheter [16], and surgical [17] interventions [18].

Embryology
The pulmonary veins and parenchymal tissue form from outpouchings of the embryonic foregut, whereas the heart forms from different precursor tissue. The concept of embryonic growth of the pulmonary veins towards the left atrium, with eventual incorporation of the veins into the left atrium, is
Figure 27.1 Pathophysiology of left ventricular inflow obstruction. Obstruction of pulmonary venous return at any level causes pulmonary venous hypertension. Pulmonary edema results in tachypnea in infants and dyspnea in older children and adults. If increased lymphatic flow is inadequate to compensate, pleural effusions may occur. Bronchial venous collaterals may develop and distend, leading to hemoptysis. Pulmonary arteriolar constriction results in pulmonary artery hypertension and elevated right heart pressures. Right heart failure may result in elevated systemic venous pressure, hepatomegaly in infants, and also jugular venous distension and peripheral edema in older children and adults. RVEDP, right ventricular end-diastolic pressure. (Adapted from Lucas RV Jr. Congenital causes of pulmonary venous obstruction. *Cardiovasc Clin* 1972;**4**:19–51.)

useful in understanding the postnatal pathologic anatomy, especially that of total and partial anomalous pulmonary venous return (see Chapter 34) and cor triatriatum, but is less able to account for pulmonary vein stenosis, particularly its progressive nature.

Pathologic anatomy and major associated anomalies

The causes of PVS, and especially the progressive nature of the disease, are not understood, although the rather constant but nonspecific histopathology has been well described for decades [3]. Many have referred to a localized collar of intimal fibrous thickening, usually at the venoatrial junction [3,19]. Distinctive gross pathology types have been described and classified [20], but may have less clinical prognostic significance than associated cardiac malformations. Various genetic syndromes (trisomy 21 being the most prevalent) have been observed in about one-third of patients in two series [2,5], but no characteristic genetic cause is known. Familial occurrence of PVS has been reported [21].

The histopathology of PVS is possibly due to abnormal proliferation of myofibroblasts, which has been demonstrated in the absence of fibrosis, inflammation, or thrombosis [22]. Although other myofibroblastic diseases have sometimes been treated with antiproliferative regimens, including chemotherapy and radiation, we are not aware of successful treatment of PVS in this way. As active proliferation of myofibroblasts has not been consistently demonstrated, cell proliferation may occur episodically, and subsequent intimal expansion by extracellular matrix and the resulting lumenal narrowing is an important factor in PVS [23].

Clinical features

Clinical history

The clinical diagnosis is challenging. The disease is often not recognized in early infancy, despite onset of symptoms, which are usually respiratory, and diagnosis may occur only after repeated diagnostic studies [5,14,24]. An association has been observed with prematurity [2] and many patients

have been diagnosed with bronchopulmonary dysplasia prior to definitive diagnosis with PVS [5].

Physical examination

Physical examination reflects nonspecific findings of pulmonary hypertension, including a loud second heart sound, and abnormal lung sounds from pulmonary edema. Tachypnea, even at rest, may be due to pulmonary edema or, in severe obstruction, to compensation for metabolic acidosis resulting from inadequate cardiac output. Tachycardia may reflect the limited filling of the left heart in severe obstruction. In this setting, an increase in heart rate is the only mechanism whereby cardiac output can increase as stroke volume is limited by the obstruction to venous return from the lungs.

Electrocardiographic features

The electrocardiogram shows progressive right ventricular hypertrophy/enlargement, and right atrial enlargement if pulmonary hypertension becomes severe. When PVS is accompanied by other cardiac malformations, the EKG findings characteristic for that lesion may predominate.

Chest X-ray

The radiograph classically shows a small heart, but increased pulmonary vascular markings, often with hyperinflation. The cardiac silhouette is small because of the small volume of blood returning to the heart from the lungs. Because PVS can be bilateral, unilateral, or even segmental, the X-ray may reflect nonhomogeneous vascular markings. Pulmonary edema and pleural effusions may be seen.

Echocardiography

Stenosis of the pulmonary veins can be among the most challenging diagnoses, especially as the obstruction may be progressive and early echocardiography may not detect obstruction. PVS is best demonstrated by Doppler as flow acceleration from the veins into the left atrium, rather than as narrowing of the vein lumen seen by two-dimensional echo.

In neonates, the problem is particularly acute, as right-to-left (pulmonary artery-to-aorta) flow via the ductus and right-to-left atrial level shunt via the foramen ovale result in limited flow across the stenoses, making flow acceleration impossible to detect, and because normal neonates may have transient flow acceleration via normal pulmonary veins [25].

Cardiac catheterization and angiography

Cardiac catheterization can be definitive, and allow precise imaging by selective contrast injection of affected pulmonary segments. Hemodynamic findings reflect the post-capillary nature of the obstruction, with pulmonary arterial capillary wedge pressures that are elevated, in the presence of pulmonary artery hypertension. Wedge injection of contrast has been used to demonstrate obstructed pulmonary veins (see Videoclip 27.1).

Direct measurement of elevated pressure via a catheter inserted into an individual pulmonary vein, along with a pressure gradient demonstrable on pullback, can be a dramatic demonstration of true stenosis. However, a large catheter in a small but normal vein can create a functional stenosis, a potential false positive.

Other imaging modalities

Magnetic resonance imaging (MRI) and computed tomography (CT) have been successfully used to diagnose obstruction and provide high-quality images of the veins and level of obstruction [26]. Images obtained have advantages over cineangiography but, as hemodynamic data and transcatheter intervention are limited or unavailable, these techniques often serve a complementary role with catheterization. Pulmonary perfusion scintigraphy can provide quantitative estimates of whole lung and lobar blood flow distribution but, like catheterization, results in some radiation exposure. MRI can provide segmental estimates of relative lung perfusion, and can be especially helpful in demonstrating improvement following interventions [27].

Management

Medical

Medical management is limited to supportive measures and nonspecific therapy for pulmonary hypertension, but without definitive and successful gradient relief the outcome is poor. Some infants with progressive PVS refractory to surgical and catheter treatment have undergone treatment with anti-inflammatory and antineoplastic drugs in the hope of attenuating the basic mechanism involved in the stenosis, but with little success.

Surgical

The prime surgical indication is significant symptomatic obstruction, especially with progression. The definitive treatment is to achieve gradient relief at the site of any and all obstructions and to restore as normal a pathway as possible for pulmonary venous return.

Surgical techniques have included patch enlargement with autologous left atrial appendage [28] and so-called "sutureless" techniques using an *in situ* pericardial patch to avoid anastomotic scarring at the site of stenosis reconstruction [29]. Unfortunately, restenosis and progression to obliteration in many children have necessitated multiple operations [17] and the long-term outcome remains poor in many patients.

Catheter-based therapies include balloon dilation or balloon dilation with stent placement [30], either in the catheterization laboratory or in the operating room at the time of surgery, as a "hybrid" procedure.

Long-term history of treated and untreated children and adults

Many have suggested that early intervention may possibly produce better outcomes, although this assertion remains unproven. When PVS progresses to obliteration, the conventional wisdom is that intervention must precede complete occlusion to salvage the lung segment involved. However, the nature of the disease appears highly pleomorphic, with some children responding favorably to a single operation, with no long-term sequelae or reobstruction, whereas others succumb to progressive and incessant obstruction, despite aggressive and repeated interventions.

Cor triatriatum

Literally meaning a "heart with three atria," the term usually refers to *cor triatriatum sinister* in which defective embryonic incorporation of the common pulmonary vein into the left atrium results in an "accessory" or proximal chamber between the pulmonary veins and the distal "true" left atrial chamber.

Incidence and genetics

Cor triatriatum is rare, reportedly found in 0.1–0.5% of congenital heart patients [31]. It can present at any age but most patients are affected in infancy [31–33]. Variable degrees of obstruction between the common pulmonary vein and the left atrium determine the degree of clinical severity.

Isolated forms of cor triatriatum are probably less common than cor triatriatum associated with other congenital heart malformations. Early series tended to be based on autopsy and showed a greater clinical association with ventricular septal defect, coarctation, atrioventricular canal, and tetralogy of Fallot, but later series observed less severe lesions, including atrial septal defect, partial anomalous pulmonary venous return, and persistent left superior vena cava [31,32,34].

Embryology

Cor triatriatum has been referred to as "stenosis of the common pulmonary vein," reflecting the idea that incomplete embryonic absorption of the coalesced pulmonary veins [the common pulmonary vein (CPV)] into the left atrium results in various degrees of obstruction, with the level of

connection between the CPV and the true left atrium determining the shape of the defect.

Pathology

There is a fibromembranous septum between the proximal common pulmonary vein and the left atrium, yet the shape of this barrier is variable, with tubular, hourglass, and membranous types having been described, and also with variable sized openings from the proximal to distal chambers [34]. The foramen ovale (or secundum atrial septal defect) is usually found between the right atrium and true left atrium, but sometimes is found between the proximal common pulmonary venous chamber and the right atrium [33,34] (Figure 27.2). The left atrial appendage communicates with the left atrial chamber.

Clinical features

Clinical findings resemble other forms of pulmonary venous obstruction. Dyspnea and other respiratory signs and symptoms predominate. Nonspecific physical findings, such as a loud second heart sound and tricuspid regurgitation murmur, reflect pulmonary venous and pulmonary arterial hypertension. Murmurs may be absent. Many are mistakenly diagnosed as chronic lung disease.

Electrocardiogram and chest X-ray

The electrocardiogram and chest radiograph are nonspecific. Right ventricular and right atrial enlargement and hypertrophy are present if the patient survives the neonatal period. Cardiomegaly, pulmonary edema, pleural effusions, and pulmonary artery enlargement may be seen. The dilated common pulmonary venous chamber may erroneously suggest left atrial enlargement, making radiographic differentiation from mitral stenosis impossible.

Echocardiography

Echocardiography provides the most likely diagnostic modality to identify the "membrane" between the pulmonary venous chamber and the true left atrium, and Doppler allows identification of the communication between the two chambers. The velocity and flow pattern by Doppler can be used to estimate the pressure gradient. Transesophageal, three-dimensional, and contrast echocardiography have all proved useful in the evaluation of cor triatriatum, particularly in adults [35–37].

Cardiac catheterization and angiography

Cardiac catheterization can confirm the diagnosis, but balloon dilation has not proved useful. Pulmonary artery and pulmonary capillary wedge pressures are elevated. When a patent foramen ovale or atrial septal defect is present, it
Figure 27.2 Morphology of cor triatriatum. (a) Cor triatriatum with patent foramen ovale below obstructing diaphragm. The common pulmonary venous chamber is separated from the atrial septum medially and immediately below the left inferior pulmonary vein laterally. The lateral attachment is also closely related to the mitral valve. The left atrial appendage is in the distal chamber. Clinical presentation is that of pulmonary venous obstruction (like mitral valve stenosis) when the hole in the diaphragm is small. The distal chamber communicates with the right atrium through the foramen ovale, but left-to-right shunt is small. (b) Cor triatriatum with patent foramen ovale above obstructing diaphragm, through which the common pulmonary venous chamber may communicate with the right atrium. Clinical presentation in this situation is that of a large left-to-right shunt or may mimic total anomalous pulmonary venous connection. (Reproduced with permission from Kouchoukas NT, Blackstone EH, Doty DB, *et al.*, *Kirklin/Barratt-Boyes Cardiac Surgery*, 3rd edn. Philadelphia: Churchill Livingstone Elsevier, 2003, Copyright Elsevier 2003.)

almost always communicates with the true left atrium, and a catheter advanced across the atrial septum can be used to demonstrate normal left atrial and left ventricular pressures. Occasionally, the proximal chamber can be entered with a catheter passed retrograde from the left atrium, revealing a pressure gradient. Angiography in the right ventricle or pulmonary arteries may demonstrate delayed transit through the pulmonary veins and allow imaging of the common pulmonary venous chamber proximal to the obstruction, yet there is a risk that pulmonary vascular tone may worsen.

Other imaging modalities

Magnetic resonance imaging and computed tomography can demonstrate the cor triatriatum, especially in adults presenting late [26]. These techniques have less fidelity and are often more subject to motion and heart rate artifact [38] in infants than echocardiography.

Surgical management

Surgical resection of the obstructing tissue is usually curative. Despite the reliability of two-dimensional echocardiography in establishing the diagnosis of cor triatriatum, considerable variability in the precise location of the membrane and adjacent structures mandates a general surgical approach that may require intraoperative modification.

The patent foramen ovale (or atrial septal defect) may lie above or below the membrane (Figure 27.2). A persistent left superior vena cava may be present, which may connect to the coronary sinus draining into the right atrium or directly to the upper left atrium (unroofed coronary sinus).

In neonates and small infants, continuous hypothermic cardiopulmonary bypass with preparations for brief periods of low flow perfusion or circulatory arrest is advisable to optimize exposure. In small patients, a right atrial approach is preferred. The foramen ovale (atrial septal defect) is enlarged by incising the atrial septum to provide access to the left atrium. Before excising the membrane, the surgeon must ascertain whether the proximal or distal chamber has been entered. The upper (proximal) chamber contains the pulmonary venous orifices and the lower (distal) chamber the mitral valve and left atrial appendage. The hole within the membrane is located and enlarged for visualization. While excising the membrane, care is taken to identify adjacent structures accurately, because the lateral attachment of the membrane is usually close to the orifice of the left inferior pulmonary vein and the mitral valve.

When the common pulmonary venous chamber is enlarged in older children and adults, a left atrial approach anterior to the right pulmonary veins may be convenient. Excision of the obstructing membrane begins at the

fenestration connecting the upper and lower chambers. Resection proceeds leftwards while accurately visualizing and preserving the mitral valve and left inferior pulmonary vein, and avoiding penetration of the left atrial free wall. The repair is completed with closure of the foramen ovale and atrial incision.

Results of surgical repair

Hospital deaths are uncommon after repair of isolated cor triatriatum, even in critically ill infants. Mortality following surgery for complex cor triatriatum is generally related to the risk of repairing the associated cardiac malformations.

Supravalvar mitral stenosis

Supravalvar mitral stenosing ring is a rare lesion consisting of a membranous disc situated just proximal to, and often in continuity with, the mitral valve leaflets. It may exist as an isolated lesion [39] but is more often described in association with other left heart obstructions [40], often mitral valve anomalies.

Incidence and genetics

The etiology of supravalvar mitral stenosis is unknown, but postoperative "acquired" and recurrent forms have been described [41], and some infants seem to develop and then have progressive lesions [42]. Therefore, deranged transmitral flow may lead to abnormal tissue growth, analogous to that considered to lead to fibromuscular subaortic stenosis [43].

Pathology

The pathology has been described in autopsy series [40]. The ring is supravalvar but often partially involves the mitral valve.

Pathophysiology

The pathophysiology resembles other left ventricular inflow obstructions, yet the hemodynamic effect of associated lesions, especially mitral valvar stenosis, typically predominates.

Clinical features

Clinical findings mimic mitral stenosis, or those of the hemodynamically most significant associated lesion. However, a supravalvar ring may be an unsuspected incidental finding by echocardiography, or at the time of surgery for other lesions.

Echocardiography, catheterization, angiography, and other imaging modalities

The diagnosis is most often made by echocardiography. Cineangiographic and CTA and MRI detection may be more

difficult, perhaps due to the proximity to the mitral valve itself, and due to the superior beat-to-beat resolution of two-dimensional echo.

Management

Catheter-based treatment (balloon dilation) is generally ineffective. If associated lesions potentially amenable to balloon dilation, such as mitral valvar stenosis, exist then balloon dilation is not considered advisable due to the supravalvar ring [44].

Surgical resection is usually indicated if the lesion is hemodynamically significant, yet not all patients have stenosis. The surgical observation that the ring is supravalvar proximal to the mural or posterior mitral valve leaflet, but intravalvar and attached to the opposing anterior mitral valve leaflet, means that careful resection must be performed to avoid damage to the anterior mitral leaflet [45].

Mitral Stenosis (MS) and mitral annular hypoplasia

Incidence and genetics

Acquired

Most mitral valve disease, both stenosis and insufficiency, is acquired as a result of rheumatic fever. Although rheumatic fever has become relatively rare in countries with advanced economies, the worldwide burden of patients with rheumatic valvar disease dwarfs that of congenital heart disease survivors (see Chapters 61 and 62).

Rheumatic MS accounts for almost all patients presenting in adulthood [46,47]. The typical pathology involves fibrous thickening and calcification of the leaflets, and fusion of the chordae [46].

Rare causes of "acquired" progressive childhood mitral valve thickening and dysfunction include storage diseases such as mucopolysaccharidoses, and endocrinopathy, such as hyperthyroidism, and genetic conditions, particularly Williams syndrome, yet in these conditions mitral regurgitation predominates and stenosis is usually not significant.

Congenital

The mitral valve and its tensor apparatus constitute one of the most complex functional units in the human body. Given that virtually any derangement of structure can lead to major impairments of function, many differing classification systems exist.

Congenital forms of MS are rare and often associated with other cardiac anomalies, including various forms of left heart hypoplasia. In an early surgical era, congenital MS comprised 0.017% of admissions to a tertiary children's hospital, yet 1.2% of autopsied congenital heart disease cases from the same center [48], likely reflecting the

increased lethality of the lesion relative to other congenital heart malformations.

Genetic factors are only now being elucidated [49], although family clustering of individuals with various and often discordant types of left heart lesions, including mitral valve abnormalities, have been reported [50–52].

Embryology

The atrioventricular valve and atrioventricular septum form from embryonic tissue, the endocardial cushions, and are the end result of a complex cascade of molecular and cellular events. Although the developmental morphometry is well described in embryos [53,54], the understanding of normal and abnormal differentiation of the endocardial cushions into septae and valves is incomplete.

Like other left heart lesions, MS may result in part from altered flow through the left heart. Although some lesions can be created experimentally by disrupting the normal flow in the developing heart, a genetic component is likely present also.

Pathologic anatomy and major associated anomalies

Several pathologic types are recognized, although pathologic descriptions, surgical classification, and functional correlation vary widely among authors [47,55–57].

Atresia and hypoplasia

Mitral atresia and hypoplasia are defining features of the relatively common hypoplastic left heart syndrome (HLHS) (see Chapters 38 and 39), with management limited to univentricular palliation. Rarer, less extreme, forms of MS, allowing for biventricular repair, are discussed here.

Parachute mitral valve

The most common anomaly resulting in congenital MS involves a single papillary muscle with chordal attachments to the leaflets that give the appearance of a person suspended beneath a parachute. The interchordal spaces are fewer and shorter than normal.

Mitral arcade

An arch-like fusion of the papillary muscles occurs, with shortened chordae and malformed leaflets.

Commissural fusion

Various forms of commissural fusion may result in incomplete opening of the valve, but it almost always accompanied by some degree of papillary muscle and chordal abnormality.

Double orifice mitral valve (also see chapter 28)

A double orifice mitral valve may exhibit two well-formed orifices and no stenosis or regurgitation, or various degrees of stenosis may be present. A short-axis parasternal
Figure 27.3 Double orifice mitral valve. Two-dimensional echocardiogram in parasternal short-axis view of the left ventricle at the level of the open mitral valve leaflets, showing the distinctive double orifice. In this patient, the finding was hemodynamically insignificant, as no stenosis or regurgitation was present.

echocardiogram view is characteristic (Figure 27.3) (see Videoclip 27.2), although it may be confused with cleft mitral valve.

Shone complex

As originally described, the complex comprised four anomalies: supravalvar stenosing ring, parachute mitral valve, subaortic stenosis, and coarctation of the aorta [40]. Most patients in the original report did not have each of the four lesions, yet the complex was speculated to result from deranged left heart flow interfering with normal development of proximal and distal structures, and the term "Shone" has come to refer loosely to multiple left heart inflow and outflow obstructions.

Other associated anomalies

Other anomalies, in addition to those seen in the Shone complex, include atrial and ventricular septal defects, double outlet right ventricle, and pulmonary stenosis [57]. In the neonate, atrial left-to-right shunt at the fossa ovalis (or atrial septal defect) and right-to-left shunt via the ductus arteriosus attenuates the hemodynamic effects of MS [58], but result, via the ductal level shunt, in arterial desaturation in the lower body.

Pathophysiology

As in other forms of left ventricular inflow obstruction, increased pulmonary venous pressure leads to pulmonary hypertension and attendant right heart failure. In MS, manifestations involving left atrial dilation may help differentiate MS from other forms such as pulmonary venous stenosis. Left atrial dilation, stretch, and progressive fibrosis are arrhythmogenic.

The degree of obstruction can be expressed quantitatively in various ways. For most cardiac obstructions, the pressure gradient is perhaps the most direct and commonly used parameter, but as the normal mitral valve has no gradient, and as the diastolic gradient in symptomatic MS is often deceptively small, and dependent on the transvalvar flow (equal to the cardiac output in patients without associated mitral regurgitation), a knowledge of the flow and the gradient can be combined to derive a cross-sectional orifice area [59]. This mitral valve area (MVA) can be calculated at catheterization [59] or by Doppler, using the continuity equation [60], or the area can be estimated directly from two-dimensional echocardiogram images of the open valve [61].

In adults, the normal mitral valve area is 4–5 cm^2. In adults with MS, symptoms do not usually occur if the MVA is >2.5 cm^2, but patients with mild stenosis (MVA >1.5 cm^2) may not have symptoms at rest yet typically develop dyspnea and other symptoms with any increase in cardiac output demand, such as during fever, anemia, exercise, or pregnancy, or if they develop atrial arrhythmia. Then, as cardiac output increases, the transmitral gradient increases exponentially [62], pulmonary venous and pulmonary artery hypertension increase, and ultimately, the expected increase in cardiac output will be blunted. Patients with moderate stenosis have an MVA 1.0–1.5 cm^2. An MVA <1.0 cm^2 is considered severe MS and patients may be symptomatic at rest [63].

The MVA may be indexed to body surface area (BSA), to compare values in children with the experience with adult MVA values. BSA, however, is not linear with age. In a series of children with severe congenital MS, the indexed MVA ranged from 0.44 to 2.1 cm^{2}m^{-2} with a mean of 1 cm^{2}m^{-2} [48]. This should not be confused with a similarly named and indexed value, commonly calculated by measuring the *annulus* echocardiographically [64], as it does not express *orifice* area, or include a factor for transmitral flow.

Natural history

The natural history of MS depends upon the etiology and severity, and whether the lesion is isolated or associated with other malformations, such as coarctation, which may predominate clinically.

In neonates with borderline or inadequate left ventricular size, MS is often lethal without surgery or transplant. Infants with less severe stenosis may escape detection and present at 1–2 years of age with pulmonary hypertension, often during an acute febrile respiratory illness. This reflects both their fragile cardiac output reserve and the propensity dramatically to increase further their already elevated pulmonary vascular resistance.

Mild forms of congenital MS may be well tolerated and produce no symptoms at rest, leading to delayed diagnosis in adulthood.

In longstanding MS, left atrial dilation may lead to atrial arrhythmias, such as atrial fibrillation. Embolic stroke is more likely due to the dilated atrium, even in the absence of atrial fibrillation.

Clinical features

Clinical history

Isolated MS in neonates may be well tolerated and asymptomatic, yet with age and growth, signs of tachypnea, poor feeding, and growth failure develop. Mitral stenosis is often clinically silent in the presence of other clinically evident lesions, such as coarctation or left ventricular outflow obstruction.

Physical examination

Classically, and in rheumatic disease, MS produces a mid-diastolic or proto-systolic murmur, which may be preceded by an opening snap occurring just after the second heart sound (S$_2$) and at the end of isovolumetric relaxation. An apical diastolic thrill may accompany the murmur. The opening snap and the mid-diastolic murmur, however, are rarely noted in congenital MS [58]. The first heart sound (S$_1$) is loud, presumably from delayed and therefore more forceful systolic mitral valve closure, unless the stenosis is very severe. A loud S$_1$ originating from the tricuspid valve may be a consequence of right ventricular hypertension.

Pulmonary hypertension leads to a loud S$_2$ and, rarely, the early diastolic murmur of pulmonary regurgitation (first described by Graham Steell in rheumatic mitral stenosis), and a holosystolic murmur of tricuspid regurgitation. However, differentiation of these right heart murmurs from the murmurs of associated aortic valve insufficiency and mitral regurgitation may be challenging.

Electrocardiogram

The electrocardiogram may reflect left atrial dilation, atrial arrhythmia, and pulmonary hypertension. It may be normal in mild mitral valve stenosis, or associated lesions, such as left ventricular outflow tract obstruction, may dominate.

Atrial dilation is manifest as broad, often biphasic, M-shaped P waves of "P-mitrale." This feature differentiates MS from most other congenital forms of left ventricular inflow obstruction.

In longstanding MS, atrial arrhythmias, often chronic, such as atrial fibrillation, develop.

Pulmonary hypertension manifests as varying degrees of right ventricular hypertrophy and right atrial enlargement.

Chest X-ray

The chest X-ray, as in other forms of left heart inflow obstruction, may reflect pulmonary hypertension, pulmonary edema, and pleural effusions, but the left atrial enlargement in MS helps to differentiate valvar from supravalvar and pulmonary venous forms. The lateral images typically show left atrial dilation as the posterior heart border projecting towards the vertebral bodies. In infants and children, this finding is generally more useful than features of left atrial

enlargement on the frontal images, such as elevation of the left main bronchus, and a double density. A redistribution of pulmonary blood flow to the upper lobes (cephalization) may be seen in some children, yet a generalized increase in pulmonary vascular markings may result from associated left-to-right shunt lesions [48].

Echocardiography

Echocardiography is usually the most valuable means of collecting data about the morphology and function of the mitral valve and in assessing associated lesions. Associated findings such as supravalvar mitral ring can be difficult to differentiate from pure valvar forms of MS.

Scoring of four variables, subvalvar thickening and leaflet mobility, thickening, and calcification, have been used to predict the efficacy of balloon dilation of rheumatic MS [65].

Mitral annular dimensions are usually measured by two-dimensional echo or angiographically, but because the valve annulus is best thought of as a saddle-shaped structure, simplified to that of an ellipse for the purposes of measurement, care must be taken to measure the valve with technique comparable to published normal values. The mitral valve diameter is often indexed to BSA and expressed as a Z statistic to represent the variance from the mean of normal patient values [66,67].

Doppler of the mitral valve diastolic signal allows estimation of the pressure gradient and derived values, including valve area, by the continuity equation technique [63]. The mitral valve peak gradient may be estimated from the Doppler peak velocity, but the mean gradient [68] is more commonly used; both values correlate well with catheterization-derived gradients. Mean mitral valve gradients in adults correlate clinically as follows: mild, <5 mmHg; moderate, 5–10 mmHg; and severe, >10 mmHg. [63] In a series of congenital MS, retrospective risk stratification by mean gradient at the initial infant echocardiogram ($\leq$2; 2–5.5; and $\geq$5.5 mmHg) based on longitudinal outcomes suggests that intervention or death is unlikely in the low-gradient group, very likely in the high-gradient group, and of intermediate risk with mid-range gradients [69].

A simpler echocardiographically derived value expressing only the annular, not orifice, area of the mitral valve has been used more commonly than the Gorlin calculation in infants to make decisions regarding suitability for biventricular repair versus single ventricle palliation (<4.75 cm^2 m^{-2} or <–2Z) [64,70,71]. This annular mitral valve area and the Gorlin hydraulic calculation of orifice MVA are different parameters and should not be compared with each other. (See Videoclip 27.3.)

Cardiac catheterization and angiography

Catheterization allows the collection of diagnostic data and therapeutic options (balloon dilation). The diagnostic role of catheterization and angiography has been largely replaced by echocardiography, although evaluating associated lesions and confirming mitral valve findings by catheterization remains common. Elevated pulmonary artery pressure and resistance are common. The pulmonary capillary wedge pressure is elevated, reflecting elevated left atrial pressure. Transatrial catheter puncture (Brockenbrough procedure) allows for direct measurement of the left atrial hypertension, and is ideally performed with simultaneous measurements of left ventricular pressure, allowing for instantaneous gradient measurements and calculation of valve area [59]. Without associated left heart obstructions, or mitral regurgitation, the left ventricular end diastolic pressure (LVEDP) is usually normal.

The left atrial injection, using axial angiography [72], demonstrates the level of obstruction, but does not usually offer a level of resolution comparable to echocardiography. Angiography, pulmonary arteriography in particular, may result in clinically adverse increases in pulmonary vascular resistance.

Other imaging modalities

Both CTA and MRI have been used to delineate mitral valvar stenosis, although these techniques generally offer better image and functional data in adolescent and adult patients with slower heart rates.

Management

Management options include symptomatic and palliative treatments, yet the ideal treatment, gradient relief of the stenosis, requires balloon dilation, surgical valvoplasty, or valve replacement.

There is no single criterion for seeking gradient relief. A variety of clinical factors (i.e., failure to thrive, dependence upon mechanical ventilation, etc.) and laboratory data (i.e., gradient, mitral valve area, degree of pulmonary hypertension, etc.) are considered, in addition to the potential to delay intervention until the child is larger.

Medical

Medical management of MS is limited to symptomatic treatment of right heart failure, including peripheral edema and pleural effusions. Pulmonary hypertension does not typically respond to medical treatment, but is often rapidly (within hours) reversible with effective gradient relief of MS.

Catheterization

Balloon dilation has been successful for rheumatic MS [73] and may be effective for congenital MS [74]; however, significant mitral regurgitation is a potentially severe complication in at least 25% of patients [44]. Balloon dilation is not effective for mitral valvar stenosis with associated supravalvar ring.

Surgical management

In congenital MS, the broad spectrum of mitral valve pathology, the large number of possible combinations of associated lesions, and the relative rarity of patients with the disease

make the comparison of surgical treatment outcomes difficult. Surgical options broadly involve repair versus replacement. Mortality and morbidity remain relatively high compared with many other malformations.

Associated conditions, such as coarctation and aortic stenosis (valvar and subvalvar), are often more easily remedied and with less risk. Closure of septal defects, such as ventricular septal defects, and patent ductus arteriosus may eliminate enough left heart volume overload to reduce the relative flow across the mitral valve and improve signs and symptoms, obviating or at least delaying the need for a direct intervention of MS.

Repair is generally considered preferable to and with better long-term outcomes than replacement, yet outcomes largely depend on the underlying anatomy and associated defects [75,76].

Although congenital MS can involve a single component of the mitral apparatus, usually multiple components are affected. In the absence of severe LV hypoplasia, the mitral valve annulus is usually not itself obstructive. Leaflet anomalies are common, with congenital absence of one or both commissures leading to a continuous sheet of leaflet tissue. Leaflet incisions can be made in the location of expected commissures, taking care to leave the created leaflet margins with adequate chordal support. The subvalvar apparatus may contribute to obstruction from short, fused chordae or, rarely, complete chordal absence with direct fusion of leaflet tissue on to the papillary muscles. Surgical maneuvers include splitting of fused chords and papillary muscles, creating new interchordal spaces, and cutting noncritical secondary chords that are tethering mitral leaflets. If annulus hypoplasia is severe, with a measured Z-value of less than –2, then repair is rarely feasible.

Because these reconstructive maneuvers may result in important mitral insufficiency, intraoperative evaluation with transesophageal echo (TEE) is essential. If TEE indicates important mitral regurgitation and elevated left atrial pressure after discontinuing cardiopulmonary bypass, mitral valve replacement is advisable.

Currently, mechanical mitral valve prostheses as small as 15 mm in diameter are available. If the annulus is too small to accept an available prosthesis, a portion of the prosthesis can be implanted in the supra-annular position, using an elliptical patch of Dacron to create a larger effective annulus size.

Valve replacement in children is problematic because a small prosthetic valve itself has some intrinsic impedance due to its support structures, long-term anticoagulation is necessary, and, most importantly, the prosthesis does not grow as the child grows. Surgically induced atrioventricular block is also an important complication. The risk and technical difficulty in a subsequent surgical revision to a larger prosthesis can be considerable. Early postoperative hemodynamics after supra-annular implantation often remain poor, despite the reduction in transvalvar gradient

[77]. Long-term data suggest that children who have an annular rather than supra-annular prosthesis have a better outcome [78]. The long-term outcome of children who require mitral valve replacement can be gratifying. Their care remains challenging [79] and the close monitoring of anticoagulation is critical.

Surgical management of rheumatic MS is often more efficacious relative to congenital forms, as patients usually present as older children or adults, and because the annulus is of normal size. Valvoplasty, annuloplasty, and valve replacement (particularly in patients with accompanying mitral regurgitation) are all effective and relatively low-risk options.

Long-term history of treated and untreated adults

Although congenital forms of all of the various types of pulmonary venous stenosis and left ventricular inflow obstructions have been reported to present in adult patients, these are usually minimally obstructive lesions with normal or near-normal hemodynamics.

The long-term outlook for adults with high-grade stenoses requiring intervention in childhood depends mostly on the effectiveness of the treatment in restoring the hemodynamics to normal. Pregnancy in women with mitral stenosis in particular can significantly alter the hemodynamics, because of both the increase in cardiac output and the decrease in the diastolic filling time associated with the increased heart rate [80].

28 Left Ventricular Inflow Regurgitation

Pierre-Emmanuel Séguéla, Bertrand Léobon & Philippe Acar

Toulouse University Hospital, Toulouse, France

Mitral regurgitation may occur as a component of a cardiac malformation, such as endocardial cushion defect, or as an independent abnormality, the latter as a congenital anomaly of the mitral valve mechanism or a component of a systemic disease such as Marfan syndrome or as a sequel of rheumatic fever or other rheumatic and connective tissue diseases (see Chapters 61, 62, 67 and 69).

Anatomy of the normal mitral valve

The mitral valve prevents backflow into the left atrium during ventricular systole. The mitral valvar complex comprises the annulus, the anterior and posterior leaflets, the chordae tendineae, and the papillary muscles. The valve is obliquely located in the heart and is closely related to the aortic valve.

Mitral annulus

The annulus is defined surgically as the level of visible transition between the left atrial myocardium and the whitish leaflet. It is considered as the fibrous hingeline of the valvar leaflets [1]. Due to fibrous continuity between the aortic valve and the anterior (or aortic) mitral leaflet, defining its exact limits is extremely difficult [2]. The annulus is either D-shaped or saddle-shaped [3] (Figure 28.1a), and decreases in size during systole [1].

Leaflets

The mitral leaflets are uninterrupted structures of variable shape and circumferential length. They are usually divided into anterior and posterior segments. Many authors have separated them into aortic (anterior) and mural (posterior) leaflets because of their connection with the aortic valve.

Unlike the tricuspid valve, the mitral valve leaflets are not attached to the ventricular septum. During systole, when the leaflets meet to close the ventricle, the line of coaptation looks like a smile.

A commissure is the meeting point between the anterior and posterior leaflets, and is located at each end of the closure line, that is, the anterolateral commissure and posteromedial commissure. According to Carpentier's classification [4], the free edge of the posterior leaflet is divided into three scallops: P1 (lateral), P2 (middle), and P3 (medial). The anterior leaflet is subdivided into the A1, A2, and A3 regions that oppose the scallops of the posterior leaflet (Figure 28.1b).

Tendinous cords

Chordae tendineae connect the leaflets to the papillary muscles. The cords have several shapes and are attached to the leaflets at various sites (Figure 28.2a). Thus, the marginal cords (attached to the free edge), rough zone cord (attached to the rough zone), and strut cord (attached to the basal portion of the posterior leaflet) have been identified [3].

Papillary muscles

The papillary muscles are usually organized as two groups of closely packed papillary muscles as opposed to two distinct muscles. These arise from the apical two-thirds of the left ventricular wall. The tendinous cords extend from their tips (Figure 28.2b). Papillary muscles are in anterolateral and posteromedial positions (Figure 28.3). The anterolateral (or superior) muscle is vascularized by an artery from the circumflex or anterior descending branch of the left coronary artery [1]. The posteromedial (or inferior) muscle is usually supplied by the right coronary artery.

Figure 28.4 Carpentier's functional classification of mitral regurgitation. Type I: leaflet motion is normal and mitral insufficiency is due to mitral annulus dilatation or valvar perforation (endocarditis). Type II: motion, of one or both leaflets, is excessive (mitral valve prolapse, chordal rupture). Type III: leaflet motion is restrictive.

Chronic compensated mitral regurgitation

When regurgitation is progressive, the left atrium dilates to accommodate the increase in volume and reduces the left atrial pressure. Eccentric cardiac hypertrophy allows left ventricular enlargement, and enables the forward stroke volume (the total stroke volume is increased) to be maintained The contractile function is normal and the ejection fraction is increased [6].

When mitral regurgitation is trivial or mild, patients are asymptomatic. A soft (grade 1–2/6), high-pitched holosystolic murmur with maximum intensity at the apex and radiation to the axilla is heard. Electrocardiography and chest radiography are usually normal.

When mitral regurgitation is moderate, fatigue, exercise limitation, and poor weight gain are common. The systolic murmur is louder (grade 3/6), maximum at the apex, and radiates to the axilla. A third heart sound and mid-diastolic murmur may be detected at the apex. The ECG shows left ventricular hypertrophy and left atrial enlargement. Cardiomegaly is noted on chest radiography and is proportional to the degree of regurgitation.

Chronic decompensated mitral regurgitation

In the decompensated phase, left ventricular contractile dysfunction (due to the lengthening of cardiac myocytes) reduces both total and forward stroke volume and increases the left ventricular filling pressure [5,6]. Ventricular dilatation aggravates mitral regurgitation as it increases the mitral annular diameter.

Signs of pulmonary edema are common. The apical pulse is displaced downwards to the left. In most instances, supraventricular tachyarrhythmias complicate chronic severe regurgitation.

According to Carpentier [7], three types of mitral valve dysfunction are observed. In this functional classification based on leaflet motion (Figure 28.4), etiology and valvar

Physiological and clinical presentation

Three hemodynamic forms are described: acute, chronic compensated, and chronic decompensated mitral regurgitation. Pulmonary hypertension (leading to pulmonary edema and congestive heart failure) may be observed in both acute and chronic decompensated phases.

Acute severe mitral regurgitation

In acute mitral regurgitation, filling of the left ventricle is increased because the pulmonary venous return volume is combined with the regurgitant volume. Despite the increase in total stroke volume, the major part is regurgitated into the left atrium and the forward volume is reduced. As a result, the end-diastolic pressure is increased. The elevated left atrial pressure, in a non-prepared left atrium (low compliance), causes pulmonary venous hypertension. The ventricular muscle function is normal [5].

Signs of congestive heart failure (orthopnea, dyspnea on exertion, fatigue) may occur. There is a short and unimpressive systolic murmur. A third heart sound is sometimes heard. The apical impulse is not displaced. Pulmonary congestion is found by chest radiography.

lesions have not been taken into account voluntarily in order to facilitate surgical management. Leaflet motion is described as normal (type I), excessive – prolapse (type II) or restrictive (type III). Complex mitral valve anomalies may include these three mechanisms to various degrees.

Anatomic malformations

Mitral valve prolapse

Mitral valve prolapse (MVP) occurs when the leaflets extend above the plane of the mitral annulus during ventricular systole [8]. The complications are endocarditis, sudden cardiac death, and severe mitral regurgitation. It is the most common cardiac valvar anomaly in developed countries. MVP is generally sporadic but is associated with disorders affecting the connective tissue, including Marfan and Ehler–Danlos syndromes, osteogenesis imperfecta, dominant cutis laxa, and pseudoxanthoma elasticum. The most common auscultatory observation is a mild systolic click heard at the cardiac apex and frequently associated with a late systolic murmur.

Previously, MVP was overestimated due to inconsistent echocardiographic definitions. New echocardiographic criteria have been established based on the understanding of the three-dimensional nonplanar shape of the mitral annulus. Since then, echocardiographic MVP has been defined as a single or bileaflet prolapse of 2 mm or more beyond the long-axis annular plane, with or without a thickening of leaflets [8]. Only prolapse shown in a parasternal long-axis view represents true MVP (Figure 28.5). Prolapse simply observed in a four-chamber view does not satisfy the diagnosis [9]. Classic prolapse is defined as a leaflet thickening exceeding 5 mm whereas a prolapse with a lesser degree of leaflet thickening is referred to as nonclassic.

In adults, the incidence of complications is proportional to the degree of leaflet thickening. Based on these criteria, the Framingham study, with its community-based population (as opposed to hospital-based populations in previous studies), revealed that 1.3% of the 3491 subjects had classic mitral valve prolapse and 1.1% had nonclassic mitral valve prolapse [10]. No difference was noted according to gender. MVP is uncommon before adolescence and its prevalence increases subsequently.

Causes

In adults, myxomatous degeneration is the most common etiology. Accumulation of proteoglycans and structural alterations of collagen are responsible for both leaflet thickening and redundancy, with interchordal hooding, chordal elongation, and annular dilatation [8]. Most myxomatous MVP are sporadic family-type instances and are described with mapped gene mutations.

Figure 28.5 Mitral valve prolapse. 2D echocardiography parasternal long-axis view. Leaflets are thickened and the superior displacement of the anterior leaflet exceeds 2 mm in a young patient with Marfan syndrome.

MVP may be secondary to distortion of the left ventricular geometry as in unrepaired atrial septal defect (right ventricular volume overloading and left ventricular size reduction). The mitral valve is normal histologically and the prolapse usually resolves postoperatively.

MVP is also observed in connective tissue disorders [8], especially in children. In Marfan syndrome, the percentage of MVP ranges from 40 to 91% [8,11]. In an adult population, however, fewer than 2% of patients with MVP have a related connective tissue disorder.

The Marfan syndrome is associated with mutations in fibrillin-1 on chromosome 15q21.1 and with mutations in TGF-β receptor 2 on chromosome 3p24.2-p25 [12]. Severe mitral valve disorders associated with the Marfan syndrome are generally observed in infants. As for adults, most complications are due to aortic aneurysm [13].

MVP most commonly involves both leaflets and is symmetrical (Figure 28.6), whereas it more frequently affects one leaflet (posterior) in myxomatous degeneration [11].

Management

Most patients with MVP have an excellent prognosis and are asymptomatic. Although mitral regurgitation is usually trivial or mild, long-term follow-up is recommended because the prolapse can progress slowly over the years. The most serious complication is severe mitral valve regurgitation, which is uncommon [14]. Patients with thickened valve leaflets, posterior leaflet prolapse, increased left ventricular dimensions, hypertension, and an increased body mass index are at high risk of developing severe mitral regurgitation. Vasodilator therapy is not recommended for treating asymptomatic patients with severe mitral regurgitation and a normal left ventricular function, as this may increase the
Figure 28.6 Mitral valve prolapse. Apical four-chamber view showing a bileaflet prolapse causing moderate mitral regurgitation in a child with Marfan syndrome.

risk of paradoxical worsening in mitral regurgitation [8]. Men aged >50 years are more likely to need valve surgery. Mitral valve repair, rather than replacement, is reserved for patients with symptomatic severe mitral regurgitation or ventricular enlargement or dysfunction in an asymptomatic patient.

The risk of endocarditis is higher for patients with MVP than for the general population, especially if the valve has thickened [8]. Antibiotic prophylaxis is not recommended according to the new ACC/AHA guidelines [15].

The incidence of sudden cardiac death is increased (twice as high as expected for the general population) in patients with MVP, but the mechanism is unknown [8,10,16].

MVP may confer a small risk of cerebrovascular events in older patients with advanced mitral regurgitation [8,16]. Prophylactic aspirin is sometimes used to prevent such events in patients with severe regurgitation.

Isolated cleft of the mitral valve

Although a cleft in the mitral valve can be present in either the anterior or posterior leaflet of the valve, it is usually in the anterior leaflet.

Isolated cleft of the anterior mitral valve leaflet (Figure 28.7)

This is rare with a pediatric incidence of 1/1340 [17]. The defect is a slit in the mid-portion of the anterior mitral leaflet, unassociated with an atrioventricular septal defect. It might be due to abnormal development of the embryological endocardial cushion tissue.

Isolated cleft of the anterior mitral valve leaflet is morphologically different from a cleft as observed in atrioentricular septal defect [17], even if some authors consider it as a forme fruste [18]. In isolated cleft of the anterior mitral valve leaflet, the mitral valve is supported by an annulus, which is separated from the right side of the heart by well-formed atrioventricular structures. In contrast, in atrioventricular septal defect, the valve ring is common to both atrioventricular valves. Furthermore, the isolated cleft points to the left ventricular outflow tract when the valve opens during diastole, whereas in atrioventricular septal defect, the cleft is directed towards the ventricular inlet septum [17].

A cleft anterior leaflet may also occur with a ventricular septal defect, coarctation of the aorta, transposition of the great arteries, double-outlet right ventricle, patent arterial duct, anomalous pulmonary venous connection, tricuspid atresia, and tetralogy of Fallot [19]. Chordal attachments may connect the edges of the cleft to the ventricular septum and subsequently create a subaortic obstruction [20].

Repair of isolated cleft of the anterior mitral valve leaflet associated with mitral regurgitation is preferred to replacement and usually consists in direct suture of the cleft [19,20]. Sometimes, an additional pericardial patch is used to close the cleft.
Figure 28.7 Isolated cleft of the anterior mitral valve leaflet. (a) 2D apical four-chamber color Doppler view. Mitral regurgitation is going through the anterior leaflet. (b) 2D parasternal short-axis color Doppler view showing the split anterior leaflet. (c) 3D left atrial view of the mitral valve providing a precise anatomic description of the cleft in order to define the ideal approach for surgical reconstruction. (d) Surgical view of the cleft.

Isolated cleft of the posterior mitral valve leaflet (Figure 28.8)

The predominant localization of the cleft is within scallop P2 [21], but it can occur at any segment of the posterior leaflet. The cleft may be isolated or associated with papillary muscle malrotation [22], accessory mitral valve leaflet [23], mitral valve prolapse [24], chordal rupture, and anterior leaflet cleft [25,26]. Mitral regurgitation is severe in 50% of clefts. Reconstruction of the mitral valve is the preferred management [27].

Double-orifice mitral valve

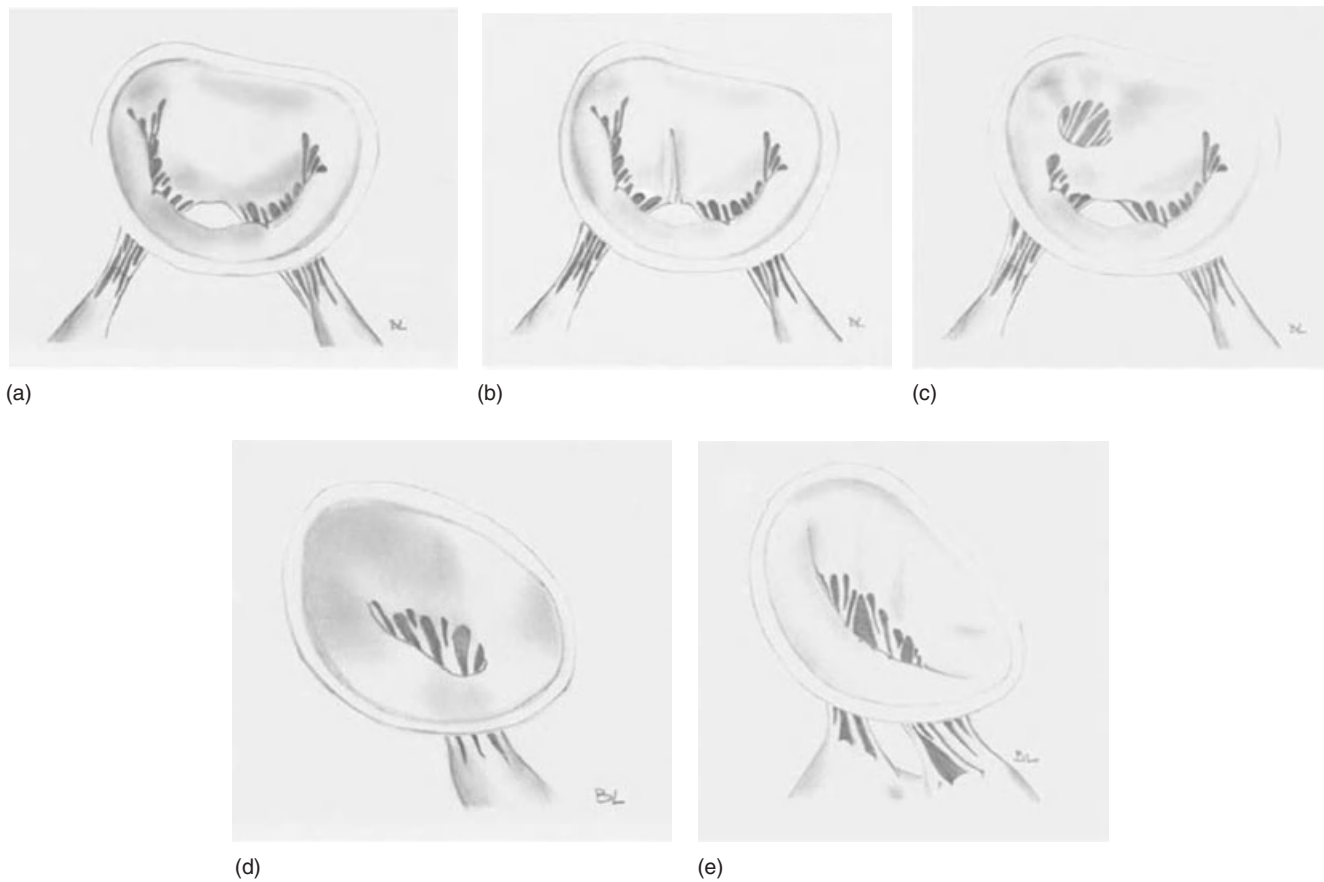
Double-orifice mitral valve (DOMV) is a rare anomaly characterized by a mitral valve with a single fibrous annulus and two orifices (Figure 28.9C). DOMV usually is associated with more complex cardiac anomalies [17], particularly
Figure 28.8 Isolated cleft of the posterior mitral valve leaflet. (a) 2D apical four-chamber view. The regurgitant jet is laterally directed and goes through the cleft. (b) 3D left ventricular view of the mitral valve. The posterior leaflet is divided into two equal parts by the cleft. AL, anterior leaflet; PL, posterior leaflet.


Figure 28.9 Surgical views of congenital mitral malformations causing mitral regurgitation. (a) Normal mitral valve. (b) Isolated cleft of the anterior mitral valve leaflet. (c) Double-orifice mitral valve (eccentric accessory orifice). (d) Parachute mitral valve. (e) Hammock mitral valve.

atrioventricular septal defect [28]. Thus, echocardiographic identification of DOMV is usually accidental because symptoms are not related solely to this anomaly. The mitral valve functions normally in 50% of patients [29]. Mitral regurgitation is the most frequent functional anomaly, but mitral stenosis, when either isolated or associated with regurgitation, is uncommon. According to the Baño-Rodrigo classification [29], DOMV almost always consists of abnormal holes in essentially normal leaflets, rather than abnormal fibrous bridges or adhesions between normal leaflets. Two types of DOMV are described: the eccentric hole with a small accessory orifice located at one of the commissures (85%) and the central hole with two equal-sized orifices (15%). The tensor apparatus of the mitral valve is always abnormal. Various malformations are observed such as a chordal ring, accessory papillary muscles, subdividing muscular ridge, parachute mitral valve, crossing chordae tendineae or central fibrous subdivision. DOMV is diagnosed and assessed through two- and three-dimensional echocardiography [30]. The management of DOMV is either continued observation or valve repair or replacement.

Parachute mitral valve

In an echocardiographic study of 13 400 subjects, parachute mitral valve was found in 0.17% [17]. Parachute mitral valve is characterized by the attachment of mitral chordae to a single or fused papillary muscle [17,31] (Figures 28.9d and 28.10). In a variant, parachute-like asymmetric mitral valve (PLAMV), there are two papillary muscles with one papillary muscle receiving most or all of the mitral chordae [31]. In this variant, the dominant papillary muscle is normal and the other is elongated and displaced towards the mitral annulus. Chordae tendineae are commonly attached

to the posteromedial papillary muscle in both parachute mitral valve and PLAMV. Oosthoek *et al.* [32] assumed that disruption of the development of papillary muscles occurs between the fifth and nineteenth weeks of gestation and causes their condensation into a single muscle. Mitral valve leaflets are thickened and their motion is usually restricted.

Doppler echocardiography shows significant mitral stenosis. Mitral regurgitation is less common but more progressive. Due to the left inflow obstruction, parachute mitral valve and PLAMV are associated with other obstructive lesions affecting the left heart [17,33], such as the supravalvar mitral ring, subaortic stenosis, and coarctation of the aorta. This combination produces either a complete or incomplete form of Shone's complex. The outcome is generally poor in patients with multilevel heart obstruction [31,33].

Hammock mitral valve

The hammock mitral valve is a very dysplastic valve without chordae and having the two papillary muscles directly fused with the leaflet tissue at the expected locations of the commissures (Figure 28.9e). This malformation causes mitral stenosis or regurgitation, or both. From the atrial side, it looks like a hammock. It may be difficult to distinguish parachute mitral valve and the hammock valve.

Anomalous mitral arcade

The mitral arcade is extremely rare and is characterized by thickened mitral leaflets with either shortened chordae or no chordae at all. The enlarged and elongated papillary muscles [34] are inserted directly into the leaflets by a typical fibrous tissue bridge acting as a single "muscle arcade" [35].

393

This fibrous continuity restricts valvar motion and limits coaptation of the leaflets. Mitral regurgitation progresses and may be associated with stenosis.

Mitral valve chordal rupture

Chordal rupture of the mitral valve is often associated with endocarditis, trauma, or acute rheumatic fever. Few examples of spontaneous rupture have been reported [36]. Common signs include acute pulmonary edema with severe mitral regurgitation. Echocardiography reveals a flail mitral valve leaflet with moderate to severe mitral regurgitation [37]. Both the left ventricle and atrium are normal in size. A linear structure moving around within the left heart chambers in a "whipping" manner is usually observed. Corrective surgery is required.

Submitral left ventricular aneurysm

Submitral left ventricular aneurysm occurs almost exclusively in young black African people. This anomaly is believed related to a congenital tissue weakness of the fibrous annulus at the connection point of the posterior mitral valve leaflet [38]. A submitral left ventricular aneurysm protrudes into the pericardial space either towards the floor of the left atrium or behind the left ventricle. Mitral regurgitation is caused by a limited leaflet motion and diminished coaptation due to distortion of the mitral annulus. Complications include calcification, thromboembolism, ventricular arrhythmia, compression of the left circumflex artery, and aneurysmal rupture into the left atrium. Surgical repair using either a transmitral or a transatrial approach is the best method to prevent the aneurysm. A meticulous description of the relationship existing between the aneurysm, the mitral valve, and the annulus is required for successful repair [39]. Echocardiography (transthoracic or transesophageal), MRI, and cardiac catheterization are usually used to define the anatomy.

Ebstein's malformation of the mitral valve

This exceptional anomaly is due to the downward displacement of the posterior leaflet of the mitral valve, which produces a functional atrialization of the proximal part of the left ventricle [40]. It causes a high mortality and occurs isolated or with another cardiac malformation.

Functional mitral regurgitation

Mitral regurgitation may occur with a normal mitral structure when the geometry of the valve is modified by another disease that increases left ventricular volume, including ventricular septal defect, patent ductus arteriosus, or dilated cardiomyopathy.

Dilated cardiomyopathy

Among cardiomyopathies, dilated cardiomyopathy is the most common in children with a high rate of mortality. It represents the main indication for the need for a heart transplantation in over 5-year-olds [41]. Mitral regurgitation is caused by dilatation of the annulus. Severe mitral regurgitation is an independent predictor of death [42]. Some authors have reported that mitral annuloplasty is sometimes efficient and may delay or replace the need for heart transplantation [43].

Ischemic mitral regurgitation

Abnormalities of the coronary arteries can cause myocardial ischemia leading to papillary muscle dysfunction (see Chapter 48). Regurgitation is due to disturbances of the posterior leaflet displacement, left ventricular dilatation, annular dilatation, and papillary muscle discoordination.

Congenital anomalies of the coronary system require prompt recognition and treatment because of the high lethal risk. Thus, an anomalous origin of the left coronary artery, congenital atresia of the left coronary artery, and coronary aneurysm (usually due to Kawasaki disease) must be meticulously detected. Cardiac catheterization or a CT scan may be particularly helpful in this context.

An anomalous origin of the left coronary artery from the pulmonary artery concerns one out of 300 000 live births [44]. After surgery, the majority of patients normalize mitral regurgitation. Regurgitation might sometimes persist or become worse. In this lesion the initial mitral insufficiency is due to a restrictive leaflet motion which itself is secondary to both the regional myocardial dysfunction and ischemia of the papillary muscle [45]. Due to myocardial desynchronyzation, chordae are elongated and cause a leaflet prolapse, which is the persistent mitral regurgitation mechanism. Direct coronary reimplantation is the preferred technique for repair in order to restore a two-coronary circulation system [46]. Associated mitral valve plasty seems to increase postoperative mortality and may not be required upon initial repair. Nevertheless, a few patients might need additional mitral valve repair for persistent severe mitral regurgitation [44].

Quantification of mitral regurgitation

Two-dimensional echocardiography

Left heart size and function

Two-dimensional echocardiography is used to assess the shortening and ejection fractions by measuring the left ventricular end-diastolic and end-systolic dimensions. Left ventricular volumes can be calculated using Simpson's method. Left ventricular size increases progressively in chronic mitral regurgitation. In contrast to adults, in children no validated values are available to determine the

Figure 28.11 PISA method. (a) Radius of the isovelocity area for an aliasing velocity of 30.8 cm s^{-1}. (b) Velocity–time integral of the mitral regurgitation jet.
timing of surgery because the left ventricular size normally increases during childhood and depends on body weight. Nevertheless, changes in ventricular size and function must be serially monitored. A rapid increase in the end-systolic dimension reflecting the ability of the ventricle to eject the increased preload is reliable evidence of left ventricular pump failure. Measurements of left atrial volumes are also helpful for assessing the severity of mitral regurgitation.

Quantitative doppler method

The regurgitant volume is defined as the difference between the forward stroke volume across the mitral valve and the cardiac output at the aortic valve. It can be determined by using the pulsed Doppler technique and the following calculation:

$$MV = MSA \times VTI_M$$

$$AV = ASA \times VTI_{Ao}$$

$$RV = MV - AV$$

where MV = mitral stroke volume, MSA = mitral surface area, AV = aortic stroke volume, ASA = aortic surface area, RV = regurgitant volume, VTI_M = mitral velocity time integral of mitral inflow, and VTI_{Ao} = aortic velocity time integral.

The mitral annular diameter is calculated from an apical view and the aortic annular diameter from a parasternal long-axis view.

This method is applicable only in pure mitral regurgitation (with no associated aortic insufficiency). A small error in the diameter measurement leads to large variations of the annular area. Finally, this method assumes a circular geometry of the valve even though the mitral annulus is more D-shaped.

The regurgitant fraction (RF) is defined as

$$RF = \frac{RV}{MV}$$

Mitral regurgitation is classified as mild ($RF < 30\%$), moderate ($30 < RF < 49\%$) and severe ($RF \geq 50\%$).

The effective regurgitant orifice area is calculated by using the Doppler technique and the equation

$$OA = \frac{RV}{VTI_{MR}}$$

where ROA = regurgitant orifice area and VTI_{MR} = velocity time integral of the mitral regurgitation jet.

All of these values may also be more difficult to determine by two-dimensional volume analysis.

Proximal Isovelocity Surface Area (PISA) method (Figure 28.11)

The color Doppler technique is used to assess RV and ROA. Assuming that PISA is a hemisphere, RV and ROA are calculated with the following equations:

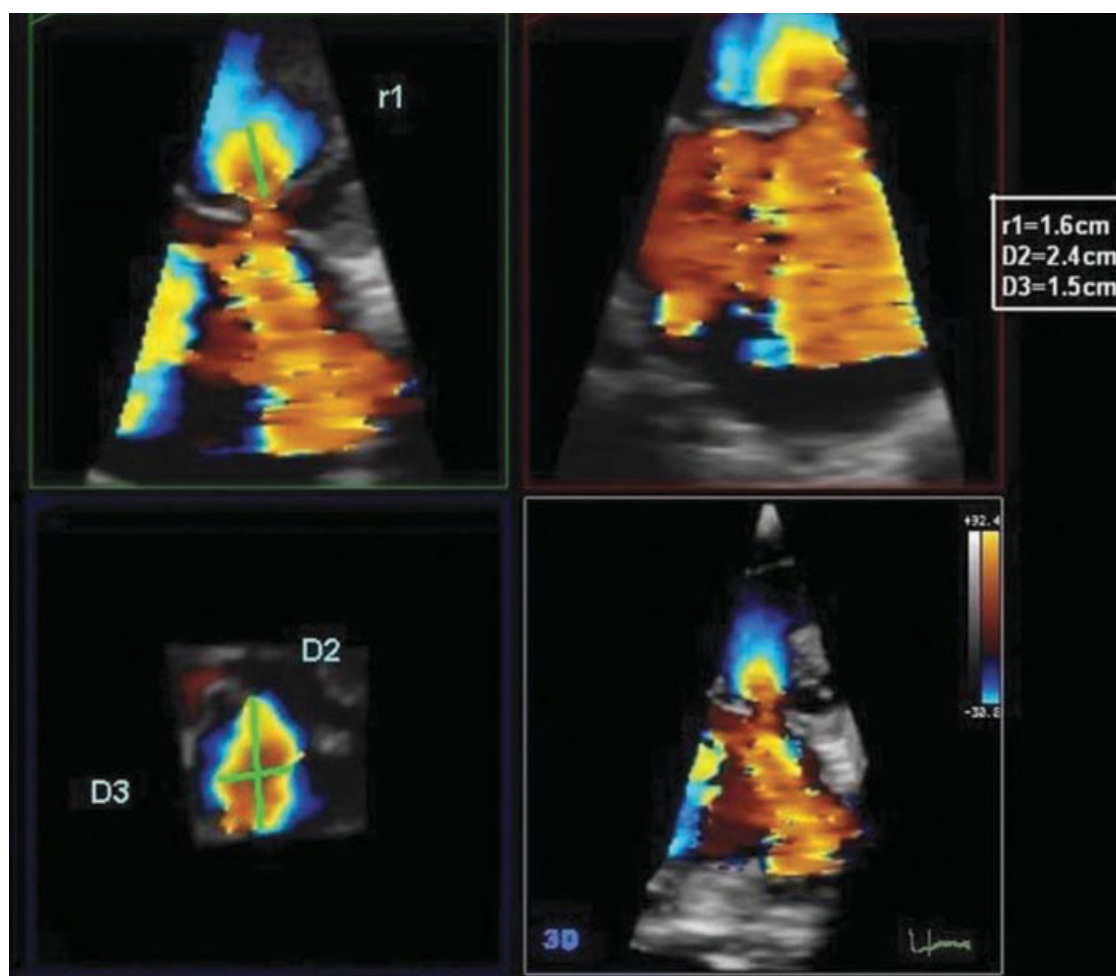
$$QMR = 2\pi r^2 \times VAL$$


Figure 28.12 3D echographic PISA analysis. The isovelocity radius is measured in the longitudinal plane (r1) and the two diameters are measured in the transversal plane at the orifice level. The PISA shape is estimated according to these three measurements. (Reproduced with permission from Ziani *et al. Arch Cardiovasc Dis* 2009;**102**:185–91.)

$$ROA = \frac{Q_{MR}}{V_{MR}}$$

$$RV = ROA \times VTI_{MR}$$

where Q_{MR} = regurgitant flow rate, r = radius of the PISA, V_{AL} = aliasing velocity, ROA = regurgitant orifice area, V_{MR} = peak of regurgitant velocity, and VTI_{MR} = velocity time integral of the mitral regurgitation jet.

Three-dimensional echocardiography

Three-dimensional echocardiography assesses the severity of mitral regurgitation by determining the stroke volume or using the proximal isovelocity surface area (PISA method) [47]. Because the isovelocity surface is rarely hemispherical, regurgitation is frequently overestimated with the two-dimensional echocardiography PISA method. The isovelocity radius (measured in the longitudinal plane) and two diameters (measured in the transversal plane) are required to calculate the surface of the PISA (Figure 28.12). Thus, according to the mechanism, the PISA shape is described as hemispherical (20%), prolate hemispheroid (27%), oblate hemispheroid (47%), and hemiellipsoid (6%) (Figure 28.13).

Cardiovascular Magnetic Resonance (CMR)

CMR is a noninvasive technique that allows the accurate measurement of ventricular volumes. When quantification of mitral regurgitation is difficult by echocardiography, CMR may be particularly helpful. The regurgitant fraction, regurgitant volume, and direct planimetry of the anatomic regurgitant lesion are easily determined [48,49].
Figure 28.13 PISA geometries: mathematical model representations and their 3D visualization. (a) Hemispherical PISA shape. (b) Prolate hemispheroid PISA shape. (c) Oblate hemispheroid PISA shape. Surgical management

Because of the wide range of mitral anomalies and the frequent associated lesions, performing mitral valve surgery

on children is very delicate. When possible, mitral valve repair is preferred to replacement, because of the latter's mortality and morbidity. In children, bioprosthetic valves have early valve failure. Therefore, mitral valve replacement is performed with a mechanical prosthesis. Mitral valve replacement is complicated by the limited availability of adequate-sized prostheses for small children and the need for lifelong anticoagulation. In contrast, with repair, the subvalvar apparatus and ventricular geometry are maintained and left ventricular function is preserved. Significant predictors for poor freedom from reoperation and midterm survival are age <1 year, hammock mitral valve, and associated cardiac anomalies [50].

Mitral valve surgery is performed through a median sternotomy under cardiopulmonary bypass. According to the lesion, different techniques are used to repair the valve, as follows:

Annulus dilatation

Various annuloplasty techniques exist to treat a dilated annulus. The following are the most commonly performed. Strip materials, either autologous pericardium or Gore-Tex, are commonly used. There are several techniques:

- Posterior annuloplasty using strip or suture plication.
- The commissure plication principle (Kay–Wooler-type annuloplasty) consists in shortening the posterior annulus by a suture placation (Figure 28.14a). It is frequently used for small infants.
- Strip plication (Paneth-type annuloplasty) is used in children and adolescents. The posterior annulus is shortened with strip reinforcement (Figure 28.14b).
- Artificial ring annuloplasty is used for older children (Figure 28.14c).

Leaflet prolapse

Elongated chordae are either shortened or artificial chordae (Gore-Tex) are used.

Isolated cleft

The direct suture technique is the preferred method, although a pericardial patch is sometimes used to close the cleft.

Parachute valve

Following a careful commissurotomy, the papillary muscle is incised to divide it into two portions (Figure 28.14d).

Hammock valve

Splitting the papillary muscle is a difficult technique because the new papillary muscles must have a sufficient thickness to perform their function.

Chordal rupture

When prolapse of P2 of the posterior leaflet is caused by a chordal rupture, the flail segment is plicated towards the ventricle by a V-shaped suture line with stabilization of

(a)

the posterior annulus by a strip such as for Gerbode-type annuloplasty.

Perioperative echocardiography allows an immediate functional evaluation of the mitral valve and may help the surgeon improve reconstruction (Figure 28.15).

Conclusion

In children, mitral regurgitation results from a number of anatomic variations, the most common being mitral valve

prolapse and isolated cleft of the anterior mitral valve leaflet. Echocardiography allows both quantification of mitral regurgitation and morphological analysis of the mitral valve apparatus. It should be used to assist the surgeon during operation. Surgery is often difficult and mitral valve repair is always preferred to mitral valve replacement.

29 Right Ventricular Inflow Obstruction

James H. Moller
University of Minnesota, Minneapolis, MN, USA

Right ventricular inflow obstruction is relatively uncommon, occurring in ~3% of children with a cardiac malformation. The two most frequent causes are tricuspid atresia and pulmonary atresia with intact ventricular septum, each accounting for ~1.4% of congenital heart disease. They are discussed in Chapters 35 and 40, respectively. This chapter reviews rare and unusual congenital and acquired conditions which obstruct blood flow into the right ventricle. Some are found predominately in neonates and others occur in older children and adolescents.

Neonatal period

In the neonatal period, right ventricular inflow obstruction is predominantly associated with either tricuspid atresia (Chapter 35) or pulmonary atresia with intact ventricular septum (Chapter 40). Other causes are very uncommon in this age group, but despite their rarity must be considered in the differential diagnosis because treatment and prognosis varies.

Cardiac malformations obstructing blood flow into the right ventricle have several common features that are well recognized in the two anomalies with an atretic valve, either tricuspid or pulmonary. Because of the obstruction, the right atrium is enlarged and usually the right ventricle is hypoplastic. An atrial right-to-left shunt occurs through a patent foramen ovale or atrial septal defect; the shunt is usually large (often 100%), so the neonate is intensely cyanotic. The pulmonary circulation is derived from flow through a ductus arteriosus while it remains patent. There is either no murmur or that of a patent ductus. The transverse diameter of the cardiac silhouette is enlarged primarily by the right atrial shadow to the right of the midline. The pulmonary arterial vascularity is decreased. Administration

of prostaglandin E_1 to maintain ductal patency benefits the neonate and allows time for accurate diagnosis and planning for treatment.

Three other conditions must be considered in the differential diagnosis of right ventricular inflow obstruction and distinguished from either tricuspid atresia or pulmonary atresia with intact ventricular septum.

Isolated hypoplastic right ventricle

In isolated hypoplastic right ventricle, the tricuspid valve is hypoplastic and its orifice narrowed by the small size of the tricuspid annulus, but the valve leaflets are diminutive but otherwise normal. This is distinct from congenital tricuspid stenosis, in which the valve orifice is narrowed by commissural fusion, forming a membrane-like structure with a small aperture [1]. Because of the hypoplasia, right ventricular volume is reduced and pulmonary blood flow limited. Right atrial pressure is elevated and a right-to-left shunt occurs through a patent foramen ovale or atrial septal defect. Usually the patients present in the neonatal period with intense cyanosis and tachypnea. There are no murmurs. The clinical picture resembles pulmonary atresia with intact ventricular septum.

Patients with milder degrees of hypoplasia are less cyanotic and relatively asymptomatic as newborns. Such patients do not need immediate treatment and can be followed until they are larger and older, even into adulthood. The ECG is not diagnostic, resembles that of pulmonary atresia with intact ventricular septum, and characteristically has a normal QRS axis, tall peaked P waves, and a small r wave in lead V1 and a prominent R wave in lead V6. The chest X-ray shows cardiomegaly and diminished pulmonary vascular markings. An echocardiogram helps to distinguish this condition from

pulmonary and tricuspid atresia and from Ebstein's malformation. On subcostal and apical cross-sectional views, there is an enlarged left ventricle and an adjacent small right ventricle. Although the diameter of the tricuspid annulus is reduced, the tricuspid and pulmonary valves appear normal. Doppler interrogation shows anterograde flow across both the valves. A right-to-left shunt is seen across the atrial septum and the size of the communication can be assessed. Cardiac catheterization and angiography are not needed for diagnosis or management decisions. Right atrial pressure may be elevated but right ventricular and pulmonary artery pressures are normal. It is one of the few anomalies with a right-to-left shunt and normal right ventricular systolic pressure.

Although the etiology is unknown, three families have been reported in which more than one sibling had this anomaly, and in one of these families more than one generation was affected [2]. Medd *et al.* [3] reported two infant siblings who died with this anomaly. We have cared for three siblings who presented in the newborn period with cyanosis [4–6]. Two died shortly after admission and the third following an aortopulmonary shunt. They were admitted over a 5 year period at a time when echocardiography was unavailable and the clinical diagnosis was pulmonary atresia with intact ventricular septum. An autopsy was preformed on each. Each component of the right ventricle was present but diminutive. The tricuspid valve was normal but the annulus was hypoplastic. Valproate administration to a pregnant woman has also been associated with this anomaly in a neonate [7].

Treatment has varied. Often the initial step is placement of an aortopulmonary shunt. Later, in some with only moderate hypoplasia, closure of the atrial defect by a device [8] or surgery [9] has been done, establishing a two-ventricle circulation. In those with more severe hypoplasia, cavopulmonary shunt procedures are performed.

Cor triatriatum dextrum

In the fetus, blood flow from the inferior vena cava is directed across the atrial septum by the inferior sinus venosus valve [10]. By 9–15 weeks, the valve differentiates into the eustachian (valve of the inferior vena cava) and thebesian valves (valve of the coronary sinus). If the inferior sinus venosus valve persists and extends towards the superior vena cava, the right atrium is divided into two parts, one receiving the systemic venous return and the other portion containing the tricuspid valve and the right atrial appendage [11,12]. The systemic venous return may be directed across the atrial septum through a perforation in the sinus venosus valve and some blood can reach the tricuspid valve. The quantity of blood presenting to the tricuspid valve and right ventricle is limited, so both of these structures can be hypoplastic. The clinical presentation is that of tricuspid or pulmonary atresia [12–15]. Echocardiography, particularly

from subcostal views [16], allows identification of the flow passing from the inferior vena cava towards the superior vena cava. The right-to-left shunt is found across the atrial septum. The size and characteristics of the tricuspid valve and size of the right ventricle can be assessed.

Once recognized, the anomaly can be treated by resection of the membrane dividing the right atrium.

A variant is persistence of the eustachian valve, which if large and redundant can obstruct the tricuspid valve. At times it may form a windsock that prolapses into the right ventricle. In patients with a large valve eustachian there may be an atrial right-to-left shunt and some right ventricular hypoplasia [17]. In another variant, a 20mm long narrow tube-like structure from the sinus venosus valve passed through the tricuspid valve and resembled a mass on an echocardiogram [18].

Cor triatriatum dextrum may not be recognized until an older age and the symptoms include ascites, weight loss and other signs of elevated venous pressure [19].

Rhabdomyoma

As indicated in Chapter 66, rhabdomyomas are the most common cardiac tumor in children overall and by far the most common in neonates. Associated with tuberous sclerosis in many (30–50%), they can arise in any cardiac chamber, but more frequently in the left side of the heart. Typically they arise in papillary muscles, from the ventricular septum, or in either atrium. In any location they are intramyocardial and not pedunculated. If large they obstruct flow through cardiac chambers. We have seen two neonates with a tumor that obstructed RV inflow arising in the right ventricle immediately below the tricuspid valve. Because of the obstruction, cyanosis occurred from an atrial septal defect. The tumors can be multiple and vary in size. They may be identified by echocardiography as a bright reflective mass(es). Although they may regress, they also can increase in size, becoming more obstructive. In cyanotic neonates the tumor can be resected with a risk of ~5%.

In two other conditions of neonates, a tumor-like mass can be present in the right atrium and prolapse through the tricuspid valve, causing obstruction. Premature infants weighing <1.5 kg are particularly prone to fungal infections because they are immunocompromised, require invasive therapy, such as indwelling catheters, and usually receive broad-spectrum antibiotics and occasionally steroids [20]. They can develop intracardiac fungal masses often attached to an indwelling catheter. We have seen them as large as 2 × 2cm, prolapsing through the tricuspid valve during diastole. Portions can embolize to the lung. The mass can be removed by cardiac surgery using inflow stasis [21].

Multiple small pinpoint cysts are commonly found on the atrial surfaces of atrioventricular valves at autopsy of infants up to 6 months of age. A cyanotic 4-month-old was found

with a large cyst shown by cineangiography to move freely though the tricuspid valve [22]. This angiogram also showed an atrial right-to-left shunt. At operation, the right atrium was filled by a large smooth bluish mass attached to septal leaflet by a thin 5 mm pedicle. The mass protruded into the right ventricle. It was found to be a unilocular cyst filled with blood and lined by endothelium.

Children and adolescents

Whereas much emphasis in this chapter has focused on neonates and infants, the lesions obstructing flow into the right ventricle can persist or appear in older children and adolescents. In these, the jugular venous pulse can be elevated, the liver enlarged, ascites present, and exudative enteropathy present. The patient may have mild cyanosis from an atrial right-to-left shunt as in older patients with a mildly hypoplastic right ventricle. The features resemble those of constrictive pericarditis (Chapter 59) or restrictive cardiomyopathy (Chapter 58).

Tricuspid stenosis (TS)

In tricuspid stenosis, abnormalities of each component of the valve can lead to obstruction. The tricuspid valve may be affected in rheumatic fever and develop changes associated with rheumatic heart disease. It is part of rheumatic multi-valvar disease, in which the mitral and aortic valves are also abnormal (see Chapter 62). The valve can become stenotic with fused commissures, thickened leaflets, and fixed stenotic orifice. Tricuspid stenosis of this cause is found predominantly in the developing world.

Congenital TS accounts for 0.3% of all congenital heart disease and usually coexists with other cardiac anomalies. Various types of deformity of leaflets (thickened, redundant), chordae (shortened, reduced interchordal spaces), commissures (fused) and annulus (narrowed), occurring alone or in combination, can narrow the tricuspid orifice [23,24]. The mortality is related to the age of the patient and underlying etiology. Tricuspid stenosis has been significantly reduced by balloon valvoplasty [25–27]. Rarely, TS is related to systemic lupus erythematosis or with endocarditis. Endocarditis on TV is relatively uncommon, even in i.v. drug users [28–30]. It can occur in children with a structurally normal heart. A large vegetation may obstruct the valve orifice.

Congenital polyvalvular disease

It was Bharati and Lev who gave the name congenital polyvalvular disease to a complex in which each of the cardiac valves is involved in a dysplastic process [31]. The leaflets are irregularly thickened, immobile, redundant, and often stenotic. The chordae are shortened, thickened, and nodular. There is an increase in spongiosa with degeneration and a lack of elastic tissue in the leaflets [32]. An increased amount of acid mucopolysaccharides is found in the valves. The condition has been found in trisomy 18 and trisomy 13–15 and is rare otherwise [33].

Tricuspid stenosis from interventional procedures

Tricuspid stenosis can follow interventional procedures. Reports have described the development of tricuspid stenosis years after placement of pacemaker leads through the tricuspid valve into the right ventricle [34–36]. The valvar change has been attributed to perforation of a cusp and to inflammation and fibrosis of the leaflets from a redundant pacemaker lead. It leads to elevated venous pressure and can result in ascites and can be treated by balloon valvoplasty. Severe tricuspid stenosis has also followed placement of an Amplatzer device for closing a perimembraneous ventricular septal defect in which the device caused adherence of the device to the septal leaflet [37].

Right atrial myxoma

These tumors can be found in patients as young as 3 years of age, but much more commonly in adolescents. Overall they are predominately found in adults, ~75% in females. As indicated in Chapter 66, atrial myxoma accounts for half of primary cardiac tumors. Up to 25% are found in the right atrium. In the right atrium they can reach twice the size of one in the left atrium before causing symptoms [38]. Usually originating from the atrial septum by way of a pedicle, they can protrude into the tricuspid orifice and cause obstruction. The patient experiences fatigue and peripheral edema and then progressive signs of right heart failure.

Portions of the tumor may embolize to the lungs, causing acute symptoms or the findings of pulmonary hypertension if the emboli are small, multiple, and recurrent. There may be constitutional symptoms of fever, joint pains, and weight loss, with laboratory findings of increased acute-phase reactants. The tumor is recognizable by echocardiography and can be resected with a small risk of recurrence.

Carcinoid syndrome

Carcinoid syndrome is characterized by diarrhea, flushing of the head and upper chest, and bronchospasm. It results from a carcinoid tumor often located in the appendix, but it can arise elsewhere in the gastrointestinal tract. The tumor may

metastasize and those which do to the liver are believed to cause carcinoid cardiac disease [39]. The cardiac lesions are thought to result from large amounts of circulating serotonin. The lesions are found predominantly on the ventricular surface of the tricuspid valve and the arterial surface of the pulmonary valve, the endocardial surfaces of the right ventricle, and the lining of the vena cava and pulmonary artery. Plaques of fibrous tissue form on the tricuspid valve, making it thick, rigid, and stenotic, and at times regurgitant. An echocardiogram shows valvar thickening. The youngest patient with carcinoid syndrome was 10 years old.

30 Left Ventricular Outflow Obstruction: Aortic Valve Stenosis, Subaortic Stenosis, Supravalvar Aortic Stenosis, and Bicuspid Aortic Valve

Colin McMahon

Our Lady's Children's Hospital, Crumlin, Dublin, Ireland

Introduction

Left ventricular outflow tract (LVOT) obstruction describes any obstruction to the egress of blood from the left ventricular cavity to the aorta. This may include one or more forms of obstruction, including subvalvar aortic stenosis (SAS), valvar aortic stenosis (AS), or supravalvar aortic stenosis (SVAS). SAS is unique as it is an acquired form of congenital heart disease whereas AS and SVAS obstruction tend to be congenital. The aortic valve morphology varies significantly in AS, although a bicuspid aortic valve (BAV) may exist with or without significant obstruction.

Incidence and genetics

The incidence of AS is reported as 0.4 per 1000, of SAS as 0.09 per 1000, and of SVAS as 0.05 per 1000 [1]. LVOT obstruction is not unique to humans. SAS is commonly encountered in Newfoundland puppies and similarly to humans tends to occur outside the neonatal period [2]. Genetic factors have been implicated in several forms of LVOT obstruction. BAV occurs in several families and is strongly associated with coarctation of the aorta [3]. Elastinopathies occur in both recognized syndromes such as Williams syndrome (chromosome 7q11.23 gene deletion) and familial non-Williams SVAS [4,5]. There are rare familial examples of SAS, but this is less common than familial SVAS [6].

Aortic valvar stenosis

Valvar AS accounts for 60–75% of LVOT obstruction. BAV is the most common congenital cardiac anomaly but may not come to attention until later in life when aortic valve dysfunction in the form of either stenosis or regurgitation ensues [7,8]. Valvar AS accounts for 3–6% of all cardiac defects [9]. There is a male to female ratio of 4:1. Recurrence risk is reported as 8% for mothers and 3.8% for fathers with AS [10]. Associated anomalies are recognized in 20% of patients and include coarctation of the aorta, interrupted aortic arch, ventricular septal defect and pulmonary stenosis.

Pathology

Valvar AS is associated with malformation in the aortic leaflet cusps and commissures. The valve develops by cavitation of three tubercles, two of which are positioned on the distal edge of truncal swellings involved in partitioning the primitive trunk and the third opposite to these [11]. Stenosis results from a failure of separation of the tubercles. The valvar leaflets are thickened with reduced excursion of the leaflets due to fusion of the commissures. There is a wide variation in the valve morphology, including unicuspid, bicuspid, tricuspid, or quadricuspid. There may be only a tiny aperture in critical stenosis. The most common pattern is a BAV with a single fused commissure and eccentric orifice. The deficient or absent commissure is intercoronary in the majority of bicuspid valves with right anterior and left posterior functional commissures. When the left

noncoronary or right noncoronary commissure is deficient, the commissures are left anterior and right posterior.

During systole, the limitation in valve opening often results in valve leaflet doming. The aortic annulus is hypoplastic in many patients. Critical neonatal AS results in severe left ventricular hypertension, left ventricular hypertrophy, and finally endothelial disruption represented as endocardial fibroelastosis (EFE) [12]. EFE occurs initially in the subendocardial region and rarely extends to the subepicardial region. In such patients, left ventricular filling is compromised, reducing atrial level shunting; consequently, right ventricular output through the ductus predominates, with resultant hypoplasia of the ascending aorta and aortic arch, left ventricle, and mitral valve. In older children, the left ventricular pressure loading results in left ventricular hypertrophy but not EFE.

Physiology

Valvar AS is characterized by a systolic pressure gradient between the left ventricle and aorta because of obstruction at the valve. LVOT gradient is a function of flow and annulus/aortic orifice size. This is not a linear relationship, however, and a doubling of blood flow has a squared result in gradient (increased by four). The Gorlin equation calculates the aortic valve area, AVA (cm^2 m^{-2}), as [13]

$$
\begin{aligned}
AVA \; &(\text{cm}^2 \, \text{m}^{-2}) \\
&= \frac{\text{flow / systolic - second (ml m}^{-2})}{44.5\sqrt{\text{mean gradient (mmHg)}}} \\
&= \frac{\text{stroke volume (ml m}^{-2}) \, / \, \text{systolic ejection time (s)}}{44.5\sqrt{\text{mean gradient (mmHg)}}}
\end{aligned}
$$

Severe aortic obstruction has an AVA of <0.5 cm^2 m^{-2}, moderate between 0.5 and 0.8 cm^2 m^{-2}, mild >0.8 cm^2 m^{-2}, and normal 2.0 cm^2 m^{-2}. Changes in preload or afterload systemic resistance may alter the true LVOT gradient, and simultaneous flow and pressure need to be measured to calculate LVOT obstruction accurately. Generally, a peak systolic pressure >60 mmHg and an aortic orifice <0.5 cm^2 m^{-2} constitute severe AS.

Hemodynamics

Valvar AS results in increased left ventricular systolic pressure, increased wall stress, and peak myocardial force. Wall stress increases as the left ventricular pressure increases but returns to normal in the setting of compensatory left ventricular hypertrophy (LVH). In older children, left ventricular function tends to be preserved or hyperdynamic, as a consequence of left ventricular hypertrophy and reduction in LV cavity size. Only in younger children or neonates is the development of left ventricular dysfunction typically encountered. End-systolic wall stress is inversely related to left ventricular function and hyperdynamic systolic function. In patients with AS, hyperfunction is a result of reduced end-systolic wall stress rather than increased myocardial contractility.

End-systolic wall stress is reduced because end-systolic wall thickness is increased, and end-systolic pressure is normal. At twice the normal cardiac output, increased cardiac output depends primarily on increase in heart rate and less so on increase in stroke volume. At higher exercise levels, there is a progressively higher stroke volume with a sharp increase in gradient, the change being proportional to the square of the increase in flow velocity. This reduces the filling time, which restricts coronary blood flow, particularly in the subendocardial region where flow is almost entirely diastolic. An estimate of potential coronary flow can be made from the area between the aortic and left ventricular diastolic pressures, the diastolic pressure time index (DPTI) [14]. The left ventricular oxygen requirement can be obtained from the area under the ventricular pressure curve during ejection, the systolic pressure time index (SPTI). In the absence of coronary disease, the DPTI/SPTI ratio allows a measure of the oxygen supply/demand ratio (see Chapter 4). Patients with an aortic valve area <0.7 cm^2 m^{-2} and a heart rate of 100 beats per minute have a DPTI × arterial oxygen content (g dl^{-1})/SPTI ratio <10, consistent with subendocardial ischemia [15]. With exercise-induced tachycardia, the diastolic filling time is reduced even more than the systolic ejection time, and myocardial oxygen delivery is decreased as systolic work is increasing.

Electrocardiographic ST depression appears consistently in left ventricular leads during exercise in patients with a resting LVOT catheter gradient of ~50 mmHg [16]. This level of obstruction can result in myocardial injury and subendocardial fibrosis, which may manifest as chest pain, syncope, arrhythmia, or sudden cardiac death. Ventricular arrhythmia is particularly a risk in a scarred dilated ventricle. Left ventricular baroreceptors may contribute to syncope in AS [17]. Any stimulus that elevates left ventricular systolic pressure may stimulate these receptors, resulting in vasodilatation that could reduce coronary flow. Left ventricular diastolic function may be impaired even when systolic function is well preserved [18]. As LVH progresses, elastic recoil and ventricular relaxation rate are reduced, so that passive chamber stiffness increases and active relaxation becomes impaired.

Natural history

The natural history of AS is related to the degree of LVOT obstruction. About 10% of patients presenting in childhood develop congestive heart failure in the first year of life, two-thirds in the first 2 months [19]. Patients with AS with hypoplastic left heart syndrome who are "duct dependent" experience circulatory collapse once ductal closure occurs

(see Chapter 38). Patients with borderline left ventricular dimensions may manage to maintain reasonable cardiac output, but at the cost of developing pulmonary venous and arterial hypertension later in life.

Patients with trivial AS may show minimal progression. Half of patients presenting with mild or moderate AS remain unchanged over one to two decades [20]. In a large natural history study of over 400 patients over 2 years of age, predicted survival in an age-matched normal population was 96%; 25-year survival of study patients was 92.5% for those with an initial catheter gradient <50 mmHg and 81% in those with a gradient ≥50 mmHg [21]. Sudden death from cardiac arrhythmia increases when the catheter-derived gradient exceeds 50 mmHg. An increase in severity occurred in 30–50% of patients with mild AS (gradient <40 mmHg) and 70–90% of patients with moderate AS (50–79 mmHg) [21,22].

History and physical examination

Persons with trivial to mild AS are asymptomatic and may present with a murmur. In patients with moderate to severe AS, symptoms may include exercise intolerance, chest pain, dyspnea, or syncope. Neonates with critical AS (including hypoplastic left heart syndrome) often present with circulatory collapse presenting with tachypnea, dyspnea, pallor, thready pulses, and acidosis. Failure to re-establish ductal patency promptly results in death secondary to acidosis, multiorgan failure, and arrhythmia.

Although a typical ejection murmur may be heard at birth with mild to moderate AS, the murmur is often minimal when obstruction is extreme and flow is low. Infants with mild or moderate AS have signs similar to those in older children. Beyond 1 year, most patients with mild AS (Doppler gradient 30–40 mmHg or catheter gradient 25–30 mmHg) have no cardiac symptoms, and 95% show normal growth and development [23]. Symptoms are rare in patients with moderate AS (Doppler gradients <70 mmHg or catheter gradients <55 mmHg), although as this level is approached a lack of competitive stamina is sometimes evident. Syncope occurred in 9% of patients with a catheter gradient >80 mmHg. In children, the typical signs of mild AS include normal venous pressure and a pulse that is normal or slightly jerky. There is a long ejection systolic murmur radiating to the suprasternal notch and usually associated with a thrill, and the second heart sound varies normally with respiration. As the severity of AS increases, the frequency of the murmur rises. With moderate obstruction, the A wave amplitude of the jugular venous pulse becomes more prominent over the years, resulting from impaired right heart filling from LVH. The signs most reliably related to moderate obstruction are not the intensity of the murmur but a reduction in pulse pressure and the respiratory variation in splitting of the second heart sound. A slowly rising pulse as a sign of severity is much less common in children than in adults.

Splitting of the second heart sound is narrowed as there is delayed valve closure due to prolonged left ventricular ejection interval. In some patients, splitting of the second sound may only be heard in expiration. An ejection click often present after the first heart sound is best appreciated in the fourth left intercostal space, apex, and lower left back. With increased stenosis, the click moves closer to the first heart sound. Aortic regurgitation (AR) is characterized by a diastolic descrescendo murmur. An Austin Flint murmur secondary to the regurgitant jet abutting the anterior leaflet of the mitral valve may be appreciated in mixed aortic valve disease.

Electrocardiography and exercise testing

A normal ECG does not exclude significant AS. LVH does not discriminate between the AS severity (Figure 30.1). However, LVH with a strain pattern usually indicates severe AS. Right ventricular dominance is usual regardless of the severity of AS in the early weeks of life, but left ventricular dominance and hypertrophy become manifest in three-quarters of older infants with important AS and normal left ventricular volume [24]. A sum of the voltages of the S wave in V_2 and the R wave in V_6 of 40 mm carries ~70% probability of LVH at any age. ST or T wave depression is virtually diagnostic of significant LVH.

Exercise stress testing adds further information regarding the severity of AS. There is some correlation between severity of AS and exercise duration, systolic blood pressure response, and ST segment depression with maximal exercise. ST depression >1 mm for more than 0.08 s after the J point has been reported to indicate a resting gradient >50 mmHg by catheter [25]. However, further studies showed a false-positive rate of up to 40% in patients with gradients of 30 mmHg [26]. Stress testing does not reliably indicate severity of AS.

Chest radiography

In infants with congestive heart failure secondary to AS, the chest radiograph demonstrates cardiomegaly with plethoric lung fields. In older children, the degree of pulmonary plethora is less significant. In critical neonatal AS, left-to-right shunting at the atrial level contributes to the pulmonary overcirculation. In older patients, poststenotic dilatation of the ascending aorta is a feature.

Echocardiography

Echocardiography is central in assessing AS and has supplanted the need for diagnostic cardiac catheterization. Standardized imaging planes include subcostal, apical parasternal, and suprasternal imaging planes.

Parasternal long-axis views allow evaluation of leaflet thickening and doming of the aortic valve in systole. Imaging in the parasternal short-axis plane usually allows visualization of leaflet anatomy, establishing the orientation of the

(a)
(b)

Figure 30.2 Two-dimensional echocardiograms in the parasternal short-axis plane demonstrating (a) a bicuspid aortic valve and (b) a unicommisural valve with dilated aortic root.

opening plane and allowing judgment of leaflet numbers and structure (Figure 30.2a). A valve that appears to be tricommissural in diastole (even though somewhat distorted) is frequently shown in systole to be essentially bicommissural but with a raphe in the fused leaflet. Some degree of fusion is also frequently shown at one of the two commissures; if marked, this can effectively produce a unicommissural valve (Figure 30.2b). Detailed two-dimensional and M-mode measurements are required to measure the aortic annulus and septal and free wall thickness and assess papillary muscle anatomy, left ventricular dimensions, and ventricular

function [27,28]. All values are compared with normal values. Assessment of the adequacy of the left ventricle and aortic arch, mitral valve, and aortic valve is particularly important in critical AS in the newborn. A highly echogenic endocardium suggests EFE, particularly with regional motion abnormalities.

Pulsed-wave, continuous-wave, and color Doppler interrogations assess the site and severity of obstruction and associated lesions [29,30]. Assessment can be based on the left ventricular aortic gradient with the modified Bernoulli equation [31] or the valve area according to the

continuity equation [32]. The reliability of the simplified Bernoulli equation [2]:

$$\text{pressure gradient} = 4 \times \text{peak velocity}^2$$

has been validated. The peak instantaneous gradient is generally significantly higher than the peak-to-peak gradient recorded at cardiac catheterization [33], due partly to sedation or damping in catheter systems, but mainly to the difference in the phase of the pressure pulses recorded. The peak instantaneous and mean gradient are higher in patients with higher pulse pressures, a finding which may be associated with a lesser degree of AS and increased by the presence of coexisting AR. There is no consistent correction factor to allow comparison between catheter peak-to-peak and echocardiographic-derived peak instantaneous calculations. On average, catheter-derived measurements are 80% of the echocardiographically derived gradient in patients with critical stenosis.

An echocardiographically acquired *mean* gradient correlates better with the catheter-derived figure [29]. With echo Doppler, valve area is derived from a direct application of the continuity equation:

$$\text{valve area} = A(\text{LVOT}) \times \frac{V(\text{LVOT})}{V(\text{AV})}$$

where A = area, LVOT = left ventricular outflow tract, V = mean velocity, and AV = aortic valve. Meticulous alignment of the Doppler signal is essential. Because the LVOT and aorta share the same ejection volume, measurement is valid in the presence of AR.

Cardiac MRI

Cardiac MRI can accurately define aortic valve morphology (Figure 30.3) and also provides accurate flow velocity and valve gradient data using velocity-encoded cine magnetic resonance imaging. This demonstrates good correlation with Doppler-derived gradients [34].

Cardiac catheterization

Catheterization is rarely required to define the severity of stenosis. It is indicated in severe AS or children with symptoms such as syncope, dizziness, or angina with a mild to moderate AS. Cardiac output is measured using the Fick methods or thermodilution. Left and right heart catheterization are performed. The left heart is accessed either anterograde with the transseptal puncture technique or in many centers retrograde via the femoral artery. The simultaneous recording of pressure in the left ventricle and ascending aorta is best to determine valve gradients, although a "pullback" of the catheter across the valve will also determine the gradient. The Gorlin equation is used to calculate valve area. This equation assumes that 100% of the pressure drop across
Figure 30.3 ECG-gated MRI cine bright blood with fast gradient echo image demonstrating trileaflet aortic valve in the short-axis view. AOV, aortic valve.

the aortic valve produces flow. Discrepancies have been noted between valve areas calculated from the Gorlin equation and actual measured areas, with questionable increases during exercise and questionable measurements at low flows [35–37]. An *in vitro* model showed that the estimate from the Gorlin equation of a known area increased directly with increase in flow, so that substantial errors are to be expected at both low and high flows [38]. At a critical point, small errors become important – an area of $0.6\,\text{cm}^2\,\text{m}^{-2}$ is on the margin of the severe range, and an area of $0.8\,\text{cm}^2\,\text{m}^{-2}$ is in the mild to moderate range. The Gorlin equation remains the basis for comparisons with other methods, but it is by no means a true "gold standard."

Gaining retrograde access to the left ventricle may be challenging in a severely stenotic valve and requires careful, delicate manipulation of the catheter. Left ventricular angiography allows visualization of the valve doming, tethering of leaflets, and the jet of AS. This is best performed using cranial tilt of the left anterior oblique view and straight

oblique views (usually about 60° left anterior oblique and 30° right anterior oblique) of the annulus.

After valve dilatation, the degree of AR should be assessed. A typical convention describes the AR as mild if opacification of the left ventricle does not equal that of the aorta, moderate if opacification is equalized after three cycles, and severe if it is equalized in less than three cycles [39]. The AR volume can be calculated by subtraction of net forward flow (calculated by the Fick method) from the total flow derived from angiography.

Comparison between catheter- and doppler-derived gradient

In adults, catheter peak-to-peak gradients averaged about 80% of Doppler peak instantaneous gradients with reasonable correlation but moderate scatter [40]. Interestingly, Doppler peak instantaneous gradients in these studies averaged only slightly above 80% of catheterization peak instantaneous gradients, primarily due to poor alignment of the Doppler signals in adult studies. Currie *et al.* showed an excellent correlation between simultaneous catheter and echocardiographic peak instantaneous gradients in children [41]. Assessments of mean gradients by echo Doppler and catheterization are much closer, catheter figures ranging from 2 to 4 mmHg higher on average than echo Doppler figures. Although more accurate, the mean gradients warranting intervention are less well established. For example, in an adult population judged to need operation because valve area was <0.75 cm², all patients had a mean gradient of >30 mmHg, and more than half >50 mmHg [42]. In children, by contrast, 11 patients with a mean gradient in the range 17–27 mmHg were judged to need operation [30]. A Doppler peak instantaneous gradient of 90–100 mmHg (equivalent to a peak-to-peak catheter gradient of >75 mmHg) or a valve area of 0.5 cm² m⁻² usually justifies early intervention. A Doppler peak instantaneous gradient of 70 mmHg (equivalent to a peak-to-peak gradient of ~55 mmHg) or an area <0.7 cm² m⁻² warrants intervention in the presence of symptoms or LVH with strain. Intervention may be judged appropriate in patients with a catheter or Doppler mean gradient of 30 mmHg, but a level of 50 mmHg is more common in older patients.

Treatment

Treatment is dictated by the severity of LVOT obstruction in addition to the size of the left heart structures and left ventricular volume. In the majority of children with mild AS there may be no indication for therapy. Treatment of AS can be described for children before and after 1 year of age and in the fetus. The UK National Institute for Health and Clinical Excellence (NICE) guidelines report increased risk of endocarditis in patients with valvar disease with either significant stenosis or regurgitation [43].

Fetal management of aortic valvar stenosis

Fetuses with AS have demonstrated progressive arrest of growth of the left ventricle, aortic valve, and mitral valve. This prompted the development of *in utero* interventional treatments in an attempt to alleviate LVOT gradient and allow potential biventricular repair. Kohl *et al.* reported the first series of 12 patients in which seven procedures were successful but only one fetus survived [44]. Other early reports demonstrated technical success but poor outcome [45]. A recent study of 70 fetuses with critical AS reported technical success in 74% with 17 patients reaching biventricular repair [46]. Nine pregnancies did not survive. Despite the investigators devising a multivariable threshold scoring system to define patients with poor prognosis, patient selection remains a challenge (see Chapter 16).

Management of infants younger than 1 year

Neonatal aortic stenosis

Infants presenting with critical AS or AS with the hypoplastic left heart syndrome or a borderline left ventricle represent the most seriously affected group. They may undergo acute cardiogenic collapse from ductal constriction or closure and loss of right ventricular systemic output. Immediate initiation of prostaglandin therapy is needed to re-establish cardiac output. Cardiorespiratory and inotropic support and mechanical ventilation are required. Balloon valvoplasty is the appropriate procedure in isolated AS. In neonates with a hypoplastic mitral valve and left ventricle, a single ventricle strategy is best adopted if parents agree. The most challenging group of patients is those with AS and a borderline left ventricle. Pursuing a biventricular approach in these infants may result in survival but at the cost of later pulmonary hypertension that may make cardiac transplantation impossible. Patients with severe AS and a small left ventricle and marked EFE may not respond well to valvoplasty and high left heart filling pressures may result in progressive pulmonary hypertension.

The aortic valve annulus, mitral annulus, and left ventricular volumes should be indexed to BSA and Z-scores derived. Additional features including non-apex forming left ventricle, hypoplastic mitral valve, EFE, infarction of papillary muscles, mitral regurgitation, and retrograde flow in the ascending aorta should be considered in the decision for biventricular repair [47,48]. Specific factors associated with a poor outcome include end-diastolic volume <20 ml m⁻², left ventricular inflow dimension (aortic annulus to apex) <25 mm, aortic annulus <5 mm, and mitral annulus <9 mm [49]. The Rhodes score was derived to predict likelihood of

good prognosis in neonates with aortic valve stenosis. This correctly predicted outcome in ~90% of patients, a discriminating score less than −0.35 predicting death:

$$score = 14.0(BSA) + 0.943(AOi) + 4.78(LAR) + 0.157(MVAi) - 12.03$$

where *BSA* is body surface area, *AOi* and *MVAi* are aortic sinus dimension and mitral valve area indexed to body surface area, respectively, and *LAR* is the ratio of the long axis of the left ventricle (from the plane of the mitral valve annulus to the apex of the ventricle) to the long axis of the heart (apical four-chamber view of the distance from the crux of the heart to the apical endocardium, either left or right ventricle, whichever forms the apex of the heart) [50].

If the score is below the critical level, a single ventricle palliation may be offered. There may be a higher risk of poor outcome in neonates with a borderline LV and significant LV mass in a single ventricle due to LV–RV interaction. Other crucial parameters in outcome are left ventricular function, rate, and potential for growth of left heart structures postoperatively. Colan *et al.* highlighted that minor errors in measurements of left-sided structures could result in an erroneous score [51].

Surgical intervention

Surgical valvotomy for isolated AS is less frequently required, given the improvements in interventional catheterization technology and techniques. Valvotomy is palliative and not curative. It may be indicated if the valve is unsuitable for balloon valvoplasty, cannot be crossed, or does not respond to dilatation. Valvotomy has excellent results with a low mortality among patients with normal ventricular function. Aortic commissurotomy can be performed with excellent alleviation of LVOT obstruction and minimal aortic valve regurgitation. When the surgeon attempts to abolish the valve gradient completely, moderate to severe AR may result. In one recent study of 36 patients after surgical valvotomy, 15 of whom had depressed left ventricular systolic function [52], there were no deaths among patients with normal left ventricular function but mortality increased to 47% among those with depressed left ventricular function. Several reports have demonstrated a good reduction in gradient with low mortality [53–58]. Aortic valve morphology has a significant impact on outcome. Commissurotomy resulting in trileaflet anatomy reduced mortality (0 versus 5%) and risk of reintervention (33 versus 92%), aortic reoperation (45 versus 92%) and aortic valve replacement (57 versus 100%) compared with patients with BAV [59]. Actuarial survival was 100% compared with 85% in favor of trileaflet valve morphology. A subgroup of children undergoing surgical valvotomy with restrictive left heart filling developed persistent pulmonary hypertension [60].

Balloon valvoplasty

Balloon valvoplasty is recommended in most centers if the severity of AS exceeds 60 mmHg gradient with a normal cardiac output or an effective aortic orifice <0.5 cm^2 m^{-2}. Valvoplasty is also indicated in patients with LVH and strain or with symptoms at a lower gradient. In some centers, valvoplasty is undertaken with a gradient exceeding 50 mmHg. Valvoplasty is often undertaken in children with coexisting coarctation but not with other significant intracardiac lesions or the presence of mild or more severe aortic valve regurgitation.

Reports of valvoplasty in the 1980s demonstrated this to be an effective mode of treatment [61–63]. A balloon to annulus (BAR) ratio of 0.9–1.0 is advocated with many centers using a balloon diameter 1 mm less than the aortic annulus to avoid creating significant AR. Successful valvoplasty is considered to be a 60% reduction in peak-to-peak systolic echo gradient [64–67]. A recent study reviewed 1004 patients between 1 day and 18 years of age who underwent balloon aortic valvoplasty between 1985 and 2006 at 20 European centers [68]. The mean pressure gradient decreased from 65 (±24) to 26 (±16) mmHg and remained stable during a mean follow-up of 32 months. Newborns in the study had the most significant disease, with 60% manifesting impaired LV function predilatation. Complications occurred in 15% of newborns, 11% of infants, and 6% of older children. Freedom from intervention at 10 years was 50%. Severe AR may result from a tear of the valve cusp or raphe or valve detachment (Figure 30.4). Other complications from

valvoplasty include arrhythmia, bleeding, stroke, thrombosis, mitral valve injury, and rarely death. In the collaborative Valvuloplasty and Angioplasty of Congenital Anomalies (VACA) Registry, four of the five deaths among 204 patients occurred in infants younger than 1 month, as did all three life-threatening arrhythmias [69]. Loss of the femoral pulse may occur in 10% of children younger than 1 year of age [70]. Failed balloon valvoplasty, defined as residual gradient >60 mmHg or >50% of predilatation gradient, occurs in up to 30% patients. Factors in such patients include a dysplastic thickened valve, BAR ratio <0.9, age <3 months, and unrepaired coarctation. Balloon valvoplasty exacerbates AR in 20–70% of patients, 10% of which may be severe [71,72].

Technical aspects of balloon valvoplasty

Aortic valvoplasty may be performed via the femoral artery, carotid artery, or the umbilical artery. Outcomes are similar with either anterograde or retrograde approaches [64]. The femoral artery approach is often used in older children but the carotid approach may be required in neonates. The umbilical arterial approach has been used but it limits balloon manipulation. In older children, an anterograde approach can be used with a transseptal procedure and this is increasingly employed in neonates. Retrograde access can be achieved by placing an appropriately curved catheter above the aperture in the valve and advancing a small-gauge soft-tipped wire to the left ventricle. From an aortogram, the jet stream can be identified, which will aid entry into the left ventricle. Once entered, an extra-stiff wire with a soft tip can be curled in the left ventricle to maintain balloon stability.

The balloon should have a BAR ratio of 0.9–1.0. Firm control of the catheter shaft avoids displacement to either the left ventricle or aorta. Adenosine has been used in the past to produce temporary asystole and prevent valve tearing during valvoplasty [73]. Rapid ventricular pacing has also been used to stabilize balloon inflation [74]. Full dilatation should be maintained for about 4–5 s, and the balloon should be withdrawn to the aorta after dilation. Additional valvoplasty is not performed as it may exacerbate AR. A trivial increase in AR has been reported in 14% and moderate or severe AR in 4% of patients [75,76]. The risk of AR is greater in unicuspid valves. Permanent pulse loss occurred in 5–10% of patients, the risk being higher in infants. The use of low profile compliant balloons in adults achieves excellent alleviation of the aortic valve gradient with no mortality or worsening of AR [77]. Left bundle branch block, complete atrioventricular block, ventricular ectopics, and ventricular tachycardia have also been reported. Cardioversion or temporary pacing may occasionally be required. The mortality rate is 1%. The success rates of balloon aortic valvoplasty and surgical valvotomy are comparable [65,78].

Hybrid approach in children with borderline left ventricle

A hybrid approach may allow some children with a borderline left ventricle to achieve a biventricular repair. This approach includes ductal stenting, balloon atrial septostomy (± stent implant), and banding of the pulmonary arteries. This approach gives the left ventricle several months to adapt to lower pressure and normoglycemic conditions, and may allow the infant to bridge to a biventricular repair [19].

Management of children older than 1 year

Surgical intervention

The surgical mortality is less than 2% in this age group [61–63]. The commissures are incised judiciously to mobilize the fused leaflets and yet avoid AR. Patients >1 year of age have a better prognosis than younger children as the left ventricle is capable of sustaining cardiac output. Survival after surgical valvotomy is 95% at 5 years, 85% at 15 years, and 75% at 25 years [79]. Mild to moderate AR was reported in 10–28% of patients after valvotomy; AR may progress and be underestimated on clinical examination. In the Second Natural History Study, moderate or severe AR was diagnosed at follow-up of unoperated patients in 8% by clinical evaluation and 24% by echocardiography [80]. Among the operated patients, these figures were 12 and 30%, respectively. The need for reoperation begins 4–5 years after the first procedure, and up to 40% of patients require a second operation by 25 years [80].

Surgical intervention may include a Ross procedure, in which the pulmonary valve is placed within the aortic valve position and a biological valve replaces the native pulmonary valve. This procedure has the benefit of the valve growing as the child grows and avoids the need for anticoagulation. It tends to be favored in young children and older adults. It remains an option for younger adults. In a recent study of 487 patients who underwent the Ross procedure, survival was 82% at 16 years and hospital mortality 3.9% [81]. Freedom from reintervention was 82% and from autograft failure was 83%. Other studies have demonstrated similar freedom from valve reintervention of 95% at 8 years of follow-up [82]. A disadvantage of the Ross procedure is operating on both semilunar valves in a single valve disease. There have been several reports of neoaortic root dilatation, usually most dramatic in the first year, after which it levels off [83,84]. In a small group of patients, significant AR developed particularly when the Ross procedure was undertaken for AR [85,86]. The degree of AR is usually mild and remains relatively static. The need for further aortic valve replacement is 10% over 20 years. Additional postoperative complications include pulmonary homograft obstruction, usually amenable to balloon dilatation or percutaneous valve implantation.

Patients with combined AS and SAS may undergo a Ross–Konno procedure in which the subvalvar area is extensively reconstructed using an aortic ventriculoplasty.

Balloon valvoplasty

Balloon valvoplasty remains the treatment of choice in older children as it is less invasive and avoids cardiac bypass. Gradients on average are decreased from 70 mmHg or higher to 30 mmHg [69,87,88]. In the VACA study, 192 of 204 patients showed some benefit [69]. In patients in whom the BAR ratio is 0.9–1.0, there is minimal risk of valve damage and significant AR. Annulus size should be measured by echocardiography and aortography to ensure accurate measurement.

Prognosis

Long-term prognosis is worse in those presenting at a younger age with a significant obstruction or left ventricular dysfunction. Continued medical management helps preserve left ventricular function and minimize the risk of both sudden death and heart failure. Many patients will require future aortic valve replacement. Approximately 50% of patients avoided the need for aortic valve replacement at 10 years following balloon valvoplasty [68]. Long-term survival has been around 75% at 5 years, 60% at 10 years, and 40% at 15 years [89]. Although intervention in patients with aortic valve stenosis is often palliative, exercise capacity, NYHA status, and survival are generally good.

Percutaneous aortic valve replacement

Percutaneous aortic valve implantation (PAVI) is a procedure gaining popularity and becoming more widely used for the treatment of patients with severe AS at high risk for operation. Two devices are under evaluation, the CoreValve ReValving System and the Edwards SAPIEN valve [90]. Both devices are generally deployed retrogradely, mainly trans-femorally or via the subclavian artery, or, less commonly, transapically. Initial experience has been encouraging, with good short-term outcomes. Long-term data are lacking. Currently PAVI is advocated only for symptomatic high-risk older patients with AS. One series reported a reduction in peak LVOT gradient from 83.8 ± 23 to 12.6 ± 6 mmHg [91]. In a recent study of 30 adult patients (mean age 80 years) who underwent PAVI using the CoreValve ReValving System [92], implant was successful in 90% of patients with a reduction of peak from 76 ± 24 to 22 ± 7 mmHg at 30 days after device placement. Major adverse cardiovascular and cerebral events occurred in seven patients.

Subaortic stenosis

Subaortic stenosis (SAS) is a heterogeneous group of conditions that are either isolated in one-third of patients or associated with specific congenital cardiac lesions including atrioventricular septal defect, ventricular septal defect, coarctation, interrupted aortic arch, or double-chambered right ventricle [93–95]. It may develop after surgical repair of primum atrial septal defect [96]. SAS accounts for 15–20% of patients with LVOT obstruction and may be familial [97,98]. It is more common in males. In Shone syndrome, it is associated with a supravalvar mitral ring, parachute mitral valve, and coarctation of the aorta [99]. SAS is not a congenital lesion and typically develops after infancy [2,100].

Pathology

The most common forms of SAS include fibromuscular ridge, discrete membrane, and tunnel SAS. These may be combined, for example, a ridge with a discrete membrane. The membrane or ridge may extend to either the anterior leaflet of the mitral valve or the undersurface of the aortic valve leaflets. Histologically the ridge consists of irregularly oriented acellular dense collagen fibers, smooth muscle cell layer, elastic tissue, and abnormal myocytes with their own capillaries. There may be an intermediate group possessing some characteristics of ridge and membranous obstruction. Long narrow tunnel SAS can also occur in Shone syndrome. The degree of obstruction is SAS varies and may cause LVH. Some patients have an associated bicuspid aortic valve and a variable degree of AS. Over time, aortic valve function may be compromised by a systolic jet striking the aortic valve leaflets and in 40% of patients AR develops [101,102]. Aortic valve deformation may also result from extension of the ridge or membrane on to the aortic valve [103]. Feigl *et al.* described the involvement of at least one cusp of the aortic valve in 16 of 18 postmortem specimens and speculated that this is the mechanism of aortic valve damage and AR [104].

Pathogenesis

Although one fetus has been reported with SAS, the lesion develops after infancy and is recognized as an acquired condition [105]. The etiology is not fully known. An increased aortoseptal angle, increased mitral–aortic separation, and aortic override have been implicated in its development [106,107]. One study in patients with ventricular septal defect and coarctation reported an increased risk of SAS developing in patients with aortoseptal angle >135° or mitral–aortic separation >4 mm. The positive predictive value was 83% and the negative predictive value was 90% [107]. Another study demonstrated aberrant flow patterns by color Doppler flow in the LVOT proximal to the region of SAS, probably reflecting abnormal flow which would result in abnormal wall stress and endothelial proliferation [108].

Natural history

SAS tends to progress [109–111]. The median age of diagnosis is typically between 5 and 9 years [112,113]. Progression occurs in 75%, particularly in tunnel-type SAS and in patients younger at the time of diagnosis. The increase in

gradient across the LVOT may relate to an increase in thickness of the membrane or ridge or a narrowing of the LVOT tract in the tunnel-type obstruction [114]. This causes further septal and LVH that exacerbates the LVOT gradient. Detection of SAS has increased since the widespread availability of echocardiography and has resulted in its earlier diagnosis. Patients with coarctation, interrupted aortic arch type B, or double-chambered RV should be examined carefully because of an increased risk of SAS [115].

Over time, the SAS jet deforms the aortic valve and causes regurgitation. One study reported aortic regurgitation in 30% of patients at diagnosis, and this increased to 54% at a mean follow-up of 3.7 years [113]. Another study of 220 patients with SAS (109 of whom had SAS resection and 111 had no surgery) showed that risk factors for moderate to severe aortic regurgitation were older age at diagnosis, previous balloon or surgical aortic valvoplasty, and a longer follow-up period [102]. Excluding patients with previous surgical or balloon aortic valvoplasty, a higher maximal Doppler gradient was an independent risk factor for moderate to severe AR. Although there is an increased risk of bacterial endocarditis, the incidence is low.

Clinical findings

Many children with SAS are asymptomatic and have a short systolic murmur. As the SAS progresses to moderate or severe obstruction, symptoms may include fatigue, dyspnea, syncope, or rarely chest pain. Physical findings may include a prominent left ventricular impulse, and at the left lower to right upper sternal edge a long ejection systolic murmur radiating to the carotid arteries. The A2 component softens. In some patients with aortic regurgitation, a diastolic murmur can be detected. Differentiating SAS from valvar AS may be challenging. Typically, an ejection click is not heard except in those with a BAV and AS.

Chest radiography is typically normal. Unlike valvar AS, the ascending aorta is not prominent. The electrocardiogram may demonstrate left ventricular hypertrophy with strain in patients with severe LVOT obstruction. The electrocardiogram, however, may not detect progressive severe LVOT obstruction.

Echocardiography

Echocardiography is the diagnostic modality of choice. A thorough segmental analysis should be performed in all patients. Two-dimensional imaging is performed in standard views (Figure 30.5). Color Doppler and spectral Doppler interrogation of the LVOT complete the data set. The anatomic details of the LVOT and involvement of the aortic valve and mitral valve leaflets should be evaluated carefully. Doppler interrogation of the LVOT should start at the LV apex in the four-chamber view and the cursor moved across the LVOT to the ascending aorta to determine the peak instantaneous gradient. The severity of AR should be determined using the vena contracta diameter, aortic

Figure 30.5 Two-dimensional echocardiogram in the parasternal long-axis view during systole demonstrating discrete fibromuscular ridge (arrow) in the subaortic region. Aortic valve leaflets (thin arrows) lie against aortic wall. AOV, aortic valve; LA, left atrium; LV, left ventricle; SAS, subaortic stenosis.

annulus/vena contracta ratio, and the presence of retrograde flow in the descending aorta [102,116–118]. Typically, measurement of the aortoseptal angle and mitral aortic separation is not performed [107]. In older patients, transesophageal echocardiography may be required for accurate analysis of SAS [119].

Cardiac catheterization

Cardiac catheterization is rarely needed in patients with SAS. If transthoracic echocardiography cannot define the subaortic gradient or severity of AR, then transesophageal echocardiography usually provides this information. In patients with coexisting valvar AS and SAS, a gradient pullback will help to define the location of the gradient as being primarily at the valvar or subvalvar level. If a left ventriculogram is performed, the optimal angiographic views of the LVOT are biplane axial angiography and cranial angulation in either left anterior oblique or lateral projections. Aortic angiography quantifies the severity of AR. Balloon angioplasty of SAS can be carried out, but the results are mixed [120].

Management – surgical intervention

Surgical resection usually involves ridge or membrane excision or enucleation, with or without surgical myectomy [121–123]. It remains contentious whether myectomy is required and whether this reduces risk of recurrence [123,124]. Any membrane or ridge that has extended on to the undersurface of the mitral valve or aortic valve leaflets is carefully peeled from the valve [125]. There is a very low morbidity and mortality from isolated membrane or ridge resection. A myectomy may increase the risk of complete heart block. Recurrence has been reported in 7–25% of patients at a mean follow-up of 4–5 years [123–128].

Progressive AR may occur in patients with unoperated SAS. Children with mild SAS gradients often exhibit little progression of valve dysfunction [121]. In those with a higher gradient, AR may progress after surgical intervention [121,129]. Endocarditis is rare after surgical intervention [121]. Indications for operation in fixed SAS remain contentious. Because the incidence of residual stenosis is increased in patients with a high preoperative gradient [130], and AR is associated with more severe obstruction, some have advocated excision or enucleation with a catheter gradient of 25–30 mmHg or a mean Doppler-derived or catheter-measured gradient of 30 mmHg [130,131]. Others recommend operation when the gradient is higher, or when there is progression of obstruction or regurgitation, because some patients with a mild or moderate gradient remain stable for many years. Surgical resection is generally recommended when the Doppler-derived peak instantaneous gradient is >50 mmHg or when there is associated mild or greater AR. Serial echocardiography is required to evaluate progression of SAS and AR. A model exists to predict the progression of the SAS gradient [132].

Patients with tunnel-type SAS undergo a Konno procedure in which the LVOT is augmented by an aortoventriculoplasty or valve replacement [133,134]. There is a higher risk of complete heart block with the Konno procedure [135]. In some patients who require aortic valve replacement also, a Ross–Konno procedure is undertaken [136]. Progressive dilatation of the neoaortic root may occur in the Ross population, particularly in patients with mismatch between the sizes of native aortic and pulmonary valves [137].

Recurrence of SAS

Recurrence risks range from 7 to 25% [123–128]. In a study of 111 patients following successful surgical resection of SAS [125], predictors of reoperation in 16 patients (14%) were a distance of <6 mm between the aortic valve and the obstruction and a Doppler peak gradient ≥60 mmHg. If intraoperative variables are also considered, peeling of the membrane from the aortic valve or mitral valve at first operation, a distance of <6 mm between the SAS and the aortic valve, and a Doppler peak gradient ≥60 mmHg were associated with recurrence. Dodge-Khatami *et al.* studied 58 patients and found younger age at operation, complex defects, residual postoperative gradient, and an aberrant right subclavian artery increased recurrence in 19% of patients [127]. Myectomy in addition to membrane resection, even in simple lesions, did not reduce the risk of reoperation.

Supravalvar aortic stenosis

Supravalvar aortic stenosis (SVAS) accounts for 6% of LVOT obstruction [138]. There is a strong association with Williams–Beuren syndrome, an elastin gene mutation on chromosome 7q11.23 [139]. Features of the syndrome include a characteristic "elfin" facies, hypercalcemia, and developmental delay [140]. Half of SVAS occurs in patients with Williams syndrome. Familial SVAS has been described in an autosomal dominant pattern (25% of patients) [6]. A further 25% of patients have sporadic SVAS. SVAS has been reported in 37–73% of patients with Williams syndrome [141].

Pathology

The classic pattern of SVAS is an "hourglass" deformity of fibromuscular hypertrophy at the level of the sinotubular junction. The stenosis is a localized, hourglass deformity of the ascending aorta in 80% of patients and more diffuse in 20% [142]. The aortic wall at this level has a characteristic pathologic appearance involving all three layers with intimal hyperplasia, fibrosis, loss of the internal elastic lamina with indistinct intimal medial junctions, medial hypertrophy and dysplasia with distorted elastic fibers, and adventitial fibroelastosis [143].

One-quarter of patients have associated BAV [144]. As many as 60% of patients have coexisting branch pulmonary arterial stenosis which may extend into the distal branch pulmonary arteries and varies from mild to severe [145]. Other associations include renal artery stenosis, mitral valve stenosis/regurgitation, atrial and ventricular septal defect, PDA, and coarctation.

The coronary arteries may be obstructed at the ostial origin or the arterial wall may be involved by the medial hypertrophy, intimal fibrosis, and hyperplasia. This may cause myocardial ischemia or myocardial infarction.

Pathophysiology

The degree of obstruction correlates with the degree of left ventricular hypertension and LVH. Coronary arterial involvement produces myocardial subendocardial ischemia particularly when associated with significant LVH. The jet through the supravalvar narrowing often hugs the aortic wall (Coanda effect), with the right brachial artery pressure being greater than the left.

Natural history

Half of patients present at <5 years of age. This syndrome is rarely diagnosed initially in adulthood. Patients with Williams syndrome and severe generalized arteriopathy have a higher mortality than children without an underlying genetic condition. Peripheral pulmonary arterial stenosis may affect the course of patients with Williams syndrome. Those with extensive pulmonary arterial disease may be relatively asymptomatic and survive for a prolonged period, as even severe pulmonary arterial stenosis tends to improve over time [146,147]. Patients with suprasystemic RV pressure, however, have a poorer prognosis [148].

Echocardiography

Imaging from the parasternal and suprasternal windows identifies the pattern and site of obstruction. In patients with

(a)　　　　　　　　　　　　　　(b)
Figure 30.6 Frames from cineangiograms in two patients with supravalvar aortic stenosis and dilatation of aortic valve ring and sinuses. (a) Injection into left ventricle in right anterior oblique projection in a 15-year-old girl with severe stenosis (arrowhead) above the aortic valve. The diameter measured 15 mm compared with 26 mm across the aortic sinus. The left coronary artery (L) is dilated. (b) Left ventricular injection in left anterior oblique projection in a 7-year-old boy with moderate supravalvar stenosis (arrowhead), diameter 6 mm. The ascending aorta is mildly hypoplastic, diameter 12 mm. The aortic valve leaflets are thickened and domed, and adherence of the left leaflet obstructed flow into the dilated left coronary artery (L).

an hourglass deformity or diffuse hypoplasia of the ascending aorta, the diameter of the proximal ascending aorta is less than that of the aortic annulus. Careful imaging is required to detect coronary ostial abnormalities; intermittent coronary artery obstruction by tethered aortic valve leaflets may be difficult to diagnose. The aortic valve morphology and gradient across the LVOT are assessed. Serial obstruction (at the valve and supravalvar level) may result in an overestimation of the gradient, whereas the modified Bernoulli equation may underestimate the gradient when there is long-segment stenosis. Echocardiography may also identify branch pulmonary arterial stenosis and elevated right ventricular systolic pressure.

Cardiac catheterization

Catheterization may complement echocardiography. Cineangiograms demonstrate the extent and morphology of SVAS, involvement of the coronary arteries (Figure 30.6), and the degree of involvement of the branch pulmonary arteries. Pulmonary arterial stenosis may include discrete stenosis at the origin of the pulmonary arterial origins or diffuse branch pulmonary arterial stenosis [145,149].

Magnetic resonance imaging

MRI can assess the extent and severity of SVAS using black blood and gradient spin echo sequences. Phase contrast imaging can assess the velocity of blood flow through the area of obstruction. Additionally, quantification of left ventricular systolic function, LV mass, pulmonary arterial stenoses, and pulmonary arterial flow can be performed [150].

Management – surgical intervention

Surgical repair is the treatment of choice for SVAS, and balloon angioplasty has no role except for pulmonary arterial stenosis. Patients with symptoms, left ventricular strain pattern on electrocardiography or gradients >50 mmHg at cardiac catheterization or 75 mmHg at echocardiography require surgery. Patch angioplasty extends from above the area of stenosis down to the aortic sinuses [151,152]. There is a low mortality but reintervention may be required in up to 10–20% of patients for restenosis at the distal end of the patch. Patients with BAV may require valve replacement or the Ross procedure [153].

Bicuspid aortic valve

Bicuspid aortic valve (BAV) is the most common congenital cardiac anomaly [154] It usually occurs in isolation but is associated with coarctation of the aorta, interrupted aortic arch, ventricular septal defect and hypoplastic left heart syndrome [155–158]. There is a high incidence in Turner syndrome [159]. BAV may be familial, transmitted in an autosomal dominant fashion, or occur sporadically [160]. There is a male predominance of 2–4:1 which suggests an X-linked etiology. Mutations in the NOTCH1 gene (chromosome 9) may cause signal abnormalities which give rise to valvar calcification in addition to a bicuspid valve [161]. Downregulation of ubiquitin fusion degradation 1-like (UFDIL) gene on chromosome 22 has also been implicated [162]. Other genetic associations include 22q11 deletion,

ACTA2 gene mutation, and endothelium-derived nitric synthase expression [163,164].

Pathology

In BAV, the deficient or absent commissure is intercoronary in half of patients. The functional commissures are right anterior and left posterior, although the degree of obliquity may vary. When either the right noncoronary or the left noncoronary commissure is deficient, the commissures are left anterior and right posterior. In most patients, the combined leaflet is larger than the single leaflet. If a raphe cannot be identified, the valve is classified as indeterminate when the coronary arteries arise from separate sinuses.

Fewer than 10% of valves have equal sized cusps and two sinuses of Valsalva. Right and left coronary cusp fusion occurs in 80%, right and non-coronary cusps in 15%, and left and noncoronary cusps in 3% [165]. Echocardiographic studies have shown right–left fusion in 70% of cases and right–noncoronary fusion in 30% [166]. Usually the larger cusp has two sinuses and the nondominant cusp has a single sinus. The valve appears like a fish mouth because of partial valve opening. Unicuspid and quadricuspid valves are less common. Most BAV are non-stenotic but flow turbulence gives rise to a systolic murmur.

The aortic wall often demonstrates three distinctive histopathologic features: loss of vascular smooth muscular cells, fragmentation of elastic fibers, and increases in basophilic ground substances within cell-depleted areas of the ascending aorta media [167]. Patients with BAV demonstrate a reduction in fibrillin-1 relative to those with a trileaflet valve [168]. Fibrillin-1 is a glycoprotein which maintains the structural integrity of the wall and leaflets by tethering vascular smooth muscle cells to a matrix of collagen and elastin.

Incidence

Various studies have reported the incidence to be from 0.44 to 2.25% [169–171], the variability reflecting reporting based on patients with infective endocarditis or a predisposition to males. The incidence is probably closer to 1%, as found in a study of 293 bicuspid valves among 21 417 postmortem specimens [172].

Natural history

Typically, BAV thicken and calcify over the decades. Early signs of calcification become evident in the second to third decade of life and most patients in their sixth decade have calcified sclerotic valves. Progressive calcification results in valvar stenosis, but eventually AR may predominate. Valve deterioration may be accelerated in patients with right–noncoronary fusion compared with right–left fusion [16]. In children there is often little valve dysfunction and as the child develops into a young adult AR predominates. Older age is associated with increasing AS. Pachulski and Chan studied 51 patients from 21 to 67 years old, 31 of whom had a peak gradient <25 mmHg [173]. Over a mean follow-up of 21 months, 4/31 patients developed severe AS and 3/31 developed significant AR. Once older patients become symptomatic with congestive heart failure, the mean survival is 2 years [174]. Isolated AR tends to occur in a younger patient. This is better tolerated than AS, although in patients with significant AR left ventricular dilatation may result in progressive left ventricular dysfunction.

Aortic root dilatation

The diameters of the ascending aorta and aortic root are significantly dilated with BAV compared with a trileaflet valve. Dilatation of the root and ascending aorta was present in 56% of persons <30 years old and in 88% of those >80 years old [175]. The rate of growth of the ascending aorta ranges from 0.2 to 1.9 mm per year [176]. Larger aortas have a greater rate of growth and a high risk of rupture when the aortic diameter reaches 6 cm. For patients with aortic diameter >6 cm, the annual risk of rupture was 3.6%, dissection 3.7%, and aorta-related death 10.8% [177]. Serial review of these patients should include echocardiography, MRI or ECG-gated multidetector CT with three-dimensional reconstruction.

First-line medical therapy includes beta-blockers, but there is no evidence to suggest that ACE inhibitors, statins, or ACEII receptor blockers have a role [178,179]. Recent published criteria for surgical intervention include aortic diameter >4.5 cm when other clues indicate severe disease or if there is rapid dilatation of the aorta of >0.5 cm per year [180]. Surgical intervention is rarely needed in childhood.

Echocardiography

Two-dimensional echocardiography in the parasternal long and short axes allows detailed imaging of the valve. Pulse- and continuous-wave Doppler can quantify the LVOT gradient from the apical four-chamber and suprasternal views. Color Doppler imaging allows the determination of AR in the parasternal long- and short-axis views. The aortic valve morphology can be assessed in parasternal short-axis views and doming of the aortic valve can be visualized in parasternal long-axis views (Figure 30.7). Close attention to the pulmonary valve to assess the degree of regurgitation is important in assessing suitability for the Ross procedure.

Cardiac MRI

Black-blood double inversion–recovery fast spin-echo imaging of the ascending aorta can be performed in a sagittal plane to provide accurate aortic arch and root dimensions. Cine bright blood steady-state precession with fast gradient echo image demonstrates the systolic flow jet through the stenotic valve (Figure 30.8). Magnetic resonance angiography with three-dimensional reconstruction following gadolinium administration allows excellent delineation of the aortic arch [181].

CT imaging

Spiral CT angiography is generally used for routine arch evaluation. Where indicated, multidetector CT with three-dimensional reconstruction should be used with minimum radiation using ECG-gated imaging [182].

Figure 30.7 Two-dimensional echocardiogram in the parasternal long-axis view demonstrating prominent doming of bicuspid aortic valve.

Management – surgical intervention

In patients with significant AR, aortic homograft replacement, or Ross procedure are potential surgical interventions. Increasingly, older patients with other co-morbidities may be candidates for percutaneous CoreValve replacement for significant AS.

Surgical repair of BAV has become more popular recently in patients with isolated AR secondary to cusp disease, with or without aortic root disease. Boodhwani *et al.* reported 122 patients who underwent surgery for AR (43%), aortic root disease (14%), or both (43%) [183]. Raphe repair was performed by shaving (21%), resection with primary closure (60%), or pericardial patch (18%). Aortic annuloplasty was undertaken using sub-commissural annuloplasty, ascending aortic replacement, or aortic root replacement using a reimplantation or remodeling technique. At discharge, 93% of patients had either no or minimal aortic regurgitation and 7% grade 2 aortic regurgitation. Freedom from aortic valve reoperation was 94 and 83% at 5 and 8 years follow-up and freedom from aortic valve replacement was 96 and 92%, respectively.

In patients in whom aortic valve repair is not possible, prosthetic valve replacement is a successful option. A recent adult study of 1000 patients, mean age 70 years, who

(a)

(b)

underwent Carpentier–Edwards valve replacement, at a mean follow-up of 6 years reported surgical mortality of 7% with only 2.6% of patients requiring reoperation [184].

Endocarditis and bicuspid aortic valve

A recent study reported 50 adult patients with BAV developing endocarditis among 856 patients [185]. Patients with BAV were younger, had fewer co-morbidities, and had a higher risk of paravalvar abscess formation. Surgery was required in 72% of patients with BAV with a perioperative mortality of 8%. The UK NICE guidelines report that patients with aortic valve disease including stenosis or regurgitation have an increased risk of endocarditis [43].

31 Left Ventricular Outflow Regurgitation and Aortoventricular Tunnel

Vijaya Joshi[1] & Roxane McKay[2]
[1]University of Tennessee Health Science Center, Memphis, TN, USA
[2]Rochester, MN, USA

Introduction

In hearts with concordant ventriculoarterial connections, the left ventricular outflow extends from the area of fibrous continuity between aortic and mitral valves to the sinutubular junction between the ascending aorta and sinuses of Valsalva [1]. It thus encompasses portions of the left ventricular free wall, the muscular and membranous interventricular septums, the aortic valvar leaflets, arterial wall of the aortic sinuses, and the ostia of the coronary arteries. Although "left ventricular outflow obstruction" (see Chapter 30) is widely used to describe a variety of anomalies that impede blood flow through any portion of this area, from the left ventricle into the systemic circulation, its hemodynamic opposite, "left ventricular outflow regurgitation," is a less familiar concept. These are lesions which place a volume overload on the left ventricle, independent of a shunt, and cause the systemic blood pressure to approximate that in the left ventricle during diastole. The morphologic substrates for left ventricular outflow regurgitation include aortic, neo-aortic, and prosthetic valve disease, left ventricular aortoventricular tunnel, sinus of Valsalva fistula to the left ventricle (see Chapter 25), and coronary arterial fistula to the left ventricle (see Chapter 48). Although this chapter addresses only the first two and is limited to normally connected hearts, obstruction and regurgitation may also affect the left ventricular outflow of hearts with discordant, solitary or double-outlet ventriculoarterial connections.

Incidence

Regurgitant lesions of the left ventricular outflow tract are rare in children, yet encompass a wide spectrum of congenital and acquired pathology. They may be conveniently divided into those affecting primarily the valvar leaflets (Table 31.1) and those in which regurgitation results from disease of the supporting vascular wall, with or without leaflet involvement (Table 31.2).

Because it is the commonest congenital heart defect, affecting ~1% of the population, a two-leaflet aortic valve is probably the most common cause of aortic regurgitation. However, in the absence of balloon valvoplasty, only about 7% of children with a bicuspid valve develop aortic regurgitation of at least moderate severity [2], and this generally presents with some degree of obstruction after about 8 years of age. In infancy, the most common cause of left ventricular outflow regurgitation is aortoventricular tunnel [3].

Embryology

The leaflets and sinuses of the aortic valve derive from two embryologic components of the developing proximal outflow tract [4]: the septal endocardial cushion, with an ephemeral neural crest contribution, gives rise to the right and left coronary aortic sinuses and leaflets, while the noncoronary leaflet and sinus are formed from the rightward, inferior (aortic) intercalated cushion or "disc." Before this time, approximately Carnegie stages 18–20 in the human embryo, the septal and parietal cushions have fused progressively from the distal to the proximal outflow tract, dividing it into aortic and pulmonary trunks, with the so-called "dog-leg bend" indicating the ultimate site of sinutubular junctions. By mechanisms not yet fully understood but possibly related to changes in the extracellular matrix, myocardium that surrounds the developing valvar sinuses then regresses, leaving the right ventricular outflow supported by a free-standing muscular infundibulum, and the left communicating with the

extracardiac space. Coronary arteries grow through this muscular cuff before its disappearance, into what become the left and right aortic sinuses, when the leaflets and sinuses finally assume their respective tissue types.

The commonest type of bileaflet (or bicuspid) aortic valve is that in which the right and left coronary leaflets are fused, with both coronary arteries arising from the conjoined R–L sinus. This morphology is associated most often with coarctation of the aorta and aneurysms of the ascending aorta. In contrast, valves with fusion of the right and noncoronary aortic leaflets retain a coronary orifice in each sinus and tend to have more rapidly progressive stenosis and regurgitation. Observations in hamsters and mice [5] suggest that the former result from abnormal fusion of the septal cushions (or their contributions from the neural crest or second heart field), whereas the latter are produced by fusion of the septal cushion with an intercalated disc. Interestingly, fusion of the left and noncoronary aortic leaflets is exceedingly rare, and it is this commissure with its interleaflet triangle

that is virtually always conserved in the neonatal "unicusp" aortic valve [6]. Aorto-left ventricular tunnels are found in the tissue plane between the definitive aortic and pulmonary trunks, nearly always lie above the right or left aortic sinus, sometimes involve coronary arterial ostia, may be associated with bicuspid aortic or pulmonary valves, and usually communicate with the ventricle through the fibrous interleaflet triangle between left and right aortic leaflets, all of which support speculation that they too represent malformations of septal cushions, perhaps at an earlier stage of development [3].

Aortic regurgitation

Pathologic anatomy
Regurgitation through the aortic valve occurs whenever there is loss of coaptation between the leaflet free edges or a defect within the body of a leaflet. With inflammatory

[a]Association refers to genetic or molecular associations.
[b]Also affects leaflet tissue.

processes, such as rheumatic fever or autoimmune diseases, the leaflets become thickened with subsequent scarring that shortens their body and retracts the now bulky, rolled free edges from each other. This contrasts with regurgitation resulting from aneurysmal expansion of the aortic root, where, initially at least, normal, thin leaflets are stretched across an enlarged outflow, allowing central regurgitation.

In patients with ventricular septal defect and aortic regurgitation, one leaflet of the valve (usually the right coronary cusp) is poorly supported and "sucked" down into the defect by a Venturi effect, usually with elongation of the body of the cusp. Enlargement of the leaflet conserves coaptation, but eventually the prolapsed leaflet becomes thickened and retracted, resulting in valvar regurgitation. Subaortic stenosis may cause aortic regurgitation by two mechanisms: acceleration of an eccentric jet of blood through the fibrous ring damages the ventricular surface of the valve or, less frequently, the membrane extends up onto the ventricular aspect of a leaflet and restricts its mobility.

Congenitally malformed valves, generally with two leaflets, may have shortening of the leaflet free edge relative to the valve circumference. This results from abbreviated interleaflet triangles [6] and leaves insufficient tissue for effective coaptation. Alternatively, the conjoined leaflet, when larger and lacking in support by a normal interleaflet triangle, may prolapse into the ventricle and fail to oppose its opposite number. If the "raphe" of the fused leaflet is anchored to the wall of the aortic sinus by a thread of fibrous tissue, rupture of this structure allows sudden leaflet prolapse and produces acute regurgitation in a previously competent bicuspid valve.

Discrete holes in a leaflet are usually produced by infection, but are sometimes due to a wayward suture during ventricular septal defect closure, damage during surgical enlargement of a ventricular septal defect or resection of subaortic stenosis, and inappropriate resection of infundibular muscle during repair of tetralogy of Fallot. These latter complications tend to occur near the leaflet hinge points. In regurgitation following balloon valvoplasty or blunt chest trauma, it is usually the mid-portion of a leaflet that is ruptured completely from free edge to hinge point.

In all of the above, regurgitation through the valve causes turbulence and shear stress, producing further distortion of the leaflet tissue, which progressively intensifies valvar dysfunction.

Pathophysiology

Chronic aortic regurgitation subjects the left ventricle simultaneously to increased preload from the regurgitant volume, and to increased afterload from greater wall stress resulting both from increased end-diastolic volume and systolic hypertension when an enlarged stroke volume is not accommodated within the systemic vascular compliance. Early on, compensation at a molecular level by division of myocardial sarcomeres, combined with enlargement of myofibrils and myocytes, produces eccentric ventricular hypertrophy. This conserves the ratio of cavity radius-to-wall thickness and maintains normal wall stress and normal systolic function. With time, ventricular hypertrophy becomes insufficient to compensate for progressive cavity dilatation, resulting in impaired systolic function. Subsequently, elevation of end diastolic pressure transmits pressure back into the left atrium and pulmonary circulation, while reduction of coronary arterial flow occasionally compounds heart failure from aortic regurgitation with myocardial ischemia. Pathologic hypertrophy and dilatation, and also some degree of systolic dysfunction, are reversible,

however, if the left ventricular volume overload is relieved before contractility is impaired.

Acute aortic regurgitation, in contrast, subjects the left ventricle to a sudden volume overload for which the only compensatory mechanism is an increased heart rate. If inadequate to maintain cardiac output, left atrial and left ventricular end-diastolic pressures rise, leading to pulmonary edema and circulatory collapse (shock).

Systolic aortic regurgitation occurs in the rare combination of an incompetent aortic valve with a systemic blood pressure exceeding that of the left ventricle. It has been observed after the Damus–Kaye–Stansel procedure, with ventricular arrhythmias, and in patients on extracorporeal support. Although its pathologic significance is uncertain and probably variable, the phenomenon does reflect ineffective contraction of the underlying ventricle.

Natural history

Patients with acute aortic regurgitation generally become symptomatic with dyspnea and tachycardia within hours of its onset. Without intervention, the ventricle fails over several days, culminating in cardiac arrest and death. With infective endocarditis, less than one-third of patients who develop acute valvar regurgitation survive for 1 year. However, if the left ventricle was previously hypertrophied, as in balloon valvoplasty for critical aortic stenosis, acute regurgitation may be surprisingly well tolerated. Similarly, if the degree of regurgitation is not large, as in a limited cusp perforation, there may be time for ventricular adaptation to evolve to chronic aortic regurgitation.

Patients with chronic aortic regurgitation generally remain compensated with normal systolic ventricular function and no symptoms for many years or even decades. In adults [7], only ~3.5% per year experience deterioration of ventricular function in the absence of symptoms, and <6% per year develop either left ventricular dysfunction or symptoms. In contrast with obstruction of left ventricular outflow, the risk of sudden death is extremely low, <0.2% per year. The onset of impaired systolic ventricular function, however, portends clinical deterioration, with ~25% of such patients becoming symptomatic each year thereafter. Whereas >90% of patients survive 5 years after a diagnosis of *severe* aortic regurgitation, <10% are still alive at 10 years. Factors associated with death include severe left ventricular hypertrophy on the electrocardiogram, a cardiothoracic ratio of >0.6 on the chest X-ray, ventricular extrasystoles, and symptoms of heart failure.

Clinical features

Aortic regurgitation is usually associated with aortic valve stenosis, conal septal abnormalities, and ventricular septal defect. Thus, it is most commonly found during evaluation of (1) aortic root abnormalities, such as Marfan syndrome; (2) bicuspid aortic valve, often accompanied by a dilated aortic root; (3) rheumatic heart disease; or (4) endocarditis. Severe aortic regurgitation during early gestation is likely incompatible with fetal or neonatal viability [8]. In a child with a trileaflet aortic valve, rheumatic heart disease should be considered, especially with mitral valve regurgitation.

Children encountered in office practice rarely describe symptoms. The vital signs are notable for elevated systolic and decreased diastolic pressures. The patient is best examined sitting and leaning forward. On palpation, the apical impulse migrates towards the inferior lateral chest as the left ventricle enlarges. Auscultation discloses an early high-pitched diastolic decrescendo murmur along the mid-left sternal border. With increasing severity of regurgitation, the murmur becomes louder and longer, extending throughout diastole. The pulse pressure widens due to both an increased systolic stroke volume and also the retrograde diastolic runoff into the left ventricle. This abrupt upstroke and collapse are described as a "Corrigan's" or "water hammer" pulse. A high stoke volume may also produce a soft, systolic ejection murmur at the base of the heart from the increase ejection across the aortic outflow area. The Austin Flint murmur, heard at the apex as a rumbling diastolic sound, is attributed to fluttering of the mitral valve with severe regurgitation or to a posterior and laterally directed jet of regurgitation. Acute aortic regurgitation will not have these classic features if there is left ventricular decompensation, and then tachycardia and a third heart sound dominate the physical findings.

Echocardiography

Although cardiac magnetic resonance imaging (CMR) has become a standard for quantifying the severity of aortic regurgitation [9], in part because of inconsistency and lack of agreement by even experienced echocardiographers regarding the grading of moderate or severe regurgitation [10], most patients can be managed satisfactorily with echocardiography as the primary imaging tool. The left ventricular outflow tract is best assessed and measured in the parasternal long axis. The morphology of the aortic valve is scrutinized for leaflet motion, coaptation, and vegetations or leaflet perforation. A discrete subaortic membrane is seen best from the subcostal or apical projections, because this provides the most surface area for echo detection. Deformation of the right aortic sinus should raise the suspicion of an infundibular ventricular septal defect, which has been occluded by the aortic root. Diameters of the aortic valve annulus, aortic root, and the sinutubular junction are measured in early to mid-systole [11]. Although morphologically the subaortic region may be elliptical, a circle is assumed by measuring its maximum dimension. Dimensions of the left ventricle should also be quantified. Three-dimensional echocardiography can often provide excellent images of valve morphology, and also quantification of left ventricular volumes and ejection fraction. However, technical limitations still thwart its use in younger children.

Color flow Doppler localizes the region of regurgitation. The vena contracta (the smallest area of the jet of regurgitation, usually in or just below the valve plane) should be measured from at least the parasternal long- and short-axis views (Figure 31.1). It must be scrutinized from multiple projections. Continuous-wave Doppler measurement of the terminal aortic regurgitation velocity slope and the pressure half-time, useful especially for serial evaluation, are sensitive to alterations both in ventricular diastolic function and systemic vascular resistance. An increasing deceleration rate and a decreasing pressure half-time correlate with an increase in aortic regurgitation. A recently developed model employs a two-variable parasternal vena contracta-derived area divided by body surface area, and an abdominal aorta Doppler retrograde velocity–time integral divided by anterograde velocity–time integral to predict severity of regurgitation [12].

Cardiac catheterization and angiography

Cardiac catheterization and angiography are usually unnecessary in managing isolated aortic regurgitation but occasionally may be needed to document left ventricular end diastolic pressure or coronary artery anomalies. Angiography should be done with a pigtail catheter skillfully positioned in the ascending aorta, so as not to cause leaflet distortion. Long axial oblique and a companion right anterior oblique views will generally display the left ventricular outflow tract.

Other imaging modalities

If echocardiography imaging is suboptimal, CMR offers a robust alternative. Indeed, it has substantial advantages over both echocardiography and angiography for quantification of valve regurgitation, as it permits the quantification of both flow and ventricular volume. Cine CMR to image ventricular volume typically utilizes gradient recalled echo (GRE) or more commonly a steady-state free precession (SSFP). During image acquisition, the regurgitation is depicted as a dephasing intervoxel artifact retrograde into the ventricle. It is important to quantify both right and left ventricular volumes. If there is no other significant regurgitation or shunting, then left ventricular end systolic (LVESV) and diastolic volume (LVEDV) can be compared with right ventricular end systolic (RVESV) and diastolic volume (RVEDV). LV stroke volume – RV stroke volume then estimates the aortic regurgitation. Alternatively, phase contrast magnetic resonance (PCMR) maps flow velocity. The flow and velocity are measured through a slice placed immediately above the aortic root or, if possible, in the subvalvar plane. The resultant image shows the aorta as a circle. The estimated retrograde volume is divided by the prograde volume to derive a regurgitation fraction. The severity of aortic regurgitation, in adults, is arbitrarily graded by this regurgitant fraction: trivial <10%, mild 10–20%, moderate 21–39%, severe >40% [13]. A very similar scheme has been used in children [12].

Table 31.3 Grading severity of aortic regurgitation[a].

Method	Mild	Moderate	Severe
Diastolic murmur	≤Grade 1, short	Grade 2	≥Grade 2, long
Pulse pressure	Normal	↕	↕
LVEDD z score	<3	3–5	>5
Color flow Doppler central jet width	<25% of LVOT	25–64% of LVOT	≥65% of LVOT
PW Doppler descending aortic diastole flow	Brief, low velocity	Intermediate	Pandiastolic, high velocity
MR phase contrast or LV–RV SV calculation	<20%	21–39%	≥40%

[a]LVEDD, left ventricular end diastolic dimension; LVOT, left ventricular outflow tract; LV, left ventricle; RV, right ventricle; PW, pulse width; MR, magnetic resonance; SV, systolic volume.

Methods for grading aortic regurgitation are summarized in Table 31.3. However, it is always important for the physician to integrate the data from various sources into the proper context for managing an individual patient.

Management

Medical

In children with a dilated aortic root, slowing the rate of its progression would not only reduce complications and the need for surgery, but also preserve aortic valve function. Beta-blockers have disappointing efficacy in retarding root dilation in the Marfan syndrome [14], but angiotensin II blockade with, for example, losartan has demonstrated benefit in small cohorts [15].

Medical therapy for valvar aortic regurgitation should improve forward stroke volume, reduce the regurgitation, and preserve left ventricular function. There have been no large pediatric studies on this issue, however. Among 18 children with moderate-to-severe aortic regurgitation treated with angiotensin-converting enzyme (ACE) inhibitors for an average of 2.3 years, there were no significant effects on left ventricular dimensions or shortening fraction, but there was a small increase in the aortic regurgitation [16]. A study of patients treated with captopril, most of whom had rheumatic heart disease, showed favorable effects on left ventricular volume and aortic regurgitation over 1 year; but this cohort likely included subjects with spontaneous improvement [17]. The American College of Cardiology and American Heart Association Task Force report (concerned primarily with adult patients) recommends vasodilator therapy and especially noted the use of nifedipine [18]. However, in a well-designed controlled trial on adults, neither nifedipine

nor enalapril favorably changed left ventricular dimensions, aortic regurgitation volume, or timing of surgery [19]. Therefore, with normal ventricular systolic function and without root enlargement, no good evidence supports the use of any medicine.

Different types of athletic activity and physical work have varying effects on the heart. Aerobic exercise decreases systemic vascular resistance and thus decreases aortic regurgitation. High-intensity isometric work, such as power weight lifting, however, transiently increases blood pressure, systemic resistance, and therefore aortic regurgitation. This physiology mandates limitations on patients who do more than a modest amount of isometric work. Aortic root enlargement (at $z \geq 3.5$) alone warrants restriction from high intensity static work or sports with collision potential. Under medical supervision, athletes having mild or moderate aortic regurgitation *and* a left ventricle that is only mildly enlarged can participate in all competitive sports. After scrutiny of the cardiac rhythm and exercise testing, athletes with aortic regurgitation and moderate left ventricular enlargement can engage in moderate static and high dynamic competitive sports. Those with severe aortic regurgitation and more than moderate root enlargement should only participate in low-intensity sports. If there is root enlargement, greater than 45 mm (corresponding to a z value of about 5), activity should be limited to only low-intensity sports [20].

Surgical

Indications for surgery in aortic regurgitation are similar in pediatric and adult patients, although clinical judgment in children may be additionally influenced by associated cardiac or noncardiac malformations, patient size, and institutional experience. The indications are based on five parameters: symptoms, degree of aortic regurgitation, left ventricular systolic function, left ventricular dilatation, and degree of aortic dilatation. Symptoms, ventricular dysfunction (ejection fraction <50%), and ventricular enlargement (comparable to more than an adult end systolic diameter of 55 mm) each individually constitutes a class I or class IIa indication for operation. Referral for an operation is therefore an easy decision in a child with decreased physical work capacity, or symptoms from heart failure, angina, or ventricular arrhythmia.

When the degree of aortic regurgitation is severe and accompanied by either impaired systolic left ventricular function or severe left ventricular dilatation, operation is indicated even in the absence of symptoms. For regurgitation secondary to aortic root dilatation in connective tissue disorders, a diameter of 50 mm in patients with Marfan syndrome and 40 mm in those with Loeys–Deitz syndrome generally trigger surgery. This threshold may be lowered by unusually rapid progression of enlargement or a family history of complications.

As aortic regurgitation begins to increase from a mild or moderate degree, its serial quantification can provide insight and guidance for management. By echocardiography, increasing z-value for left ventricular end diastolic dimension, increasing ratio of aortic regurgitation vena contracta to left ventricular outflow tract and to body surface area, increasing retrograde flow velocity, or increasing relative descending aorta VTI ratio are used to time an operation. By magnetic resonance imaging, a regurgitant fraction of >40% leads to consideration of operation.

The goal of surgery is conservation or restoration of left ventricular function and removal of the risk of complications, but there is no perfect valve substitute with which to accomplish this. Hence all procedures on the left ventricular outflow tract should be regarded as palliative. Accordingly, valve reconstruction should be the first option, either as a valve-sparing root replacement [21] or by leaflet repair [22]. In the authors' personal, unpublished experience this proved possible in all of an unselected, consecutive series of 25 infants, children, and young adults operated for severe aortic regurgitation from a variety of causes (including two-leaflet valves). Operative and late death now approach zero, and long-term follow-up showed a 60% freedom from aortic valve replacement as long as 18 years after repair [22].

When conservation of the native valve is not possible (usually in acute endocarditis or at a reoperation), the two implants that offer a completely unobstructed, hemodynamically superior outflow are the aortic homograft and the pulmonary autograft (Ross operation). Early and late mortality for these procedures in patients with all types of aortic valve disease is ~1% today, and freedom from autograft reoperation at 15 years is 89% [23]. Moreover, the Ross procedure appears to confer a survival advantage over mechanical valve replacement (<4% versus 50% mortality), in patients <5 years of age (most of whom are operated on for aortic stenosis rather than regurgitation) [24]. Implantation of the pulmonary autograft in the subcoronary position is virtually always possible in patients with aortic regurgitation and may avoid late autograft dilatation, the commonest cause of autograft failure following the Ross operation.

Mechanical prosthetic valves, in theory and in contrast to the above, should have infinite durability and a lower rate of reoperation. Nevertheless, even when it is possible to implant an adult-sized valve, there remains a constant, late-phase risk of mortality and morbidity, from ingrowth of pannus, complications of anticoagulation, and infection [24]. Moreover, the necessity for anticoagulation places major life-style restrictions upon young patients, and when a mechanical valve fails (due to thrombosis, for example), it is often sudden and catastrophic.

A final option for larger children is a bioprosthetic prosthesis (pericardial or porcine). Although these valves have reduced durability in young patients (sometimes lasting less than 1 year and rarely >5 years) and, in smaller sizes,
Figure 31.1 Aortic regurgitation. Color flow Doppler echocardiography of the left ventricular outflow tract in the parasternal long-axis view shows an 8 mm jet of aortic regurgitation (arrow), compared with a left ventricular outflow diameter of just over 12 mm.

may cause a significant gradient across the left ventricular outflow, they do not require anticoagulation and can be replaced with very low morbidity and mortality. As such, they may serve to transition a teenager or young adult through periods of participation in contact sports, noncompliance with drug therapy, or pregnancy, after which a mechanical prosthesis may become a more acceptable alternative.

Long-term history of treated and untreated adults

Provided they do not contract endocarditis, patients who reach adulthood with mild, stable aortic regurgitation from isolated valve disease generally enjoy a normal life span. When regurgitation is severe, however, systolic left ventricular function tends to deteriorate, usually producing symptoms, at a rate of ~5% of patients per year. Once symptomatic, deterioration accelerates to ~25% 5 year and 50% 10 year mortality among untreated adults. With heart failure, survival drops below 50% at 2 years. Restoring a competent valve improves ventricular function and prolongs life, both for patients who undergo operation as adults and those operated in childhood, although documentation of very long-term outcomes in the latter group is limited. Overall, there seems to be a constant rate of late reoperation among patients surviving into adulthood after aortic valve surgery. Depending upon a variety of factors, this ranges from ~1% to as much as 10% per year. When regurgitation is associated with other congenital heart malformations or is secondary to a systemic disease, those conditions usually determine overall clinical course and outcome.

Aortoventricular tunnel

Pathologic anatomy

Aortoventricular tunnel is a tubular, extracardiac structure connecting the ascending aorta above the sinutubular junction with the left ventricular outflow, usually through the interleaflet triangle between right and left coronary aortic valve leaflets (Figure 31.2) [3,58]. The most common variant of this rare anomaly lies above the right aortic sinus and passes through the tissue space between the aortic root and subpulmonary muscular infundibulum to reach the cavity of the left ventricle immediately below the hinge point of the aortic valve. Massive, diffuse enlargement of the ascending aorta is almost invariable. The size of both the aortic and ventricular openings of tunnels, and also the diameter of the tunnels themselves, are highly variable, ranging from a slit-like defect of a few millimeters to a structure >1 cm in diameter. Either the left or the right coronary artery may arise within a tunnel, or an ostium may be absent. Stenotic or atretic aortic and pulmonary valves are among the more frequently associated lesions, and tunnels have been observed in hearts with atrial septal defect, ventricular septal defect, or tricuspid atresia [3].

Pathophysiology

Despite the occasional occurrence of valve-like tissue within its walls, a tunnel affords unobstructed flow of blood from the left ventricle to the aorta during ventricular systole, and from the aorta into the ventricle throughout diastole. The volume-overloaded ventricle hypertrophies and dilates, and may suffer ischemia from inadequate coronary flow secondary to the large diastolic run-off. Because it is unsupported on its ventricular aspect, the right coronary leaflet tends to prolapse into the ventricle over time, compounding regurgitation through the tunnel with valvar regurgitation. A very large tunnel may displace the subpulmonary infundibulum and cause right ventricular outflow obstruction.

Natural history

In general, patients with aortoventricular tunnel develop symptomatic heart failure within the first year of life, if not during the neonatal period. The natural history, however, is difficult to characterize because of its variability and the rarity of the defect. Spontaneous closure of a very small tunnel, asymptomatic survival into adulthood, death *in utero*, and sudden death in infancy have all been described. Given the developmental basis of the anomaly and its ascending aortic enlargement, it would not be surprising if patients surviving into adulthood were eventually to manifest aortic aneurysms and dissections.
Figure 31.2 Aortoventricular tunnel. Schematic drawing of the most common type of tunnel, with an aortic orifice above the right sinus of Valsalva, and the ventricular opening in the fibrous interleaflet triangle between right and left coronary aortic leaflets. The potential for compression of the right ventricular outflow tract may be appreciated, although this usually occurs at a more proximal level than illustrated due to the position of the subpulmonary infundibulum. Ao, aorta; LV, left ventricle; N, non-coronary sinus of Valsalva; PA, pulmonary artery; R, right sinus of Valsalva.

Clinical features

The characteristic presentation of aortoventricular tunnel is a very loud "to-and-fro" murmur, heard over most of the precordium and accompanied by both systolic and diastolic thrills. Peripheral pulses are bounding, and a wide pulse pressure can be appreciated in older patients. The chest X-ray demonstrates cardiomegaly with dilatation of the ascending aorta, both of which may be out of proportion to the observed degree of heart failure. In some patients, the "bulge" of a very large tunnel may be seen along the left cardiac border. On the electrocardiogram, left ventricular hypertrophy with "strain" is usually found. On a fetal echocardiogram, hypertrophy and dilatation of the left ventricle with an enlarged aortic root and apparent aortic regurgitation are findings supporting a diagnosis of aortoventricular tunnel.

Echocardiography

Visualizing the tunnel beside the aortic root is done in a parasternal long-axis view, from which the tunnel can be followed to its aortic and ventricular ends. Using color-flow imaging, systolic and diastolic flow can be demonstrated in the tunnel. Associated valvar and coronary artery anomalies are not uncommon and should be characterized, and ventricular size and function quantified.
Figure 31.3 Aortoventricular tunnel. Single slice of a magnetic resonance angiogram using steady-state free precession imaging (FIESTA, GE Healthcare) to demonstrate the abnormal channel between the aorta and left ventricle (arrow) in a 13-year-old child. (Image provided by Dr Paul Julsrud and Dr Nandan S. Anavekar, Mayo Clinic, Rochester, MN, USA.)

Cardiac catheterization and angiography

Although an aortoventricular tunnel may be demonstrated by angiography, it is unnecessary for diagnosis. Cardiac catheterization is used to clarify coronary arterial anatomy and associated defects when these are not sufficiently elucidated by noninvasive imaging. Subpulmonary obstruction by the tunnel may cause increased right ventricular systolic pressure, but right heart hemodynamics are otherwise normal. There may be elevated left ventricular end diastolic pressure and widened aortic pulse pressure. When valvar aortic stenosis coexists, a gradient may or may not be found across the left ventricular outflow tract, as a large tunnel can obscure even atresia of the aortic valve.

Other imaging modalities

Both magnetic resonance imaging (Figure 31.3) and computed tomographic angiography offer elegant demonstrations of the complex anatomic relationships in this malformation. Their use, however, is generally more for follow-up of older or postoperative patients, as most patients are diagnosed and operated on in early infancy.

Management

Medical

Beyond resuscitation and stabilization for surgery, medical management offers little to these patients, most of whom will die from congestive heart failure without early repair.

Reversal of left ventricular dysfunction becomes progressively less likely after about 6 months of age, and distortion of the aortic valve superimposes aortic regurgitation, complicating later surgical intervention. The one exception is the exceedingly rare patient with a very small tunnel and good support of the aortic valve leaflets. As spontaneous closure of such a tunnel has been reported, observation is reasonable in this situation. However, if a tunnel is sufficiently large to require medical treatment of heart failure, it needs surgical repair.

Surgical

Most tunnels have been repaired using a pericardial patch, inserted through an aortotomy, to close the aortic end, and a prosthetic patch, inserted below the aortic valve through the opened tunnel itself, to close the ventricular end and support the valvar leaflet. When a coronary artery arises within the tunnel, it can be resected with a surrounding button of tunnel wall and reattached to the ascending aorta. Associated malformations are managed on their own merits, which may involve aortic or pulmonary valvotomy, aortic valve repair or replacement, aortic root replacement, or aortoventriculoplasty. Survival following primary repair of isolated aortoventricular tunnel now approaches 100%.

Long-term history of treated and untreated adults

Although they have not yet been followed to adulthood, patients in whom the tunnel was repaired before about 6 months of age have normalized left ventricular function on echocardiography and do not develop valvar aortic regurgitation during childhood. The ascending aorta remains enlarged, however, and in one patient showed myxomatous changes of connective tissue disease when a valve-sparing root replacement was later performed. Therefore, all patients need careful, life-long follow-up for this anomaly. Untreated adults are a very small population but have been reported. Most eventually develop aortic regurgitation and die of congestive heart failure, although occasional patients, for reasons not completely understood, remain asymptomatic [25].

32 Coarctation of the Aorta and Interrupted Aortic Arch

Eric Rosenthal

Evelina Children's Hospital, St Thomas' Hospital, London, UK

Coarctation of the aorta

Coarctation of the aorta is a narrowing of the aortic lumen at the origin of the descending aorta with obstruction to blood flow. First described by the anatomist Johann Meckel in 1750 and expanded upon by Paris in 1791, clinical recognition occurred from the early 1900s [1–3]. Coarctation is usually discovered in infancy, although adult presentation is more frequent (although not exclusively) in third-world populations. Coarctation occurs in 7% of live births with congenital heart disease [4]. The prevalence per 10 000 live births is significantly higher for white males (6.52) than for white females (3.17), but less common in black populations with no significant difference between the sexes (2.64 males and 1.69 females) [5].

Coarctation usually occurs sporadically, although occasionally more than one family member is affected [6]. There are also reports of monozygotic twins concordant for coarctation [7]. In girls with Turner's syndrome (46 XO), the incidence of coarctation is 10% [8,9].

Pathology and embryology

Pathology

The coarctation narrowing is in the thoracic aorta distal to the origin of the left subclavian artery and opposite the ductus arteriosus or ductal ligament [10]. The narrowing may be discrete but in some a more diffusely narrowed segment occurs. The literature divides coarctation into two common types, "preductal" or infantile and "postductal" or adult, and a third less common type, "juxtaductal" [11]. Clinically, however, juxtaductal is sufficiently descriptive, and the postductal position in adult coarctation is probably acquired during growth. The eccentric narrowing is formed by a posterior "ridge-like" infolding of the aortic wall medial layer containing a shelf of tissue that is ductal in origin and connected as a sling around the aorta to the ductus arteriosus [12,13]. Ductus smooth muscle extends into the aortic wall above and below the coarctation.

Intimal thickening is usually present. Beyond the obstruction, the aorta is often dilated (poststenotic dilatation), and the aortic wall demonstrates intimal proliferation and medial and elastic tissue disruption. Infective endarteritis may occur in this location as may aneurysm formation and dissection in later life [14]. The *posterior shelf* is the earliest echocardiographic marker of coarctation in the descending aorta in neonates even before a significant gradient develops. Hypoplasia of the aortic arch to varying extents is a common accompanying feature [15]. The origin of the left subclavian artery may be hypoplastic, and anomalous origin of the right subclavian artery below the coarctation occurs in >5% of patients [10]. Rarely, a coarctation is present in other locations, such as in the aortic arch before the left subclavian artery or in the descending thoracic or abdominal aorta [16]. Renal and mesenteric artery involvement frequently occurs, with abdominal coarctation found more commonly in girls [17].

The commonest associated cardiac anomaly is a bicuspid aortic valve, followed by a ventricular septal defect (isolated or multiple), aortic stenosis (valvar or subvalvar) and mitral valve anomalies (supravalvar ring, dysplasia of mitral leaflets, and "parachute" mitral valve). The combination of coarctation of the aorta, subaortic stenosis, and mitral stenosis is known as Shone syndrome [18]. Other cardiac lesions commonly associated with coarctation include double-outlet right ventricle, especially Taussig–Bing anomaly; tricuspid atresia, especially with d-transposition of the great arteries; d-transposition of the great arteries with an inlet ventricular septal defect and right ventricular hypoplasia; atrioventricular septal defect;

hypoplastic left heart syndrome; double-inlet left ventricle; and l-transposition of the great arteries. The arch is often hypoplastic with these complex defects. A bicuspid valve occurs in >50% of patients [19].

As a result of aortic obstruction, there is a progressive development of collateral blood flow around the coarctation segment, mainly from the subclavian artery and its branches through the internal mammary, intercostal, musculophrenic, transverse cervical, scapular, lateral thoracic, superior epigastric, and spinal arteries [4]. Dilatation of the left subclavian artery increases over time and the dilated and tortuous collateral arteries may erode the lower margins of the ribs in older children to produce "rib notching" on the chest X-ray. Berry aneurysms may develop in the circle of Willis due to the raised upper body blood pressure [20,21].

Embryology

The embryonic origin of coarctation is not completely defined and two competing theories prevail. The first considers coarctation as the result of an intrinsic defect in the media of the aortic wall. In mice, a deficiency of endothelin-1 has been associated with the development of tubular hypoplasia of the aortic arch, aberrant right subclavian artery, ventricular septal defect, abnormalities of the left ventricular outflow tract, and interrupted aortic arch [22]. An alternative theory is that abnormal fetal hemodynamics promote the development of coarctation [23]. The aortic isthmus between the left subclavian artery and the ductus arteriosus normally receives <10% of the combined ventricular output and is smaller in diameter than either the ascending or descending aorta in fetal life. Cardiac lesions that reduce left ventricular output may decrease blood flow through the aortic isthmus and lead to coarctation. Consistent with this hypothesis is the frequency of coarctation with a ventricular septal defect that is associated with posterior malalignment of the outlet septum and the fact that coarctation does not occur with pulmonary atresia. Similar considerations of fetal flow patterns apply to the higher incidence of a persistent left superior vena cava in coarctation patients [24]. The hemodynamic theory alone, however, does not explain the pathogenesis of isolated coarctation.

Pathophysiology

In fetal life, there is little effect of the coarctation, although when severe or with marked arch hypoplasia, the right ventricle and pulmonary artery are dilated early in gestation and the left ventricle and aorta are mall [25–27]. After birth, obstruction in the aortic arch elevates pressure and resistance in the upper extremity arteries and increases left ventricular work. Closure of the ductus postnatally increases acutely left ventricular afterload and left ventricular failure develops – often causing acute cardiovascular collapse. Decreased blood flow to the descending aorta leads to ischemia of abdominal organs and the lower extremities. Metabolic acidosis and renal failure ensue. Although closure of the ductus does not always lead to instantaneous collapse, with severe coarctation the elevated left ventricular afterload is eventually no longer tolerated and decompensation follows.

In infants with milder coarctation, the left ventricle adapts to the increased afterload, and overt heart failure does not always occur. Activation of the sympathetic nervous system initially increases the heart rate, myocardial contractility, and peripheral arteriolar constriction to maintain perfusion of the descending aorta and the abdominal organs. The left ventricular end-diastolic volume and pressure increase (Frank–Starling mechanism), and to a point sustain a nearly normal cardiac output. Subsequently, left ventricular hypertrophy enables the left ventricle to develop increased systolic pressure while maintaining a normal or nearly normal left ventricular wall stress [28]. The renin–angiotensin–aldosterone system is activated secondary to reduced renal perfusion, and raises systemic blood pressure, increasing perfusion to the lower body. Finally, as the child develops a collateral circulation, systemic arterial pressure and afterload decrease and blood supply to the abdominal organs and kidneys improves.

Associated cardiovascular lesions may aggravate the hemodynamic burden associated with coarctation. The increased systemic afterload increases both the amount of left-to-right shunting through atrial and ventricular septal defects and the amount of atrioventricular valve regurgitation in an atrioventricular septal defect. In coexisting aortic stenosis and coarctation, both left ventricular afterload and myocardial oxygen demand are further increased.

Natural history

Untreated coarctation of the aorta beyond infancy significantly decreases long-term survival, and death frequently occurs within the fourth to fifth decade of life [29,30]. Early postmortem studies showed that of those who survived the first 2 years of life, 25% died before age 20 years, >50% before 31 years, 75% before 43 years, and 90% before 55 years [31]. Causes of death with an unrepaired coarctation of the aorta include congestive heart failure (26%), aortic rupture (21%), bacterial endarteritis (18%), and intracranial hemorrhage (12%) [29,30]. Both intracranial hemorrhage and ruptured aorta also occurred in children and young adults without exceptionally high blood pressures [32]. The risk of endocarditis in unrepaired coarctation of the aorta was 1.3% per year before the surgical era and improvements in public health and dental hygiene [32].

History and physical examination

Clinical features depend on the age at presentation (Table 32.1). Despite the frequency with which coarctation is now suspected prenatally and routine childhood auscultation is performed, neonatal collapse and late detection in adolescence and adulthood still occur as in previous eras [33,34].

Table 32.1 Presenting features of coarctation.

Fetal life
Ventricular disproportion (right ventricle enlargement)
Great vessel disproportion (small transverse arch)
In association with other congenital heart disease
Nuchal thickening/chromosomal abnormality (Turner syndrome)

Neonates
Acute collapse with shock and acidosis
Heart failure
Systolic/continuous murmur radiating to back
Weak or impalpable femoral pulses
Upper limb hypertension

Infants
Heart failure and failure to thrive
Systolic/continuous murmur conducted to back
Weak or impalpable femoral pulses
Upper limb hypertension
Cardiomyopathy rarely

Children, adolescents, and adults
Systolic/continuous murmur conducted to back
Collateral murmurs over scapula
Weak or impalpable femoral pulses
Radio-femoral delay
Upper limb hypertension
Exercise intolerance
Claudication and leg fatigue
Cold feet
Cardiac arrest (left ventricular hypertrophy, and arrhythmia)
Hypertensive retinopathy/encephalopathy
Intracranial bleeding
Aortic dissection/rupture
Infective endocarditis

Neonates and infants

Neonates typically present with acute heart failure in the first 2–3 weeks of life shortly after duct closure when the compensatory mechanisms (see above) are inadequate. They are well at discharge from the hospital (the duct is still patent and femoral pulses are palpable) and present with a sudden onset of tachypnea and pallor. If not immediately diagnosed and correctly treated, shock, acidosis, and death can occur rapidly. A neonate presenting in shock from a critical coarctation (or aortic stenosis) is often erroneously diagnosed as septic or with a metabolic disorder, delaying appropriate management. Other infants with coarctation have a more insidious presentation with congestive heart failure. Typically, such infants have a history of dyspnea from shortly after birth and sweating with feeding, but failure to thrive brings them to medical attention. Rarely, an infant presents with an apparent dilated cardiomyopathy and a minimal gradient across the coarctation (due to low cardiac output), which can cause diagnostic difficulty.

Asymptomatic detection of a murmur during infancy is an occasional presentation.

Children, adolescents, and adults

Most individuals with coarctation are asymptomatic and the coarctation is detected when the arterial blood pressure is measured incidentally (e.g., for headache or nose bleeding). Reduced or absent femoral pulses (if looked for!) rapidly leads to the diagnosis. If symptoms are present, they are usually related to reduced blood supply to the lower extremities causing exercise-induced claudication (rare) or, even less commonly, complications of upper extremity hypertension (cerebral bleeding, aorta rupture) [35]. Endocarditis is now extremely rare.

Physical findings

The hallmarks of coarctation of the aorta are absent or diminished femoral pulses and hypertension in the upper extremities, together with a systolic murmur radiating to the back. Less commonly, the femoral pulses can be maintained by collateral flow, and upper limb hypertension in addition to the murmur is the clue [36]. Because the left subclavian artery is frequently involved with the coarctation segment or there is associated arch hypoplasia in some, the right arm is the preferred location for measuring upper extremity blood pressure in children.

Sometimes almost no blood pressure gradient or pulse difference will be found on physical examination:

1 In neonates with a patent ductus arteriosus, the right ventricle perfuses the lower part of the body at systemic pressure, eliminating a pressure difference between the arms and legs. Even when the pulmonary artery pressure falls, the duct ampulla may serve as a "bypass" around the developing coarctation.

2 Infants in severe heart failure, with poor left ventricular function, cannot maintain cardiac output and all extremity pulses are weak, so blood pressure differences may not be detectable.

3 In those with an aberrant right subclavian artery that arises below the coarctation, there is no difference in blood pressure between the right arm and lower extremities.

4 In a few adults, collateral size and flow are adequate to maintain similar pressures between the upper and lower extremities. Because of the long collateral pathway, however, there is usually a detectable delay between the right radial and the femoral pulses.

A prominent left ventricular heave may be present. A systolic thrill is uncommon and usually due to associated cardiovascular anomalies. The first heart sound is normal. A systolic ejection click is frequently present with a bicuspid aortic valve. The second heart sound is normal except in infants with congestive heart failure and pulmonary hypertension, when the second heart sound is narrowly split with increased intensity of the pulmonary

component. A grade 2–3/6 systolic ejection murmur is usually heard along the left sternal border and between the spine and the left subscapular region. Systolic murmurs may also be from aortic stenosis, mitral regurgitation, or a ventricular septal defect. In older children with an unrepaired coarctation, continuous murmurs, due to collateral blood flow, can be heard over the back and chest. Collateral pulsation may also be felt, especially over the scapular margins or under-side of the ribs. Enlarged tortuous retinal arteries may be seen on retinoscopy. Neonates with congestive heart failure usually have a gallop and significant hepatomegaly.

With abdominal coarctation, a loud murmur is heard in the abdomen and not the chest and is associated with more severe elevation in diastolic blood pressure. Collateral pulsations are usually absent.

Electrocardiogram

In the neonate or infant with congestive heart failure and coarctation of the aorta, right ventricular hypertrophy is usual [37], and reflects the *in utero* right ventricular dilatation and the postnatal pulmonary hypertension required to perfuse the descending aorta via the patent ductus arteriosus. T wave inversion may be present in the left precordial leads, but if significant left ventricular hypertrophy is present, there is likely to be coexisting severe aortic stenosis. By the second to third year of life, a pattern of left ventricular hypertrophy gradually emerges. Patients with isolated coarctation of the aorta may have a normal electrocardiogram even into adult life.

Chest film

In a neonate, the chest film shows cardiomegaly and increased pulmonary vascular markings (consistent with pulmonary edema). In an older child, the typical radiologic features of coarctation are a "3" sign consisting of the ascending aortic knob and the poststenotic dilatation that is usually present. After 5 years of age, rib notching may begin to be noted (Figure 32.1). The rib notching is most prominent on the lower margins of the upper ribs; if notching of the lower ribs is present, the diagnosis of an abdominal coarctation should be considered. More commonly, however, the chest X-ray appears normal.

Pseudocoarctation is a "kinking or buckling" of the aorta that results in an X-ray picture similar to coarctation of the aorta. In pseudocoarctation, unlike in coarctation, there is little or no obstruction to blood flow. Although pseudocoarctation is usually benign, in some patients dilatation and aneurysm formation develop just distal to the pseudocoarctation [38].

Echocardiographic features

Echocardiography has replaced cardiac catheterization as the primary diagnostic tool for coarctation of the aorta [39–42]. Associated lesions such as a patent arterial duct, ventricular

Figure 32.1 Chest X-ray showing rib notching (arrows) in unrepaired coarctation.

septal defect, aortic stenosis, and more complex congenital heart disease are all readily evaluated.

The hallmark finding in coarctation is a posterior shelf with narrowing of the descending aorta in the juxta-ductal position (Figure 32.2). It is associated with turbulent color flow and an increased velocity with diastolic extension of the systolic waveform and a double envelope. There is often left ventricular hypertrophy and dilatation in older patients. Aortic arch hypoplasia and aberrant origin of the subclavian artery should be sought. A bicuspid aortic valve is present in half of patients.

In neonates, the diagnosis is not always immediately apparent. When the ductus is patent and the ductal sling around the aorta has not contracted, the coarctation shelf may not be fully developed. Prominence of the anterior duct ampulla, which overlies the coarctation area in some views, should not be interpreted as a sign of coarctation. Although initially flow at ductal level may be right to left, this changes to left to right as the pulmonary resistance falls. As the ductus constricts, the coarctation begins to be unmasked, but may not be clearly apparent until complete closure of the ductus or indeed even some weeks later [24].

Fetal echocardiography

In fetal life, the coarctation is not easily identified due to lack of flow across the isthmus [the ascending and descending aorta are perfused by the left and right (via the ductus) ventricles, respectively, which have an identical pressure] and the arterial duct (with high flow) overlies the coarctation site [25–27]. Furthermore, constriction of the
Figure 32.2 Echocardiogram in neonate showing coarctation shelf (arrow) in 2D (a) and the turbulent color jet (b). The continuous-wave Doppler trace shows continuous flow and a double envelope (c). After repair by end-to-end anastomosis, the arch is widely patent with echogenicity at the suture line (d) and laminar flow (e). The Doppler trace is now normal (f).

ductal sling around the aorta does not occur until after birth. The finding of right ventricular dilatation early during fetal life is a pointer towards coarctation development – especially when associated with additional transverse arch hypoplasia (Figure 32.3). Right ventricular dilatation in late gestation is common and without concomitant aortic arch hypoplasia is a much less specific sign of coarctation [25]. Antenatal detection is variable with a low rate in general obstetric units where great vessel assessment is not routine and mild ventricular disproportion may be ignored [41–43]. Even in dedicated fetal cardiology units there is a significant false-positive rate with more than two-thirds being normal at birth. Similarly, in those suspected to have a coarctation and a ventricular septal defect, two-thirds had only a ventricular septal defect postnatally [25,44]. When the disproportion between the ventricle and great vessels is marked, this may indicate progression to hypoplastic left heart syndrome, particularly if blood shunts left to right across the foramen ovale. Then continued evaluation is required until term.

Cardiac catheterization and angiography

With echocardiography and cross-sectional imaging with MRI, cardiac catheterization is no longer needed for anatomic assessment. It is performed primarily for interventional treatment. It retains a role in the hemodynamic assessment of mild or borderline coarctation or recoarctation associated with an increased Doppler gradient and mild hypertension.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) with 3D reconstruction, supplemented by gadolinium contrast, has become the imaging modality of choice after clinical findings and
Figure 32.3 Fetal echocardiogram at 20 weeks' gestation showing right ventricular dilatation in early gestation (a). The aorta is smaller than the pulmonary artery in (b) and (c) and the isthmus is smaller than the duct in (c). An extended arch repair was performed a few days after birth. Ao, aorta; La, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.
Figure 32.4 MRI scan in a 19-year-old asymptomatic male with an incidental blood pressure of 220/135. Black blood sequence in (a) shows a discrete coarctation beyond the left subclavian artery (LSCA). In (b) an SSFP sequence shows the coarctation with a jet of high turbulence (arrow). The ascending aorta (AAo) is dilated in (c). AAo, ascending aorta; DAo, descending aorta; LSCA, left subclavian artery; PA, pulmonary artery.

echocardiography have established the diagnosis. MRI gives unparalleled definition of the entire ascending and descending aorta and great vessels. Both the coarctation and hypoplasia of the aortic arch are clearly demonstrated and allow planning of interventional or surgical management. Demonstrating an aberrant subclavian artery is essential to planning the correct surgical approach. Following repair, MRI can demonstrate recurrent coarctation and aneurysm formation [45]. In addition, comprehensive assessment of aortic valve and left ventricular function are obtained during the same examination [46] (Figure 32.4). It has virtually supplanted diagnostic cardiac catheterization. It can diagnose pseudo-coarctation that has a fold in the medial aortic wall (inner curvature of the arch).

Management

Antenatal diagnosis

With suspicion of severe coarctation, the fetus should be delivered in a pediatric cardiology center so that a prostaglandin (PGE$_1$) infusion (5 ng kg^{-1} min^{-1}) can be commenced immediately. After echocardiographic confirmation of a posterior shelf at the coarctation site, prostaglandins are continued until elective surgical repair a few days later. When the findings are less convincing, the fetus is delivered and observed closely without prostaglandins while the duct closes. Regular monitoring of the four-limb blood pressure and femoral pulses and daily or alternate daily echocardiograms are performed until it is clear whether

a coarctation is developing. After ductus closure, those without a coarctation are allowed home but should be reviewed again in 4–6 weeks and finally at 6 months because of the occasional late detection of coarctation in the antenatally suspected cohort [25].

Early postnatal presentation

Neonates presenting with cardiovascular collapse require full resuscitation (intubation, ventilation, inotropes, and correction of metabolic acidosis) before transfer and surgery Prostaglandin (PGE$_1$) infusion to reopen the ductus, initially 50–100 ng kg^{-1} min^{-1}, may be needed for some hours to re-establish ductal patency, then the dose is reduced gradually to 5–10 ng kg^{-1} min^{-1}. Reopening of the duct together with inotopic support improves the hemodynamic status and corrects the acidosis so that an operation can be performed with the neonate in an optimal condition. With complex associated lesions, such as transposition, the coarctation is repaired at the time of the corrective surgery. When a ventricular septal defect (VSD) is the only additional lesion, a varied approach is taken;. either repair of all lesions on cardiopulmonary bypass or coarctation repair and banding of the pulmonary artery for later repair or even coarctation repair alone, deferring VSD repair until clinically indicated (heart failure or pulmonary hypertension) [47–50].

Infantile presentation

In older infants in whom the diagnosis is established because of clinical findings, development of mild cardiac failure, and/or failure to thrive, elective surgery is undertaken shortly after the diagnosis has been established. Rarely, an infant presents with an apparent dilated cardiomyopathy and a low gradient across the coarctation (due to low cardiac output), which can cause diagnostic difficulty. Since 1980, the surgical mortality for simple coarctation has progressively declined and is significantly lower than medical management [51]. Surgical repair is now routinely performed in neonates and infants at the time of diagnosis [52].

Childhood, adolescent, and adult presentation

In children beyond the first year of life, adolescents, and adults, both catheter intervention and surgery are options – the choice often depending on the views of individual centers. In adolescents and adults, catheter intervention is more likely to be used than surgery.

There are rare individuals with a mild coarctation, a systolic arm–leg gradient <20 mmHg, normal arm blood pressure, and normal ventricular function in whom no intervention is necessary. They should be examined periodically because aortic obstruction can increase and local complications can occur.

Operative repair

The first successful repair of coarctation of the aorta using primary end-to-end anastomosis was reported in 1945 by Craaford and Nylin [53] and by Gross [54]; neonatal repair was reported in 1952 by Kirklin *et al.* [55].

Resection and end-to-end anastomoses

Resection with end-to-end anastomosis is classically performed through a left posterior lateral thoracotomy (Figure 32.5). Extensive mobilization of the aorta from the left subclavian artery past the ductus arteriosus to the descending aorta is required. The ductus is divided and ligated. Sacrifice of dilated collateral intercostal arteries is often necessary for exposure. Adequate repair requires excision of the entire coarctation segment and the creation of a tension-free anastomosis. Early repairs using silk suture in a continuous running fashion were associated with a high incidence of restenosis [56]. Most surgeons advocate a continuous suture posteriorly and an interrupted layer anteriorly [57,58]. This operation theoretically removes all abnormal ductal and coarctation tissue and avoids the use of prosthetic material. When a tension-free anastomosis is impossible, an alternative method of repair may be required.

Prosthetic patch aortoplasty

The prosthetic patch aortoplasty was introduced in 1957 (Figure 32.5) [59]. A longitudinal incision is made in the aorta, the coarctation shelf is excised, and an elliptical patch of either Dacron or polytetrafluoroethylene is sutured to the aortotomy edges. This technique avoids extensive dissection and a prolonged operating time. Because of the late development of aneurysms on the posterior aortic wall opposite the patch, especially when Dacron was used [60–63], patching is now used only in selected circumstances.

Aneurysm formation has been attributed to excision of the posterior coarctation membrane weakening the posterior aortic wall or altered hemodynamics arising from the difference in tensile strength between the prosthetic patch and the posterior aortic wall [60–65].

Subclavian flap aortoplasty

Subclavian flap aortoplasty, introduced in 1966, is used extensively in infants and small children (Figure 32.5) [66]. The left subclavian artery is mobilized and divided and used to patch over an incision across the coarctation. The procedure is simple, avoids extensive aortic dissection and prosthetic patch material, and allows for growth. Disadvantages include complications from sacrificing the major vascular supply to the left arm [67,68], development of aneurysms [69,70], and recurrences from inadequate resection of ductal tissue [71]. It is currently less favored, although some centers continue with the technique [72].
Figure 32.5 Diagrams of coarctation (a) repair using an end-to end anastomosis (b), interposition graft (c), subclavian to descending aorta conduit (d), Dacron patch repair (e, f), and subclavian flap repair (g, h).

Interposition grafts

A prosthetic or homograft interposition graft, first described in 1960, is currently used only for either older individuals with an associated aneurysm or recoarctation when end-to-end anastomosis cannot be accomplished (Figure 32.5) [73]. Disadvantages include predisposition to infection, aneurysm formation, and their lack of growth potential. In other patients, a subclavian artery (or carotid artery after a previous subclavian flap repair) to descending aorta graft is placed. Ascending to descending aorta bypass grafts can be used for repair of complex coarctation and aortic arch abnormalities – usually after prior surgery [74].

Extended end-to-end anastomosis

Extended end-to-end repair was introduced in the mid-1980s to correct both the coarctation and associated aortic arch hypoplasia [75–77]. After resecting the coarctation, an incision is made on the inferior surface of the arch and the distal aorta is then brought up and sutured to this incision (Figure 32.6). Temporary occlusion of the left subclavian artery and/or left carotid artery and part of the right innominate artery may be needed. The most obvious advantages are excising potentially abnormal aortic tissue and, by extending the incision across the isthmus and transverse aortic arch, correcting the transverse arch hypoplasia [78]. Recoarctation rates are as low as 3–6% after neonatal repair [79–82]. Disadvantages are similar
Figure 32.6 Diagram of coarctation and hypoplastic arch (a) repair using an extended end-to end anastomosis (b).

to those of end-to-end repair: extensive dissection and sacrificing of collateral arteries. A tension-free anastomosis is necessary, and occasionally is achieved by sacrificing the left (and even right) subclavian artery. There is a risk of tracheal and left bronchus compression. Extended end-to-end anastomosis is now the preferred technique for most infants. Its use for routine extended arch repair when the transverse arch is mildly hypoplastic, however, has been questioned, as adequate treatment of the coarctation site alone results in rapid remodeling of the hypoplastic arch in

many infants [83,84]. Failure to perform an extended arch repair when the arch is hypoplastic, however, leads to a significant incidence of arch obstruction despite "successful coarctation repair," and may lead to repeat surgery via a sternotomy and bypass approach [85]. In infants with a severely hypoplastic arch and in those needing intracardiac repair of associated lesions, repair is performed on cardiopulmonary bypass.

Early complications after surgical repair

Major operative complications include hemorrhage, paradoxical hypertension, stroke, paraplegia, and damage to adjacent structures. Bleeding is an early postoperative complication related to the extent of the dissection, a coagulopathy, and excessive tension along the suture line, and is worsened by paradoxical hypertension. Turner syndrome is associated with an increased incidence of hemorrhage because of abnormal tissue fragility [86]. Currently, surgical repair is performed with a low mortality even in neonates.

Paradoxical hypertension occurs after transection of the aorta and damage to sympathetic nerves [87,88]. During the initial phase of hypertension, the sympathetic nervous system is activated with a marked increase in systemic catecholamine secretion. The catecholamine hyperactivity activates the renin–angiotensin–aldosterone system, ultimately leading to sustained hypertension and fluid retention. If untreated, the hypertension can result in post-coarctation syndrome (severe abdominal pain, distention, and tenderness, and also fever) [89]. Acute inflammatory changes in the mesenteric arteries (possibly due to over-distention of these thin-walled arteries previously exposed to a low blood pressure) cause intestinal ischemia, necrosis, and death. Paradoxical hypertension can be either prevented if β-blockers are administered before surgery [90], or treated early postoperatively by the intravenous administration of β-blockers, converting enzyme inhibitors, or nitroprusside. The incidence is very low in neonates and infants [91].

Stroke and paraplegia are rare postoperative complications. Prolonged or excessive cross-clamping of cerebral vessels may cause ischemia, but is uncommon now. In the few who need repair with cardiopulmonary bypass, the risk may be higher. Paraplegia occurs in 0.4% of patients [92]. Predisposing factors include inadequate collaterals, anomalous origin of the right subclavian artery, and prolonged distal hypotension, but surprisingly neither sacrificing intercostal arteries nor aortic cross-clamp time was related [93]. To prevent spinal cord paraplegia, most surgeons try to maintain distal aortic pressure >50mmHg. If pharmacologic measures are ineffective in preventing distal hypotension, a temporary shunt or femoral bypass with a distal pump oxygenator is used [94]. Paraplegia is more of a concern for repeat surgery involving extensive dissection when the collaterals have diminished and the risk may be as high as 2.6% [95]. Paraplegia sometimes occurs weeks after surgery and may

respond to spinal decompression [95]. Undertaking late and complicated repeat surgery with cardiopulmonary bypass and deep circulatory arrest or with left heart bypass through a lateral thoracotomy has been proposed to reduce morbidity and allow full repair [96–98]. Ascending to descending aorta bypass grafts may reduce the risk of paraplegia by avoiding a repeat left thoracotomy [74,99].

Adjacent structure damage can involve injury to the phrenic nerve, resulting in diaphragmatic paralysis, injury to the recurrent laryngeal nerve affecting the vocal chords, damage to the sympathetic trunk, resulting in Horner's syndrome, and, rarely, the development of chylothorax due to injury of the thoracic duct.

Mortality for coarctation repair even in the neonatal period and infancy is low. because of adequate preoperative stabilization and improved anesthesia, surgery, and intensive care [100]. In early series mortality rates were >30%, but are now ~3% [52,101,102]. Primary coarctation repair in adults carries a higher risk. The aorta above and below the coarctation is atheromatous and friable, and there are often large, thin-walled intercostal aneurysms.

Catheter intervention

Percutaneous balloon angioplasty to avoid the risks of coarctation surgery or repeat surgery for recoarctation dates back to 1979, when Sos *et al.* demonstrated successful balloon dilatation of aortic coarctation in postmortem neonates [103]. Shortly thereafter, balloon dilatation was performed clinically, and in many centers it became the procedure of choice [104–108]. Stent implantation was first reported in 1991 and is becoming preferred to balloon dilatation, particularly with the development of covered stents in the early 2000s [109–111].

Balloon dilatation

Balloon dilatation acts by stretching and tearing the thickened intimal coarctation shelf and adjacent media layers, but tears in the adjacent "normal" aortic wall also occur, perhaps reflecting an inherent aortic weakness in coarctation [112,113]. Limiting damage to the coarctation shelf is not always possible and adventitial extension can lead to acute rupture, dissection, and aneurysm formation. For recoarctation, with added external support from previous scarring, it rapidly became the treatment of choice [114–118]. Acute rupture and dissection are rare, but aneurysms can develop later [119,120].

Safety is improved by avoiding overdilatation of the coarctation segment. In general, the balloon size should not be greater than either the aorta proximal to the coarctation (isthmus) or at the level of the diaphragm. After initial enthusiasm, balloon dilatation is now generally avoided in the first 6–12 months of life because of a high incidence of recoarctation (postulated to be due to elastic ductal tissue stretching and recoiling without sufficient tearing of the
Figure 32.7 Coarctation (a) treated with a bare metal stent implantation in (b) abolishing the gradient. In another patient (c) an aneurysm (black dots) develops following bare metal stenting (white lines indicate length of stent) and is treated with a covered stent inside the first stent (white lines indicate length of second stent). Videoclips 32.1 and 32.2 demonstrate the acute effect on collateral flow of the patient in Figure 32.7a and b. (Reproduced from Eric Rosenthal, *Heart*, 2005; 91(11): 1495–1502, with permission from BMJ Publishing Group Ltd.)

coarctation shelf) and femoral artery damage [121]. The development of stenting has virtually restricted balloon dilatation to children weighing <25 kg [123,124].

Stent implantation

Stent implantation overcomes the natural recoil of elastic tissues after balloon dilatation and leads to greater relief of obstruction without excessive dilatation. The stent struts also splint any smaller tears against the aortic wall, preventing progressive dissection and aneurysm formation. Mild coarctation is less amenable to balloon dilatation and large balloons are needed to overcome the natural recoil with a risk of aortic tearing. Stent implantation allows mild coarctation to be easily treated, albeit with a small risk of stent migration [123]. Nevertheless, over-dilatation of a tight coarctation has caused aneurysm formation and rupture [124,125]. To prevent this, submaximal dilatation during the first procedure, allowing a period for healing, and further dilatation at a second procedure can be employed [126]. This strategy produces excellent results and stent implantation rapidly began to replace balloon dilatation (Figure 32.7 a and b; Videoclips 32.1 and 32.2). When aortic valve or root replacement or coronary bypass grafting is needed, presurgical stenting of the coarctation removes the need to dissect the coarctation area or to recover from cardiopulmonary bypass in the face of an aortic obstruction [127]. Stent implantation is also used for aortic arch hypoplasia either at the time of coarctation stenting or after prior successful treatment of the original coarctation [128].

For delivery of a stent large enough to open the aorta to adult size, the size of the delivery sheath in the femoral artery precludes use in most children weighing <25 kg [129,130]. In older children, the stents can be redilated after growth. [131]. Stents have been implanted in smaller children and even in neonates when surgical risks are considered to be too high [132,133]. The longer-term outcome of these "rescue" procedures is unknown.

Covered stent implantation

Covered stents were initially developed to treat acute dissection and aneurysm formation after aggressive stent implantation. A polyurethane sleeve attached to the outside of the stent sealed any tears from distension by the blood pressure. It subsequently found a role for primary implantation in tight coarctation in place of bare metal stents (Figure 32.7c and d). The disadvantages include the need for larger femoral artery sheaths to advance the covered stent, and a risk of occluding arch vessels when stenting the transverse arch. These stents are also used to seal existing aneurysms occurring either spontaneously or after surgical repair or catheter intervention. For more extensive aneurysm formation and dissection of the aorta longer than 25 mm, vascular stent-grafts, mounted on 22–24F delivery systems which require femoral or iliac exposure are used [134,135].

Early complications after catheter intervention

Early complications after catheter intervention are uncommon and include hemorrhage, femoral artery damage,

cerebrovascular accidents, and dissection and rupture. When performed after the first year of life, morbidity and mortality are lower than with surgery.

Regarding *femoral artery damage*, occlusion immediately after the procedure due to spasm and thrombosis responds to a heparin bolus and/or infusion for a few hours. If signs of occlusion persist, thrombolysis is usually effective. Less commonly, a dissection flap causes obstruction and surgical reconstruction of the puncture site is needed. Pseudo-aneurysm formation from inadequate compression after sheath removal can be treated by local thrombin injection and compression. Surgery is not needed. Acute rupture or avulsion of a femoral or iliac artery from a large sheath is extremely rare but requires emergency vascular repair. The leak can be occluded temporarily by a balloon inserted from the opposite femoral artery. With modern low-profile balloon catheters and femoral sheaths, the complications are reduced, although for stent implantation larger sheaths are still required.

Cerebrovascular accidents are rare and usually relate to inadequate heparinization and failure to de-air and flush the long sheath. The long guide-wire may also be a source of emboli.

Acute dissection and rupture are very rare and potentially life-threatening complications requiring immediate action. Initially a period of balloon tamponade allows volume replacement and then placement of a long covered stent. If this fails, then open surgery is performed.

This complication can occur when dilating a native coarctation without surrounding surgical scarring or after intervention for recoarctation [120,136]. Stent implantation with less aggressive dilatation has reduced but not abolished the occurrence [111,126]. *Stent migration* can be managed by capturing the stent on the balloon (or a larger balloon) and re-inflating to oppose the stent more closely to the aortic wall. If it is not possible to reposition the stent in the coarctation, it is expanded in an adjacent segment of the descending aorta or aortic arch and a new stent is implanted into the coarctation. Migration of a covered stent is a greater concern if it blocks either the arch or abdominal vessels and requires surgical removal.

Paraplegia has not been reported after catheter intervention. It occurs infrequently with stent-graft placement for extensive atheromatous dissection [135].

Surgery or catheter intervention – which to use?
