The effectiveness of coarctation repair has evolved as each new technical approach has been introduced and refined. There are no sizeable randomized trials and few comparative series, and we are limited by retrospective analysis. In most centers, repair in the first year of life is performed through a left thoracotomy with either an end-to-end anastomosis or an extended arch repair when the arch is hypoplastic. In children beyond the first year of life, surgery or balloon dilatation are

common approaches depending on the views of individual centers, and in adolescents and adults catheter intervention with stent implantation is increasingly being used. A choice between the two approaches is not without controversy [111,137–144]. The difficulty in making a direct comparison is confounded by the concept that two catherizations may be better than one thoracotomy. Recurrence of the coarctation after surgery is invariably treated by catheter intervention and this is less controversial! [74,99,145].

Long-term outcome

Although coarctation of the aorta appears to be a simple, correctable lesion with operative repair in neonates or by catheter intervention in older patients, ongoing issues persist [146].

In 1987, the first large long-term series of 226 survivors of coarctation surgery with 15–30 years of follow-up reported a late mortality of 12% and hypertension in 68% (despite normal blood pressure after surgery) [147]. An even larger series of patients operated on from 1946 to 1981 revealed significant morbidity and mortality in the 571 survivors with a median follow-up of 20 years. Deaths due to coronary artery disease, sudden death, heart failure, cerebrovascular accidents, and ruptured aortic aneurysm occurred in 15% at a mean age of 38 years and were associated with systolic hypertension. Additional surgery was required in 11% and hypertension required treatment in 25%. Operations before the age of 9 years resulted in the best long-term survival [148]. A longer-term study of 254 survivors followed for 24–53 years revealed a cardiovascular mortality of 18% at a mean age of 34 years after surgery due to coronary artery disease and re-operation. Hypertension was present in 35%. [149].

Currently, the acute results from repair in infancy show a low mortality and morbidity. Coupled with the benefits of catheter intervention for recoarctation, the long-term results should be better than in the early series. Until this evidence emerges, however, a patient with a treated coarctation should be considered palliated rather than cured [19,150].

Long-term surveillance is required to monitor for:
- recoarctation
- persistent or developing hypertension with attendant cardiovascular complications
- aortic aneurysm formation
- aortic valve disease progression with ascending aorta dilatation and the risk of dissection.

Recoarctation

Recoarctation may follow surgical or catheter intervention, but the relative incidence is difficult to assess. Partly this is due to definitions. Previously, recoarctation was diagnosed when heart failure or hypertension was severe enough to mandate repeat intervention. Milder "recoarctation" with minimally elevated blood pressure might not have been categorized as such. The designation of recoarctation as an arm to leg blood pressure gradient of 20 mmHg *and*

hypertension has recently been changed to a 30 mmHg gradient *and* hypertension [151,152]. Obstructions at arch level with a "perfect" result at the coarctation site have been labeled as recoarctation by some but not others. When stent implantation deliberately underdilated the coarctation to stage the treatment, some (often surgeons!) classified this as recoarctation [126]. In reviewing the literature, the distinction between an inadequate initial repair with immediate "recoarctation" and true late occurrence of recoarctation is not always evident. Even more difficult has been the interpretation of gradients that develop with exercise in patients with normal blood pressure and gradients less than 20–30 mmHg at rest. It is unclear whether this reflects recoarctation or results from differential responses of the peripheral vasculature in the upper and lower body segments that persist despite correction [153,154].

For patients younger than 3 months treated between 1985 and 1990, freedom from recoarctation after 4 years was 57% after subclavian flap repair, 77% after end-to-end anastomosis, and 83% after extended end-to-end anastomosis [155]. Following changes to the technique of end-to-end repair and with the development of the extended end-to-end repair, recoarctation rates are now <10% after neonatal repair [79–82].

It is difficult to compare angioplasty with surgical correction of coarctation, as the technique has been evolving since the mid-1980s and there are no large randomized studies. The recoarctation rate in children under 1 year of age is high, with rates up to 31–50% [122,156]. For children older than 1 year, the recurrence rates after balloon dilatation are much lower [157]. In 102 patients followed up to 10 years after balloon dilatation for native coarctation, immediate success was achieved in 93 patients, of whom 21 (22%) required a repeat intervention. Most of these were younger than 7 months – for those children older than 7 months, the incidence of recoarctation was only 10% [158].

A randomized study of 36 children aged 3–10 years, of whom 20 underwent balloon dilatation and 16 surgical repair of native coarctation, showed no statistical difference in the incidence of recoarctation [159]. Late follow-up of 21 of these patients, an average of 10 years after intervention, showed no difference in the blood pressure, gradients, or reintervention rate, although the aneurysm rate was higher after balloon dilatation [160]. A nonrandomized study of 46 children showed a low recoarctation rate with both procedures (<7%) and no aneurysms in either [161]. Another nonrandomized retrospective study of 80 patients found a reintervention rate of 32% in the catheter intervention group (some had stenting) and 0% in the surgical group [162].

Management of recoarctation

Before 1983, reoperation was the accepted treatment for recoarctation. Repeat surgery, however, did not always abolish the residual obstruction, mortality was 3–33%, and significant morbidity included spinal cord damage and cerebrovascular

events [117,163–166]. Balloon dilatation rapidly became the method of choice for recoarctation after surgical repair [167]. Recoarctation after balloon dilatation could be treated with either repeat dilatation or surgery. Surgery is not compromised by the previous balloon dilatation, although when collaterals have regressed femoral bypass or extra-anatomic repair are performed to prevent paraplegia [74,99,145]. Since the introduction of stent implantation (and covered stent implantation), recoarctation after previous balloon dilatation is more likely to be treated by catheter intervention. Small aneurysms that previously might have been treated surgically rather than by catheter intervention can now be addressed at the same time with a covered stent [111,168].

Aneurysm formation

Aneurysms may occur spontaneously in coarctation, particularly if it is untreated for many years. They also occur after any type of coarctation surgery, but most often with Dacron patch repair. and after balloon dilatation and stent implantation. The incidence is low after covered stent implantation, which is also used to treat aneurysms [111,168]. Because of varying definitions of aneurysms and the lack of randomized studies, their incidence is unknown. Many surgical and balloon dilatation series report no aneurysm formation but the incidence rises with the duration of follow-up [14,169–175].

A 16% incidence of ascending or descending aortic wall complications causing death or requiring a surgical or catheter intervention was reported in 235 adults (182 surgical repair, 28 catheter intervention, and 26 untreated) [175]. Ascending aortic complications were three times more frequent than in those in the descending aorta (coarctation site). Age or type of repair did not predict aortic wall complications, but age at the time of follow-up and a bicuspid aortic valve were predictive. Importantly, even untreated patients with a mild coarctation had a 15% incidence in aortic wall complications. A smaller study of 124 adults after coarctation repair revealed a bicuspid aortic valve in 62%, and 28% required an aortic valve intervention. Ascending aorta dilatation >4.0 cm was present in 28% [176]. Bicuspid aortic valve is an independent risk factor for ascending aorta dilatation [177]. Presumably, minor increases in systemic blood pressure and/or a transverse arch or coarctation site gradient may accentuate the ascending aorta dilatation in coarctation patients with a bicuspid aortic valve.

Hypertension

Treatment of coarctation, whether by catheter or surgery, usually results in a rapid fall in upper limb blood pressure. In the longer term, however, numerous series report hypertension requiring medication in about one-third of patients. Hypertension contributes to the high mortality seen in the long-term studies of patients operated on many years previously. Although recoarctation is an obvious cause of ongoing hypertension, it is not the only factor [178,179].

Often a degree of transverse arch hypoplasia that did not warrant surgery in early life appears on MRI scanning later to be more significant and is associated with hypertension and increase in left ventricular mass [180,181]. Acceptance of gradients of 5–25 mmHg across the aortic arch or coarctation site may also be responsible for the incidence of hypertension [182]. In earlier years, a "perfect" result was less important than survival without major morbidity, and so recoarctation was defined by what was achievable. The long-term results of the extended end-to-end repair should address these issues. A counter argument is that the repair site, even if wide enough, cannot distend during exercise or acts as an obstruction to the arterial wave form, thus causing a gradient [183]. The incidence of hypertension may relate to the age of repair. Thus, either the early renal hypoperfusion prior to correction has "reset" the renin–angiotensin–aldosterone system or the upper limb hypertension has "reset" the aortic baroreceptors permanently [184,185]. Even early repair is accompanied by hypertension and increased arterial stiffness [186–188].

Ambulatory blood pressure should be obtained from the right arm so that the effects of the hypoplastic arch and left subclavian involvement in the coarctation or its repair do not falsely lower the blood pressure reading. Blood pressure measurements during exercise have been used to assess the repair state and blood pressure response. The significance of an exaggerated response in a patient with normal or minimally elevated blood pressure is unclear [189,190].

Coronary artery disease

Coronary artery disease seems accelerated in postoperative coarctation patients with early cardiac death observed [147–149,191]. Accelerated atheroma of the internal mammary arteries has been observed [192]. Although the etiology of this accelerated atherosclerotic heart disease is unknown, a number of factors probably play a role, including hypertension, residual mild obstruction, aortic valve disease, peripheral vasculature abnormalities, and the coronary microcirculation [154]. After coarctation repair, in the arm but not the leg, resistance is elevated and has a reduced hyperemic response [154,193,194]. The pulsatility of the poststenotic aorta, which is severely impaired prior to repair, does not return to normal, and the degree of impairment may correlate with the age at surgery [195]. The intima–media thickness in the precoarctation segment (carotid artery) remains greater than in the postcoarctation segment (femoral artery) after repair [196]. More recently, abnormal long-axis ventricular function and subendocardial ischemia in patients with a "good" repair have been found [197,198].

Future directions

Advances in prenatal detection should allow more accurate prediction of coarctation postnatally and avoid the risk of acute cardiovascular collapse in undiagnosed neonates. Pulse oximetry in the nursery also detects some patients not otherwise suspected of this diagnosis. Longer-term follow-up of current neonatal repair will reveal the likelihood of cure without ongoing hypertension and the risk of other cardiovascular complications. Fundamental issues such as the cause (and effect) of aortic elastic impairment and abnormal vascular reactivity need to be addressed [153,154]. Newer stents that are biodegradable may encourage implantation in small children [199], and lower profile delivery systems will reduce the risk of vascular access complications.

Interrupted aortic arch

Interrupted aortic arch differs from coarctation of the aorta in that continuity between the ascending and descending aorta is absent. When a fibrous cord is present across the interruption, the anomaly is called aortic arch atresia, but it has identical clinical presentation. In arch atresia with fibrous continuity at the level of the coarctation, the clinical presentation resembles severe coarctation because of collateral development. In some infants, a severe coarctation may progress to acquired atresia. Interrupted aortic arch is a rare anomaly that accounts for <1.5% of all congenital heart disease [200].

Pathology and embryology

Celoria and Patton [201] classified interrupted aortic arch into three types according to site of the interruption: A, distal to the left subclavian artery; B, between the left subclavian artery and the left common carotid artery; and C, between the left common carotid and innominate arteries (Figure 32.8). Types A and B have been subdivided into A2 and B2 when the right subclavian artery arises anomalously from the descending aorta. The most common type is B, and C is the rarest [201–203]. Interruption is invariably associated with other intracardiac anomalies, the commonest being a ventricular septal defect. In a series of 105 patients [202], a ventricular septal defect was present in 98, and the only coexisting malformation in 58. The ventricular septal defect is usually a perimembranous or muscular outlet with varying degrees of posterior deviation of the outlet septum that can cause subaortic obstruction, but doubly committed defects also occur [204]. Other coexisting anomalies include aortopulmonary window, double-outlet right ventricle, ventriculoarterial discordance, congenitally corrected transposition, and Shone syndrome. There are no reports associating interruption with pulmonary atresia. The most common extracardiac association is DiGeorge syndrome, due to microdeletion in the long arm of chromosome 22 [205], occurring in up to 44% of patients with type B interruption.

The most widely accepted theory on the embryologic basis of interrupted aortic arch is that the posteriorly deviated malaligned outlet septum alters fetal hemodynamics so that
Figure 32.8 Anatomic classification of interrupted aortic arch.

reduced aortic flow hampers development of the aortic arch. Thus, the magnitude of blood flow through the fetal arch is critically important to both its enlargement and its evolution [206,207]. The rare patient of Pillsbury *et al.* [208], without any intracardiac malformations, however, suggests that morphogenic factors in addition to anterograde aortic blood flow are involved.

Pathophysiology

At birth, blood flow to the descending aorta depends on a patent ductus arteriosus. When the ductus closes, perfusion to the lower part of the body and kidneys becomes inadequate, renal function becomes impaired, urine output diminishes, and severe metabolic acidosis leads to hemodynamic collapse. If the ductus remains patent, then as the pulmonary resistance falls, pulmonary blood flow increases at the expense of reduced systemic perfusion. This is accompanied by left ventricular volume overload and acidosis that leads to progressive biventricular failure. Without treatment of interrupted aortic arch, the median age of death is 4–10 days [200]. Long-term survival is only possible with persistent patency of the ductus arteriosus and the development of pulmonary vascular disease from the increased right ventricular systolic pressure needed to perfuse the lower body.

History and physical examination

Patients with interrupted aortic arch often present with severe symptoms soon after birth – most with severe congestive heart failure during the first 2 weeks of life [200].

The physical findings depend on the size of the ductus arteriosus, the pulmonary vascular resistance, and the type of intracardiac malformations. The neonate is tachypneic with retractions, tachycardia, and hepatomegaly, and usually has rales. Precordial activity is always increased, and the second sound is accentuated. A systolic murmur is heard along the left sternal border due to increased pulmonary blood flow. A mid-diastolic rumble over the mitral valve from excessive pulmonary blood flow may also be heard. A gallop rhythm is usually present and an ejection click if the aortic valve is bicuspid.

Femoral pulses are usually weak, and there is almost always a blood pressure difference between upper and lower extremities. The difference in pulse character can be helpful in differentiating the type of interrupted aortic arch. In type C interruption, absent femoral and left carotid and brachial pulses and a normal right carotid and brachial pulse are found; type B interruption may have absent left brachial and femoral pulses, yet normal right and left carotid pulses; type A is similar to coarctation with only absent femoral pulses. If the right subclavian artery arises aberrantly from the descending aorta, the right carotid pulse is strong and the right brachial pulse weak. When the ductus is widely patent, there is little difference in upper and lower extremity pulses and blood pressures. With severe hemodynamic collapse, differences in pulses are often not apparent until resuscitation has improved the cardiac output.

In individuals who have normally related great arteries, differential cyanosis between the upper and lower parts of the body may be noted (a pink head and blue abdomen), but this is usually not striking because of massive intracardiac left-to-right shunting. In patients with double-outlet right ventricle or d-transposition, the upper part of the body may be cyanotic whereas the lower part of the body is acyanotic, resulting in reversed differential cyanosis. Although these differences in oxygen saturation may not be detected by physical examination alone, they can frequently be detected by pulse oximetry. In the rare natural survivors, finger clubbing is present in the cyanotic segment.

Electrocardiogram and chest film

The electrocardiogram is not diagnostic and its pattern depends on associated anomalies; there are usually right-axis deviation and right ventricular hypertrophy. The chest film is also not diagnostic, showing cardiomegaly and increased pulmonary vascular markings. Absence of a thymus shadow may suggest an associated 22q deletion.

Echocardiographic features

The site of interruption can be visualized from suprasternal arch views [209,210]. In interrupted aortic arch, type B, the
Figure 32.9 MRI scan to clarify the anatomy in a neonate with a right arch and interruption between the carotid arteries which was not clear on echocardiography. This is exquisitely demonstrated in Videoclip 32.3. Asc Aorta, ascending aorta; Desc Aorta, descending aorta; LCCA, left common carotid artery; LSCA, left subclavian artery; MPA, main pulmonary artery; RCCA, right common carotid artery; RPA, right pulmonary artery; RSCA, right subclavian artery.

ascending aorta is smaller than usual and can be seen to terminate in the left carotid artery, and the ductus arteriosus continues into the descending aorta which is large (Videoclip 32.3). There is no evidence of an aortic arch linking the ascending and descending portions of the aorta. Flow to the left subclavian artery is retrograde from the descending aorta. If there is an anomalous right subclavian artery, this too can be seen.

The apical and parasternal views can delineate the margins of the ventricular septal defect and its relationship to the great arteries and other intracardiac anomalies. Evidence of or potential for left ventricular outflow tract obstruction, which occurs in >50% of these children, is assessed. Useful preoperative echocardiographic predictors of left ventricular outflow tract obstruction include the cross-sectional area of the left ventricular outflow tract, an aortic valve annulus <4.5 mm and a Z score <−5 [211,212]. Type B interruptions have a higher incidence of outflow tract obstruction than type A, as does an aberrant right subclavian artery.

Cardiac catheterization and angiography

Cardiac catheterization has been supplanted by echocardiography. When the exact arch anatomy remains unclear, then tomographic cardiac CT or MRI are more frequently used than angiography to clarify the anatomy (Figure 32.9; Videoclip 32.3) [213]. Angiography is rarely needed for defining anatomic features that have not been clearly resolved by other imaging techniques. It has a role for intervention after surgical repair.

Medical management

When diagnosed prenatally, the neonate should be delivered at a cardiac center and commenced on a prostaglandin E_1 infusion (5 ng kg^{-1} min^{-1}) to maintain ductal patency until corrective surgery. In those who present in shock or heart failure, urgent stabilization, including mechanical ventilation, inotrope therapy, and prostaglandin infusion, is required. Higher doses of prostaglandin (50–100 ng kg^{-1} min^{-1}) are needed for some hours to re-establish ductal patency in these neonates. Once the hemodynamics have stabilized and the acidosis is resolved, surgery is performed. A high inspired concentration of oxygen is avoided as it may reduce the pulmonary vascular resistance and by increasing pulmonary blood flow reduce systemic perfusion and worsen the acidosis. Calcium levels should be measured because of the high incidence of DiGeorge syndrome and *irradiated blood should be used for transfusion*.

Surgical management

The first successful repair of interruption was in 1955 by Merrill *et al.* [214], who divided the ductus and performed an end-to-side anastomosis between the ascending and descending aorta in a 3½-year-old child. Two ventricular septal defects were subsequently closed 4 years later.

Re-establishment of continuity between the ascending and descending aorta is ideally performed without a prosthetic conduit. Although effective at relieving the aortic obstruction, conduits require replacement with growth of the child and increase morbidity and mortality from reoperating in a heavily scarred area [215]. Currently, a direct anastomosis is performed if possible [216]. This requires meticulous dissection to mobilize the proximal and distal ends of the aorta for a tension-free anastomosis and removal of all ductal tissue. Frequently, the left subclavian artery is ligated and divided for this purpose. When there is an anomalous right subclavian artery originating from the descending aorta, this too may need sacrificing. It is then impossible to measure an upper limb blood pressure. The recurrent laryngeal and phrenic nerves on the left can be damaged, and the spinal cord may be at risk during clamping of the descending aorta after the ductus is ligated and excised. The left main bronchus may be compressed by the newly constructed arch and may require subsequent surgical aortopexy [217,218]. Narrowing at the repair site responds well to balloon dilatation (and may be repeated with growth), but reoperation is needed in some [216,219,220]. Repeat surgical options include patch enlargement, extra-anatomic bypass, and subclavian or carotid turn-down procedures.

The approach to correcting the intracardiac anomalies has evolved since the first repairs when palliation for the intracardiac anomalies was invariable (Figure 32.10). The change to primary repair is well illustrated by Menahem *et al.* [220]. From 1979 through 1984, 15/17 infants underwent a two-stage repair with initial reconstruction of the arch and pulmonary artery banding with a surgical mortality of 65%. From 1984 through 1988, 22/29 had a single-stage repair with a mortality of 13%. Although single-stage repair is now routine, an individualized approach may be needed – for
Figure 32.10 Diagram of interruption repair with interposition graft and pulmonary artery banding and duct ligation (a) and complete one-stage repair with a direct arch anastomosis and ventricular septal defect closure (b). LCA, left carotid artery; LSCA, left subclavian artery; PA, pulmonary artery; RCA, right carotid artery; RSCA, right subclavian artery; VSD, ventricular septal defect.

example, in low birth weight or premature neonates, staged repair is still more commonly used [220–225].

During single-stage repair, the most challenging aspect is managing left ventricular outflow tract obstruction [226,227]. Although complete repair including a subaortic myotomy/ myectomy is ideal, leaving a residual mild subaortic obstruction may be better than damaging the aortic valve by too extensive a dissection. Other approaches include the following: (1) Ross–Konno procedure –aortic root replacement with a pulmonary autograft combined with incision into the outlet septum and a pulmonary homograft placed in the right ventricular outflow tract [228,229]; (2) patching the ventricular septal defect to create a double-outlet left ventricle, aortopulmonary anastomosis, and conduit from right ventricle to pulmonary artery [230]; (3) resecting part of the outlet septum from a right atrial approach with patch closure of the enlarged ventricular septal defect to widen the subaortic area [231]; (4) placing the ventricular septal defect patch on the left side of the septum to deflect the outlet septum anteriorly and away from the subaortic area without resecting the outlet septum [223]; and (5) abandoning repair of the left ventricular outflow tract in favor of transplantation [232] or the Norwood procedure [233].

Currently, in patients with interruption and more complex intracardiac anomalies, for example, truncus arteriosus or double-outlet right ventricle, a biventricular repair is undertaken during the neonatal period, although the results are not as favorable. In a series of 50 neonates with interruption and truncus arteriosus who underwent predominantly one-stage repair, the survival at 6 months was 44% and at 10 years 31% [234]. Even in the setting of interruption and aortic valve atresia, single-stage repair is possible by repairing the arch and performing a Damus–Kaye–Stansel procedure [235].

When interruption is associated with a functional single ventricle, subaortic obstruction can be addressed by a Damus–

Kaye–Stansel procedure or the Norwood procedure. If outflow obstruction resection is required, it is ideally performed without a ventriculotomy to preserve ventricular function for a future single-ventricle repair. Good results have also been achieved with initial pulmonary artery banding followed by the Damus–Kaye–Stansel procedure [236].

Long-term outcome

Regardless of the type of repair, a high incidence of recurrent arch narrowing, left ventricular outflow obstruction, and bronchial compression are reported. The largest prospective study reported 472 neonates with interrupted arch and ventricular septal defect [237]. In this multi-institutional study, neonates were enrolled from 1987 to 1997. Nineteen died before repair from complications of prematurity and poor cardiac function. Of those who underwent surgery, the survival was 67% at 16 years, with 28% undergoing a second procedure. (The same group reported a 63% survival at 4 years when only 183 neonates had been enrolled [224].) In the subgroup who also underwent a left ventricular outflow tract procedure, survival was 63% at 16 years, with 28% undergoing a second procedure. A second arch procedure was performed in 109 patients, 52 by catheter intervention. Although direct anastomosis resulted in a lower mortality than with PTFE patch augmentation of the arch, the need for reintervention was similar. The risk factors for death and for left ventricular outflow tract procedure were low birth weight, younger age at repair, female gender, type B interruption, and major associated cardiac anomalies. The predicted mortality for an "ideal patient" – male, 3.5 kg, ventricular septal defect closed at the time of repair without PTFE augmentation of the arch and no other cardiac anomalies, was 7% at 16 years [237].

Other series have reported better results, but are much smaller with selected patient populations, retrospective, and often with shorter lengths of follow-up [215]. Although the mortality rates from surgery for this condition have improved, concerns remain about the neurodevelopmental outcomes [238]. Selective cerebral perfusion has improved mortality rates but not reduced neurodevelopmental disability [239]. Whereas the duration of deep hypothermic circulatory arrest correlates with worse developmental indices, as do chromosomal abnormalities, presentation with circulatory collapse and acidosis may also contribute.

Future directions

Improved surgical techniques are needed to minimize cerebral dysfunction during repair and correction of left ventricular outflow obstruction. Better prenatal diagnosis should prevent preoperative cardiovascular and neurological compromise.

33 Right Ventricular Outflow Tract Obstruction

Philipp C. Lurz[1], Ingo Daehnert[1] & Philipp Bonhoeffer[2]

[1]University of Leipzig – Heart Center, Leipzig, Germany
[2]Great Ormond Street Hospital for Children, London, UK

Right ventricular outflow tract obstruction may occur within the ventricle, at the valve itself, or in the pulmonary arteries. The obstruction may be solitary or occur at multiple levels. As an isolated lesion, pulmonic stenosis accounts for ~10% of cardiac malformations. In association with other lesions, the incidence may be as high as 25–30% of congenital heart disease.

Valvar pulmonic stenosis

Incidence and genetics

This is a common lesion that may occur sporadically or recur in families (>3% of siblings also have pulmonic stenosis) [1]. It may occur in the Noonan syndrome, the LEOPARD syndrome, or neurofibromatosis [2,3].

Embryology

The pathologic process has been ascribed to an abnormality in the development of the distal bulbus cordis [4]. The exact cause is unclear.

Pathology

Pulmonic stenosis may occur in a tricuspid, bicuspid, or dysplastic pulmonic valve. Usually, there are three cusps with fusion of the commissures. As a result, the valve becomes dome shaped and projects into the pulmonary trunk [5]. The stenotic valve orifice is usually central, but is occasionally eccentric. The valve cusps are usually thin, but can be thickened and even calcified.

As a result of the obstruction, generalized right ventricular hypertrophy occurs. This may be more marked in the infundibular region, where dynamic obstruction may develop. The right atrium may become dilated if the stenosis is severe and compliance of the right ventricle decreased.

The wall of the right atrium may thicken, and the foramen ovale dilate.

The pulmonary artery shows post-stenotic dilatation, which may extend into one of the branches and is almost always present after infancy. The left pulmonary artery is usually dilated as the "jet" through the stenotic orifice is directed towards the left pulmonary artery. There is no correlation between severity of the obstruction and the degree of post-stenotic dilatation. Although post-stenotic dilatation may occur in a dysplastic valve, its incidence is lower than in patients with classic pulmonic stenosis.

An important pathologic subgroup (having clinical and therapeutic implications) is that of the dysplastic valve, with an incidence in Noonan syndrome of ~60%. This valve consists of three thickened, immobile cusps with little, if any, commissural fusion. The cusps are composed of disorganized myxomatous tissue. The valve annulus is usually narrow, and the supravalvar area of the pulmonary trunk is also hypoplastic.

Pathophysiology

Regardless of the features of the pulmonary valve, the physiologic effects depend on the degree of stenosis. As the valve orifice diminishes, right systolic ventricular pressure increases (roughly as a squared function) to maintain the cardiac output. Right ventricular hypertrophy develops in proportion to the right ventricular systolic pressure. The ventricular trabeculations are increased. In severe stenoses, the right ventricular cavity is decreased in size.

Rarely in severe stenosis with suprasystemic right ventricular systolic pressure and especially if it is long-standing, myocardial ischemia may occur and lead to myocardial fibrosis and eventually congestive cardiac failure [6]. Rudolph has made a significant contribution to our understanding of fetal and neonatal factors contributing to the physiology in

such patients [7]. An essential difference in the response of the very young to afterload is hyperplasia in addition to hypertrophy of myocardial fibers. In the neonatal response to afterload, the number of capillaries is increased. This provides the capacity to produce extremely high systolic ventricular pressures. The stroke volume is usually maintained by the hypertrophied muscle although, after a period of sustained elevated pressure, cardiac failure may occur if the ventricle dilates. Cardiac output is usually maintained.

Pulmonary blood flow is decreased and cyanosis is present when right-to-left shunting occurs at the atrial level in association with right ventricular fibrosis (and decreased compliance), right ventricular failure, or decreased size of the right ventricle (due to hypertrophy, which also causes decreased compliance). Hypoplasia of the right ventricle, a separate entity, may simulate the last condition [8]. There is a continuum between severe neonatal pulmonary stenosis and pulmonary atresia with intact ventricular septum.

Clinical features

Clinical history

Neonates with critical stenosis may be in congestive heart failure or cyanotic from a right-to-left atrial shunt. In the first days of life, the gradient increases as pulmonary vascular resistance decreases. Symptoms may be mild provided that the arterial duct is patent and rapid deterioration may occur with duct closure.

Beyond the neonatal period, most patients are asymptomatic, even with severe stenosis. Currently, most patients undergo treatment to relieve the stenosis before symptoms appear (certainly those beyond the neonatal period). In infancy, symptoms are rare, but can include dyspnea and fatigue on effort. Even in severe stenosis, marked symptoms are unusual because the right ventricle maintains cardiac output for long periods before decompensation. Rarely, chest pain, syncope, and even sudden death may occur during exercise in patients with severe stenosis.

Cyanosis is rare in childhood but possibly occurs in adults as right ventricular compliance decreases and shunting occurs through a patent foramen ovale.

In nonsyndromic patients, intelligence is usually normal.

Physical examination

Growth and development are usually normal, regardless of the degree of the stenosis. Facial and other features may be specific in the Noonan syndrome [2,3], the LEOPARD syndrome, and neurofibromatosis. In the first two conditions, there are triangular facies, ptosis, and hypertelorism. In those with the Noonan and LEOPARD syndromes, both growth and development may be subnormal (often below the 10th percentile).

Cardiac findings depend on the severity of the obstruction. Signs of congestive cardiac failure are usually present only in severe stenosis during infancy. The peripheral pulse and systemic blood pressure are normal. The jugular venous pulse may be altered in severe stenosis, with a prominent *a* wave. A right ventricular heave may be found, depending on the degree of right ventricular hypertrophy. A systolic thrill at the second and third left intercostal spaces is common; it does not parallel severity of the lesion and is often present in mild to moderate stenosis.

Auscultation is particularly accurate in predicting the severity of the lesion, probably more so than in any other congenital lesion [9,10]. The first heart sound is usually normal. An early ejection systolic click is a typical and often identifying feature of classic pulmonic valvar stenosis. The ejection sound is heard with mild or moderate stenosis. It does not occur in subvalvar or supravalvar stenosis and is absent in patients with severe stenosis or a dysplastic valve. The click becomes louder during expiration and softer in inspiration. In expiration, the right atrial contractile force decreases so that the pulmonary valve is in a relatively closed position when the right ventricle contracts; therefore, its systolic excursion is increased, and the ejection sound is louder.

A systolic ejection murmur is heard best at the upper left sternal border. It may be transmitted throughout the precordium and importantly to the left upper back. In general, louder murmurs indicate more severe stenosis, but the distinction is imperfect.

The length and timing of the peak of the murmur vary with the severity of stenosis, which obviously determines the length of contraction. In patients with mild stenosis, the murmur is relatively short, and the peak does not occur beyond mid-systole. In moderate stenosis, the peak occurs later, and the murmur may end at or slightly beyond the aortic component of the second heart sound. With severe stenosis, the peak occurs even later in systole, and the murmur ends beyond the aortic component of the second sound. With increasing severity of stenosis, the frequency of the murmur also increases because the velocity of flow through the narrow orifice is increased.

The degree of splitting of the second heart sound varies with severity. In mild stenosis, the split is normal, and the pulmonic component is clearly audible. The degree of splitting increases with increasing severity and the pulmonic component becomes softer in severe stenosis so that the duration of the split may be 0.12–0.14 s and the pulmonic component soft or inaudible. In addition, if it is audible, the split may be almost unchanging because of a fixed right ventricular volume. A fourth heart sound may be heard in patients with severe stenosis. In infants with severe stenosis, an additional systolic murmur that increases with inspiration, indicating tricuspid insufficiency, may be audible.

Electrocardiographic features

The electrocardiographic changes are right atrial enlargement, right-axis deviation, and right ventricular hypertrophy [11]. In mild valvar stenosis, the electrocardiogram is often
Figure 33.1 Typical 2D and color Doppler image of isolated valvar pulmonary stenosis in a modified parasternal long-axis view. The right ventricular outflow tract is not stenotic. Arrow points to doming valve.

normal, with only mild right-axis deviation and often an rSR′ or rR′ pattern in lead V1. In moderate stenosis, the electrocardiogram is abnormal in >90% of patients. Right-axis deviation may be present (usually between 90 and 30° mean frontal axis). On occasion, right atrial enlargement is found. An rR′ or RS complex is usually present in lead V1. In severe stenosis, the P wave is abnormal. The mean frontal axis varies from +100 to +170°. In lead V1, a pure R wave or RS or QR pattern may be present. The T waves may remain negative but often become upright in severe stenosis. An R wave above 30 mV in lead V1 correlates with severe stenosis. Although the electrocardiogram may be normal in aortic stenosis, even if severe, this is extremely rare in pulmonic stenosis.

In patients with a dysplastic valve (usually those with Noonan's syndrome), the electrocardiogram is atypical with a left anterior hemiblock pattern and counterclockwise QRS frontal plane loop. The mean frontal QRS axis is superiorly directed, and deep S waves are present in the precordium, regardless of the level of systolic pressure in the right ventricle. With associated hypertrophic cardiomyopathy, left ventricular hypertrophy may be present.

Arrhythmias are rare in pulmonic stenosis. Supraventricular arrhythmia may occur in an untreated patient with severe stenosis, and ventricular arrhythmias may occur in the older untreated patients, especially during exercise.

Chest X-ray
Radiographic features are much less reliable than physical findings and electrocardiographic features in assessing the severity of the lesion. Cardiac size is usually normal. Post-stenotic dilatation of the main and often the left pulmonary

artery is present and produces a prominent pulmonary artery segment on the posteroanterior chest radiograph. The prominence of the pulmonary artery does not correlate with the degree of stenosis, and although dysplastic valves may have little or no post-stenotic dilatation, this is certainly not a general rule [12]. It is not uncommon for a normal adolescent to be referred for evaluation of possible congenital heart disease because of a prominent pulmonary artery segment on the chest radiograph.

Echocardiography
The abnormal pulmonary valve can be visualized on a parasternal short-axis view at the level of the great arteries. The valve may also be evaluated from a subxiphoid short-axis view (Figure 33.1, Videoclips 33.1 and 33.2). The valve domes during systole, appearing as a convex line of varying thickness at the pulmonary annulus. The pulmonary trunk is dilated (post-stenotic dilatation). Color Doppler imaging shows the direction of the jet through the valve, and continuous-wave Doppler imaging allows assessment of the severity of the stenosis. The peak instantaneous systolic gradient across the valve may be calculated by the simplified Bernoulli equation ($\Delta P = 4 \times V_{max}^2$). A gradient ≤40 mmHg is considered mild, 40–70 mmHg is considered moderate, and >70 mmHg is severe. The right ventricular systolic pressure is increased according to the severity of the pulmonic stenosis. The severity of stenosis may be assessed qualitatively by the degree of thickening of the right ventricular wall or by the presence or absence of systolic flattening of the intraventricular septum on a short-axis view. However, flattening of the septum appears even when the systolic pressure in the

right ventricle is less than systemic. Due to increased wall stress of the RV free wall, there is prolonged right ventricular shortening as compared with left ventricular shortening, causing the septum to bow leftwards in late right ventricular systole, which coincidences with early left ventricular diastole/filling. If there is tricuspid regurgitation, the right ventricular systolic pressure may be assessed quantitatively by applying the simplified Bernoulli equation to the regurgitation jet. The right ventricular systolic pressure equals the peak systolic gradient of this jet in addition to the right atrial pressure (usually 5–10 mmHg). This pressure may be compared with the systemic blood pressure measured by the blood pressure cuff.

In neonates there might be a patent arterial duct with left-to-right shunt.

In infants with severe valvar pulmonic stenosis, a right-to-left shunt across the foramen ovale may be demonstrated by color Doppler or contrast-enhanced echocardiography. In these infants, some hypoplasia of the right ventricular cavity may be present, and this decreases the compliance of the ventricle and enhances the right-to-left shunt. Bowing of the atrial septum from right to left may be seen with a right-to-left shunt at the atrial level because of the increased right atrial pressure. In a dysplastic pulmonary valve, the leaflets are markedly thickened and move poorly, and there may be hypoplasia of the pulmonary valve annulus and narrowing of the pulmonary trunk.

Cardiac catheterization

Cardiac catheterization is principally performed for balloon valvoplasty. In most patients, oxygen saturation data do not demonstrate an intracardiac shunt, although the combination of pulmonic stenosis and a secundum atrial septal defect is common. In patients with severe obstruction and associated intracardiac communication, a right-to-left shunt through a foramen ovale may be detected.

The severity of the stenosis is determined by the peak systolic pressure gradient across the pulmonary valve and the systolic pressure ratio of the right ventricle to the aorta or the left ventricle. Carefully obtained withdrawal pressure tracings from the pulmonary artery to the right ventricle provide information concerning the site and severity of the stenosis.

When the resting right ventricular systolic pressure is <50 mmHg or the gradient is <30 mmHg, the stenosis is characterized as mild. In moderate valvar pulmonic stenosis, the right ventricular systolic pressure may equal that of the aorta or the gradient may be 30–50 mmHg. In severe obstruction, the resting right ventricular pressure is suprasystemic, and the gradient is >50 mmHg (the gradients measured at catheterization are usually less than those measured by Doppler echocardiography.) The pulmonary valve area may be calculated the Gorlin equation and is normally about 2 cm² m⁻². Because cardiac output is usually normal, even in severe stenosis, the valve area is only rarely calculated. The most important hemodynamic factor that influences the systolic pressure gradient is the heart rate.

The end-diastolic pressure in the right ventricle may be normal, but when there is severe obstruction or right ventricular dysfunction, it may be elevated. Tall right atrial *a* waves are usually present in severe pulmonic stenosis, particularly when there is only a small interatrial communication. Tall right atrial *v* waves are present when moderately severe tricuspid insufficiency is associated. In severe stenosis, the pulsatility of the pulmonary artery pressure tracing is absent. Associated infundibular stenosis may be present, especially in severe stenosis, and may be suspected from the withdrawal pressure tracing.

Angiography

Right ventriculograms in the PA and lateral projections with a 25° cranial tilt provide information about the right ventricular size and function, any associated infundibular stenosis, and the pulmonary valve (Videoclip 33.3).

The right ventricular size is usually normal, although there can be moderate to severe right ventricular hypoplasia, especially in neonates. The typical stenotic valve is thickened and domes during systole. The annulus is usually normal but may be hypoplastic in neonates or infants and in those with severe valvar pulmonic stenosis. Post-stenotic dilatation of the pulmonary trunk and left pulmonary artery is usually seen. In a dysplastic valve, the leaflets are thickened and relatively immobile. The main pulmonary artery and the annulus may be moderately hypoplastic. There may be post-stenotic dilatation of the pulmonary trunk, although this is less marked than in classic valvar stenosis.

In patients with severe valvar pulmonic stenosis, diffuse narrowing of the right ventricular outflow tract due to hypertrophy may be seen during middle to late systole, but this narrowing disappears during diastole.

Other imaging modalities

Magnetic resonance imaging (MRI) represents an important noninvasive imaging tool apart from echocardiography. Although in neonates the spatial resolution is an important limitation of this technique, its role is increasing, especially in adults. The static, three-dimensional anatomic features of the RVOT can easily be appreciated on MRI. Further, cine images give dynamic information on the function of the RVOT; for instance, they can nicely demonstrate any dynamic muscular RVOT obstruction. MRI also offers a quantitative analysis of pulmonary regurgitation in those patients who develop pulmonary insufficiency after surgical or interventional treatment. Most importantly, MRI represents the most valid technique to determine right ventricular size, function, and wall thickness and thereby facilitate the assessment of pathophysiology in the presence of RVOT dysfunction.

If MRI is contraindicated, cardiac computed tomography (CT) can be used for the three- dimensional assessment of the anatomy, and three-dimensional reconstruction of the RVOT throughout the cardiac cycle ("four-dimensional imaging") is possible. These images help in planning interventional strategies in these patients. Nevertheless, echocardiography represents the most important and easily accessible noninvasive imaging technique in the setting of RVOT obstruction.

Management

Patients with mild valvar pulmonic stenosis do not require intervention. They should be treated as normal children and not restricted from physical activity [13–15]. An indication for treatment in infants, children, and adolescents, with or without symptoms, is a transvalvar gradient >40 mmHg in the absence of fixed subpulmonary obstruction or additional lesions that need operative interventions. Most patients are asymptomatic, even with severe obstruction. The successful relief of obstruction improves clinical outcome. Severe valvar pulmonic stenosis leads to symptoms and signs of right-sided heart failure, especially in long-standing obstruction in adults [16–20].

Neonates

In contrast to older infants and children, critical pulmonic stenosis in neonates requires emergency treatment to prevent death [21–23].

Initially, infusion of prostaglandin E_1 or E_2 should be commenced as early as possible to maintain ductal patency until definitive treatment is available. Treatment, when necessary, consists of balloon valvoplasty, which gives excellent results. Surgical valvotomy is limited to patients with more complex lesions or those with dysplastic valves in whom balloon dilation has failed.

Successful dilatation occurs in >95% of neonates [24–40]. In some neonates, the smaller and noncompliant right ventricle may be inadequate for maintaining normal pulmonary blood flow. Prolonged prostaglandin infusion gives time for the right ventricular compliance to improve after regression of its hypertrophy. If slow recovery is to be expected, prostaglandin is not tolerated or if cyanosis persists (oxygen saturation <80%) after 3 weeks of prostaglandin infusion, ductal stenting or a systemic-to-pulmonary artery shunt should be considered.

Complications are more common in neonates than in older patients, with a mortality rate of 3%, major complications 3.5%, and minor complications 15% [24–34,41]. On longer follow-up, about 10–15% of patients need reintervention, either repeated balloon dilatation or surgery for either infundibular stenosis or a dysplastic valve. Morphologic follow-up studies have confirmed that the valve matures from its dysplastic appearance, and the annulus and right ventricular cavity grow [39]. The results compare favorably with operation [40]. Hence we currently consider balloon valvoplasty to be the treatment of choice in neonates with isolated critical valvar pulmonic stenosis, regardless of mild right ventricular hypoplasia or valve morphology.

Infants

Asymptomatic infants with severe valvar pulmonic stenosis should be treated electively, usually around the age of 9–12 months. Balloon valvoplasty may be performed earlier if the lesion is extremely severe. The rationale for intervention has included relief of symptoms, prevention of secondary changes in the right ventricle and pulmonary artery, and prevention of progression to more severe obstruction. Successful relief of obstruction is associated with an improved clinical outcome [16–20].

Balloon valvoplasty

After hemodynamic measurements of the right ventricle/aortic pressure ratio and the transvalvar gradient, accurate measurements of the diameter of the valve annulus are obtained from AP and lateral angiocardiograms. A guidewire of appropriate stiffness is positioned in a distal pulmonary artery. With the wire carefully fixed in place, the balloon dilatation catheter is advanced over the wire until the valve lies exactly half way along the length of the balloon. When a single balloon is used, the balloon diameter should be ~20% larger than the diameter of the pulmonary valve annulus. The balloon is inflated until the waist is abolished and not beyond its prescribed pressure. The balloon is then rapidly deflated, with the entire cycle of inflation and deflation taking no more than 10–15 s. The inflation–deflation process is repeated with the balloon repositioned slightly forwards or backwards between each inflation if the waist could not be abolished or the balloon position was not stable during inflation (Figure 33.2, Videoclip 33.4).

For a larger valve annulus, a double-balloon technique was developed. For this technique, a second exchange wire for a second balloon can be used. Alternatively, a multi-track balloon catheter allows for the advancement of two balloons over the same wire. When two balloons are used, the combined diameters of the two balloons should be at least 1.6–1.8 times the diameter of the valve annulus. The two balloons are inflated and deflated simultaneously. Although double-balloon dilatations are rarely required, several added advantages immediately become apparent for large patients. The two balloons inflate and deflate faster than a single larger balloon. This, coupled with the persistent "lumen" through the valve between the two inflated balloons, results in much less effect on the systemic arterial pressure at maximal inflation than with a single balloon. Even in a smaller valve, the relatively smooth contour of the two much lower profile balloons results in less trauma to the vessels at the site of introduction. Because of these advantages, the double-balloon technique has been adapted for most pulmonary valve
Figure 33.2 Lateral right ventricular angiograms (LAO 90°) of an infant with valvar pulmonary stenosis undergoing balloon dilation. (a) Before the intervention with a thick, doming valve and post-stenotic dilation of the main stem pulmonary artery. (b) The dilating balloon with a tight waist at the level of the stenosis. With higher pressure the waist disappears. (c) Typical result with a good central opening of the valve and a narrow right ventricular outflow tract ("reactive infundibular stenosis") which is due to right ventricular hypertrophy and will diminish over time.

dilatations in adult patients, even if a single adequate-sized balloon is available.

The goal of the pulmonary valve dilatation is to relieve outflow tract obstruction with residual gradient as low as possible. Often, the gradient across the valve can be reduced to <10–15 mmHg. However, particularly in patients with more severe stenosis, there may be dynamic subvalvar right ventricular outflow tract obstruction. Once the valvar obstruction is relieved, the subvalvar gradient becomes manifest, and angiographically the subvalvar area narrows markedly. This reaction was recognized long ago by the surgeons as the "suicide right ventricle" after operative relief of severe valvar stenosis. Fortunately, in the catheterization laboratory, without the trauma of operation and cardiopulmonary bypass, this is a nonfatal reaction, and the stenosis regresses with time if the valvar stenosis has been adequately relieved.

Some severely dysplastic pulmonary valves cannot be dilated adequately. Unless there are extreme degrees of these echocardiographic and angiocardiographic features, the valve may be mildly dysplastic and possible to dilate. An attempt should be made to dilate these valves when significant stenosis is present.

The safety and efficacy of balloon valvoplasty of a stenotic pulmonary valve in infants, children, adolescents, and adults have been confirmed by numerous studies [42–72]. Acute and long-term results are excellent, with reduction of valve gradient in most patients to a hemodynamically insignificant level. In comparison with valvotomy, balloon valvoplasty provides equivalent long-term gradient relief with only trivial to mild pulmonary insufficiency during follow-up in most patients [41,48,49–66].

Follow-up data for 533 patients from 22 institutions up to 7 years after an initial balloon valvoplasty [73] demonstrated that 23% of patients had a suboptimal outcome because of either a residual peak systolic gradient ≥36 mmHg or need for further treatment of pulmonic stenosis by repeated balloon pulmonary valvoplasty or surgical valvotomy. Significant independent predictors of suboptimal long-term outcome are an earlier year of the initial valvoplasty, a small valve hinge point diameter, and a higher immediate residual gradient. A small ratio of balloon-to-valve hinge point diameter significantly predicted suboptimal outcome for patients with valves morphologically classified as either typical or complex (primarily post-surgical valvotomy) but not for patients with dysplastic or combined morphologic features (dysplasia with commissural fusion). The patient's age, Noonan's syndrome or associated cardiac lesions, pre-balloon valvoplasty gradient, and use of the double-balloon technique did not independently predict follow-up outcome [61]. Other investigators [74] found that intervention in patients with a systolic gradient between 40 and 60 mmHg achieved a lower long-term gradient and fewer late symptoms.

Results of balloon pulmonary valvoplasty for patients with a dysplastic pulmonary valve vary and depend on the relative contribution to the degree of obstruction made by the thickened and immobile leaflets, the nodular tissue in the leaflet, the sinuses, and the commissural fusion, all of which may form a continuum with typical pulmonic stenosis. Because the degree of valve fusion is difficult to define, in the absence of a hypoplastic annulus (<75% of that predicted for age and body surface area), and perhaps the finding of a dilated pulmonary trunk, balloon valvoplasty should be attempted [41,48,75–80]. Although undersized balloons may be associated with a poor acute result, the use of oversized balloons increases the risk of valve disruption, outflow tract damage, and vascular complications [81]. Unsuccessful results were generally due to an inability to cross the valve, especially in neonates.

The experience in adults confirms the technical simplicity and hemodynamic improvement seen in the pediatric age groups [21,82–92].

Surgical valvotomy

Surgical valvotomy should be limited to patients with more complex lesions or those in whom balloon dilation is contraindicated or failed (severe dysplastic valves).

Surgical valvotomy may be performed by an open or closed technique, although almost all are performed under direct vision [22]. The approach is through the pulmonary artery, and valvotomy is performed. With a dysplastic pulmonary valve, the same approach is used. Balloon valvoplasty is attempted; should this fail because of either the thickened leaflets or the supravalvar stenosis, operative treatment is necessary. Valvotomy alone does not usually suffice, and valvectomy, partial or total, may be necessary. Enlargement of the annulus and patch enlargement of the pulmonary trunk may also be necessary.

The results of the surgical valvotomy on nondysplastic valves are excellent. Mortality is minimal.

After an operation, some pulmonary insufficiency may be present. This is usually minor and clinically insignificant and only rarely needs valve replacement. Associated infundibular hypertrophy, which occurs in severe stenosis and is probably secondary or functional, poses a special situation. Occasionally, infundibular obstruction does not regress after valvotomy, or the obstruction increases postoperatively. Death has been reported from the so-called suicidal right ventricle. Significant subvalvar obstruction recurring immediately after valvotomy may require treatment with a β-blocker. If there is no response, resection may be necessary. In most patients, however, the secondary obstruction decreases and resolves with time.

Natural history and long-term history of treated and untreated adults

The Natural History Study produced important information on the natural history of patients with valvar pulmonic stenosis [15,18]. In mild pulmonic valvar stenosis (defined as a gradient <30–35 mmHg), no intervention is indicated and long-term outcome is excellent in almost all patients. Exercise tolerance is normal or only mildly reduced [93]. Further, in postoperative patients with mild stenosis, reoperation is rarely necessary.

Patients with pressure gradients <25 mmHg did not experience an increase in gradient with time. If the gradient was >50 mmHg, valvotomy was deemed necessary. The management of patients with a gradient between 40 and 49 mmHg was controversial. There were 22 deaths, 19 in the surgically managed patients and three in the medically managed patients [15]. In the medical group, two of the three deaths were noncardiac and the third death was a result of ventricular fibrillation during catheterization. In the surgical group, 12 of 19 patients died of cardiac-related causes, including eight perioperative deaths. Morbidity after admission to the study was uncommon but was significant in individual patients, related to conditions such as bacterial endocarditis, brain abscess, syncope, congestive cardiac failure, stroke, and pacemaker implantation.

Apart from residual stenosis, both surgical valvotomy and balloon valvoplasty can induce relevant pulmonary regurgitation acutely or during follow-up. The incidence of severe pulmonary regurgitation long after balloon valvoplasty has been reported to be >15% [94].

Chronic severe pulmonary regurgitation late after surgical repair of tetralogy of Fallot is related to impaired exercise performance, right ventricular dilatation, and/or dysfunction and increased risk for arrhythmia [95–97]. However, the effect of long-standing, isolated pulmonary insufficiency on morbidity and mortality remains unknown. Accordingly, the indications and timing for pulmonary valve replacement in isolated severe pulmonary regurgitation are controversial.

Importantly, the currently used valved conduits (homografts, Hancock conduits, etc.) for pulmonary valve replacement all exhibit a limited lifespan, which ranges from 10 to 15 years [98–104]. Because of this limited life span, patient management strategies have been based on delaying surgical intervention for as long as possible (so that number of open-heart surgeries performed on any individual patient is kept to a minimum) but not beyond a theoretical point when RV dysfunction and functional impairment might be irreversible. Finding the right parameter to detect the point of no return in right ventricular volume overload has been described as the Holy Grail of pediatric cardiology [105], particularly for adults with congenitally malformed hearts, emphasizing the complexity of this issue.

With advanced cardiac magnetic resonance imaging, efforts have been made to establish volume thresholds as predictors for outcome after conduit placement. Cut-off points for end-systolic and end-diastolic right ventricular volumes have been reported [106–108] The end point in these studies was normalization of right ventricular volumes after correcting pulmonary regurgitation, with or without surgical remodeling of the right ventricular outflow tract. However, the effect of the timing of pulmonary valve replacement on RV function, exercise performance, and in particular long-term survival and risk for arrhythmia remains undefined.

Currently, we recommend pulmonary valve replacement for the following if this impairment cannot be explained adequately by extracardiac factors: symptomatic pulmonary regurgitation; moderate to severe right ventricular dilatation with a right ventricular volume of >150 ml m^{-2}; right ventricle to left ventricle end-diastolic volume ratio of >1.5; moderate to severe right systolic dysfunction; progressive tricuspid regurgitation; or significantly impaired exercise capacity (<65% of predicted maximal oxygen consumption on cardiopulmonary exercise testing).

Peripheral pulmonary artery stenosis

Incidence and Genetics

Peripheral pulmonary artery stenosis (PPAS) accounts for >3% of all congenital heart defects. PPAS may be sporadic or familial. It may be an isolated lesion (40%) or combined with other cardiac lesions (60%), such as valvar pulmonic stenosis, atrial septal defect, ventricular septal defect, and patent ductus arteriosus; about 20% of patients with tetralogy of Fallot have associated PPAS. Other complex-associated lesions include mitral obstruction and transposition of the great arteries. Another important association is with supravalvar aortic stenosis [109], classically present in the Williams syndrome and also as the central feature of a developmental complex that includes supravalvar stenosis of the aorta and pulmonary trunk, dysplasia of valves, and stenosis of ostia of coronary arteries and branches of the aortic arch [110]. In this complex, histologic examination of the aorta and major pulmonary arteries showed two patterns that may alternate from segment to segment in a given patient. One pattern is of a mosaic orientation of medial elements, and the other is of thickening of the media that appears to have an excess number of units of elastic and intervening layers. Syndromes that have PPAS as an important feature also include the rubella, Alagille, Keutel [111], cutis laxa, Noonan, and Ehlers–Danlos syndromes and familial supravalvar aortic stenosis.

Specific genetic abnormalities have been described for several syndromes associated with isolated PPAS. In Williams syndrome, a genetic deletion within chromosome 7 has been identified, which results in abnormal elastin production [112]. Further, a deletion in chromosome 20 is linked with the Alagille syndrome [113].

Embryology

Although probably multifactorial, the exact pathogenesis of PPAS remains unclear. In contrast, teratogenic agents such as the rubella virus are believed to affect directly the pulmonary artery tree.

Pathology

Functional or *physiologic* PPAS is relatively common in both premature and full-term neonates. The stenosis, evidenced by the typical murmur and a small gradient (echo Doppler), is mild. With time, these arteries grow, and the murmur disappears within a few months and almost invariably is gone by the first birthday.

PPAS may occur at a single site or, more commonly, at multiple sites of obstruction. The stenosis may be present at any level above the pulmonary valve and may involve one or many pulmonary artery branches. In a simplified classification [114], four types of obstruction were described: (i) stenosis of the pulmonary trunk; (ii) bifurcation stenosis extending into the right or left pulmonary arteries (or both); (iii) multiple peripheral pulmonary artery stenoses; and (iv) stenoses of both the pulmonary trunk and peripheral arteries.

PPAS also follows post-surgical aortopulmonary shunt placement. Insertion of the shunt into either the left or right pulmonary artery can lead to distortion and upward pulling of the pulmonary branches during somatic growth, resulting in significant obstruction.

Sometimes, closure of the ductus arteriosus leads to isolated stenosis of the left (or. in the presence of ductal or aortic arch anomalies. right) pulmonary artery. This lesion is called "pulmonary coarctation."

Pathophysiology

The pathophysiology and hemodynamics resemble valvar pulmonic stenosis. Proximal to the obstruction, the systolic pressure is elevated, and distally it is normal or low. Therefore, depending on the degree of obstruction, the right ventricular systolic pressure is elevated, as is the pressure in the pulmonary artery proximal to the obstruction. The diastolic pressure is often low and equal in the pulmonary artery both proximal and distal to the obstruction. Hence pressure tracing in the proximal pulmonary artery resembles the right ventricular pressure contour, although the diastolic pressure is not zero.

The pathophysiologic consequences of increased right ventricular afterload have been described above.

Another consequence of PPAS is unequal pulmonary perfusion. With several severely obstructed regions, non-stenotic areas experience high flow and/or high pressure and may develop pulmonary vascular disease. On the other hand, proximally obstructed vessels often remain small and "underdeveloped."

Clinical features

Clinical history

In general, PPAS is a more severe disease than isolated pulmonary stenosis. The patient's general appearance is either normal or that of an associated syndrome involved with possible typical facial features of the Noonan, rubella, Williams, or Alagille syndromes. Growth and development are normal in most patients or possibly delayed in the syndromes. Most patients are asymptomatic. With severe obstruction, fatigue or dyspnea on exertion is usually present. Signs of congestive cardiac failure are rare.

Physical examination

Decreased compliance of the right ventricle may be associated with a right-to-left shunt at the atrial level and cyanosis. In mild to moderate stenosis, no thrills or heaves are palpable; with severe obstruction, a right ventricular heave may be palpable.

The first heart sound is normal. The second sound is split, the width intensifying with the increasing severity of the

stenosis. No ejection click is present. Typically, the murmur is absent or soft over the precordium. It is heard below both clavicles. Of particular importance is the wide distribution of the murmur over the back and axillae; this is a major clinical clue pointing to the diagnosis. With multiple PPAS or an associated left-to-right shunt, a continuous murmur may be present and widely distributed over the precordium, back, and axillae. Its intensity varies with the degree of stenosis.

Electrocardiography

The electrocardiographic features are similar to those of valvar pulmonic stenosis. They vary from normal to those of severe right ventricular hypertrophy and even "strain" pattern.

Chest X-ray

Pulmonary vasculature is usually normal regardless of severity, although decreased vasculature may occur in severe stenosis. The main pulmonary artery segment is not prominent (as opposed to valvar stenosis). In severe unilateral stenosis, a difference in vasculature may be seen between the two lungs. Often with marked differences of stenosis in the two lungs, no significant differences in vasculature may be evident.

Echocardiography

Narrowing of the pulmonary artery branches may be present in either diffuse or discrete forms. The proximal right and left pulmonary arteries may be imaged from the suprasternal, high parasternal short-axis, or subxiphoid view. Flow into the narrow pulmonary artery branches is anterograde throughout the cardiac cycle, and this causes a characteristic systolic–diastolic high-velocity flow on Doppler study. The systolic Doppler gradient across a long obstruction is unreliable, but the severity of the narrowing may be assessed by the right ventricular systolic pressure.

Cardiac catheterization

Cardiac catheterization is important to confirm the diagnosis of PPAS and may be an important therapeutic modality for balloon angioplasty and endovascular stent implantation. The indications for cardiac catheterization are symptoms or noninvasive evidence of right ventricular hypertension (greater than two-thirds of systemic pressure), echocardiographic or X-ray findings of asymmetric pulmonary perfusion, and assessment after surgical repair (e.g., after repair of tetralogy of Fallot or the Fontan operation).

Carefully obtained withdrawal pressure tracings from the distal branches demonstrate systolic pressure gradients across the narrowest segment of the arteries. Systolic pressure gradients >10 mmHg are considered abnormal. With unilateral stenosis, a pressure gradient is usually present across the narrowed segment, but the proximal pulmonary artery pressure is normal. Sometimes, pressure is also elevated in the contralateral pulmonary artery. The pressure tracing proximal to the obstruction has a contour similar to that of the right ventricle in length and time up to the dicrotic notch; it also has a wide pulse pressure that becomes more pronounced with increasing severity of the obstruction. In unilateral or partial PPS, the pressure gradient is often lower than anatomically expected because there is increased flow to the nonobstructed regions with decreased flow to the contralateral lung.

Angiography

Selective angiography is important to define the location, extent, and distribution of the lesions in each pulmonary artery. The right pulmonary artery is best seen in an AP view and the left pulmonary artery in a left anterior oblique view with cranial angulation. Demonstrating stenosis in the main pulmonary artery and the origin of both left and right pulmonary arteries requires cranial angulation. Aortography should be performed to exclude frequently associated systemic arterial stenoses.

Other imaging modalities

MRI represents the most accurate and reproducible imaging technique for assessing right ventricular size, function and wall thickness. MR contrast agent (gadolinium)-enhanced three-dimensional angiography provides a noninvasive technique for visualizing the pulmonary artery tree. The sensitivity and specificity for assessing PPAS of the proximal and up to the third to fourth generation pulmonary arteries have been shown to be ~100%. Further, repeated accurate measurements of PPA dimensions are possible with this technique. There are, however, some limitations to visualizing the distal pulmonary vasculature; intravascular stents can significantly reduce the diagnostic performance of MRI in patients with PPAS.

Lung perfusion scintigraphy had been a useful noninvasive method for accurately determining relative pulmonary blood flows, allowing the clinician to plan and follow up transcatheter interventions in the pulmonary arteries [115–118]. However, "washout" effects from additional blood supply to the lung can make flow quantification inaccurate. Currently, MRI represents the gold standard for assessing differential blood flow to the lungs as derived by flow calculation in the branch pulmonary arteries.

Especially in patients with multiple previous stenting of the pulmonary tree, CT imaging is preferred. Similarly to MRI, contrast-enhanced CT provides excellent imaging of the proximal and distal pulmonary vasculature. For assessing hemodynamic relevance, however, catheterization remains the gold standard.

Management

Mild or moderate unilateral or bilateral PPAS does not usually require treatment. The indications for treating severe PPAS include cardiovascular symptoms, such as exercise intolerance, dyspnea, cyanosis, and signs of right-sided heart

failure; near-systemic (or higher) right ventricular pressure; markedly decreased flow to affected lung segments; hypertension in the unobstructed pulmonary artery; and documented stenosis in distal pulmonary arteries not easily accessible as a surgical prelude to definitive repair of a coexisting cardiac anomaly [117,118].

An operation performed to relieve pulmonary artery stenosis directly is difficult and often ineffective in relieving obstruction, with a success rate of ~30% [119–121]. In the surgical approach, a pericardial or Dacron ellipsoid patch is used to widen the lumen of the vessel. Furthermore, the surgical approach is confined to a small group of patients with well-localized stenosis of the pulmonary trunk or bifurcation of the origins of the main branch pulmonary arteries. The intraparenchymal pulmonary arteries are surgically inaccessible. For patients with multiple PPS or hypoplastic pulmonary arteries, there is no surgical alternative; therefore, interventional options such as balloon angioplasty and endovascular stent placement have been developed.

Successful angioplasty results in longitudinal or oblique intimal tears, medial disruption, and, in some patients, transmedial tears, with organization of intramural hemorrhage and scar formation as the mode of healing [122,123]. Pseudoendothelialization is complete in 3–6 weeks; areas of mural thinning within the scar may predispose to aneurysm formation. After angioplasty, perivascular fibrosis may reinforce the outer vessel wall, but several months must pass to allow complete tissue granulation and healing of transmedial tears induced by catheter intervention [123,124].

Balloon dilatation is usually well tolerated and should be considered an initial form of intervention, at least for postoperative stenosis. Acute technical success is judged by the modified criteria of the Boston group [117], and includes at least two of the following criteria: an increase in vessel diameter of >50% of the predilatation diameter, an increase of >20% in the relative blood flow to the affected lung, and a decrease to <60% of the systolic right ventricular/aortic pressure ratio. Balloon angioplasty for PPS has been effective according to these criteria in 50–60% of patients [117,118]. Restenosis occurs in 15–20% of patients and a long-term favorable result is achieved in 35–50% of patients [118,125] by the following criteria: resolution of the stenosis and avoidance of surgical intervention; optimization of future surgical intervention, judged by one of two standards: (1) pulmonary artery anatomy or pressure suitable for surgical repair in patients with pulmonary artery anatomy or pressure that was previously considered a contraindication for surgical repair or (2) obviating the need for surgical intervention in the areas of balloon angioplasty during the succeeding surgical repairs and reduction of the systolic right ventricular/aortic pressure ratio to <60% [126,127].

Significant complications may follow percutaneous balloon angioplasty of PPAS [124–128]. These complications include a mortality rate of ~1–2%, usually from exsanguination from a ruptured pulmonary artery during dilatation. Other complications include hemoptysis, transient pulmonary edema, thrombosed iliac veins, pulmonary artery aneurysm, cyanosis, and hypotension. Late death may also occur from aneurysm rupture.

Even after a technically successful procedure, these patients require careful serial evaluation and may need repeat cardiac catheterization to evaluate accurately the mid- and long-term results of the angioplasty procedure. Patients who develop aneurysms should be observed even more closely because the prognosis of these aneurysms remains unknown.

Importantly, although intuitively suggested, the clinical benefit of balloon dilatation of native PPS cannot yet formally be demonstrated.

Endovascular stents

The incidence of recurrent narrowing after balloon angioplasty (~17%) could be related to the elastic recoil of the pulmonary artery wall. The efficacy of endovascular stents to relieve such obstructions and the safety of implantation have been demonstrated with a success rate of >96% [129–132]. Excellent long-term results have been reported [133,134]. If obstructions are near to the bifurcation or side branches, simultaneous implantation of stents is recommended [133]. Sometimes resistant stenoses remain or develop within or adjacent to the stents following implantation, which can be treated effectively with ultra-high-pressure balloons [135] (Figure 33.3).

Major complications are few but include death from pulmonary artery embolism, vascular rupture, pulmonary bleeding, and embolization of incorrectly placed stents [136–139]. Compression of coronary arteries may also occur and must be excluded by simultaneous test-balloon dilation and coronary angiography [140]. Bronchial compression has been described [141].

Minor complications include occlusion of side branches, [136,139], longitudinal break of the stent during redilatation, acute thrombosis of the pulmonary artery distal to the stent that resolves after thrombolytic therapy, and balloon rupture during expansion [130].

Natural history and long-term history of treated and untreated adults

In PPAS in association with other cardiac defects, such as Williams and Noonan syndrome or tetralogy of Fallot, the long-term history is determined by the severity of the cardiac and extracardiac manifestation of the disease. In patients with mild to moderate PPAS, the degree of obstruction often remains stable or even reduces with growth. In severe PPAS and failure of stenting or surgery, prognosis, however, can be poor. Right ventricular failure due to chronic pressure overload can be observed as a terminal event. Untreated isolated PPAS in adults is rare, but has to be excluded in the presence

Figure 33.3 Pre- and post-interventional bilateral angiograms [(a) and (c) LAO 20°, cranial 20°; (b) and (d) LAO 90°] of a 20-year-old female with severe residual left pulmonary artery stenosis following multiple operative and percutaneous pulmonary valve implantation. Panels (a) and (b) show the stenosis distal to the bifurcation with contrast injection through a pigtail catheter in the left pulmonary artery. Panels (c) and (d) show the result of stent implantation with guidewire and balloon catheter still in place. Contrast is administered through a long delivery sheath with the tip just proximal to the stent-mounted pulmonary xenograft valve.
of a long-standing murmur since childhood. Long-term results of effectively treated supravalvar or peripheral stenosis are usually good [134]. Large stents positioned in an extra-anatomic, especially retrosternal, position may suffer from fatigue of the material, leading to compression or breaking [142].

Subvalvar stenosis

Two main types of obstruction may occur within the right ventricle: isolated infundibular stenosis and anomalous muscle bundles.

Isolated infundibular stenosis
This rare condition consists of narrowing of the infundibulum. The narrowing is either muscular or fibromuscular.

Physiology
The hemodynamics resemble those of other right-sided obstructions with a gradient within the right ventricle, causing hypertrophy of the proximal chamber. Clinically, the general features are similar to valvar stenosis. The features of right ventricular hypertrophy depend on the severity of obstruction. A systolic ejection murmur is heard along the left sternal border or in the pulmonary area. In severe stenosis, cyanosis develops from a right-to-left shunt at the atrial level.

The absence of an ejection click and the often lower position of the murmur help in differentiation from valvar stenosis. The murmur is often harsher than in valvar stenosis. The second sound is usually narrowly split. The electrocardiogram is nondiagnostic and varies with the degree of right ventricular hypertrophy. The chest radiograph shows normal cardiac size. The main pulmonary artery is not dilated; the pulmonary vasculature is usually normal. The apex may be elevated in severe stenosis.

Echocardiography
An infundibular subpulmonic obstruction may be present permanently or transiently after relief of valvar pulmonic stenosis. Normally, the tunnel-like obstructed subvalvar region is easy to recognize, but sometimes the entire right ventricular outflow tract must be visualized with 2D and color Doppler to find a discrete stenosis which is more typical for
Figure 33.4 Bilateral angiograms [(a) RAO 0°; (b) LAO 90°] of a 23-year-old patient with circumscribed muscular stenosis of the right ventricular outflow tract forming the so-called double-chambered right ventricle. The long, thin arrow points to the anomalous muscle bundle and the short, thick arrow to the position of the pulmonary valve.

the double-chambered right ventricle (see below). A characteristic Doppler jet with a concave downstroke is indicative of dynamic subvalvar narrowing. When a fixed obstruction is present, the jet has a regular, convex downstroke.

Natural history
The degree of obstruction tends to increase with age.

Treatment
Definitive treatment is surgical, which has good results. In dynamic stenosis, β-blockers can temporarily reduce the gradient and thereby allow for postponement of surgery.

Anomalous muscle bundles
The other form of stenosis within the right ventricle is anomalous muscle bundles.

Physiology
In this condition, muscle bundles divide the ventricle into two chambers (hence the synonym *double-chambered right ventricle*) [143] (Figure 33.4). The muscle bundles pass from the septal wall close to the base of the anterior papillary muscle to the anterior wall of the right ventricle. A ventricular septal defect is present in most patients, although in some patients the muscle bundles may functionally close the septal defect. In

addition, a discrete membranous subaortic membrane completes a triad of commonly associated pathologic findings.

Right ventricular obstruction often progresses. Clinically, the patients are usually asymptomatic. The position of the ventricular septal defect may occasionally affect the clinical picture. If the septal defect is situated above the muscle bundles, a left-to-right shunt may predominate and even lead to heart failure. However, right-to-left shunting may be present only occasionally when the septal defect is below the muscle bundles.

The most striking clinical feature is a long, usually harsh, ejection systolic murmur heard along the left sternal border, possibly radiating to the pulmonary area. A thrill is often present. The heart sounds are usually normal. A systolic click is not present. The electrocardiogram shows different degrees of right ventricular hypertrophy, depending on the severity of the obstruction. The radiographic features are nonspecific.

Echocardiography
On echocardiography, the muscle bundle may be well imaged from a subxiphoid short-axis or a right anterior oblique view, which can be obtained by counterclockwise rotation of the transducer. The severity of the obstruction may be assessed by continuous-wave Doppler imaging.

Cardiac catheterization

Usually no evidence of shunt is found. On occasion, left-to-right or right-to-left shunting may be present. A pressure gradient is measured by catheter withdrawal.

Angiocardiography

The muscle bundles are characteristically demonstrated by filling defects in the right ventricle. The left-to-right or right-to-left shunt may also be demonstrated.

Treatment

When indicated by the severity of the gradient, treatment is surgical with removal of the muscle bundles. A characteristic dimple on the right ventricular free wall is the surgical landmark of the muscle bundle attachment. The associated ventricular septal defect is closed, and the subaortic membrane is excised.

Rare causes of right ventricular outflow tract obstruction

Rare causes of right ventricular obstruction include:
- pouch-like structures in the right ventricle, such as the "windsock" lesion
- tumors in the right ventricle – rhabdomyoma
- prolapse of right aortic cusp through a ventricular septal defect
- sinus of Valsalva aneurysm, which may prolapse into the right ventricular outflow region [144].

34 Total Anomalous Pulmonary Venous Connection

**Shiv Kumar Choudhary, Sachin Talwar &
Sivasubramanian Ramakrishnan**
All India Institute of Medical Sciences, New Delhi, India

Introduction

Anomalous pulmonary venous connections are rare congenital anomalies that can be either total or partial. Total anomalous pulmonary venous connection (TAPVC) encompasses anomalies in which the pulmonary veins are connected to the systemic venous circulation through persistent splanchnic connections. In partial anomalous pulmonary venous connection (PAPVC), only some of the pulmonary veins drain into the systemic venous system.

Historical background, incidence, and genetics

TAPVC was first described in 1798 by Wilson [1]. Friedlowsky (1868) first described an isolated supracardiac TAPVC [2]. Kirklin and Burroughs performed the first surgical repair under cardiopulmonary bypass in 1956 [3].

TAPVC is rare, representing 1.5–2% of all congenital cardiovascular abnormalities [4]. In a population-based registry, TAPVC represented 1.5% of all congenital cardiovascular malformations and had a prevalence of 6.8/100 000 live births [5]. The genetic basis for TAPVC is not understood. Most instances are sporadic, although there are a few reports of TAPVC recurring among siblings, father and two children, and twins [6,7]. TAPVC is rare in other genetic syndromes or chromosomal anomalies. Lead and pesticide exposure during pregnancy may be related to TAPVC [5]. Pesticide exposure and family clustering are related, suggesting that there could be a genetic predisposition to pesticide related injury.

Embryology

During early development of the lungs, blood drains to the splanchnic plexus, which in turn connects to the paired common cardinal and umbilicovitelline veins. The right common cardinal vein evolves into the right horn of the sinus venosus that ultimately develops into the right superior vena cava and the azygos vein. The left common cardinal vein evolves into the left horn of the sinus venosus, which ultimately develops into the left superior vena cava and the coronary sinus. The umbilicovitelline system becomes the inferior vena cava, ductus venosus, and portal vein.

During early development, the pulmonary venous plexus is not in direct communication with the left atrium, but retains connections to the right superior vena cava, left superior vena cava, and portal system. At 27–29 days' gestation, an endothelial out-pouching occurs from the posterior superior left atrial wall and represents the primitive (common) pulmonary vein that connects with the pulmonary venous plexus by 30 days' gestation. The tributaries to the common pulmonary vein form a common chamber which progressively incorporates into the posterior wall of the primitive left atrium. The pulmonary venous part of the splanchnic plexus gradually loses its connection with the cardinal and umbilicovitelline veins.

Most forms of TAPVC result when the common pulmonary vein fails to develop or fails to connect with the pulmonary venous plexus. This leads to the persistence of one or more earlier venous connections. Connection to the right common cardinal vein results in TAPVC to the left vertical vein/innominate vein or to the right superior vena cava. Persistence of connection to the left common cardinal vein

results in TAPVC to the coronary sinus, and persistent connection to the umbilicovitelline vein leads to infracardiac TAPVC. Failure of the septum primum to form normally, or abnormal septation of the sinus venosus, can lead to direct connection of the pulmonary veins to the right atrium.

Pathologic anatomy and major associated anomalies

The affected heart of all forms of TAPVC has in common dilatation and hypertrophy of the right ventricle and right atrium, dilatation of the pulmonary artery, a normal-sized left ventricle, and reduced left atrial size and volume. The specific findings depend on the type of TAPVC. The pulmonary veins usually form a confluence, also known as a common chamber, directly behind the left atrium. An anomalous channel termed the vertical vein connects the pulmonary venous confluence to the systemic venous system.

The classification proposed by Darling and colleagues [8] is widely followed and consists of four types: supracardiac, cardiac, infracardiac, and mixed. TAPVC can further be classified by the presence or absence of obstruction. The potential sites of connection of various forms of TAPVC are given in Table 34.1.

A supracardiac connection is present in ~55% of patients with TAPVC. Classically, the pulmonary vein confluence drains superiorly into the innominate vein via a left-sided ascending vertical vein. The common chamber is behind the left atrium and the vertical vein passes anteriorly, usually anterior to left pulmonary artery and left main bronchus, but sometimes between them. Rarely, the vertical

vein may drain directly to right or left superior vena cava, or azygos vein. Anomalous connection to the right superior vena cava is often associated with complex cardiac malformations [9].

A cardiac connection occurs in ~30% of patients with TAPVC. The pulmonary venous confluence drains into the coronary sinus near the AV groove. The coronary sinus ostium is enlarged, but is normally placed. Rarely, the pulmonary venous confluence may connect directly by a short channel into the posterior aspect of the right atrium, usually near the midatrial septum, or individual pulmonary veins may connect directly into the right atrium.

Approximately 13% of patients with TAPVC have an infracardiac connection. A vertical vein from the pulmonary vein confluence descends anterior to the esophagus and traverses the diaphragm through the esophageal hiatus. Most commonly it drains into the portal venous system. Rarely, it drains into the ductus venosus, hepatic veins, or the inferior vena cava.

Finally, a mixed type of TAPVC occurs in ~ 2–5% of patients and can involve any or all components of the previous three types. Most commonly, the left pulmonary veins connect via a left vertical vein into the left innominate vein and the right pulmonary veins drain directly into the right atrium or coronary sinus.

Obstruction is uniformly present in the infracardiac type because the pulmonary venous blood must pass through the sinusoids of the liver, and may worsen due to constriction or closure of ductus venosus. The obstruction may also occur as the descending vein travels through the diaphragm or at its junction with the portal vein system. Obstruction, considered rare in the cardiac type, has been underestimated and may occur in 22% of patients [10] when a very short, narrow channel connects the horizontally placed pulmonary veins to the coronary sinus. In supracardiac TAPVC, obstruction can be either intrinsic or extrinsic: obstruction most commonly occurs from compression of the ascending vertical vein between the left main stem bronchus posteriorly and left pulmonary artery anteriorly, but rarely intrinsic anatomic narrowing occurs at the pulmonary vein confluence and vertical vein, or at the insertion of the vertical vein into the innominate vein. In all forms of TAPVC, narrowing of individual pulmonary vein(s) can also produce varying degrees of obstruction.

A patent foramen ovale or an atrial septal defect is always present and considered a part of the TAPVC complex. A patent ductus arteriosus (PDA) is usually found in neonates presenting with TAPVC. TAPVC occurs alone in two-thirds of patients and occurs as part of a group of heart defects (e.g., heterotaxy syndromes) in approximately one-third of patients. Asplenia or right isomerism is characterized by two atrial chambers of right atrial morphology. TAPVC is a common feature in right isomerism as these hearts lack a morphological left atrium and coronary sinus.

Table 34.1 Classification of TAPVC according to the site of anomalous connection.

TAPVC	Site
Supracardiac TAPVC	Left brachiocephalic (innominate) vein[a]
	Right superior vena cava
	Azygos vein
	Left superior vena cava
	Hemiazygos vein
Cardiac TAPVC	Coronary sinus[a]
	Right atrium
Infracardiac TAPVC	Portal venous system[a]
	Splenic vein
	Splenic, superior mesenteric vein confluence
	Ductus venosus
	Hepatic veins
	Inferior vena cava

[a]Commonest sites of drainage.

Pathophysiology

The physiologic consequence of TAPVC in fetal life is negligible as only a small amount of blood normally flows through the lungs. When the neonatal lungs expand, pulmonary flow increases markedly, but because of the anomalous connection in all patients with TAPVC, the systemic blood flow depends on a right-to-left shunt through an atrial septal defect or patent foramen ovale. Venous obstruction and size of the atrial septal defect are the critical determinants of the size of the morphological left atrium and coronary sinus, and hemodynamics and clinical presentation.

Obstructed TAPVC increases the pulmonary venous pressure, and usually presents with pulmonary edema in neonates. Increase in pulmonary lymphatic flow, recruitment of pulmonary-bronchial venous anastomoses, and reflex pulmonary vasoconstriction ensue as compensatory mechanisms. All these changes increase pulmonary artery and right ventricular pressures. Right ventricular compliance decreases and consequently pulmonary blood flow diminishes. Because flow across an atrial septal defect is determined by the relative compliance of the pulmonary and systemic circulations, right-to-left shunting across the atrial septum increases, causing marked hypoxemia. Progressive hypoxia leads to acidosis, shock, and multiorgan dysfunction. Thus, obstructed TAPVC in a neonate is characterized by pulmonary edema, pulmonary hypertension, reduced pulmonary blood flow, and intense cyanosis.

The size of the atrial septal defect determines the systemic blood flow. In a few patients, the atrial septal defect or foramen ovale is small. Neonates with a restrictive atrial septal defect present early. During fetal life, the flow across the foramen ovale is only mildly increased in TAPVC. Hence 70–80% of patients with isolated TAPVC have only a patent foramen ovale at birth. As pulmonary blood flow increases after birth, pulmonary venous return also increases. Rapid growth in the first few weeks increases the demand for systemic output that a relatively restrictive foramen ovale is unable to accommodate. Hence right atrial, pulmonary venous, and pulmonary arterial pressures increase, producing systemic and pulmonary venous congestion. There is a large increase in pulmonary blood flow with a reduced systemic blood flow.

In unobstructed TAPVC, the oxygenated pulmonary venous drainage mixes with systemic venous drainage. Hence saturations are the same or nearly the same in the right and left cardiac chambers beyond the point of admixture. With a nonrestrictive atrial septal defect, the relative pulmonary and systemic blood flows depend on the relative compliances of the ventricles. Normally, a low pulmonary vascular resistance is associated with a compliant right ventricle and the pulmonary blood flow is significantly increased.

Hence mild cyanosis exists with increased pulmonary blood flow, and significant enlargement of the right atrium, right ventricle, and pulmonary artery. Conversely, the left atrium and left ventricle are small. Pulmonary artery hypertension develops in obstructed TAPVC and also in longstanding unobstructed TAPVC. With an increase in pulmonary vascular resistance, the right ventricle hypertrophies and become less compliant. The pulmonary arterial blood flow decreases and cyanosis increases. Severe pulmonary artery hypertension leading to Eisenmenger syndrome may also develop in a minority [11].

Natural history

With obstruction, the lifespan is brief. Pulmonary edema and right ventricular failure ensue within days to weeks of birth. Most infants die in the first few days or weeks of life and survival for up to 3–4 months is exceptional [12]. The natural history is unfavorable even in patients with unobstructed TAPVC, most of whom die within 3–6 months of birth; 75–90% of symptomatic infants do not reach 1 year of life. Heart failure and infections are the major causes of mortality. The minority who present after the first year of life invariably have a low pulmonary vascular resistance and a nonrestrictive atrial septal defect.

Clinical features

Patients with TAPVC with pulmonary venous obstruction often present in the early neonatal period, whereas patients with unobstructed TAPVC may present later; the majority present in infancy. The sex distribution is equal in supracardiac TAPVC, in contrast to the female preponderance in atrial septal defect. A strong male preponderance (3:1) is observed in infra-diaphragmatic TAPVC [13]. Cyanosis and respiratory distress are marked in symptomatic neonates with obstructed TAPVC. Pulmonary edema and shock may occur. In infra-diaphragmatic TAPVC, feeding may exacerbate symptoms due to worsening obstruction at the esophageal hiatus or an increase in intra-abdominal pressure. With a restrictive atrial septal defect, symptoms of heart failure and mild cyanosis on crying start in the first month of life and worsen progressively. Cyanosis is mild in unobstructed TAPVC and may escape clinical attention. Infants often present with tachypnea, feeding difficulties, diaphoresis, and failure to thrive. Pulmonary infections worsen the clinical course and are especially common in developing countries. Exceptional adult survivors may present like an atrial septal defect but with a dusky appearance.

In neonates and infants, physical signs are limited and are not easily appreciable owing to respiratory distress. In infants with obstructed TAPVC, signs of pulmonary hypertension

predominate. The second sound is loud and often single or closely split, and flow murmurs are usually not apparent. A soft, short, mid-systolic murmur in the pulmonary area may be the only murmur. A pulsatile liver may indicate restrictive communication at the atrial septal level.

The physical signs of unobstructed TAPVC generally resemble those of an atrial septal defect except that they begin earlier. Cardiac failure occurs in most patients before 6 months of age. There is right ventricular volume overload evident on physical examination. The tricuspid component of the first heart sound is loud and the second heart sound is widely and fixedly split. A right ventricular third heart sound is heard in most patients. A fourth heart sound may be heard in older patients. An ejection systolic murmur in the pulmonary area and a tricuspid diastolic flow murmur are frequent. Increased flow across the vertical vein, innominate vein, and superior vena cava can lead to a continuous murmur along the upper left sternal border, but is uncommon. Unlike a physiological venous hum, this murmur is not louder during diastole, and does not change with posture. As the pulmonary vascular resistance increases, the flow murmurs are attenuated. The second heart sound split narrows or disappears with a loud pulmonary component. A pulmonary ejection click and murmurs of tricuspid regurgitation and pulmonary regurgitation (Graham Steell murmur) may appear.

Chest X-ray

In neonates with obstructed TAPVC, chest radiographs reveal a normal heart size with a scattered, reticular, nodular, ground-glass pattern fanning out from the hilum (Figure 34.1). Meconium aspiration and hyaline membrane disease are important differential diagnoses for such an X-ray.

In unobstructed TAPVC, there is cardiomegaly with enlargement of the right atrium, right ventricle, and pulmonary artery. Radiological evidence of increased pulmonary blood flow becomes more apparent with increasing age. Enlargement of the anomalous channels results in distinct radiological signs, but these signs take time to develop. In supracardiac TAPVC, a "figure-of-eight" or "snowman" appearance is found (Figure 34.2). The upper part is formed by the dilated left vertical vein, innominate vein, and right superior vena cava. The dilated right ventricle and atrium form the lower portion.

Electrocardiogram

The ECG of a neonate with obstructed TAPVC shows right ventricular hypertrophy, mostly with a qR complex in right chest leads. Right atrial enlargement is infrequent. The electrocardiogram in unobstructed TAPVC resembles that of an ostium secundum atrial septal defect in most patients. The ECG usually shows right axis deviation and right atrial and ventricular enlargement with an incomplete right bundle branch block pattern.
Figure 34.1 Chest X-ray showing scattered, reticular, nodular, ground-glass pattern fanning out from the hilum and relatively small heart characteristic of obstructed TAPVC.
Figure 34.2 Chest X-ray showing snowman appearance, cardiomegaly, and increased pulmonary blood flow. The upper part of this "figure-of-8" appearance is due to dilated left vertical vein, innominate vein, and right superior vena cava. Dilated right ventricle and atrium form the lower portion.
(a)
(b)

Figure 34.3 Echocardiographic images of a typical supracardiac TAPVC. (a) Modified subcostal view showing a nonrestrictive atrial septal defect with right-to-left flow across the defect. RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle; ASD, atrial septal defect.(b) Suprasternal view showing a left-sided ascending vertical vein draining into the left innominate vein (LIV) and to the right superior vena cava (SVC).

Echocardiography

Echocardiography is usually diagnostic and can identify associated abnormalities. Right atrial and right ventricular enlargement with a smaller than normal left atrium and left ventricle are evident. The interatrial septum and interventricular septum bulge to the left and there is para-doxical ventricular septal motion. Inability to demonstrate any pulmonary veins connected to the left atrium is the initial clue. Subcostal long- and short-axis views show the size of the atrial septal defect with right-to-left shunting across it (Figure 34.3a). A restrictive atrial septal defect is

associated with a right-to-left shunt with a continuous Doppler signal. The pulmonary venous confluence is easily identified as an echo free, non-pulsatile space posterior to the left atrium. Individual pulmonary veins and their con-fluences are best identified in apical, parasternal, and suprasternal views.

The size of the individual pulmonary veins is an impor-tant independent predictor of survival in TAPVC [14]. The size of and flow patterns across the superior vena cava, cor-onary sinus, and inferior vena cava give clues to the site of drainage. Commonly, the suprasternal view (crab's view)

shows an ascending vertical vein draining into the left innominate vein (Figure 34.3b). Modifications of this view identify all the various forms of supracardiac sites of drainage. Apical four-chamber and subcostal views best identify cardiac TAPVC. Rarely, there may be more than one portal of entry into the coronary sinus and a persistent left superior vena cava [15]. The subcostal view identifies a descending vein entering ductus venosus or portal veins with increased flow across the sinusoids of liver in infradiaphragmatic TAPVC. The descending vertical vein is commonly located between the inferior vena cava on the right and the descending aorta on the left. The flow in this anomalous channel is characterized by venous-type flow away from the heart. A pulmonary venous flow velocity $>2\,\mathrm{m\,s^{-1}}$ identifies obstruction [16]. Commonly, the venous channel dilates proximal to the obstruction and there is no phasic variation in flow pattern. The size of the individual pulmonary veins, the size and location of the pulmonary venous confluence, and the course of the vertical vein must be ascertained before surgery.

Fetal diagnosis

Because the fetal blood flow through the anomalous connections is limited, TAPVC may be difficult to diagnose. All forms of TAPVC have right ventricle volume overload, an enlarged right atrium, and a leftward bowing of the interatrial septum. TAPVC should be suspected when no pulmonary veins can be seen entering the left atrium on the short-axis scan. The common pulmonary channel may be identified behind the left atrium, with the pulmonary veins draining into it. The channel may be followed to the site of its connection [17].

Cardiac catheterization

Cardiac catheterization is rarely performed these days for diagnosis of TAPVC. Current indications are atrial septostomy or balloon dilation to relieve venous obstruction, or assessment of pulmonary vasoreactivity in older infants or children suspected of severe pulmonary hypertension. Occasionally it is used to identify complex mixed pulmonary venous connections. The saturations are usually similar in all the cardiac chambers, the pulmonary artery, and the aorta, but exceptions due to selective streaming are not uncommon [18,19]. Angiograms after right and left pulmonary artery injection with venous phase follow-through identify the site of connection. A direct injection into the vertical vein or individual pulmonary vein is usually unsatisfactory in the absence of obstruction because excess flow does not allow retrograde filling of the pulmonary vein. With obstruction, excellent visualization is possible, but the injection should be made by hand and done quickly because the pulmonary venous pressure may rise to dangerous levels with a catheter across an obstruction in a neonate. Some cardiologists advise against such an injection for this reason.

Atrial septostomy offers short- and intermediate-term palliation in selected patients [20]. Atrial septostomy may be technically challenging, especially in cardiac forms of TAPVC, due to a small left atrium without pulmonary venous connections. Echocardiographic guidance is often helpful. Blade septostomy or static balloon dilatation may be needed in older patients. The success of a septostomy in TAPVC is indicated by a drop in pulmonary artery pressure, an increase in systemic pressure, and a drop in systemic saturation [21]. Atrial septostomy in a patient with a restricted atrial septal defect increases cardiac output and relieves systemic and pulmonary venous congestion. These favorable hemodynamics lead to clinical stabilization, and help in optimizing the timing of surgery.

Balloon dilatation or stent placement is occasionally performed to relieve obstruction in sick neonates presenting with obstructed TAPVC [22,23]. Palliative stenting can be potentially life-saving in sick neonates and may aid preoperative stabilization.

Other imaging modalities

A computed tomography (CT) angiogram can identify the varied patterns of pulmonary venous connection in TAPVC. One study showed CT angiograms to be more sensitive than echocardiography for the accurate diagnosis of TAPVC [24]. CT angiography clearly establishes the course of the abnormal vessel into the systemic venous system (Figure 34.4) [25]. It is especially useful in mixed and unusual forms of TAPVC.

Magnetic resonance imaging (MRI) identifies the various sites of connection, and the site and severity of obstruction. In one study, the combination of axial and coronal MRI visualized 96% of the individual anomalous pulmonary veins and all the common pulmonary veins [26]. MRI is especially useful in complex heterotaxy syndromes associated with TAPVC and postoperative patients with residual pulmonary vein stenosis.

Management

Medical management is only supportive in managing TAPVC, and only intended to stabilize the patient before surgery. Preoperative stabilization includes correcting acidosis and hypotension, fluid management, and mechanical ventilation. Prostaglandin is occasionally helpful in keeping ductus venosus open in infra-diaphragmatic TAPVC, but in other forms it is harmful [27].

Surgery for TAPVC is aimed at achieving unobstructed pulmonary venous drainage to the left atrium. The clinical condition of the patient will usually decide the timing of surgery. In general, the diagnosis of TAPVC of any type is an indication to proceed with early surgery. An emergency operation is required in neonates with obstructed forms of TAPVC.

Right & Left side Pulmonary Veins

Common Chamber

Stenosis in the Descending vertical Vein

Main Portal Vein

Figure 34.4 CT angiograms. (a) Coronal oblique multiplanar reconstruction (MPR) image shows the confluence of the pulmonary veins into a common channel, which in turn drains into the SVC. (Reproduced from Shaheen F, Gojwari TA, Andrabi M, Sofi S, Singh M, *Indian J Radiol Imaging* 2009;**19**:54–6, an open access publication.) (b) 3D reconstruction showing infracardiac TAPVC. All the pulmonary veins form a narrow, long, common chamber draining into the portal vein through a long descending vertical vein that has narrowing at the lower margin. A, anterior; L, left; P, posterior; R, right; SVC, superior vena cava.

Surgical technique

The surgical approach to all anatomic forms of TAPVC is via a median sternotomy. In patients with the cardiac type of TAPVC, a pericardial patch is often harvested and treated with 0.6% glutaraldehyde for 5–10 min. This will be used subsequently in the repair. Purse string sutures are placed on the aorta and the right atrial appendage. After adequate systemic heparinization, cardiopulmonary bypass (CPB) is established and core cooling commenced.

Supracardiac TAPVC

The vertical vein is dissected and ligated, taking care to preserve the left phrenic nerve. A variety of surgical approaches have been used to establish a communication between the pulmonary venous chamber and the pulmonary venous

atrium. These include the following: (a) In Muller's closed approach, the pulmonary venous confluence is directly anastomosed to the left atrial appendage without using CPB. (b) In Cooley's trans-atrial approach, the right atrium is opened and the interatrial septum is incised. Following this, corresponding incisions are made in the posterior wall of the left atrium and the common pulmonary venous chamber and an anastomosis is fashioned between the two, with subsequent closure of the atrial septal defect and the right atrium. (c) In Schumaker and King's transverse biatrial approach, an incision is made in the right atrium inferior to the right atrial appendage. This incision is carried posteriorly through the foramen ovale and into the posterior wall of the left atrium. The common pulmonary venous is then incised and an anastomosis is made between the left atrium and the common chamber. (d) In Tucker's superior approach, the common pulmonary venous chamber is exposed through the
Figure 34.5 (a) Operative exposure from the left side of the operating table for a patient with type I (supracardiac) TAPVC during continuous cardiopulmonary bypass and cold blood cardioplegic arrest. The heart is retracted to the right and superiorly out of the pericardial cavity to expose the confluence of the pulmonary veins and the vertical vein. The vertical vein is controlled with a snugger that can be enforced during the anastomosis. The dotted lines represent proposed incisions of the confluence of the pulmonary veins and the left atrium, respectively, for the intended side-to-side anastomosis. (b) Once retrocardiac exposure is established, the vertical vein is controlled with the snugger, and a left atrial incision is performed from the base of the left atrial appendage centrally towards the interatrial septum corresponding to the confluence of the right upper and lower pulmonary veins. The patent foramen ovale is immediately encountered toward the inferoposterior portion of the left atrium and is closed with the running suture technique. (c) Side-to-side confluence of the pulmonary veins to the left atrial anastomosis is then performed in segments as the heart is lowered symmetrically into the pericardial cavity. To achieve this, care is taken to alternate small sections of the suture line reconstruction between the superior and inferior borders. In our technique, the right pleura is completely opened and the heart is dropped into the right pleural cavity as described in the text. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LAA, left atrial appendage; LLPV, left lower pulmonary vein; LPA, left pulmonary artery; LUPV, left upper pulmonary vein; RPV, right pulmonary vein; VV, vertical vein. (Reproduced from Mavroudis C, Backer CL. *Operat Tech Thorac Cardiovasc Surg* 2001;**6**:12–23, with permission from Elsevier.)

transverse sinus of the pericardium after retracting the aorta to the left and the superior vena cava to the right. Transverse incisions are then made in the common chamber and the left atrium followed by anastomosis between the two. (e) In

Kirklin's right lateral approach, the posterior pericardial attachments of the heart are divided and the atria and vena cavae are retracted anteriorly and to the left. The common chamber is then exposed from within the pericardium and,
Figure 34.6 When type III TAPVC is encountered, the orientation of the side-to-side anastomosis should be tailored to accommodate a "best lie" configuration. This drawing shows the vertical incision in the confluence of the pulmonary veins and a corresponding incision in the left atrium, which produces the most favorable anatomic and geometric union for unrestricted flow. The anastomosis is started at the far center of the pulmonary vein confluence and left atrium as shown. Note that the inferior vertical vein is ligated and the patent foramen ovale is closed. IVC, inferior vena cava; LA, left atrium; LLPV, left lower pulmonary vein; LUPV, left upper pulmonary vein; VV, vertical vein. (Reproduced from Mavroudis C, Backer CL. *Operat Tech Thorac Cardiovasc Surg* 2001;**6**:12–23, with permission from Elsevier.)

after making corresponding transverse incisions on the common chamber and the left atrium, an anastomosis is made between the two.(f) In Ebert's posterior approach, the heart is lifted cephalad and to the right to expose the common pulmonary venous chamber, followed by incision of the chamber and the left atrium and anastomosis between the two (Figure 34.5).

At our institution, we prefer a modified posterior approach [28] (Figure 34.5). The anastomosis between the pulmonary venous chamber and the left atrium should be as large as possible and purse stringing of the suture line should be avoided.

In patients in whom the pulmonary venous confluence drains into the superior vena cava (SVC), the pulmonary venous drainage may be baffled across the atrial septal defect into the left atrium via a right atrial incision.

Cardiac TAPVC

This is approached via the right atrium. In patients with a coronary sinus type of TAPVC, the coronary sinus is unroofed by cutting back its ostium towards the ASD, and closed using a pericardial or PTFE patch. Thus the pulmonary venous return drains via the coronary sinus into the left atrium. TAPVC directly to the right atrium is repaired by using the previously harvested pericardium to create a baffle to direct the pulmonary venous return through the atrial septal defect to the left atrium.

Infracardiac TAPVC

The vertical vein is dissected to the level of the diaphragm and is ligated or divided (Figure 34.6). Care must be taken that the corresponding incisions in the pulmonary venous chamber and the left atrium are vertical and in cephalad direction, so that the resulting anastomosis is wide and unobstructed (Figure 34.6).

Mixed TAPVC

Principles of repair similar to those described above apply for the confluence of the three veins, with management of the fourth vein depending upon its size. If it is large enough, it can be re-anastomosed to the left atrial appendage or directed into the left atrium via the ASD if it is draining into the superior vena cava. However, if the vein is small and stenosis of the anastomosis is anticipated in the long term, we prefer to leave it alone and accept a small left-to-right shunt that may range between 1.02 and 1.82 [29]. Other forms of mixed TAPVC are more complex, in which two veins from either side drain to different sites. In these, repair has to be tailored to the individual anatomy, avoiding pulmonary venous obstruction.

Postoperative management

The postoperative course of many patients, in particular neonates with obstruction, tends to be prolonged. Meticulous attention to mechanical ventilatory support is required to prevent pulmonary hypertensive crises.

Immediate postoperative complications include low cardiac output, bleeding, pulmonary hypertensive crises, and bradyarrhythmias (after repair of coronary sinus type of TAPVC). Pulmonary hypertensive crisis is particularly common after repair of obstructed TAPVC. Its prevention consists in avoiding hypercarbia, acidosis, and hypoxemia and using minimal endotracheal suction. Crises are managed by hyperventilation, correcting acidosis, sedation, and paralysis, and by using pulmonary vasodilators such as sodium nitroprusside, nitroglycerin, milrinone, dobutamine, or inhaled nitric oxide. ECMO support may be needed if there is profound hypoxemia and acidosis. Delayed problems include pulmonary venous obstructive disease and arrhythmias.

Outcomes

The outcomes for patients undoing surgery for TAPVC have improved. Operative mortality was ~10–30% in the 1970s and 1980s. Currently it ranges from 5 to 9% in

patients undergoing TAPVC repair in the setting of normal biventricular physiology [30]. Independent risk factors for early mortality are preoperative pulmonary venous obstruction, univentricular heart, associated chromosomal or noncardiac syndromes, poor preoperative condition, severe pulmonary arterial hypertension, small pulmonary veins, and severe pulmonary hypertensive crisis after operation [30].

The long-term outcome for patients following repair of TAPVC early in infancy continues to be good, and more than 90% patients are in NYHA class I. Actuarial survival rates of up to 88% at 18 years have been reported [4]. In these patients, the pulmonary artery pressure and cardiac index often return to normal. In our own experience of TAPVC repair in a developing country, the actuarial survival was 73% at 9 years of follow-up [31].

Postoperative pulmonary vein stenosis occurs in 5–15% patients following repair of TAPVC [32–35]. This can be either anastomotic site stenosis or stenosis of individual pulmonary veins. Pathologically there may be an anastomotic fibrous stricture, discrete stenosis of the pulmonary venous ostia, or diffuse sclerosis of the pulmonary veins. The obstruction usually occurs in children 6–12 months after surgery and is identified by high-velocity turbulent flow exceeding $2\,\mathrm{m\,s^{-1}}$ across the vein or the site of anastomosis [36].

Most of the management options for recurrent pulmonary vein stenosis provide only temporary relief, and repeated interventions are required [33–35]. Nonoperative management consists of balloon dilatation with or without stenting, with steroids or chemotherapy to minimize the fibrosis. Recurrence is common. Surgical methods are equally unsatisfactory, and consist of patch enlargement using pericardium, native atrium, or PTFE. Ostial endarterectomy of intimal hyperplasia is another option. If the anastomosis is narrowed, consideration must be given to revising the common pulmonary vein to left atrium anastomosis. "Sutureless *in situ* pericardial repair" has also been proposed to enlarge the pulmonary veins and create a neo-atrium [37]. In this technique, the left atrium is disconnected from the pulmonary veins and the obstructed pulmonary veins are completely laid open. The opened left atrium is then sutured to the pericardium *in situ* so that suture placement into the pulmonary veins is completely avoided. Recent reports have focused on this as the primary method of repair to prevent pulmonary venous obstruction [38]. Long-term follow-up of the methods is not available.

35 Tricuspid Atresia

P. Syamasundar Rao

University of Texas at Houston Medical School, Houston, TX, USA

Introduction

Tricuspid atresia is a cyanotic cardiac malformation defined as congenital absence or agenesis of the morphologic tricuspid valve [1,2]. It is the third most common cyanotic cardiac anomaly and is the most common cause of cyanosis with left ventricular hypertrophy. The first patient with tricuspid atresia was described by Kreysig in 1817 [3], although the 1812 report by the Editors of *London Medical Review* [3] appears to fit the description of tricuspid atresia but without use of the specific term. Some authors [4,5] stated that tricuspid atresia was first described by Kühne in 1906 or Holmes in 1824, but a thorough review by Rashkind [3] suggests that this is not so.

Nomenclature

There has been a debate about terminology: tricuspid atresia, univentricular heart, or univentricular atrioventricular connection [6]. On the basis of evidence and arguments presented by Bharati and co-workers [7–9], Wenink and Ottenkamp [10], Gessner [11], and Rao [6,12], tricuspid atresia is the correct and logical term to describe this well-characterized pathologic and clinical entity [6] and is used in this chapter.

Incidence

Estimates of the incidence of tricuspid atresia based on autopsy and clinical series are 2.9% and 1.4% of cardiac malformations, respectively [13]. Assuming a prevalence of congenital heart disease of 0.8% of live births, tricuspid atresia occurs in approximately one in 10 000 live births [13]. A slight male preponderance has been suggested [4,14], but detailed analysis when gender is known [13] did not indicate a gender preponderance. However, male preponderance (66% versus 34%) was found in tricuspid atresia patients with coexisting transposition of the great arteries (types II and III) [13]. No difference in either geographic prevalence or racial background for tricuspid atresia has been described [13], although geographic differences in relative prevalence for aortic coarctation and stenosis have been found.

Embryology

The atrioventricular valves develop shortly after the atrioventricular canal divides. The tricuspid valve leaflets develop from several structures. The septal leaflet of the tricuspid valve mostly develops from the inferior and superior endocardial cushions. The anterior and posterior tricuspid valve leaflets develop by undermining of a skirt of ventricular muscle tissue. The process of undermining extends until the atrioventricular valve junction is reached. The muscle tissue undergoes resorption, producing normal-appearing valve leaflets and chordae tendineae [15–17]. Whether a muscular type of tricuspid atresia develops or well-formed but fused tricuspid–valve leaflets develop depends on the stage of development when the embryologic aberration takes place [12,17,18]. The classic muscular form of tricuspid atresia develops if the embryologic insult occurs early in gestation, and fused valve leaflets occur if the embryologic abnormality occurs slightly later than this in gestation. If the valve fusion is incomplete, stenosis of the tricuspid valve develops.

The pathologic, clinical, and electrocardiographic features of tricuspid stenosis and atresia are similar [19]. Consequently, the facts that isolated congenital tricuspid stenosis belongs

(see Chapter 29) to the group of tricuspid atresia defects and that their embryologic developments are similar are no surprise. Thus, the tricuspid valve stenosis, tricuspid atresia with well-formed but fused valve leaflets, and the muscular type of tricuspid atresia represent a spectrum of morphologic abnormalities [12,17,18].

Classification

Tricuspid atresia has been classified on the basis of valve morphology [20], radiographic appearance of pulmonary vascular markings [21]. and associated cardiac anomalies [22–24].

Classification based on valve morphology

Van Praagh et al. [20] proposed a classification based on morphology of the atretic tricuspid valve, and this was modified and expanded by that group and others [25]. The most common type is the muscular variety, characterized by a dimple or a localized fibrous thickening in the floor of the right atrium at the expected site of the tricuspid valve (Figure 35.1). The muscular type constitutes 89% of all tricuspid atresia (Table 35.1). Other types, namely membranous, valvar, Ebstein, atrioventricular septal defect, and unguarded with muscular shelf, account for the remaining 11% (Table 35.1) [7,15,20,25–31]. Pathologic, echocardiographic, and angiographic examples of the rare anatomic types can be found in previous publications [25,32].

Classification based on radiographic pulmonary vascular markings

Astley et al. [21] classified tricuspid atresia on the basis of pulmonary vascular markings on the chest radiograph: group A, decreased pulmonary vascular markings; and group B,

increased pulmonary vascular markings. To this Dick et al. [4] added a third group: group C, transition from increased to decreased pulmonary vascular markings. This categorization
Figure 35.1 Muscular type of tricuspid atresia; the right atrium is opened by cutting through the right atrial appendage (RAA). There is a dimple (arrow) in the floor of the right atrium with muscle fibers radiating around it. Atrial septal defect (ASD) is shown. Table 35.2 A unified classification of tricuspid atresia.

Type I	Normally related great arteries
Type II	d-Transposition of the great arteries
Type III	Malpositions of the great arteries other than d-transposition
Subtype 1	l-Transposition of the great arteries
Subtype 2	Double-outlet right ventricle
Subtype 3	Double-outlet left ventricle
Subtype 4	d-Malposition of the great arteries (anatomically corrected malposition)
Subtype 5	l-Malposition of the great arteries (anatomically corrected malposition)
Type IV	Persistent truncus arteriosus
Each type and subtype are divided:	
Subgroup a	Pulmonary atresia
Subgroup b	Pulmonary stenosis or hypoplasia
Subgroup c	Normal pulmonary arteries (no pulmonary stenosis)

Table 35.3 Associated cardiac anomalies in tricuspid atresia

Anomalies that form the basis of classification
d-Transposition of the great arteries
l-Transposition of the great arteries
Double-outlet right ventricle
Double-outlet left ventricle
Other malpositions of the great arteries
Truncus arteriosus

Anomalies that may need attention before or at the time of palliative or total surgical correction
Absent pulmonary valve
Aneurysm of the atrial septum
Anomalous origin of the coronary arteries from the pulmonary artery
Anomalous origin of the left subclavian artery
Anomalous origin of the right subclavian artery
Aortopulmonary fistula
Coarctation of the aorta
Common atrium
Cor triatriatum dexter
Coronary sinus septal defect
Double aortic arch
Double-outlet left atrium
Hemitruncus
Hypoplastic ascending aorta and aortic atresia
Ostium primum atrial septal defect
Parchment right ventricle
Patent ductus arteriosus
Persistent left superior vena cava
Right aortic arch
Subaortic stenosis
Total anomalous pulmonary venous connection
Tubular hypoplasia of the aortic arch
Valvar aortic stenosis
Others
Juxtaposition of the atrial appendages
Anomalous entry of coronary sinus into the left atrium

Reproduced with permission from Rao PS, Covitz W, Chopra PS. *Tricuspid Atresia*, 2nd edn. Mount Kisco, NY: Futura Publishing, 1992: 297–320.

has clinical value, although more precise noninvasive definition of the defect complex by echo Doppler studies and pulse oximetry is readily available.

Classification based on associated defects

The interrelationship of the great arteries, used by Kühne [22] in 1906 as a basis for classification, was expanded later by Edwards and Burchell [23] and popularized by Keith *et al*. [24]. A variety of other classifications have been proposed, reviewed elsewhere [1,25]. To include all variations of great artery anatomy and to maintain uniformity of subgrouping, the present author proposed a comprehensive yet unified classification [1] that is listed in Table 35.2. The primary grouping is based on great artery relationships: type I, normally related great arteries; type II, d-transposition of great arteries; type III, other malpositions of great arteries, which are subdivided into subtypes 1–5 (Table 35.2); and type IV, persistent truncus arteriosus. The major types and subtypes are divided further into subgroup a, pulmonary atresia; subgroup b, pulmonary stenosis or hypoplasia; and subgroup c, normal pulmonary arteries (no pulmonary stenosis). The status of the ventricular septum and the other associated malformations (Table 35.3) [33] should then be stated for each heart.

This unified classification considers all variations in great artery anatomy described thus far, can be expanded if new great artery positional abnormalities are described, and maintains uniformity in subgroups but preserves the basic principles of previous classifications [22–24] If one wants to follow the terminology of congenital heart disease proposed by Van Praagh [34], the remaining cardiac segment subsets (i.e., visceroatrial situs and ventricular loop) could be added, and each heart is described by the notations {S,D,S}, {S,D,D}, and {S,D,L} as shown in the schematic drawing depicted in Figure 35.2.

Pathologic anatomy

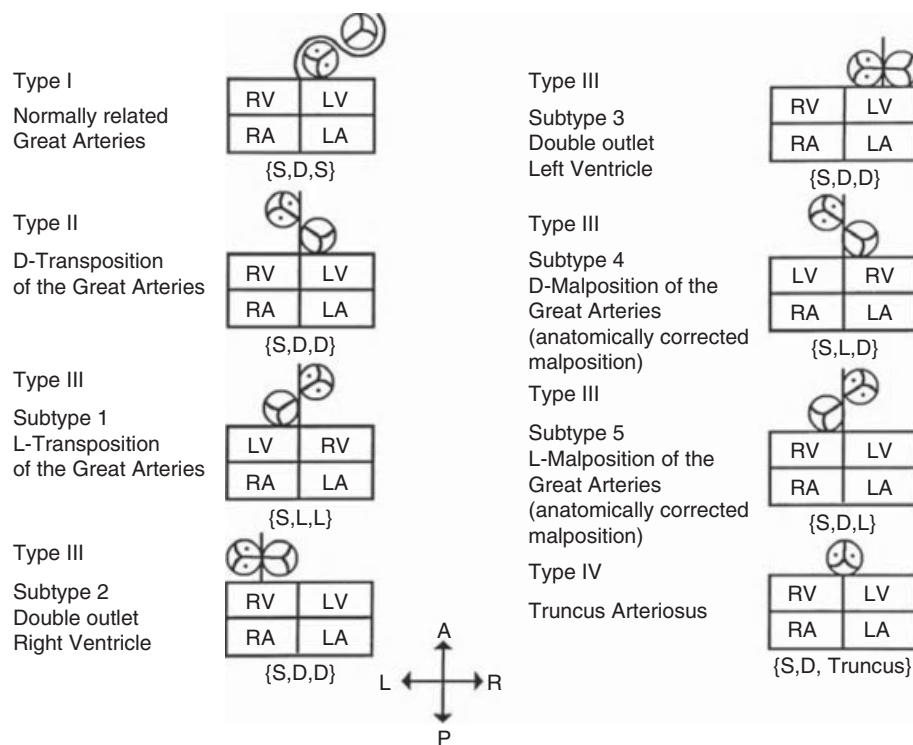
The pathology of this lesion is best described by reviewing variations in the morphology of the atretic tricuspid valve. In the most common muscular type (Figure 35.1), no valve material can be identified by either gross or microscopic


Figure 35.2 Representation of segmental subsets of tricuspid atresia with the heart in the left side of the chest. Only commonly described types are depicted. Each type can occur with dextrocardia and atrial inversion. Both double-outlet right ventricle and double-outlet left ventricle can occur with {S, D, L} and {S, L, L}. A, anterior; {–,D,–}, d-loop; {–,–,D}, d-transposition; {–, L, –}, l-loop; {–, –, L}, l-transposition; LA, left atrium; LV, left ventricle; P, posterior; R, right; RA, right atrium; RV, right ventricle; {S, –, –}, situs solitus; {–, –, S}, solitus normal great arteries. (Reproduced with permission from Rao PS. *Tricuspid Atresia*, 2nd edn. Mount Kisco, NY: Futura Publishing, 1992:59–79.)

examination [24]. Other types are described elsewhere [25,32]. In the membranous type, the atrioventricular portion of the membranous septum forms the floor of the right atrium at the expected location of the tricuspid valve [7,15,20]. An unusually high incidence of absent pulmonary valve leaflets occurs with this type of tricuspid atresia [25]. In the valvar type, the minute valve cusps are fused [24,27,28]. The Ebstein type, with fusion of the tricuspid valve leaflets (which had been displaced downwards and plastered on to the right ventricular wall), is rare [7,20,26]. In the atrioventricular septal defect type, the valve leaflet of the common atrioventricular valve seals off the only entrance into the right ventricle [31,35] The final form, in which the right atrioventricular junction is unguarded but the inlet component of the morphologic right ventricle is separated from its outlet by a muscular shelf [30], is also rare.

The right atrium is usually enlarged and its wall is thick and hypertrophied. The interatrial communication, necessary for survival, is usually a stretched patent foramen ovale, sometimes it is an ostium secundum atrial septal defect, and occasionally an ostium primum atrial septal defect. Rarely, the interatrial communication is obstructive and may form an aneurysm of the fossa ovalis. The left atrium may be enlarged, especially if the pulmonary blood flow is increased. The mitral valve is morphologically normal; the mitral orifice is large and occasionally incompetent. The left ventricle is clearly a morphologic left ventricle with only occasional abnormalities [7]; however, it is enlarged and hypertrophied. In contrast, the right ventricle is small and hypoplastic; even the largest of the right ventricles, seen in patients with a large ventricular septal defect (VSD) or transposition of the great arteries, is smaller than normal. Right ventricular size is determined by the anatomic type of tricuspid atresia. In patients with pulmonary atresia and normally related great arteries, the right ventricle may be extremely small and escape detection. However, in most patients, it is a true right ventricle [7,8], consisting of a sharply demarcated infundibulum with septal and parietal bands and a trabeculated sinus portion that communicates with the left ventricle through a VSD. The inflow region of the right ventricle, by definition, is absent, although papillary muscles may occasionally be present.

The relative position of the great vessels varies, as described in the classification section. Most have either normally related great arteries (type I) or d-transposed great arteries

(type II), but a few have other positional anomalies of the great arteries (type III) or truncus arteriosus (type IV).

Pulmonary outflow tract obstruction is common in type I tricuspid atresia. The pulmonary valve may be atretic (subgroup a), and either a patent ductus arteriosus or aortopulmonary collateral vessels supply the lungs. A stenotic pulmonary outflow tract (subgroup b) is more common. The stenosis is either subvalvar or valvar in patients with transposition of the great arteries, whereas in patients with normally related great arteries, obstruction occurs at the VSD level [36–42]. In a few patients, subvalvar pulmonary stenosis, a narrow outflow tract of the hypoplastic right ventricle, and rarely valvar pulmonary stenosis may be responsible for the pulmonary outflow obstruction. A normal pulmonary outflow tract (subgroup c) without stenosis may be present, although less commonly than those with obstruction. The ascending aorta is normal or enlarged.

The VSD may be large, small, or nonexistent, or multiple VSDs may be present. The VSD may be conoventricular or perimembranous (located inferior to the septal band), conal septal malalignment (located between the anterosuperior and posteroinferior limbs of the septal band), muscular (located inferiorly compared with the two previous types), or of the atrioventricular canal type [43] Muscular VSDs are the most common [36,37]. Most VSDs are restrictive, producing subpulmonic stenosis in patients with normally related great arteries and mimicking subaortic obstruction in patients with transposed great arteries [36–42].

About 30% of tricuspid atresia patients have associated anomalies (Table 30.3). Significant among these are persistent left superior vena cava and aortic coarctation, the latter more frequent in type II patients.

Pathophysiology

Prenatal circulation

In tricuspid atresia, both vena caval streams are shunted across the foramen ovale into the left atrium and left ventricle. Therefore, the arterial PO_2 is the same in all parts of the body. Whether a higher PO_2 in blood passing to lungs influences the pulmonary arteriolar smooth muscle development is not known [44]. The lower than normal PO_2 to the brain and upper part of the body does not seem to impair development, at least as observed clinically.

The pulmonary blood flow in type I (normally related great arteries) patients with intact ventricular septum or pulmonary atresia (type Ia) and type II (transposition of the great arteries) patients with pulmonary atresia (type IIa) must be supplied entirely through the ductus arteriosus. Because the ductus carries only the pulmonary blood flow (from left to right), representing 8–10% of combined

ventricular output in contrast to 66% (from right to left) in the normal fetus [44], the ductus arteriosus is smaller than normal. This fact and the acute angulation of the ductus from its aortic origin because of reversal of direction of ductal flow may render the ductus less responsive to the usual postnatal stimuli [44].

In type I patients with VSD, the amount of blood flow from the left ventricle through the VSD into the right ventricle, pulmonary artery, and ductus arteriosus compared with the quantity of blood flow retrograde from the aorta through the ductus arteriosus varies with size of the VSD. The larger the VSD, the greater is the amount of anterograde ductal flow.

In type I patients with either a small or no VSD, most of the left ventricular blood is ejected via the aorta to the entire body and the placenta. Thus, the aortic isthmus carries a larger proportion of ventricular output than normal; this presumably explains the rarity of coarctation of the aorta in tricuspid atresia without transposition of the great arteries. In type II (transposition) without significant pulmonary stenosis, because the VSD is usually smaller than the pulmonary valve annulus [45], a larger proportion of blood traverses the pulmonary artery and ductus arteriosus anterograde. Therefore, the isthmic blood flow is less, thus accounting for the high incidence of coarctation of the aorta and aortic arch anomalies in patients with tricuspid atresia and transposition [44,45].

Postnatal circulation

An obligatory right-to-left shunt occurs at the atrial level in most types and subtypes (exception: type III, subtypes 1 and 4; see Table 35.2) of tricuspid atresia. Consequently, the systemic and coronary venous blood mixes with pulmonary venous blood in the left atrium. This mixed pulmonary, coronary, and systemic venous blood enters the left ventricle. In type III, subtypes 1 and 4, because of ventricular inversion, the occluded morphologic tricuspid valve is left-sided and the pathophysiology is that of mitral atresia with left-to-right shunting of pulmonary venous blood.

In type I (normally related great arteries) patients with a VSD, a ventricular left-to-right shunt occurs, thus perfusing the lungs. If the ventricular septum is intact, the pulmonary circulation comes from a patent ductus arteriosus or through bronchopulmonary or persistent aortopulmonary collateral vessels. The aortic blood flow comes directly from the left ventricle.

In type II (with d-transposition of the great arteries), the pulmonary circulation is directly supplied from the left ventricle. The systemic circulation is supplied through the VSD and the right ventricle. In other type III and type IV patients, the systemic and pulmonary blood flows are determined by the size of the VSD and other associated anomalies.

Other physiologic principles

Arterial desaturation

Because of complete admixture of the systemic, coronary, and pulmonary venous returns in the left atrium and left ventricle, systemic arterial desaturation is always present. The oxygen saturation is proportional to the magnitude of the pulmonary blood flow [45,46]. The pulmonary-to-systemic blood flow ratio (Qp/Qs), which represents the pulmonary blood flow, has a curvilinear relationship with the arterial oxygen saturation. A Qp/Qs of 1.5–2.5 appears to produce an adequate oxygen saturation [46].

Pulmonary blood flow

The magnitude of pulmonary blood flow is the major determinant of clinical features in tricuspid atresia. An infant with markedly decreased pulmonary blood flow presents early in the neonatal period with severe cyanosis, hypoxemia, and acidosis. An infant with markedly increased pulmonary flow has minimal cyanosis but usually presents with signs of heart failure. Patients with decreased pulmonary flow usually belong to type I (normally related great arteries), and those with increased pulmonary blood flow are usually type II (transposition of the great arteries) and occasionally type Ic.

The quantity of pulmonary blood flow depends on the degree of obstruction to the pulmonary outflow tract and patency of the ductus arteriosus. The pulmonary outflow obstruction is either valvar or subvalvar in type II patients and valvar, subvalvar, or at VSD level in type I patients. In the present author's experience, the obstruction has been found most commonly at the VSD level [36–40]. If the VSD is large and nonrestrictive and the pulmonary valve not stenotic, the pulmonary flow is inversely proportional to the pulmonary-to-systemic vascular resistance ratio; the lower this ratio, the higher is the pulmonary flow.

Left ventricular volume overloading

Because the entire systemic, coronary, and pulmonary circulations are supplied by the left ventricle, greater than normal volume is ejected. This volume overloading is further increased if Qp/Qs is increased either because of minimal obstruction to pulmonary blood flow or a large surgical shunt, and may lead to heart failure. Normal left ventricular function is critical for a successful Fontan-type procedure. Left ventricular function tends to decrease with increasing age, Qp/Qs, and arterial desaturation [47–49].

Size of the interatrial communication

The interatrial communication is usually a patent foramen ovale. Because the entire systemic venous return must pass through the patent foramen ovale, it is not surprising to find interatrial obstruction, although this is clinically significant in only a few patients with tricuspid atresia [4]. Right-to-left shunt occurs in late atrial diastole with augmentation during atrial systole (*a* wave) [50]. A mean atrial pressure gradient >5 mmHg is usually associated with interatrial obstruction. Tall *a* waves in the right atrial pressure trace also indicate interatrial obstruction.

Natural history

With growth and development, several changes occur in patients with tricuspid atresia. The natural history of individual defects followed by that of the entire defect complex will be reviewed.

Patent ductus arteriosus

Closure of the ductus arteriosus in the early neonatal period may result in severe hypoxemia.

Interatrial communication

The size of the interatrial communication may diminish either in absolute terms or relative to the volume of the systemic venous return and cause systemic venous congestion, as alluded to above. Atrial septostomy may be required.

Ventricular septal defect

A VSD is necessary to maintain adequate intracardiac shunting essential for survival of the patient; these types of VSDs are physiologically advantageous VSDs [37–40]. Intermittent functional [40] and complete or partial anatomic [36–39, 41,42,51] closure of the VSD has been reported. Intermittent functional closure of a VSD is likely to produce cyanotic spells in tricuspid atresia. The causes of such functional closure are not clearly delineated but are likely to be similar to those suspected in tetralogy of Fallot [40,51]. Complete or partial anatomic closure in type I patients produces progressive cyanosis, increasing polycythemia, or disappearance of the heart murmur, requiring an operation earlier than planned [36,37,51]. In type II patients, partial closure of the VSD results in subaortic, systemic outflow obstruction; such obstruction may cause severe left ventricular hypertrophy which may contraindicate Fontan correction. Complete VSD closures have not been reported in these patients.

The prevalence of VSD closure in tricuspid atresia is difficult to estimate. The best estimates, based on the present author's data [36,37,51] and those of Sauer and Hall [42], are 38–44%, similar to that of spontaneous closure of an isolated VSD [52,53]. The ages at which the VSD closures take place vary, starting before 1 year and up to 20 years, with a median of 1.3 years [51]. Thus, a higher proportion of VSD closure occurs in early life, as has been found with an isolated VSD. Several mechanisms of closure have been observed, the most common being progressive muscular
Figure 35.3 Actuarial survival curves from three series compiled by Dick and Rosenthal [55] show a high initial mortality in the first year of life, a plateau between the first year and the middle of the second decade of life, and a second bout of mortality from the middle of the second decade onward, presumably related to impaired left ventricular function. (Reproduced with permission from Rao PS. *Tricuspid Atresia*, 2nd edn. Mount Kisco, NY: Futura Publishing, 1992:59–79.)

encroachment of the margins of VSD with subsequent fibrosis and covering by endocardial proliferation. The factors initiating closure of VSD are unknown. There is a great natural tendency for a VSD to close spontaneously, whether it is isolated or a part of a more complex cardiac anomaly [38,51,54]. The reason for this tendency remains unclear.

Defect complex
Actuarial survival curves from three early clinical series [4,14,55] are shown in Figure 35.3. High mortality is seen in the first year of life. This may be related to hypoxemia, heart failure, surgical intervention, and/or a combination thereof. There is a plateau between the first year through the middle of second decade. A second bout of mortality occurs from the middle of the second decade onwards, presumably related to impaired left ventricular function.

Clinical features

Clinical history and physical examination
Nearly half of the patients with tricuspid atresia present with symptoms on the first day of life, and 80% have symptoms by 1 month of age [4,55]. Two modes of clinical presentation are related to pulmonary blood flow: either decreased or increased.

Infants with pulmonary oligemia present with symptoms of hypoxemia within the first few days of life; the more severe the pulmonary oligemia, the earlier is the clinical presentation. These hypoxemic infants are cyanotic and develop hyperpnea and acidosis if the pulmonary blood flow is markedly decreased. Most are type Ib. Patients with associated pulmonary atresia (subgroup a), irrespective of

the major type, also present with early cyanosis, especially as the ductus begins to close. Hypoxic spells are uncommon in a neonate, although they can occur later in infancy. Physical examination reveals central cyanosis, tachypnea or hyperpnea, normal pulses, a prominent *a* wave in the jugular venous pulse (if there is significant interatrial obstruction), and no hepatomegaly. Presystolic hepatic pulsations may be felt if severe interatrial obstruction exists. The precordium is quiet, and no thrills are usually felt. The second heart sound is single. A soft holosystolic murmur suggestive of a VSD may be heard at the left lower or midsternal border. Diastole is clear. In patients with associated pulmonary atresia, murmurs are usually not present, except occasionally the continuous murmur of a patent ductus arteriosus. Signs of congestive heart failure are notably absent.

Infants with pulmonary plethora usually present with signs of heart failure within the first few weeks of life, although an occasional infant may present within the first week of life [56]. They are only minimally cyanotic but present with dyspnea, fatigue, difficulty in feeding, and perspiration. Recurrent respiratory tract infection and failure to thrive are other modes of presentation. Most of these patients are type IIc, although a small number may be of type Ic. The association of coarctation of the aorta with type II patients may result in early cardiac failure. Examination reveals tachypnea, tachycardia, decreased femoral pulses (with coarctation of the aorta but without a large patent ductus arteriosus), minimal cyanosis, prominent neck vein pulsations, and hepatomegaly. Prominent *a* waves in jugular veins or presystolic hepatic pulsations may be observed with interatrial obstruction. The precordial impulses are increased and hyperdynamic. The second heart sound may be either single or split. A loud holosystolic murmur of a VSD is usually heard at the left lower sternal border. A loud third sound or an apical mid-diastolic murmur is often heard. Signs of congestive cardiac failure are usually present.

Issues related to long-standing cyanosis, such as clubbing, polycythemia, relative anemia, cerebrovascular accident, brain abscess, coagulation problems, and hyperuricemia, are similar to those of other cyanotic cardiac malformations [57]. The risk for development of endocarditis resembles that observed in other cardiac abnormalities.

Patients with tricuspid atresia are particularly prone to atrial arrhythmias; atrial fibrillation is more common, occurring in older children and adolescents with long-standing cyanosis, systemic-to-pulmonary arterial shunt, and left ventricular volume overloading.

Electrocardiographic features
The electrocardiogram is virtually diagnostic of tricuspid atresia in the presence of cyanosis. The characteristic features are right atrial hypertrophy, an abnormal, superiorly oriented major QRS vector (so-called left-axis deviation) in the frontal

plane, left ventricular hypertrophy, and diminished right ventricular forces (Figure 35.4).

Right atrial hypertrophy, manifested by tall, peaked P waves exceeding 2.5 mm in amplitude, may be present in 75% of the patients with tricuspid atresia [58]. A double-peak, spike-
Figure 35.4 Electrocardiogram highly suggestive of tricuspid atresia: abnormal, superiorly oriented mean QRS vector in the frontal plane (−45°, left axis deviation), left ventricular hypertrophy and strain, and diminished anterior (R waves in leads V_1 and V_2) and rightward (S waves in leads V_5 and V_6) forces. Prominent P waves appear in several leads.

and-dome configuration of the P wave, referred to as P tricuspidale, may be present [58]. The first taller peak is contributed by the right atrial depolarization, and the second smaller peak is presumed to be from left atrial depolarization [59]. Regardless of the configuration, the P wave duration is prolonged, perhaps owing to right atrial enlargement.

An abnormal, superiorly oriented major QRS vector (ASV), more popularly called left-axis deviation, between 0 and −90° in the frontal plane, is present in most patients with tricuspid atresia (Figure 35.5). ASV is present in >80% of patients with type I anatomy (normally related great arteries), but <50% of patients with type II and type III anatomy show such a typical electrocardiographic pattern. Normal (0 to +90°) or right-axis deviation is present in a few patients, most of them with type II or type III anatomy. The mechanism of ASV has not been clearly delineated, but may include destructive lesions in the left anterior bundle, fibrosis of left bundle branch, abnormal distribution of the conduction system (unusually long right bundle branch and origin of left bundle branch close to the nodal–His bundle junction), small right ventricle, large left ventricle, and others [59]. Ventricular activation data from our group suggested that this characteristic QRS pattern in tricuspid atresia is produced by interaction of several factors, the most important being right-to-left phase asynchrony of ventricular activation, right-to-left ventricular disproportion, and the asymmetric distribution of the left ventricular mass favoring the superior wall [59,60].

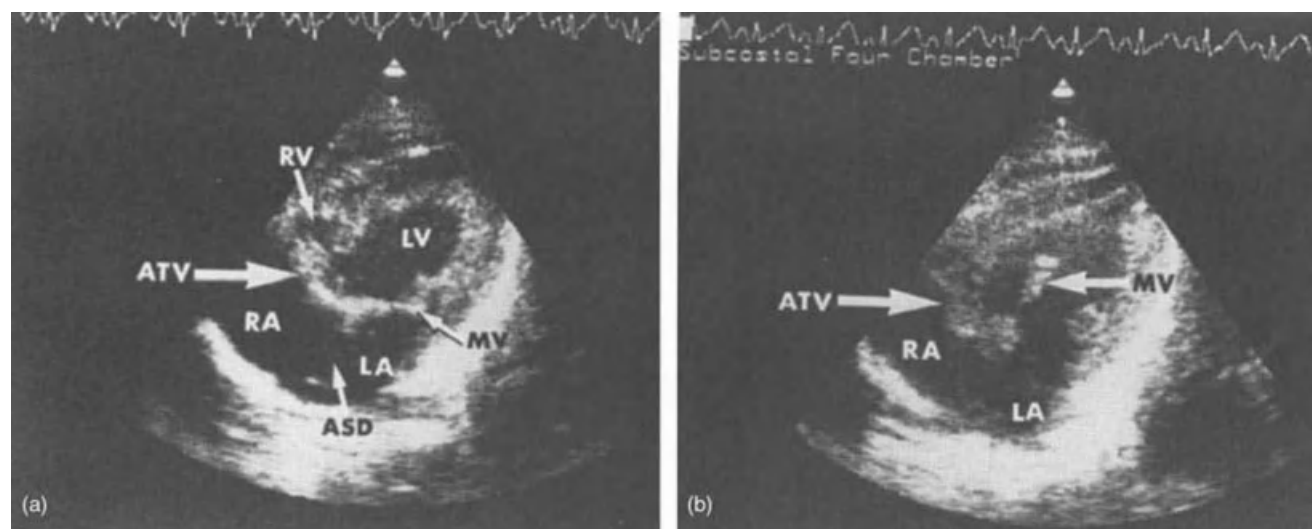
Regardless of the frontal plane mean QRS vector, electrocardiographic left ventricular hypertrophy is present in most patients, manifested by S waves in right chest leads and R


Figure 35.5 Subcostal four-chamber two-dimensional echocardiogram of a neonate with tricuspid atresia. (a) Enlarged left ventricle (LV), small right ventricle (RV), and a dense band of echoes (ATV) are shown at the site where the tricuspid valve echo should be. Atrial (ASD) and ventricular septal defects and the mitral valve (MV) are visualized. (b) Attachment of anterior leaflet of detectable atrioventricular valve to left side of atrial septum. LA, left atrium; RA, right atrium. (Reproduced from Rao *Fetal and Neonatal Cardiology*. Philadelphia, PA: Saunders, 1990: 525–40, with permission of W.B. Saunders/Elsevier.)

waves in left chest leads beyond the 95th percentile or by adult progression of the QRS in the chest leads in the neonates and infants. ST-T wave changes suggestive of left ventricular strain are present in half of patients [59]. Left ventricular hypertrophy is due to left ventricular volume overload and also lack of opposition to the left ventricular forces by the hypoplastic right ventricle. Biventricular hypertrophy may occasionally be present, and most of these patients have type II or type III anatomy with an adequately sized right ventricle [59]. Diminished R waves in right chest leads and S waves in left chest leads are related to right ventricular hypoplasia.

Electrocardiographic features of rare types of tricuspid atresia are reviewed elsewhere [59].

Chest X-ray

Radiographic features depend on the total pulmonary blood flow. In patients with decreased pulmonary flow (most infants fall into this category), cardiac size is either normal or mildly enlarged, whereas those with increased pulmonary blood flow have moderate to severe cardiomegaly. A variety of cardiac configurations have been described in the literature: "characteristic" tricuspid atresia appearance [61], *coeur en sabot* configuration [62], and egg-shaped [63], bell-shaped [64], and square [21] heart, but in the present author's and others' experience [63], no consistent pattern is diagnostic of tricuspid atresia. There may be concavity in the region of the pulmonary artery segment in patients with pulmonary oligemia and a small pulmonary artery. The right atrial shadow may be prominent.

A right aortic arch is present in 8% of patients with tricuspid atresia [63] and is less common than in tetralogy of Fallot (25%) and truncus arteriosus (40%). An unusual contour of the left cardiac border suggestive of l-transposition may be seen in association with or confused with tricuspid atresia [65].

The greatest use of the chest radiograph is its ability to categorize neonates into those with decreased pulmonary vascular markings and those with increased pulmonary vascular markings. Often, this is all that is necessary to make a correct diagnosis once a history, physical examination, and electrocardiogram have been obtained [65].

Echocardiography

M-mode echocardiographic features include an enlarged left atrium (usually proportional to the magnitude of pulmonary blood flow), a dilated left ventricle with normal or decreased left ventricular shortening fraction, a large mitral valve in continuity with the posterior semilunar valve, and a small right ventricle [65,66]. The pulmonary valve may or may not be recorded. The tricuspid valve is conspicuously absent [65].

Two-dimensional echocardiography, apart from showing an enlarged right atrium, left atrium, and left ventricle and a small right ventricle, demonstrates the atretic tricuspid valve directly. In the most common muscular type, a dense band of echoes is seen at the site where the tricuspid valve should be [65,67], and the anterior leaflet of the detectable atrioventricular valve is attached to the left side of the interatrial septum (Figure 35.5). The anatomy is best demonstrated in the apical and subcostal four-chamber views. A persistent left superior vena cava, when present, can usually be identified emptying into the coronary sinus, as can the entries of the superior and inferior venae cavae into the right atrium. Atrial and ventricular septal defects can also be demonstrated. Semilunar valves can be identified as pulmonary or aortic by following the great vessel until the bifurcation of the pulmonary artery or arch of the aorta is seen; this will identify associated transposition of the great arteries. Coarctation of the aorta, often present in type II patients, may be shown in the suprasternal notch view.

Contrast echocardiography with two-dimensional imaging clearly demonstrates sequential opacification of the right atrium, the left atrium, the left ventricle, and then the right ventricle, although this is not necessary for diagnosis.

Doppler echocardiography is helpful in demonstrating shunts and the degree of pulmonary stenosis. Right-to-left shunting across the atrial septum can be visualized by placing the pulsed Doppler sample volume on either side of the atrial defect and by color flow mapping. Most right-to-left shunting occurs during atrial systole. Left-to-right shunting, although transient, can be demonstrated by Doppler study during atrial diastole, secondary to instantaneous pressure differences across the atrial septum [50]. High-flow velocity across the VSD can be demonstrated in type Ib tricuspid atresia; the higher the velocity, the smaller is the defect. Color-guided continuous-wave Doppler, with use of the modified Bernoulli equation, is useful in quantitating the left-to-right ventricular pressure difference, thereby estimating the size of the VSD. Interrogating the right ventricular outflow tract may demonstrate subvalvar or valvar pulmonary stenosis. Careful interrogation of Doppler velocities across the VSD in type II patients identifies subaortic (at the VSD level) obstruction. Similarly, Doppler evaluation of the descending aorta is useful in demonstrating aortic coarctation.

M-mode, two-dimensional, Doppler (pulsed, continuous-wave, and color), and, when indicated, contrast echocardiography are useful in delineating most anatomic and physiologic issues related to tricuspid atresia.

Cardiac catheterization and angiography

The diagnosis of tricuspid atresia based on clinical, electrocardiographic, and echocardiographic features is relatively simple, and cardiac catheterization with selective cineangiography rarely, if ever, is essential for the diagnosis [46]. Cardiac catheterization should be performed only if sufficient

Table 35.4 Choussat criteria.

Normal vena caval connections
Normal right atrial volume
Mean pulmonary artery pressure ≤15 mmHg
Pulmonary vascular resistance ≤4 Wood units m^{-2}
Pulmonary artery to aortic root diameter ratio ≥0.75
Normal left ventricular function
Competent mitral valve
Undistorted pulmonary arteries

data needed for management are unavailable from echo Doppler and other noninvasive studies. Catheterization is generally recommended before operative correction to provide the surgeon with accurate anatomic detail. Specific information on the pulmonary artery anatomy, size, and pressures and left ventricular function is necessary before a Fontan-type procedure. Assessment of Choussat's hemodynamic and angiographic parameters [68] (Table 35.4) should be undertaken, although exceptions to some criteria can be made.

Catheter insertion and course

A percutaneous femoral venous route is used for catheterization [46,69]. The right ventricle cannot be directly entered from the right atrium because of atresia of the tricuspid valve, but the catheter can easily be advanced into the left atrium across the patent foramen ovale and from there into the left ventricle through the mitral valve. With the availability of balloon-tipped catheters and a variety of guidewires, it is usually possible to catheterize the right ventricle (through the VSD), pulmonary artery, and aorta. However, in a sick neonate, the procedure may be terminated after left ventricular angiography because further manipulation of the catheter may produce an arrhythmia or precipitate a hypercyanotic spell. In infants with clinical evidence of aortic coarctation (type II patients), retrograde femoral arterial catheterization may be necessary if left ventricular angiography does not clearly define the problem.

Oxygen saturations

Systemic venous oxygen saturation is decreased in proportion to systemic arterial desaturation and severity of congestive heart failure. Because of obligatory right-to-left shunting across the patent foramen ovale, a left-to-right shunt is ordinarily not detected. An increase in right atrial oxygen saturation, however, may be attributed to transient reversal of flow secondary to instantaneous pressure differences between the atria [50].

The pulmonary venous oxygen saturations are usually normal, with a lower left atrial oxygen saturation reflecting the atrial right-to-left shunt. Left ventricular oxygen saturation is also diminished and represents better admixture than that in the left atrium. The oxygen saturations in the left atrium, left ventricle, right ventricle, pulmonary artery, and aorta are similar. Systemic arterial desaturation is always present, the extent of oxygen desaturation being a function of the pulmonary-to-systemic flow ratio (Qp/Qs).

The vena caval, left atrial, and left ventricular oxygen saturations are generally lower in type I than in type II patients, presumably related to a greater preponderance of pulmonary oligemia in type I patients [46].

Pressures

The mean right atrial pressure is mildly increased, similar to or slightly higher than that in the left atrium. The right atrial a waves are prominent. A mean atrial pressure difference greater than 5 mmHg and giant a wave in the right atrial pressure trace indicate interatrial obstruction. When the left ventricular end-diastolic pressure is markedly elevated, lack of pressure difference across the atrial septum does not exclude interatrial obstruction [46].

Mean left atrial and left ventricular end-diastolic pressures are usually normal but increase with an elevated Qp/Qs and decreased left ventricular function. The left atrial v waves are lower than a waves in patients with decreased pulmonary blood flow. As the pulmonary flow increases, the v waves become taller.

The left ventricular peak systolic pressure is usually normal but may be elevated with aortic coarctation or subaortic stenosis. Aortic peak systolic pressure is normal unless there is associated aortic coarctation. Aortic diastolic pressure may be low because of diastolic runoff, secondary to an operatively placed aortopulmonary shunt. In a type II (transposition) patient, careful pressure pullback across the aortic and subaortic region should be performed. A peak pressure gradient between the ventricles indicates subaortic obstruction secondary to a small VSD [36,37].

The right ventricular peak systolic pressure is usually proportional to the size of the VSD in type I patients; the larger the VSD, the higher is the pressure. The pressure is occasionally high in the presence of a small VSD associated with right ventricular outflow tract stenosis. The right ventricular systolic pressure is at systemic level in type II patients.

Every attempt should be made to catheterize the pulmonary artery [46] because of the importance of measuring pulmonary artery pressure [68] in evaluating tricuspid atresia patients for corrective operation. When all methods fail, pulmonary venous wedge pressure should be measured to estimate the pulmonary artery pressure [70]. The pulmonary artery pressures are usually normal in type I patients, although they may be high in type Ic patients with a large VSD. In type II patients with transposition, the pulmonary artery pressure depends on the degree of subvalvar and
Figure 35.6 Cineangiograms from (a) superior vena cava (SVC) and (b) right atrium (RA) in frontal projection from two patients. There is sequential opacification of the left atrium (LA) and left ventricle (LV) without opacification of the right ventricle. The nonopacified right ventricular "window" (arrows) is formed by the RA on the right, the LA superiorly, and the LV on the left. This is a classic appearance of the muscular variety of tricuspid atresia. (Reproduced from Rao *Atlas of Heart Diseases*, Vol XII. Philadelphia, PA: Current Medicine, 1997: 14.1–14, with permission of Current Medicine/Springer.)

valvar pulmonary stenosis or the effectiveness of an operatively placed pulmonary artery band.

Calculated variables

Pulmonary and systemic blood flows, vascular resistances, and shunts may be calculated by the Fick principle, with either assumed or measured oxygen consumption. The principles and methods of calculation are detailed elsewhere [44,46] (see Chapter 10). The Qp/Qs ratio and pulmonary vascular resistance are the most important. The Qp/Qs ratio is diminished in type I and type II patients with pulmonary atresia and in type Ib patients with a small VSD. It may be markedly increased in type I patients with a large VSD (type Ic) and most type II patients.

Because of pulmonary outflow tract obstruction, pulmonary vascular resistance is normal in most patients with tricuspid atresia. In type Ic patients with a large VSD, type IIc patients without pulmonary stenosis, and patients with a large systemic–pulmonary artery shunt, the pulmonary resistance may be elevated.

Another calculated variable, described by Mair *et al*. [71], the preoperative catheterization index, recognizes the importance of pulmonary vascular resistance and left ventricular diastolic function. This index may be calculated as Rp + [LVEDP/(PI+SI)] where Rp is pulmonary vascular resistance (units m^{-2}), *LVEDP* is left ventricular end-diastolic pressure (mmHg), and *PI* and *SI* are pulmonary and systemic flow indices, respectively (l min^{-1} m^{-2}).

An index of ≤4 is associated with lower early and total mortality after a Fontan operation than is an index >4. This is a useful index, although with some limitations [71].

Angiography

The absence of direct anatomic continuity between the right atrium and the morphologic right ventricle is the hallmark of the angiographic features of tricuspid atresia. Selective superior vena caval or right atrial angiograms reveal successive opacification of the left atrium and left ventricle without immediate opacification of the right ventricle (Figure 35.6); this "typical sequence of tricuspid atresia" is considered characteristic. The negative shadow between the right atrium and left ventricle, named the right ventricular window, corresponds to failure of early filling of the right ventricle (Figure 35.6). These features are best demonstrated in the posteroanterior view. The size and location of the atrial septal defect are optimally shown in hepatoclavicular or lateral views and may produce the so-called onionskin or waterfall appearance (Figure 35.7) if the atrial septum is obstructive.

Reflux of the contrast material into the venae cavae and hepatic veins is seen normally after right atrial angiography. Dense opacification of the coronary sinus (Figure 35.8) suggests interatrial obstruction. The size of the right atrium and the location and size of the right atrial appendage should also be evaluated. For example, left-sided
Figure 35.7 Selective superior vena caval (SVC) angiogram in a four-chamber (hepatoclavicular) projection reveals no opacification of the right ventricle and typical, onionskin appearance of the interatrial communication (arrows). Contrast material streams into the roof of the left atrium (LA). IVC, inferior vena cava; RA, right atrium. (Reproduced with permission from Schwartz and Rao *Tricuspid Atresia*, 2nd edn. Mount Kisco, NY: Futura Publishing, 1992: 223–46.)
Figure 35.8 Selective superior vena caval (SVC) injection in four-chamber projection (hepatoclavicular) shows tricuspid atresia and filling of the left atrium (LA) through a restrictive atrial septal defect (arrows). There is retrograde filling of the coronary sinus (CS). RA, right atrium. (Reproduced with permission from Schwartz and Rao *Tricuspid Atresia*, 2nd edn. Mount Kisco, NY: Futura Publishing, 1992: 223–46.)
Figure 35.9 Selective superior vena caval injection in the right anterior oblique projection shows the right atrial appendage (RAA) juxtaposed leftwards. There is an imperforate tricuspid valve (arrowheads). LV, left ventricle; RA, right atrium. (Reproduced with permission from Schwartz and Rao *Tricuspid Atresia*, 2nd edn. Mount Kisco, NY: Futura Publishing, 1992: 223–46.)

juxtaposition of the atrial appendages (Figure 35.9) occurs more frequently in tricuspid atresia, especially when associated with transposition of the great arteries. Finally, different morphologic types of atretic tricuspid valves may be recognized [25,32,72].

Once tricuspid atresia is demonstrated, it is important to define the ventricular anatomy, type and size of the interventricular communication, ventriculoarterial connections, pulmonary artery anatomy, and associated abnormalities. Left innominate vein angiography to demonstrate a persistent left superior vena cava and bridging innominate vein, should also be performed; such information is useful in considering bidirectional Glenn and Fontan operations.

Selective left ventricular angiography reveals finely trabeculated, morphologically left ventricular anatomy. The origin and relative positions of the great arteries (Figures 35.10 and 35.11), the size and location of the VSDs, any mitral regurgitation, and the size of the right ventricle can be demonstrated. The present author initially performs left ventricular angiography in frontal and lateral views. Angiography is performed in additional views, such as left anterior oblique, hepatoclavicular, or long axial oblique,
Figure 35.10 Selective left ventricular (LV) cineangiograms in lateral (a) and four-chamber (b) views demonstrate normal position of aorta (Ao) and pulmonary artery (PA). Ventricular septal defect (VSD) is seen with visualization of right ventricle (RV). (Reproduced from Rao, P.S., in Long, W.A. Figure 35.11 Selective left ventriculogram in frontal view in infant with type II tricuspid atresia shows transposition of the great arteries. Ao, aorta; DAo, descending aorta; LV, left ventricle; MPA, main pulmonary artery; RV, right ventricle. (Reproduced with permission from Schwartz and Rao *Tricuspid Atresia*, 2nd edn. Mount Kisco, NY: Futura Publishing, 1992: 223–46.)

depending on the structures that need greater definition. Special attention should be paid in evaluating subaortic obstruction at the VSD level in patients with transposition [36·37]. Quantitative measurements of the size and function of the left ventricle [47–49] should also be undertaken. Selective injections into the right ventricle, aorta, and pulmonary artery provide greater definition of these structures. Particular attention should be paid to define sources of pulmonary blood flow and pulmonary artery anatomy. Selective angiography with the catheter positioned proximal to or in the previously created shunts is also useful in evaluating the pulmonary arteries and, of course, the shunt itself.

Other laboratory studies

Pulse oximetry is readily available in an outpatient setting for noninvasive measurement of oxygen saturation. Hemoglobin level and hematocrit along with red blood indices should be routinely obtained to assess the degree of polycythemia and hypoxemia and to identify relative iron deficiency anemia [57]. Computed tomography (CT) and magnetic resonance imaging (MRI) are useful in defining issues not clearly defined by echocardiography.

Differential diagnosis

Differential diagnosis differs with the mode of presentation (Table 35.5).

Decreased pulmonary blood flow

Causes of cyanosis with decreased pulmonary blood flow are listed in Table 35.5. The electrocardiogram is most useful in the differential diagnosis [73]. Echocardiography and cineangiography may occasionally be necessary for confirming the diagnosis, especially in complex defects.

Increased pulmonary blood flow

The differential diagnostic considerations are also listed in Table 35.5. Although the characteristic electrocardiographic pattern (abnormal, superior vector, or left-axis deviation) of tricuspid atresia is helpful, it is not always present in tricuspid atresia with transposition. Furthermore, some of the conditions listed in Table 35.5 also have a similar displacement of the mean frontal plane vector. Often, echocardiograms and angiocardiograms are necessary for final diagnosis.

Management

Physiologically "corrective" operations for tricuspid atresia [74,75] and their modifications are usually performed in patients older than 2 years. Most patients present with

---

Table 35.5 Differential diagnosis of tricuspid atresia in the neonate.

Decreased pulmonary blood flow
Tetralogy of Fallot including pulmonary atresia with ventricular septal defect
Pulmonary atresia or severe stenosis with intact ventricular septum
Tricuspid atresia
Complex cardiac anomalies with severe pulmonary stenosis or atresia including d-transposition with ventricular septal defect; l-transposition with ventricular septal defect; single ventricle, double-outlet right ventricle, and asplenia syndrome

Increased pulmonary blood flow
d-Transposition of the great arteries with large ventricular septal defect
Coarctation of the aorta with ventricular septal defect
Multiple left-to-right shunts (ventricular septal defect, common atrioventricular canal, and patent ductus arteriosus)
Single ventricle, double-outlet right ventricle, and other complex cardiac defects without pulmonic stenosis
Total anomalous pulmonary venous connection without obstruction
Hypoplastic left heart syndrome
Truncus arteriosus

---

symptoms as neonates and should be effectively palliated to enable them to reach the age at which correction can be undertaken. The objective of the management plan, apart from providing symptomatic relief and increased survival rate, should be to preserve, protect, and restore structure (good-sized and undistorted pulmonary arteries) and function (normal pulmonary artery pressure and preserved left ventricular function) to normal such that a corrective procedure can be performed later.

Medical management at the time of presentation

In infants with low arterial PO_2 and oxygen saturation and with ductus-dependent pulmonary blood flow, the ductus should be kept open by intravenous administration of prostaglandin E_1 (PGE_1) [76] (see Chapter 17). The ductal dilatation increases pulmonary blood flow, thereby improving oxygenation and reversing the metabolic acidosis so that further diagnostic studies and other interventions can be performed with relative safety.

An occasional infant with signs of congestive heart failure (more common in type II patients) should be treated with routine anticongestive measures. Patients with associated severe coarctation of the aorta may also be helped with PGE_1 infusion; this time, the ductal dilatation improves systemic perfusion. This is followed by relief of aortic obstruction by operation or balloon angioplasty [77].

Palliative treatment of specific physiologic abnormalities

The type of palliation undertaken depends largely on the hemodynamic abnormality produced by the basic lesion and associated cardiac anomalies. These may be broadly grouped [33] into decreased pulmonary blood flow, increased pulmonary blood flow, and intracardiac obstruction.

Decreased pulmonary blood flow

Systemic–pulmonary artery shunts are most commonly used in palliating pulmonary oligemia. Since the description of subclavian artery to ipsilateral pulmonary artery anastomosis in 1945 by Blalock and Taussig [78], several other types of procedures have been devised to improve pulmonary blood flow. Modified Blalock–Taussig shunt with a Gore-Tex graft interposed between the subclavian artery and the ipsilateral pulmonary artery [79] is most commonly utilized, although distortion of the pulmonary artery sometimes created by the shunt may be a problem later.

Enlarging the VSD or resecting the right ventricular outflow tract stenosis has been recommended by Annecchino *et al.* [80] to augment the pulmonary blood flow. This ingenious approach attacks the site of obstruction rather than bypassing it. However, it requires cardiopulmonary bypass and may be unnecessary in neonates [33]. Stenting the arterial duct is not currently an initial therapeutic choice because of limited experience [81]. Rarely, the predominant

obstruction may be at the pulmonary valve level and, in such patients, balloon pulmonary valvoplasty [82] may augment pulmonary blood flow.

Despite the availability of many palliative procedures to increase pulmonary blood flow, some produce complications that prevent a successful Fontan–Kreutzer procedure subsequently. The Blalock–Taussig anastomosis or one of its modified versions is the preferred procedure with the least number of long-term complications, but at the same time it preserves suitable anatomy for subsequent corrective procedures and therefore is recommended as the procedure of choice for palliation of tricuspid atresia patients with decreased pulmonary blood flow.

Increased pulmonary blood flow

Infants with a moderate increase in pulmonary blood flow may not have significant symptoms and are less cyanotic than the pulmonary oligemic patients. Markedly increased pulmonary blood flow as in type Ic and type IIc patients, however, can produce congestive heart failure.

In type I patients, aggressive anticongestive measures should be promptly instituted. Natural history studies indicate that the VSD becomes smaller, and patients with pulmonary plethora will, in due course, develop pulmonary oligemia and require a palliative shunt. Right ventricular outflow tract obstruction may also develop, resulting in decreased pulmonary blood flow. Therefore, pulmonary artery banding should not be performed initially in this group of patients. If optimal anticongestive therapy does not relieve symptoms after a time [33], pulmonary artery banding should be considered. In those without a pulmonary artery band, careful follow-up with periodic assessment of pulmonary artery pressure and timely intervention are necessary to prevent pulmonary vascular obstructive disease.

Pulmonary artery bands with absorbable material have been used for palliation in such infants [83]. The absorbable polydioxanone band decreases pulmonary artery pressure by restricting the pulmonary blood flow, and initially helps abate symptoms of heart failure. As the VSD spontaneously closes, the pulmonary artery band is resorbed and does not produce the severe pulmonary oligemia that might have been associated with a conventional nonabsorbable band. Although this is an ingenious approach, it is likely to help only a limited number of patients [84].

In type II patients, banding of the pulmonary artery should be performed once the infant is stabilized with anticongestive therapy. If there is associated coarctation of the aorta, or aortic arch interruption or hypoplasia, adequate relief of the aortic obstruction should be provided concurrently with pulmonary artery banding, and a patent ductus arteriosus should be ligated. The importance of PGE_1 administration in the control of congestive heart failure has already been alluded to.

Intracardiac obstruction

Intracardiac obstruction can occur at two different levels: patent foramen ovale and VSD.

Interatrial obstruction

The interatrial defect should be large enough to accommodate the egress of the entire systemic venous return. A mean atrial pressure difference of 5 mmHg or more with prominent *a* waves (15–20 mmHg) in the right atrium is generally considered to represent obstruction of the interatrial septum [33]. It may be necessary to relieve the obstruction by balloon atrial septostomy [85]; if that is unsuccessful, by blade atrial septostomy [86,87] and rarely by surgical atrial septostomy. Significant interatrial obstruction requiring atrial septostomy in the neonate is unusual, although this can be a significant problem later in infancy [36,87].

Interventricular obstruction

Spontaneous closure of the VSD can occur, causing severe pulmonary oligemia in type I patients and subaortic obstruction in type II patients. Functional and anatomic closures have been reported in patients with normally related great arteries [37,40]. In functional closure, cyanotic spells similar to those in tetralogy of Fallot [40] may occur, and the management is similar, namely, knee–chest position, humidified oxygen, and morphine sulfate (0.1 mg kg^{-1}). If the spells are not averted, β-blockers (propranolol or esmolol) or intravenous vasopressors (methoxamine or phenylephrine) may be given to increase systolic blood pressure by 10–20%. Correction of metabolic acidosis or anemia, if present, should also be considered. If there is no improvement, immediate operative palliation may be necessary. If the infant improves, correction by a Fontan-type procedure or palliation by a systemic–pulmonary artery shunt or a bidirectional Glenn operation may be performed subsequently.

In partial or complete anatomic closure of the VSD, pulmonary oligemia with consequent hypoxemia and polycythemia ensues. Augmentation of the pulmonary blood flow is indicated and can be accomplished by several methods (see earlier). If the age and size of the patient or cardiac anatomy and hemodynamics are unsuitable for performing a modified Fontan or bidirectional Glenn operation, a systemic–pulmonary artery shunt, such as modified (Gore-Tex) Blalock–Taussig procedure [79], should be undertaken. A classic Glenn procedure should not be performed because if the VSD closes completely, the left pulmonary artery will be without flow, which may result in thrombosis or underdevelopment of the left pulmonary artery. In addition, long-term complications of the Glenn operation [51], particularly development of pulmonary arteriovenous fistulas, are of concern. Central aortopulmonary shunts should be avoided because they tend to raise pulmonary artery pressure and resistance and kink or distort the pulmonary arteries. Thus, a Blalock–Taussig type of

shunt [classic or modified (Gore-Tex) Blalock–Taussig] or a bidirectional Glenn procedure is preferable. In the present author's view, in younger infants a Blalock–Taussig shunt is to be preferred; in older infants and children, a bidirectional Glenn procedure preparatory to a modified Fontan operation is recommended.

Partial spontaneous closure of the VSD in type II patients causes subaortic obstruction [36,37,51], which should be relieved or bypassed in case the resultant left ventricular hypertrophy poses increased risk at the time of the Fontan procedure [88]. The obstruction must be tackled at the time of either a bidirectional Glenn or a modified Fontan operation. Resection of the conal muscular septum [89,90], thus enlarging the VSD, is a direct approach, although concern for development of heart block and spontaneous closure of the surgically produced VSD remains [51]. Alternatively, the VSD, right ventricle, and aortic valve may be bypassed by anastomosis of the proximal stump of the divided pulmonary artery to the ascending aorta (Damus–Kaye–Stansel) at the time of bidirectional Glenn (or Fontan) operation. Limited data are available about the superiority of one method over the other.

Medical management after a palliative operation

Problems encountered with tricuspid atresia patients are similar to those in other cyanotic cardiac malformations. Appropriate monitoring for and treatment of relative anemia, polycythemia, coagulopathy, and hyperuricemia should be undertaken. Hyperuricemia, gout, and uric acid nephropathy can develop in adolescents and adults with long-standing cyanosis and polycythemia and should be prevented by timely palliative or corrective operative therapy. If prevention is not feasible, periodic measurement of uric acid levels and treatment with allopurinol (if the uric acid level is >8 mg per 100 ml) may have to be instituted. The risks for developing a cerebrovascular accident or brain abscess are similar to those with other cyanotic anomalies, and appropriate consultation and treatment are indicated. Antibiotic prophylaxis before any bacteremia-producing procedures or surgery is indicated, as is routine immunization plus consideration for palivizumab (for prevention of RSV infection in infancy), polyvalent pneumococcal vaccine, or influenza vaccine.

Physiologic corrective surgery

Since the original descriptions by Fontan and Baudet [74] and Kreutzer et al. [75] of physiologically corrective operations for tricuspid atresia, many modifications of these procedures have been suggested [91,92]. The Fontan operation was based on the concept of using the right atrium as a pump. As originally described, it consists of superior vena cava–right pulmonary artery (Glenn) shunt, anastomosis of the proximal end of the divided right pulmonary artery to the right atrium directly or by means of an aortic homograft, closure of the atrial defect,

insertion of a pulmonary valve homograft into the inferior vena caval orifice, and ligation of the main pulmonary artery, thus bypassing the right ventricle completely [74]. Kreutzer's concept was that the right atrium may not function as a pump and that the left ventricle is the only suction pump in the system. His original operation consisted of direct anastomosis of the right atrial appendage with the pulmonary artery or through a pulmonary homograft. The atrial septal defect was not closed and neither a Glenn procedure nor prosthetic valve insertion into the inferior vena cava was performed [75].

Initially the approach was a classic Glenn anastomosis or a valve at the inferior vena cava–right atrial junction [91,92]. A bidirectional Glenn procedure followed by direct atriopulmonary anastomosis (without a valved conduit) has becme the standard procedure for most tricuspid atresia patients.

Bidirectional glenn procedure

In the bidirectional Glenn procedure [93–95], the upper end of the divided superior vena cava is anastomosed end-to-side to the superior aspect of the undivided right pulmonary artery, thus diverting the superior vena caval blood into both right and left pulmonary arteries [93–96]. There are hemodynamic advantages associated with the bidirectional Glenn procedure, including improved effective pulmonary flow, reduced total pulmonary flow, and less left ventricular volume overloading. When both right and left superior venae cavae are present, bilateral bidirectional Glenn shunting should be performed, especially if the bridging innominate vein is absent or small.

Total cavopulmonary diversion

On the basis of hydrodynamic studies, de Leval et al. [97] concluded that the right atrium has no efficient pump function; pulsations in the nonvalved circulation generate turbulence with a consequent decrease in net flow, and energy losses occur in the nonpulsatile chambers, corners, and obstructions. They devised and performed total cavopulmonary diversion in which bidirectional Glenn procedure was performed, and the inferior vena caval blood is directed through an intra-atrial tunnel into the cardiac end of the superior vena cava, which in turn is connected to the undersurface of the right pulmonary artery. The advantages of this procedure are technical simplicity, maintenance of low right atrial and coronary sinus pressure, and reduction in risk of formation of atrial thrombus. Experimental studies by Sharma et al. [98] suggested that complete or minimal offset between the orifices of the superior vena caval connection may decrease energy losses.

Extracardiac conduit

Diversion of the inferior vena caval blood into the pulmonary artery via an extracardiac conduit [99] was conceived as an alternative to the lateral tunnel in surgical completion of the Fontan procedure.

Staged fontan procedure

Performing a bidirectional Glenn procedure initially followed later by diversion of the inferior vena caval blood into the pulmonary artery [100,101] is the norm instead of performing all Fontan connections at the same time. Staging appears to decrease overall mortality, presumably related to improving the ventricular function by avoiding/correcting afterload mismatch associated with a one-stage Fontan procedure [101].

Fenestrated fontan

The criteria (Table 35.4) outlined by Choussat *et al.* [68] have been modified or exceeded by many groups of workers. These factors, when abnormal, make a Fontan–Kreutzer operation a high-risk procedure. They should be identified at the time of preoperative evaluation. They include elevated mean pulmonary artery pressure >18 mmHg or resistance >4 Wood units m^{-2}), distorted or small (McGoon ratio of 1.8 or less) pulmonary arteries, poor left ventricular function (end-diastolic pressure >12 mmHg), significant mitral regurgitation, subaortic obstruction, and severe left ventricular hypertrophy. With one or more of these risk factors, physiologically corrective procedures of the Fontan type may carry significant risk. In such high-risk Fontan–Kreutzer patients, leaving open a small atrial septal defect to allow decompression of the right atrium in the immediate postoperative period with a plan to close the defect later has been used by some workers [102–104]. The atrial defect is closed by a preplaced suture [102,103] or by transcatheter techniques [104]. Significant improvement in postoperative pleural effusions, systemic venous congestion, and higher cardiac index and possibly shorter hospitalization have been the beneficial effects of the fenestration, but at the expense of systemic arterial hypoxemia.

Operations that divide the pulmonary and systemic venous returns (Fontan–Kreutzer) are feasible for most patients with tricuspid atresia. The age (and weight) of the patient and anatomic and physiologic substrate determine the type of surgery. In neonates and young infants (3–6 months), a modified Blalock–Taussig shunt is the procedure of choice. Between 3 (or 6) months and 1 year of age, a bidirectional Glenn procedure is the procedure of choice. Between 1 and 2 years of age, a bidirectional Glenn procedure is used unless there is a contraindication. Beyond 2 years of age, total cavopulmonary anastomosis with or without fenestration, depending on the risk factors, may be performed. However, even at this age, staged cavopulmonary connection (initially bidirectional Glenn and then an extracardiac conduit diversion of inferior vena caval blood into the pulmonary artery) is recommended.

Preoperative catheter evaluation to define the pulmonary artery pressure and anatomy and to exclude a persistent left superior vena cava (because it may divert blood away from the pulmonary arteries) prior to bidirectional Glenn surgery should be undertaken. At the time of bidirectional Glenn procedure, stenoses, if any, of the pulmonary artery should be repaired. Issues related to subaortic obstruction and mitral valve regurgitation should also be addressed. Immediately prior to Fontan conversion, cardiac catheterization should be performed to ensure normal anatomy and pressure of the pulmonary artery and normal left ventricular end-diastolic pressure. At the same time, aortopulmonary collaterals should be evaluated by means of selective subclavian artery and descending thoracic aortic angiography. Any collateral vessels should be occluded with coils or devices, as appropriate. In patients with transposition of the great arteries, early pulmonary artery banding, treatment of aortic coarctation, and relieving or bypassing subaortic obstruction should also be incorporated into the treatment plan.

Catheter interventions

A number of catheter interventional procedures are useful in managing tricuspid atresia patients:

1 During the neonatal period, obstruction at the level of the atrial septum may be treated with conventional Rashkind balloon atrial septostomy [85]. In infants and children, the interatrial septum may be too thick to be torn with balloon septostomy; therefore, Park blade septostomy should precede the Rashkind procedure [86,87].

2 The obstruction to pulmonary blood flow is at the ventricular septal defect (VSD) level or in the subpulmonary region in most patients. In a rare patient, the obstruction is at the pulmonary valve, and then balloon pulmonary valvoplasty may improve pulmonary blood flow and oxygen saturation [82]

3 If progressive hypoxemia develops after a prior Blalock–Taussig shunt and is secondary to shunt stenosis, balloon dilatation [105] or stent implantation [106] may improve oxygen saturation. If the patient is of sufficient size and age to undergo a bidirectional Glenn procedure, this should be performed instead of catheter intervention to enlarge the narrowed Blalock–Taussig shunt.

4 If severe aortic coarctation is present, particularly in patients with tricuspid atresia type II, balloon angioplasty may relieve aortic obstruction and achieve better control of congestive heart failure [107,108]

5 If significant branch pulmonary artery stenosis is present either before bidirectional Glenn and Fontan conversion surgery or after a Fontan procedure, balloon angioplasty or placement of intravascular stents [109,110] is recommended.

6 Aortopulmonary collateral vessels develop. Before the final Fontan conversion, these vessels should be occluded in the catheterization laboratory, usually with Gianturco coils. This reduces reduces left ventricular volume overloading [111,112].

7 After a Fontan procedure, some patients may develop recurrent pleural effusion, liver dysfunction, plastic bronchitis, or protein-losing enteropathy. In these patients,

obstructive lesions in the Fontan circuit, if any, should be addressed by balloon angioplasty or stent. If the problem persists, creation of an atrial fenestration to produce right-to-left shunt may be beneficial [113]. In such situations, puncture of the atrial septum by using a Brockenbrough technique followed by static balloon atrial septal dilatation [114] or stent implantation may be helpful.

8 Patients who undergo a fenestrated Fontan operation or who have a residual atrial defect despite correction may have clinically significant right-to-left shunting causing severe hypoxemia. These residual atrial defects may be closed by using transcatheter techniques [115–118].

9 Some patients may develop systemic venous-to-pulmonary venous collateral vessels following Fontan operation, causing arterial desaturation. These vessels should be defined and closed by coils, plugs, or devices, depending on the size, location, and accessibility [111,112,119,120].

10 *Emerging therapies*. Two-stage cavopulmonary connection is currently recommended for achieving Fontan circulation. Konertz et al. proposed a staged surgical-catheter approach [121]. Initially, a modified hemi-Fontan surgery is performed which is later completed by a transcatheter method [121, 122]. This approach attempts to reduce the total number of operations. The modified hemi-Fontan operation consists of the usual bidirectional Glenn procedure. In addition, the lower end of the divided superior vena cava is anastomosed to the undersurface of the right pulmonary artery. The superior vena cava is then banded around a 16-gauge catheter with 6–0 Prolene suture slightly above the cavoatrial junction. A lateral tunnel with a Gore-Tex baffle is created to divert the inferior vena caval blood towards the superior vena cava. The baffle is then fenestrated with 3–5 five mm wide holes. Thus, the first stage achieves a physiologic bidirectional Glenn circulation. At the time of the transcatheter stage, the superior vena caval constriction is balloon dilated and fenestrations are closed with devices or by implantation of a covered stent. These procedures have been performed in a limited number of patients [121–124], and preliminary data suggest that the usual post-Fontan complications, such as pleural effusion and ascites, have not occurred with this approach. Examination of the results of larger experience and longer term follow-up and the ready availability of covered stents are necessary for routine application of this innovative approach.

Follow-up after corrective operation

Close follow-up after correction is indicated. Some patients need continued inotropic and diuretic therapy. Afterload reduction with an angiotensin-converting enzyme inhibitor is generally recommended to augment left ventricular output with consequent improvement in pulmonary flow, although controlled studies substantiating this principle have not been undertaken. Because of the potential for development of thrombi in the right atrium, anticoagulants are routinely
Figure 35.12 Actuarial survival after a Fontan operation. The three upper curves are from the Mayo Clinic, the most recent series (plus symbols) from 1988–97, and the oldest series (solid triangles) from 1973–80. The two lower curves are from Toronto Sick Children's Hospital (solid squares) for operations done between 1971 and 1999, and from Bordeaux (open circles) for operations done between 1968 and 1982. The later the series began, the better the results. Over 75% survive >10 years after operation. (Reproduced from Hoffman JIE, *The Natural and Unnatural History of Congenital Heart Disease*, 2009, with permission of Wiley-Blackwell.)

used by most cardiologists. The present author recommends platelet-inhibiting doses of aspirin; others advocate warfarin anticoagulation.

Most patients do well after operation (Figure 35.12) [125]. However, several problems have been observed after corrective surgery: arrhythmia, obstructed pulmonary outflow pathways, persistent shunts, and systemic venous congestion including protein-losing enteropathy. Supraventricular arrhythmias (atrial flutter or fibrillation, paroxysmal supraventricular tachycardia) are common and should be treated with appropriate pharmacologic therapy. In a patient without adequate control, electrophysiologic study and surgical or transcatheter ablation may be indicated [126]. Revision of the Fontan pathway to a cavopulmonary connection with elimination of the enlarged right atrium has been considered an alternative solution. Sick sinus node syndrome and atrioventricular block occur in some children and may require pacemaker therapy. Ventricular arrhythmia is less frequent.

Symptoms and signs indicative of obstruction to Fontan pathways should be promptly investigated. Poor echocardiography windows make noninvasive evaluation difficult, and catheterization and angiography may be necessary. Obstructive lesions, if identified, should be treated with balloon angioplasty, stenting, or even surgery, as indicated.

A persistent shunt may be secondary to intentional fenestration of the atrial septum or a residual atrial septal defect. If significant hypoxemia is present, the residual shunt

should be closed, preferably by a transcatheter device [115,118]. Test occlusion of the defect is advisable to ensure that adequate cardiac output is maintained after occlusion.

Recurrent pleural effusion, liver dysfunction, and protein-losing enteropathy have occurred in a small number of patients. Protein-losing enteropathy has a high mortality (75%) [113,127]. The cause of protein-losing enteropathy is unknown, but appears to be related to loss of protein in the bowel by lymphatic distention secondary to increased systemic venous pressure, although this can occur in patients with reasonably "normal" pressures for the Fontan procedure. Symptoms usually appear 6 months after the Fontan–Kreutzer procedure or later, and include diarrhea, edema, ascites, and pleural effusion. Significant hypoalbuminemia and increased α_1-antitrypsin in the stool are present. Evidence for obstruction of the Fontan–Kreutzer pathway must be scrutinized and, if found, relieved [113]. A medium-chain triglyceride diet and parenteral albumin supplementation may be supportive. Some workers have used prednisone [128], with favorable effect, although the experience with this mode of therapy is limited. So, too, is experience with regular high molecular weight heparin, low molecular weight heparin, an elementary diet, calcium replacement, somatostatin, high-dose spironolactone, sildenafil, and resection of localized intestinal lymphangiectasia (if demonstrated), all with variable success. Because protein-losing enteropathy appears to be a fatal complication of the Fontan procedure, aggressive management is suggested. In these patients with so called "failed Fontan," after excluding and addressing obstructions and residual shunts apart from other conventional treatment, consider (1) reducing right atrial pressure by creating an atrial septal defect (Brockenbrough's puncture plus static dilatation of the atrial septum114), (2) right atrial and left ventricular (atrioventricular sequential) pacing [129,130], (3) converting an atrioventricular Fontan procedure to total cavopulmonary anastomosis [131,132], and/or (4) cardiac transplantation [133,134]. However, most patients do well after the Fontan–Kreutzer procedure.

Long-term history of treated and untreated adults

Although tricuspid atresia patients usually present in infancy and only 10–20% of untreated patients may survive their first birthday [4,55], improvements in early identification, neonatal care, noninvasive diagnoses, anesthesia, neonatal cardiac surgery, and normalization of pulmonary blood flow by PGE_1 infusion and aortopulmonary shunt in patients with decreased pulmonary blood flow and by banding of the pulmonary artery in patients with pulmonary plethora has improved the survival. The potential for improved prognosis exists, and therefore each patient with tricuspid atresia should be offered aggressive medical and operative therapy. The advantages of the Fontan–Kreutzer procedure [125], namely decreasing or eliminating hypoxemia and normalizing ventricular volume overloading, have further improved childhood survival. Consequently, a substantial number of

patients reach adulthood. Some of them do well, but others develop an arrhythmia (atrial flutter or fibrillation, paroxysmal supraventricular tachycardia), obstructed Fontan pathways, branch pulmonary artery stenosis, thromboembolism, persistent right-to-left shunts (Fontan fenestrations or atrial septal defects), systemic venous-to-pulmonary venous collateral vessels and protein-losing enteropathy. Detailed evaluation of these problems and appropriate treatment are mandatory to prolong survival and maintain quality of life. This is usually accomplished by a team approach in an Adult Congenital Heart Disease Clinic.

36 Ebstein Anomaly of the Tricuspid Valve

David J. Driscoll & Joseph A. Dearani

Mayo Clinic, Rochester, MN, USA

Introduction and historical background

On 28 June 1864, a 19-year-old laborer was admitted to All-Saints Hospital in Breslau, Germany, with shortness of breath and palpitations since childhood. The patient died on 6 July 1864 and Wilhelm Ebstein (1836–1912) performed the autopsy [1]. Although Ebstein is credited with this first description of the anomaly that would bear his name, he also is credited with describing postinfectious uric acid kidney stones, acute leukemia, funnel chest, and the "Pel–Ebstein" fever of lymphoma. He also studied purine metabolism, grouped obesity, gout, and diabetes as inheritable metabolic diseases, and authored a book on the treatment of obesity with a low carbohydrate diet [2].

Before the 1970s, the surgical treatment of Ebstein anomaly was poorly defined. Indeed, Engle *et al.* cautioned that even cardiac catheterization of these patients was risky because the catheter might become entangled and entrapped in the delicate tricuspid valve apparatus or provoke a fatal arrhythmia [3]. This, of course, was before the development of cardiac defibrillators. In 1974, Watson reported the outcome of 505 patients with Ebstein anomaly [4]. There were 13 deaths from 363 cardiac catheterizations. The surgical mortality was 54%. For palliative operations the mortality was 64% and for valve replacement it was 45%. He concluded that "patients … are bad surgical risks. Operation cannot be advised in the hope that if they (patients) are no better, at least they will be no worse … Palliative operations are not helpful … they have no place in treatment and are probably contraindicated."

Despite these admonitions, surgical procedures were gradually developed to treat patients with Ebstein anomaly. In the 1950s, the Blalock–Taussig procedure was used. In 1958, Hunter and Lillehei attempted to reposition the septal and posterior tricuspid valve leaflets [5]. In 1963, Barnard and Schire replaced the tricuspid valve with a prosthesis. [6] In 1966, the Glenn anastomosis was used for some of these patients [7]. Hardy and Roe, in 1969, attempted to reconstruct the valve [8,9]. In 1972, Danielson *et al.* described a technique to reconstruct the valve as a monocusp [10], an operation adopted widely for many years. In 1988, Carpentier *et al.* reported an operation in which the tricuspid valve was repositioned to the normal level [11]. In 1991, Starnes *et al.* described a technique for dealing with the highly lethal form of Ebstein anomaly presenting in the neonate [12] using a single ventricle strategy. In 2007, da Silva *et al.* described the "cone procedure," a near anatomic repair, the early results of which are fairly promising [13].

Incidence

Ebstein anomaly is relatively rare. It constitutes <1% of cardiac malformations and occurs in one in 210 000 live births. It is noted in one in 1000 autopsies.

Embryology and pathologic anatomy

The embryologic basis of Ebstein anomaly is failure of the tricuspid valve leaflets, especially the septal leaflet, to delaminate from the ventricular muscle (Figure 36.1).

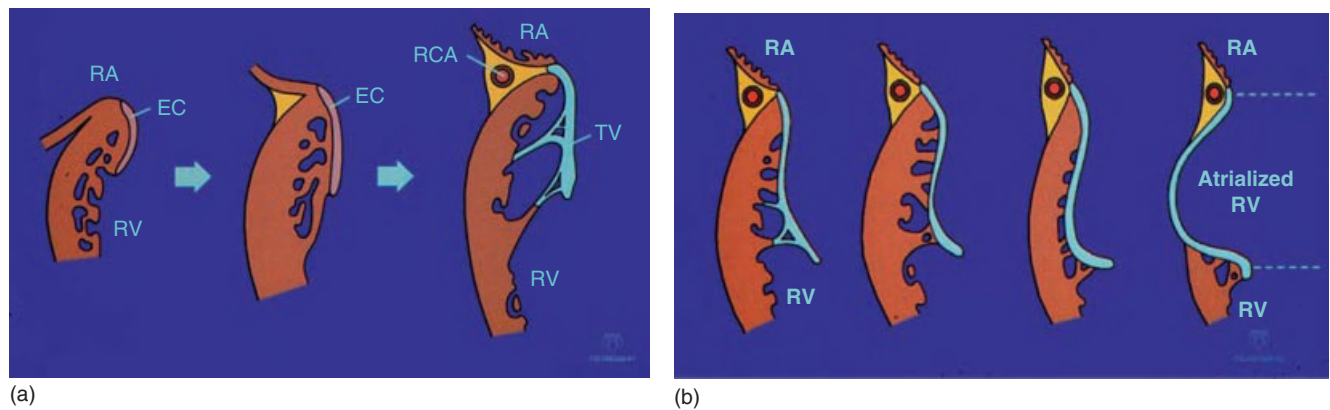
The anterior leaflet, albeit the most completely delaminated, is usually fairly large but also may have tethered attachments to the right ventricular free wall. Thus, the apparent orifice of the tricuspid valve is displaced into the right ventricle. The true orifice, however, is not displaced and the portion of the heart between the true and apparent orifice is the so-called "atrialized portion" of the right ventricle (Figure 36.2).


Figure 36.1 Artistic representation of (a) normal delamination of the tricuspid valve and (b) failure of delamination resulting in Ebstein anomaly. EC, endocardial cushion; RA, right atrium; RCA, right coronary artery; RV, right ventricle. TV, tricuspid valve.
Figure 36.2 Composite of the typical features of Ebstein anomaly. (a) autopsy specimen demonstrating marked cardiomegaly and globular shaped heart. (b) a pathologic specimen prepared to demonstrate the downward displacement of the tricuspid valve, tethering of the anterior leaflet to the right ventricular wall and shift of the ventricular septum toward the left ventricle. (c) a typical radiograph of Ebstein anomaly. (d) Echocardiogram showing downward displacement of tricuspid valve and enlarged right atrium.

The abnormalities in Ebstein anomaly are not limited to the tricuspid valve. The right ventricle is always, to a greater or lesser extent, myopathic. In some patients, the left ventricle also may show fibrosis.

About 50–70% of patients have an atrial septal defect (ASD) or stretched patent foramen ovale (PFO), and 30% have an associated a right-sided accessory bypass tract or Wolff–Parkinson–White (WPW) syndrome.

Ebstein anomaly can be associated with pulmonary stenosis or pulmonary atresia. It may be difficult to determine if a patient with pulmonary atresia and intact ventricular septum (in which the tricuspid valve is usually dysplastic and always regurgitant) should be classified as "pulmonary atresia with intact ventricular septum" or as "Ebstein anomaly and pulmonary atresia." This distinction becomes important for planning surgical strategy and for measuring treatment outcomes. It may be reasonable to classify these patients as "pulmonary atresia with intact ventricular septum" if the right ventricle is smaller than normal and as Ebstein anomaly with pulmonary atresia if the right ventricle is larger than normal.

Pathophysiology

The pathophysiology depends on the degree of dysplasia of the tricuspid valve and of tricuspid valve regurgitation or rarely tricuspid valve stenosis. In addition, determinants of clinical severity include the severity of right ventricular myopathy and presence or absence of the following: an interatrial communication, degree of right ventricular outflow tract obstruction, degree of right or left ventricular dysfunction, or ventricular pre-excitation.

Patients with an intact atrial septum do not have a right-to-left shunt and their exercise tolerance is better than those with an ASD and a right-to-left shunt. Because of tricuspid regurgitation, pulmonary blood flow and hence cardiac output may be reduced, particularly during exercise. Also, with the downward displacement of the tricuspid valve and the atrialized portion of the right ventricle, anterograde blood flow may be impeded by the contraction of the atrialized portion of the right ventricle with an unguarded true tricuspid valve annulus.

Natural history

Without treatment, survival of patients with Ebstein anomaly is significantly less than normal [14] (Figure 36.3). Poorer survival occurs with major associated anomalies, and greater degrees of cyanosis, cardiomegaly, and echocardiographic severity [15–20].

Clinical features

History
The presentation and clinical course of patients with Ebstein anomaly vary, depending upon the severity of the malformation. At one end of the spectrum fetal death can occur, one of the more common reasons for demise among
Figure 36.3 Composite survival curves of unoperated patients. (Courtesy of Dr. Julien Hoffman and reproduced from Hoffman, J., *The Natural and Unnatural History of Congenital Heart Disease*, Wiley-Blackwell, 2009, reproduced with permission of the publisher and the author.)

fetuses with a cardiac anomaly. At the other end of the spectrum, patients with mild forms of Ebstein anomaly can live a normal life span without medical or surgical intervention.

The classic presentation at birth is cyanosis and/or marked cardiomegaly. The cyanosis in neonates occurs from right-to-left shunting through a PFO or ASD, and is intensified by the high early postnatal pulmonary vascular resistance. Shunting can be so great and forward flow from the right ventricle so limited that the neonate, mistakenly, may be thought to have anatomic pulmonary valve atresia. In fact, there may be "functional" pulmonary atresia because of poor forward flow. Some have massive cardiomegaly with a cardiothoracic ratio that exceeds 85% on chest radiography. These infants have functionally small lungs and pulmonary vascular bed, and without reduction of heart size are unlikely to survive.

Beyond the newborn period, patients may present because of a murmur, fatigue, dyspnea, cyanosis, atrial arrhythmias, or cardiomegaly discovered serendipitously. Increasingly, the diagnosis of Ebstein anomaly is made prenatally using fetal ultrasound.

Physical examination
For patients with an ASD, cyanosis usually is apparent. Despite significant tricuspid regurgitation, because of the capacitance of the dilated right atrium the jugular venous pressure is usually normal. The cardiac impulse may be diffuse due to cardiomegaly and a volume overloaded right ventricle. Classically, patients with Ebstein anomaly have been described as having a "quadruple rhythm." This results from splitting of S_1 because of delay in the second component of S1, presumably because of the abnormal tricuspid valve apparatus. Splitting of S_2 is a result of right bundle branch
Figure 36.4 (a) Preoperative and (b) postoperative radiographs of a patient with Ebstein anomaly.

block. Usually there is a systolic murmur of tricuspid regurgitation. Rarely, if the valve is stenotic, a tricuspid diastolic murmur is present. In addition, there may be ventricular diastolic filling sounds. In our experience, these "classical" auscultatory findings are apparent in only ~50% of patients, possibly because the "classical" findings were described when only the most severe forms of Ebstein anomaly came to medical attention; now, with echocardiography, milder forms come to medical attention.

Patients with Ebstein anomaly may have a distinctive violaceous hue, particularly of the malar area and the upper arms, even without a right to left shunt and even after operation. The reason is unclear.

Electrocardiography

The classic finding in Ebstein anomaly is right atrial enlargement and right bundle branch block. Because 30% of patients with Ebstein anomaly have ventricular pre-excitation, these patients may have a short PR interval and a delta wave.

Chest radiography

Usually the chest radiogram shows cardiomegaly from enlargement of the right atrium and ventricle to an extent proportional to the severity of the lesion and the degree of tricuspid regurgitation (Figure 36.4). The pulmonary vasculature is diminished.

Echocardiography

Echocardiography (two-dimensional and, more recently, three-dimensional) is a mainstay in diagnosis [21,22] (Figure 36.5). The anatomy of the tricuspid valve can be delineated and associated anomalies, such as an ASD and right ventricular outflow tract obstruction, can be identified. Right atrial and right ventricular size and function can be estimated,

as can left ventricular function. The accuracy of measurement of both right and left ventricular function, however, is suboptimal because of the large size of the true and atrialized right ventricle, and the displacement of the ventricular septum towards the left ventricle (i.e., D-shaped left ventricle) by the enlarged right ventricle.

Two mathematical equations have been described to quantitate the severity of Ebstein anomaly. The first is the "displacement index," obtained by dividing the distance between the attachment of the septal leaflet of the tricuspid valve and the septal attachment of the mitral valve by the body surface area. A ratio of $\geq 0.8\,cm\,m^{-2}$ is considered diagnostic of Ebstein anomaly.

The second is the "Celermajer index," calculated by dividing the combined areas of the right atrium and atrialized portion of the right ventricle by the combined areas of the functional RV, LV, and LA [19,20]. It has been used as a marker of outcome in neonatal Ebstein anomaly. A value >1 portends a high mortality.

Echocardiography can provide detailed information about the anatomy of the tricuspid valve. In general, the four-chamber view is the most helpful because it demonstrates the degree of tethering between the tricuspid leaflets and the free wall of the right ventricle and the location of these attachments relative to the true tricuspid annulus and the right ventricular apex. It also provides information about the degree of displacement of the septal leaflet and the amount of septal leaflet present. Other valve features that echocardiography provides include the size of the anterior leaflet and the status of its leading edge (free versus tethered), and any direct muscular insertions into the leading edge of the anterior leaflet. Finally, echocardiography can define the nature of the regurgitant jet(s), that is, a single central jet of regurgitation as opposed to multiple origins of regurgitation or fenestrations of the leaflets [21,22]. When the functional

Figure 36.5 Normal four-chamber view of (a) a normal heart and (b) Ebstein anomaly. The downward displacement of the septal leaflet of the tricuspid valve (STL) is apparent, as is the "sail like" anterior leaflet. AML, anterior mitral leaflet, LV, left ventricle; RA, right atrium; RV, right ventricle. Arrows indicate separation of septal leaflets of mitral and tricuspid valves.
tricuspid orifice is markedly displaced towards the right ventricular outflow tract (i.e., tricuspid and pulmonary leaflet tissue noted in the short-axis view at the base of the heart), tricuspid valve repair can be difficult.

Magnetic resonance imaging

The utility of MRI in the management of Ebstein anomaly is undefined but, intuitively, may have an important role and is being used with increasing frequency. A major difficulty in determining the indications for operation and the short- and long-term results of treatment is the accuracy of measuring right ventricular size and function in this anomaly. Echocardiography has shortcomings in obtaining these measurements. An MRI might obviate these. Even with MRI, the "gold standard" for these measurements is unclear.

Cardiac catheterization

Cardiac catheterization is rarely necessary in a patient with Ebstein anomaly. Indications for cardiac catheterization include hemodynamic assessment in selected circumstances if a concomitant bidirectional cavopulmonary shunt is being considered, particularly if left ventricular function is depressed. It also may be necessary to exclude distortion of the pulmonary artery or pulmonary hypertension in patients in whom a systemic to pulmonary shunt had been placed previously. If anatomic pulmonary valve stenosis coexists, a balloon valvoplasty may be necessary.

Exercise testing

Patients with Ebstein anomaly have reduced exercise tolerance [23,24], the major determinant of which is right-to-left shunting in patients with an interatrial communication.

Other factors that may contribute to exercise intolerance are tricuspid valve regurgitation, reduced right or left ventricular function, and right ventricular outflow tract obstruction. After eliminating the right-to-left shunt, exercise tolerance improves significantly.

Intuitively, establishing a competent tricuspid valve should improve exercise tolerance. There are anecdotal examples to suggest that this is true, but no studies have sufficient statistical power to prove it.

Pregnancy and reproductive issues

We reported the outcome of pregnancy for 82 women who had an operation for Ebstein anomaly [25]. Before operation, 59 of these women had a total of 140 pregnancies, and after operation, 27 women had 62 pregnancies. There were no maternal deaths. The miscarriage rate before operation was 19% and after operation 33%. There were 232 liveborn children, 88 to fathers and 144 to mothers with Ebstein anomaly. Nine of the liveborn children (4%) were reported to have a cardiac abnormality including tricuspid atresia, atrial fibrillation, patent ductus arteriosus, "hole in heart" (that was surgically closed), Down syndrome with complete atrioventricular septal defect, an unspecified "valve problem," mitral valve prolapse, Ebstein anomaly, and ASD. Six were born to mothers and three to fathers with Ebstein anomaly.

Arrhythmias

Atrial arrhythmias are common in patients with Ebstein anomaly [26,27]. These can be associated with either ventricular pre-excitation (WPW syndrome) or dilated right atrium. Accessory conduction pathways should be identified and ablated during a preoperative electrophysiologic study.

Atrial arrhythmias secondary to dilated atria become less frequent after tricuspid valve repair/replacement and right reduction atrioplasty. The frequency of atrial arrhythmias, however, tends to increase again as time passes postoperatively. When paroxysmal or continuous atrial tachyarrhythmias occur preoperatively, a concomitant maze procedure should be performed at the time of operation. In selected patients, a prophylactic maze procedure can be considered at the time of operation.

Management, clinical course, and outcome

Treatment, clinical course, and outcome depend upon the severity of the deformity, age at presentation, and any associated anomalies.

Neonates with severe hypoxemia and extreme cardiomegaly are particularly challenging. Because of severe tricuspid valve regurgitation and elevated pulmonary vascular resistance, some neonates have "functional pulmonary atresia" without anatomic pulmonary atresia. They eventually respond to PGE_1. If there is anatomic pulmonary atresia or stenosis, a systemic to pulmonary shunt or a balloon pulmonary valvoplasty will be needed. Most require intubation and mechanical ventilation.

If pulmonary balloon valvoplasty is necessary and produces pulmonary valve regurgitation, the patient may demonstrate a "circular shunt." This consists of blood flowing from the aorta through the ductus arteriosus and then retrograde through the pulmonary valve to the right ventricle, retrograde through the tricuspid valve, then from the right to the left atrium, then through the left ventricle to the aorta, and finally back through the ductus. This volume of blood never participates in effective pulmonary blood flow or systemic perfusion. In these patients, some investigators have recommended discontinuing PGE_1, instituting nitric oxide inhalation, and passively allowing the ductus to close or actively closing it with indomethacin, a coil, a device, or operation [28].

Neonates who do not improve with these maneuvers may require an early operation. One option is the Knott–Craig repair of the tricuspid valve, which leads to a two-ventricle repair. This technique also includes a right reduction atrioplasty and, if possible, reduction (plication) of the size of the right ventricle [29] to allow space for the lungs. The second option is the Starnes procedure, leading to a one-ventricle repair. This technique involves placing a fenestrated patch over the tricuspid valve to exclude the right ventricle from the circulation, assuring that there is a large atrial septal defect, and performing a right reduction atrioplasty and a systemic to pulmonary artery shunt [12]. If the patient has an incompetent pulmonary valve, the pulmonary artery should be ligated. Sano et al. described a modified Starnes procedure in which the free wall of the right ventricle is resected and closed with a patch to reduce its size [30]. At a later date, these patients are considered for a modified Fontan procedure. The third option is neonatal cardiac transplantation. Transplantation rarely is required in the current era, but should be considered when there is significant left ventricular dysfunction.

Neonates without associated anomalies or extreme cardiomegaly who can be weaned from PGE_1 and/or nitric oxide and remain well can be considered for later operative repair when early mortality is substantially lower. Appropriate indications for operation must be defined because not all patients need an operation. The principle concept of operation is to provide the patient with a competent, nonstenotic tricuspid valve, eliminate right-to-left shunts, and reduce the size of the right atrium and, at times, the right ventricle. Some patients may require ablation or division of an accessory pathway, and others may require a maze procedure for atrial arrhythmias. The goal of reducing the volume overload of the right ventricle is to optimize right ventricular function and improve its longevity. Although establishing tricuspid competence by repair or replacement reduces right ventricular size after operation, there are no data to indicate that it improves right ventricular function. Indeed, because the RV is myopathic, this might not occur. In general, it is more desirable to repair than to replace the tricuspid valve, provided that a competent valve can be created.

There are several indications for operation:

1 Marked cardiomegaly or a progressively enlarging heart, because a C/T ratio >0.65–70 is associated with increased risk of sudden death and of operative death.

2 A right-to-left shunt because of the associated morbidity.

3 Declining left ventricular function because the operative mortality is higher with depressed left ventricular function. We have shown that left ventricular function usually improves after operation [31].

4 Other indications include right-sided heart failure, New York Heart Association (NYHA) class 3 or 4, progressive exercise intolerance, uncontrolled arrhythmias, and significant associated lesions such as ASD, VSD, or right ventricular outflow obstruction.

The technique for repairing the tricuspid valve has evolved over the past five decades. Many techniques have been described to repair Ebstein anomaly. Indeed, surgeons very experienced with repair of the tricuspid valve employ concepts from more than one type of repair technique to address the wide anatomic variability of the malformed valve.

Perhaps the technique used most frequently over the past 30 years has been monocusp reconstructions of either the "Danielson" type [10] or the "Carpentier" technique as described above [11]. Because of the great variability in the anatomy of the tricuspid valve with Ebstein anomaly, some valves are unrepairable and replacement is necessary. Early experience with the "cone" procedure, a near anatomic repair, suggests that this may be a superior technique with very few valves not amenable to repair [13]. Limited long-term outcome results are available for this relatively new operation. Relative contraindications to the cone repair

are age >50 years, moderate or severe pulmonary hypertension, left ventricular ejection fraction <30%, complete failure of delamination of the septal and inferior leaflets, and <50% delamination of the anterior leaflet, severe right ventricular enlargement, and severe dilatation of the true right ventricular annulus.

If the tricuspid valve cannot be repaired adequately, valve replacement is necessary. We prefer a porcine bioprosthetic valve that has proven fairly durable and avoids the need for long-term anticoagulation. A mechanical valve can be considered after failure of two bioprosthetic valves, and for patients who already are treated with warfarin because of a mechanical valve in another position. Mechanical valves should be avoided when right ventricular function is poor (as often happens with Ebstein anomaly), because the discs may not open and close properly and are thus more susceptible to thrombosis even with adequate warfarin anticoagulation.

Currently, the potential role for the so-called "bidirectional Glenn" operation as an adjunct to valve repair/replacement in Ebstein anomaly is being explored [32,33]. Indications include severe right ventricular enlargement and/or dysfunction (RV ejection fraction <25%), displacement of the left ventricular septum (D-shaped left ventricle), preoperative arterial desaturation at rest or with exercise, a post-repair RA:LA pressure ratio of >1.5:1, and a small effective tricuspid orifice after tricuspid repair. A bidirectional Glenn procedure has the potential benefit to unload volume from the dysfunctional right ventricle and to improve preload of the left ventricle. The potential disadvantage of the bidirectional Glenn operation is that it limits venous access to the heart, complicating future pacemaker lead placements or electrophysiological studies. No recent studies have demonstrated the utility of the bidirectional Glenn operation is this setting. Leaving an atrial septal fenestration routinely or when there is right ventricular dysfunction has been described [13]. Our policy is to close an interatrial communication in each patient undergoing operation for Ebstein anomaly when operation is being performed beyond the neonatal period.

We reported the long-term outcome for 539 patients with Ebstein anomaly who had operation at the Mayo Clinic from 1 April 1972 to 1 January 2006 [34]. The mean age of the initial operation at our institution was 24 years (range 8 days to 79 years). A total of 143 patients (26.5%) had a prior cardiac procedure before coming to the Mayo Clinic. At the first operation, 182 patients had tricuspid valve repair and 337 had tricuspid valve replacement. The 30-day mortality was 5.9% for the entire cohort (2.7% after 2001). Late survival was 71.2% at 20 years and the 20-year survival and freedom from reoperation was 46% (Figure 36.6).

Risk factors for mortality or reoperation can be divided into those present before the operation and those found at the time of the operation. Most are indications of increased
Figure 36.6 Kaplan Meier curve of over-all survival of 538 patients who had operation for Ebstein anomaly at the Mayo Clinic.

severity and many also predict longer operative procedures. Therefore, before operation the risk factors are a prior cardiac operation (especially a Glenn shunt), high hematocrit, larger C/T ratio on chest X-ray, right ventricular outflow tract obstruction, absence of sinus rhythm, moderate to severe right or left ventricular dysfunction systolic dysfunction, and mitral valve regurgitation judged marked enough to require operative repair. At the time of the operation, other important risk factors are the need for tricuspid valve replacement or a surgical procedure for arrythmia, and also the need for postoperative mechanical support or to reopen the chest in the ICU. Added risk factors are the absence of accessory pathways or sinus rhythm after surgery. The only unexpected risk factor was male gender.

We obtained follow-up medical survey information from 285 patients of 448 (64%) not known to be deceased at the time of the study [25]. At late follow-up (mean 6.9 years), 237 (83%) patients were in NYHA class I or II, 12% in class III, 4% in class IV, and 34% were taking no cardiac medication. A total of 103 patients (36%) reported an incident of atrial fibrillation or flutter, five patients (2%) reported having had endocarditis, and one patient (<1%) reported a stroke.

We assessed the effect of reduced left ventricular function on surgical outcome [31]. Of the 495 patients with preoperative echocardiographic assessment of LV function, 50 had moderate or greater LV systolic dysfunction. The tricuspid valve (TV) was repaired in 12 of these patients and replaced in 36 patients. One patient had a 1.5 ventricle repair and one patient had cardiac transplantation. There were five early deaths (10%). LV function after operation improved in all but four patients. and worsened in none. The 1-, 5-, and 10-year survivals were 86, 77, and 67%, respectively (Figure 36.7). Using univariate analysis, absence of sinus rhythm at dismissal ($p = 0.003$) was associated with greater overall mortality. For the entire cohort of 539 patients, LV

dysfunction, assessed echocardiographically, was independently predictive of late mortality (odds ratio 3.76, $p < 0.001$).

Tricuspid stenosis or insufficiency not associated with ebstein anomaly

Although relatively rare, Ebstein anomaly accounts for most congenital tricuspid valve dysfunction in children.

Pulmonary atresia with intact ventricular septum always is associated with tricuspid regurgitation and dysplasia of the tricuspid valve (see Chapter 40). The valve may have features reminiscent of Ebstein anomaly and, indeed, if the right ventricle is of near normal or normal size, distinguishing it from Ebstein anomaly with pulmonary atresia may be challenging. As noted above, this distinction becomes important for planning surgical strategy and for measuring treatment outcomes.

Transient tricuspid insufficiency of the newborn is associated with variable degrees of the neonatal stress such as perinatal asphyxia. It has been attributed to ischemic papillary muscle dysfunction, myocardial hypoxia associated with increased pulmonary vascular resistance, perinatal asphyxia, hypoxemia, and hypercarbia, and premature *in utero* constriction of the ductus [35–38]. These patients usually have respiratory distress and a holosystolic murmur of tricuspid regurgitation that frequently is confused with the murmur of a ventricular septal defect. Frequently, these infants are cyanotic because of right-to-left shunting across a PFO. In most instances, the tricuspid regurgitation resolves with time. Supportive therapy, mechanical ventilation and

using pulmonary vasodilators and inotropic support may be necessary in severely ill infants, and death can occur.

Congenital tricuspid valve dysplasia is a relatively rare cause of tricuspid stenosis and/or regurgitation. It can be confused with Ebstein anomaly. With proper attention to the echocardiographic features, however, this confusion should not occur. Ammash *et al.* reported 22 patients who were misdiagnosed as Ebstein anomaly [39]. The correct diagnoses were tricuspid dysplasia ($n = 9$), tricuspid prolapse ($n = 4$), traumatic tricuspid valve rupture ($n = 4$), tricuspid valve endocarditis ($n=1$), tricuspid annular dilation secondary to pulmonary regurgitation ($n = 1$), and right ventricular dysplasia ($n=3$). The management of tricuspid dysplasia depends upon the severity of the stenosis or regurgitation. Symptoms include fatigue, hepatic congestion, fluid retention, and atrial arrhythmias. Patients with tricuspid stenosis can develop protein-losing enteropathy. The indications for operations are the same as those for Ebstein anomaly.

37 Anomalies of the Coronary Sinus

Shannon M. Mackey-Bojack[1] & James H. Moller[2]
[1]Jesse E. Edwards Registry of Cardiovascular Disease, United Hospital, St Paul, MN, USA
[2]University of Minnesota, Minneapolis, MN, USA

Introduction

Compared with the coronary arteries, far less attention is paid to the cardiac veins and coronary sinus. With advancements in interventional and surgical treatment for heart disease, interest in the anatomy of the coronary sinus and coronary sinus anomalies has increased. Failure to understand and identify coronary sinus anomalies may be associated with serious consequences during surgery or interventional procedures.

Embryology

In early development, paired symmetrical veins join to form the sinus venosus and drain into the common atrium. The three sets of veins include the vitelline, umbilical, and common cardinal veins, which drain into the atrium through right- and left-sided channels [1]. Simultaneously, as development continues, the atrial septum begins to form and the venous connections become incorporated into the right atrium. A remodeling process occurs, resulting in anastomoses between the right and left systemic veins with preferential flow of blood to the right side. The right-sided venous return enlarges, continues remodeling, and becomes incorporated into the right atrium [2]. With the formation of the anastomotic channels, the left-sided venous return decreases in size. During this process, the left sinus wall becomes incorporated into the left atrioventricular groove, forming the coronary sinus. This process has been described as a fold of the left sinus venosus, which migrates to connect with the right atrium, whereby the fold itself creates the floor between the left atrium and the coronary sinus [3]; however, it appears that this is not completely accurate and the left sinus venosus actually retains its own wall and is incorporated into the left atrioventricular groove [1,4]. The proximal and transverse portions of the left sinus venosus in the left atrioventricular groove become the coronary sinus and the distal left sinus venosus and left cardinal vein normally obliterate and become the ligament of Marshall [2].

Coronary sinus anomalies

There is a range of anomalies of the coronary sinus. Mantini *et al.* divided the defects into four categories: enlarged coronary sinus, absent coronary sinus, hypoplastic coronary sinus, and atresia of part of the coronary sinus [5]. The more commonly encountered anomalies are discussed below in further detail.

Persistent left superior vena cava

Failure to identify the uncommon anomalies of the coronary sinus can have serious consequences during cardiac surgery or interventional procedures. Formed from the left sinus venosus, it can retain connection with the left cardinal vein, creating a persistent left superior vena cava (PLSVC), which is the most common thoracic venous anomaly. PLSVC as an isolated anomaly, has a reported frequency of 0.3–0.5% in autopsy studies [6–8]. PLSVC is more common in congenital heart disease and may occur with any type of congenital cardiac anomaly [5]. The frequency of PLSVC associated with other cardiac anomalies ranges from 1.3 to 10% [5,8].

In most instances of PLSVC, the left-sided embryologic venous structures persist and connect to the coronary sinus, resulting in an enlarged ostium of the coronary sinus. Rarely, the LSVC connects directly to the left atrium. A right superior vena cava (RSVC) is usually present and the left innominate vein (bridging vein), connecting the RSVC and LSVC, may or may not be present [5].

(a)   (b)
Figure 37.1 (a) Right atrial view of unroofed coronary sinus defect. The coronary sinus atrial septal defect (CS ASD) is at the posterior–inferior angle of the right atrium superior to the tricuspid valve (TV). The atrial septal defect is inferior to the fossa ovalis (FO) and inferior vena cava (IVC). (b) Left atrial view of unroofed coronary sinus defect. The CS ASD in the left atrium is superior to the posteromedial commissure of the mitral valve (MV).

The PLSVC is usually without clinical significance. It may be significant when associated with additional coronary sinus anomalies, such as unroofed coronary sinus or atresia of the coronary sinus, or when discovered during surgery while using retrograde cardioplegia or attempts at placement of pacemakers or defibrillators.

Unroofed coronary sinus

Unroofed coronary sinus consists of a range of anomalies associated with a defect in the wall between the coronary sinus and left atrium.

Complete unroofed coronary sinus, also referred to as Raghib syndrome, was first described in 1965 [3]. The syndrome is a combination of anomalies including PLSVC terminating in the left atrium, absent coronary sinus, and atrial septal defect in the posteroinferior angle of the atrial septum. Initially believed to be a result of failure of the left sinus venosus to migrate within the atriovenous fold to connect with the right atrium [3], it now appears that the anomaly results from failure in the formation of the wall between the coronary sinus and the left atrium [4]. As a result, the LSVC usually connects to the left atrium between the pulmonary veins posteriorly and the base of the left atrial appendage anteriorly [3]. These patients have the possibility of developing TIAs or brain abscess because of the right-to-left shunt (LSVC-LA). Notably, 80–90% of cases do not have a left innominate vein [3,9]. Since the coronary sinus is

absent, cardiac veins drain independently into the atria. From the right atrial aspect, the atrial septal defect is in the typical location of the coronary sinus ostium, posterior and inferior to the fossa ovalis, inferior and medial to the inferior vena cava, and superior to the septal leaflet of the tricuspid valve (Figure 37.1a). From the left atrial aspect, the defect is above the posteromedial commissure of the mitral valve (Figure 37.1b). Atrial septal tissue surrounds the defect anteriorly, superiorly, and inferiorly. The posterior left atrial wall forms the posterior boundary [3]. This condition may have an additional atrial septal defect, either at the fossa ovalis or within the endocardial cushions [9,10].

Variants

Within the range of unroofed coronary sinus is the partially unroofed or fenestrated coronary sinus defect. This condition is the result of a defect within the partially formed wall between the coronary sinus and the left atrium, resulting in a defect or fenestration between the coronary sinus and left atrium. This rare form of unroofed coronary sinus may be associated with a left-to-right shunt and may be clinically apparent. The clinical and diagnostic features resemble those of an atrial left-to-right shunt [11].

Echocardiography or MRI [12] may demonstrate the defect between the coronary sinus and left atrium. If there is a PLSVC, there may be a small right-to-left shunt into the left atrium [9]. Surgically, the defect is usually closed through

(a)   (b)
Figure 37.2 (a) Variant of unroofed coronary sinus defect with coronary sinus ostium (CSO) connecting directly to the left atrium superior to the posteromedial commissure of the mitral valve (MV). (b) Closer view of (a). The CSO connects directly to the left atrium above the MV.

the left atrium [13]. If there is no LSVC, the surgical correction is simply to close the coronary sinus ostium in the right atrium. The defect has reportedly been closed by a covered stent in an infant with cardiac failure due to a large left-to-right shunt [14]. This variant has also been associated with either right- or left-sided atrioventricular valve atresia or stenosis [9,10].

In another variant, the coronary sinus ostium opens directly into the left atrium and the distal segment is atretic. In this variant, the coronary sinus ostium is located in the posterior wall of the left atrium above the posteromedial commissure of the mitral valve and there is no right atrial component (Figure 37.2) [3,9]. This very rare variant often is not of clinical significance. It comes to cardiac surgeons' attention when they try to introduce retrograde cardioplegia during open-heart surgery and discover that there is not a coronary sinus ostium in the right atrium. It also is important to recognize this variant when attempting device placement, as the leads may enter the left atrium.

Atresia of coronary sinus

Atresia of the coronary sinus is rare and several variations exist. There may be atresia of the entire coronary sinus, a segment of the coronary sinus, or the coronary sinus ostium. If a segment is atretic, this results in a blind-ended pouch behind the left atrium. In some instances, a PLSVC coexists and the cardiac venous blood emptying into this segment travels retrograde via the LSVC to the left innominate vein, continuing to the right superior vena cava, with eventual drainage into the right atrium [15]. The terminal coronary sinus empties through the right atrial ostium and drains only a small percentage of the cardiac venous blood [16].
Figure 37.3 Right atrium with absent coronary sinus ostium. The typical location of the coronary sinus is labeled CS. There is no coronary sinus ostium in the right atrium. Tricuspid valve (TV) and fossa ovalis (FO) are normally formed.

There may be atresia of the coronary sinus ostium in the right atrium (Figure 37.3). The coronary sinus is present; however, it ends blindly behind the left atrium. Cardiac venous drainage is by retrograde flow via the PLSVC, to the left innominate vein, to the right superior vena cava, to the right atrium. Atresia of the right atrial coronary sinus ostium may be an isolated anomaly. It has also been reported with a variety of different types of cardiac anomalies. Atresia of the coronary sinus is often of little clinical significance; however, due to dependence of cardiac venous drainage via the PLSVC, care must be taken not to ligate the LSVC during surgery, which would result in myocardial congestion, distention, and ischemia [17,18].

(b) Right atrial view of same patient as in (a) demonstrating the dilated coronary sinus ostium (CSO) due to the total anomalous pulmonary venous connection to the coronary sinus. FO, fossa ovalis.

Absence of the coronary sinus is part of the complex cardiac malformations present in heterotaxia syndromes, particularly the asplenia syndrome. Common atrial components of asplenia are bilateral SVC, common atrium, and absence of the coronary sinus [5]. Malformations associated with asplenia syndrome are discussed in greater detail in Chapter 50.

Other abnormalities of the coronary sinus

Enlarged coronary sinus occurs with partial or total pulmonary venous connection. The pulmonary confluence which collects the pulmonary venous drainage connects to the coronary sinus with subsequent drainage into the right atrium (Figure 37.4) [5].

Other types of anomalous drainage to the coronary sinus include partial anomalous hepatic drainage to the coronary sinus and drainage of the inferior vena cava through the hemiazigous vein to a left superior vena cava to the coronary sinus [5].

38   Hypoplastic Left Heart Syndrome

Robert B. Hinton & D. Woodrow Benson
Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

Introduction

Although hypoplasia of the left ventricle resulting in single ventricle physiology is a cardinal feature of hypoplastic left heart syndrome (HLHS), the pathologic definition includes atresia or stenosis of both the aortic and mitral valves, and hypoplasia of the left ventricle and ascending aorta with intact ventricular septum and normally related great arteries. This definition excludes anatomic variations of left ventricular hypoplasia, including atrioventricular septal defect and double-outlet right ventricle that presumably have different causes. The diagnosis, treatment, and care of patients with HLHS have improved dramatically over the past 30 years. (Table 38.1).

Incidence and genetics

The prevalence of HLHS has been estimated as 0.06–1.20 (median 0.22) per 1000 live births [1]. This is consistent with findings from the larger epidemiologic studies, including the New England Regional Infant Care Program (NERICP) and the Baltimore–Washington Infant Study (BWIS), which place the prevalence at 0.16–0.27 per 1000 live births [2,3]. HLHS accounts for approximately 4–8% of all cardiovascular malformations (CVMs) [4]. Some fetal loss has been attributed to HLHS, but in general HLHS is viable *in utero*. HLHS is slightly more common in males; there is no ethnic or geographic association. Despite only one in 5000 live births resulting in HLHS and approximately 2000 infants born each year in the United States, the burden on society is substantial. The direct costs, medical morbidity, and utilization of a disproportionate share of pediatric cardiac resources make HLHS a central problem in pediatric cardiology [5,6].

Despite dramatic improvements in diagnosis, treatment, and prognosis, the cause of HLHS remains largely unknown. Recurrence risk provides significant evidence that HLHS has a genetic basis, but no genes have been identified. For a long time, HLHS was considered a rare, sporadic occurrence; however, Shokeir identified consanguineous families with multiple instances and proposed that HLHS was a recessive phenotype [7]. In a landmark paper, Brenner *et al.* identified a disproportionate number of first-degree relatives affected with bicuspid aortic valve (BAV) in families identified by an HLHS proband, further suggesting a genetic basis [8]. The heritability of HLHS has been estimated as 78–95% [9,10]. A large, family-based study in which all family members were screened with echocardiography for CVM identified a recurrence risk of 8% for HLHS and 22% for any CVM, including a 10-fold increase in BAV [10].

Analyses to date suggest HLHS is a complex trait, not following simple Mendelian inheritance; thus, a single gene mutation does not result in HLHS. There is substantial evidence supporting genetic heterogeneity. For example, HLHS is associated with genetic syndromes in ~10% of patients, most commonly Turner syndrome, trisomy 18, and Jacobsen syndrome [11,12]. Less common associations include Smith–Lemli–Opitz syndrome, VACTERL association, and Rubinstein–Taybi syndrome. There have been additional reports of HLHS in numerous other genetic syndromes; however, many of these reports equate left ventricular hypoplasia with HLHS (e.g.. Holt–Oram syndrome), and therefore may provide limited insight into the underlying genetic basis of HLHS. Interestingly, 25% of patients who do not have an identifiable genetic syndrome have noncardiac malformations, consistent with the idea that HLHS is a true syndrome [11]. Noncardiac anomalies include craniofacial, genitourinary (especially kidney), and central nervous system (CNS) abnormalities, and can be clinically significant in

Table 38.1 HLHS: historical landmarks.

Year	Landmark	Author
1849	Pathologic description	Canton
1952	Pathologic anatomy and classification scheme	Lev
1958	Entity named "hypoplastic left heart syndrome"	Noonan and Nadas
1970s	Genetic basis proposed	Shokeir
1980s	Surgical reconstructive palliation	Norwood
1980s	Epidemiology elucidated	BWIS
1989	Etiologic connection between HLHS and BAV proposed	Brenner
1990s	Specialized intensive care and anesthesia	Wessels
2000s	Fetal intervention	Tworetzky

the acute and chronic management of this patient population. Nearly half of all patients have CNS abnormalities, including microcephaly and evidence for preoperative white matter injury [13,14]. In addition, there is a disproportionate number of small for gestational age infants with HLHS and, in general, they have relatively low birth weights [15]. In a small number of patients, *NKX2.5* and *GJA1* mutations have been identified in HLHS probands [16,17]. Recently, two significant loci for HLHS and associated CVM have been identified on chromosomes 10q22 and 6q23 [18]. The clinical taxonomy is based on anatomy and physiology; however, as more is learned about the genetic basis of HLHS and other complex forms of CVM, this taxonomy will have to be reconciled with the emerging molecular taxonomy.

Embryology

HLHS pathology occurs in different cardiovascular tissue types, namely valve, muscle, and artery. Cardiac development for these tissues types spans primary cardiogenesis [19]. There are two hypotheses about the developmental origins of HLHS. First, in the context of reduced flow through the left-sided structures, as can happen with restriction of left ventricular outflow, for example aortic stenosis, or inflow obstruction, for example restriction of the foramen ovale, the left-sided structures fail to grow. Second, aberrant developmental programs selectively impair the left-sided structures (e.g., the aortic valve, the aorta, the left ventricular myocardium). Because aortic stenosis has been identified as part of the *in utero* natural history of HLHS in at least a subset of patients [20], a fetus may have a genetically based aortic valve malformation, which results in embryonic or fetal obstruction and subsequent growth failure of the remaining left-sided structures in the context of reduced blood flow. Given the severity of the phenotype, an early but viable insult would be expected. There are no animal models for

HLHS, although some models have recapitulated the left ventricular hypoplasia aspect of the phenotype. For example, in the chick embryo, ligation of the left atrial appendage results in reduced left atrial size and consequently left ventricular hypoplasia [21,22]. Notably, however, the aortic and mitral valves in this model are normal. The inability to induce this lesion in fetal animals combined with the striking absence of this phenotype in targeted mutagenesis mouse models of CVM further supports the idea that HLHS is a complex genetic phenotype [19,23].

Pathologic anatomy

HLHS was originally described in 1849 by Canton [24]. Lev was the first to describe the pathologic anatomy in a series of patients, and referred to the findings as "hypoplasia of the aortic tract complex" [25]. Noonan and Nadas described this constellation of findings as the "hypoplastic left heart syndrome" in 1958 [26]. Lev subsequently proposed a classification scheme based on valve morphology that continues to be in wide use. Based on these studies, four criteria are required for diagnosis (Table 38.2) and those that are diagnosed may be classified further by the status of the left-sided valves as either atretic or stenotic (aortic atresia, mitral atresia; aortic atresia, mitral stenosis; aortic stenosis, mitral stenosis) [27]. Of note, the hypothetical group aortic stenosis, mitral atresia does not occur. The surgical nomenclature defines HLHS broadly and prefers the term "hypoplastic left heart complex" to include numerous variants such as Shone anomaly [28]. This approach illustrates the heterogeneity of some of these findings, for example, left ventricular hypoplasia.

The anatomic features required to satisfy a diagnosis of HLHS include atresia or stenosis of the aortic and mitral valves and hypoplasia of the left ventricle and ascending aorta (Figure 38.1). Each of these findings has a continuum of severity, providing a breadth of subgroups. In addition,

Table 38.2 HLHS: diagnostic features and associated findings.

Feature	%
Diagnostic features	
Aortic valve atresia or stenosis	100
Mitral valve atresia or stenosis	100
Left ventricular hypoplasia	100
Hypoplasia of the ascending aorta	100
Associated findings	
Tricuspid valve abnormalities	40–65
Discrete coarctation of the aorta	20–65
Endocardial fibroelastosis	10–40
Intact/restrictive atrial septum	5–15
Figure 38.1 HLHS gross pathology showing longitudinal transection of the left-sided structures. There is hypoplasia of the aortic valve (AoV), mitral valve (MV), left ventricle (LV), and ascending aorta (AscAo). The aortic valve is bicuspid (arrowheads identify two commissures) and dysplastic.

there are features common to all patients. The left atrium is small. The right atrium, right ventricle, and pulmonary artery are enlarged. The morphologic right ventricle is hypertrophied and dilated, making the overall heart size large. A patent foramen ovale is present; in some infants, premature closure of the foramen ovale occurs *in utero*. Associated CVMs include discrete coarctation of the aorta (20–65%), tricuspid and pulmonary valve abnormalities (40–65%), and intact atrial septum (5–15%). The surprising finding of right-sided valve abnormalities has significant clinical implications and raises intriguing questions about the origin of HLHS. In some

patients, the myocardium appears normal, whereas in others there is endocardial fibroelastosis in 10–40%, subendocardial fibrosis, or left ventricle to coronary artery fistulae.

Pathophysiology

There is an obligatory left-to-right shunt at the atrial level, and in the right atrium oxygenated pulmonary venous blood mixes with the systemic venous return, and the mixed blood then flows into the right ventricle. From the right ventricle, the blood is delivered to both the pulmonary and systemic circulations. The brachiocephalic vessels and coronary arteries are perfused through retrograde flow from the ductus arteriosus into the transverse aortic arch and hypoplastic ascending aorta. These changes may be compatible with normal intrauterine growth or, in some instances, decreased somatic and head growth late in gestation.

After birth, transitional physiologic changes result in rapidly progressive hemodynamic disturbances that precipitate symptoms in the first week of life. There is a gradual decrease in pulmonary vascular resistance and spontaneous constriction of the ductus arteriosus. The gradual decrease in pulmonary vascular resistance in the first few days of life leads to a progressive increase in pulmonary blood flow, which in turn improves systemic arterial oxygen saturation but also diminishes systemic blood flow, lowers perfusion pressure, and causes volume overload of the right ventricle. The increased pulmonary blood flow is accompanied by pulmonary congestion and increased left atrial and pulmonary venous pressure. A restrictive interatrial communication, if present, further elevates left atrial pressure. Because the systemic and coronary circulations depend on flow through the ductus arteriosus, its constriction in the first few days of life leads to poor systemic perfusion, hypoxemia, and metabolic acidosis, eventually resulting in vascular shock and death. The coronary blood flow depends on the perfusion pressure in the aortic arch and the size of the ascending aorta. Various compensatory mechanisms, including redistribution of blood away from the less vital organs, such as the gastrointestinal tract, temporarily maintain nearly normal arterial pressure and coronary perfusion.

The pulmonary and systemic blood flows in infants with HLHS are determined by the ratio of the pulmonary to systemic vascular resistances. While the ductus arteriosus remains patent, most infants maintain a balance between the pulmonary and systemic resistances, resulting in adequate pulmonary and systemic perfusion. However, in some infants, excessive reduction of the pulmonary to systemic vascular resistance ratio leads to pulmonary overcirculation, with the development of congestive heart failure and diminished systemic perfusion. Less often, a higher pulmonary-to-systemic vascular resistance ratio leads to diminished pulmonary blood flow, as may occur when

pulmonary vascular resistance remains high in infants with persistent pulmonary hypertension or with an intact or restricted interatrial septum. The consequence is severe hypoxemia, progressive tissue hypoxia, metabolic acidosis, and death. The significance of the interaction between the pulmonary and systemic resistance in determining pulmonary and systemic blood flows and also systemic arterial oxygen saturation is crucial to understanding the clinical presentation of these infants and the pre- and postoperative management [29].

Clinical features

Clinical history

The circulatory hemodynamics in the fetus with HLHS appear adequate for normal development. At birth, the infant typically has normal Apgar scores without cardiovascular symptoms, and without the use of pulse oximetry may be sent home undiagnosed [30]. Symptoms usually appear within the first days of life. Clinical presentation in a neonate may occur in one of three ways: respiratory distress, shock, or cyanosis. Respiratory distress with tachypnea and mild cyanosis, the most common presentation, usually begins on the second or third day of life. Respiratory symptoms are due to the progressive increase in pulmonary blood flow and pulmonary congestion that result from the normal transitional decrease in pulmonary vascular resistance. The duskiness is due to mild hypoxemia. The second most frequent presentation, shock, occurs with precipitous constriction of the ductus arteriosus, resulting in low cardiac output as evidenced by hypotension, poor peripheral perfusion, and severe metabolic acidosis. Because this presentation may occur after neonatal discharge from the hospital, the arrival of the patient in an emergency department in vascular collapse is often mistaken for septic shock. The physical findings on examination are those of shock and severe cardiac failure; there is profound myocardial dysfunction, metabolic acidosis, and anuria. Seizures may also occur. The least common presentation is that of cyanosis, usually occurring shortly after birth on the first day of life. The cyanosis results from premature closure of the foramen ovale, inadequate atrial level shunting, or persistence of pulmonary artery hypertension of the newborn.

Physical examination

The incidence of small-for-gestational-age birth weights and microcephaly is increased. In addition, head size can be disproportionately small when indexed to somatic size. Physical examination reveals marked tachypnea and tachycardia. There is a right ventricular impulse at the xiphoid, and hepatomegaly. The peripheral pulses are diminished throughout, and there is poor capillary filling and mottling of the skin. Cyanosis is often not apparent because hypoxemia is

relatively mild and may be masked by simultaneous hyperbilirubinemia. Typically, a single second heart sound and gallop rhythm are heard. There is often a soft systolic ejection murmur audible at the bases and back bilaterally due to physiologic peripheral pulmonary stenosis accentuated by increased pulmonary blood flow. An additional regurgitant systolic murmur may be heard at the left lower sternal border if tricuspid regurgitation is present. An arterial blood gas obtained in room air usually has a PaO_2 of ~45–60 mmHg, with normal or moderately decreased $PaCO_2$ of 30–35 mmHg and low pH as a result of moderate metabolic acidosis. When the infant is breathing 100% oxygen, the PaO_2 may rise to ≥100 mmHg. Systemic arterial oxygen saturation measured by a pulse oximeter may be in the mid to high 80s or low 90s and is similar in all four extremities. With persistent poor perfusion and increasing metabolic acidosis, there may be associated hypoglycemia, hypocalcemia, and hyperkalemia and subsequently the development of disseminated intravascular coagulopathy.

Electrocardiographic features

The electrocardiogram soon after birth usually shows a dominant R wave in V_1 and a dominant S wave in V_6. This R/S reversal, rare in normal newborns, indicates left ventricular hypoplasia rather than pure right ventricular hypertrophy. Subsequent changes are related to left ventricular hypoplasia and right ventricular volume and pressure overload, and may include right atrial enlargement, right ventricular hypertrophy, and progressive diminution in left ventricular forces with absence of a Q wave in the left precordial leads and a pure R or QR in lead V_1. Right ventricular myocardial ischemic ST–T wave changes may appear. Conduction disturbances are rare.

Chest X-ray

The chest radiograph may be normal immediately after birth, but usually demonstrates cardiomegaly and increased pulmonary vascular markings on the first day of life. In infants with an intact or restricted interatrial communication, there is usually a pattern of pulmonary edema, and in those with persistent pulmonary hypertension the pulmonary vascular makings are diminished. While the infant is receiving prostaglandin E_1, progressive pulmonary edema and cardiomegaly are observed.

Echocardiography

Echocardiography is the gold standard for diagnosis, and currently >50% of patients are identified *in utero*. A prenatal diagnosis of HLHS may be made by fetal echocardiography as early as 16 weeks gestation after cardiogenesis. HLHS is typically identified during a screening obstetric ultrasound, often when there is a family history of congenital heart disease. Prenatal diagnosis has led to an improved ability to plan for care and

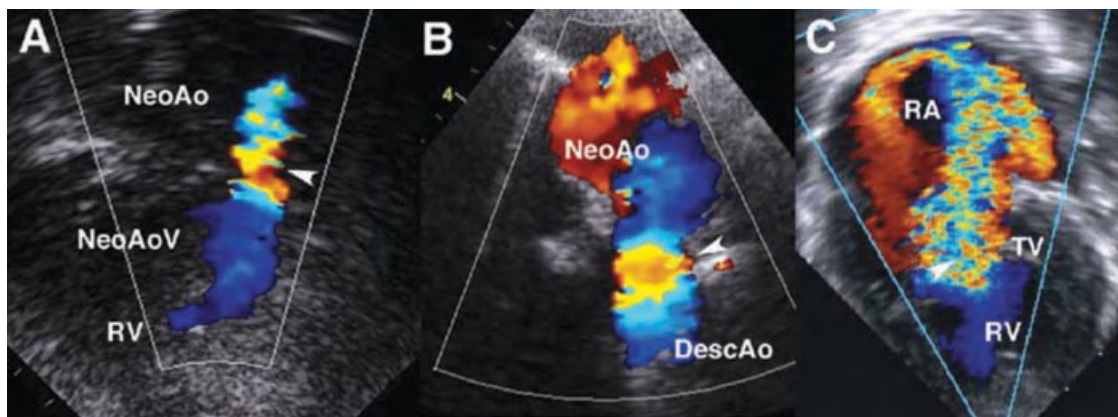
Figure 38.2 Echocardiographic findings of HLHS upon diagnosis. These show the following. (a) In the parasternal long axis view, aortic valve (AoV) atresia, left ventricular (LV) hypoplasia and mitral valve (MV) stenosis; in addition, there is mild endocardial fibroelastosis (EFE) along the ventricular septum in close proximity to the aortic valve and hypoplasia of the ascending aorta (AscAo). LA, left atrium. (b) In a modified suprasternal view, marked hypoplasia of the ascending aorta and retrograde flow in the descending (DescAo) and transverse (TAo) aorta. PDA, patent ductus arteriosus. (c) A discrete juxtaductal coarctation of the aorta (COA). (d) Thickened dysplastic tricuspid valve (TV) with abnormal chordal attachments (arrowhead). RA, right atrium; RV, right ventricle.


Figure 38.3 Interstage complications as identified by echocardiography include (a) neoartic (NeoAo) obstruction at the proximal aspect of the aortic patch (arrowhead), (b) residual or recurrent coarctation of the aorta (arrowhead), and (c) tricuspid regurgitation (arrowhead). DescAo, descending aorta; NeoAoV, neoaortic valve; RA, right atrium; RV, right ventricle; TV, tricuspid valve.

provide counseling to the family [31]. Longitudinal studies in the fetus have shown that aortic stenosis is part of the *in utero* natural history of HLHS. At mid-gestation, at the earliest stage imaging can be reliably obtained, a fetus that will have HLHS as a neonate may have obvious HLHS or isolated aortic stenosis, and severity of fetal aortic stenosis can be stratified based on physiologic parameters such as reverse flow in the transverse aorta. Interestingly, the left ventricular morphology progresses from ostensibly normal to dilated and dysfunctional and ultimately to hypoplastic during the second half of gestation.

A definitive diagnosis is made by two-dimensional and Doppler transthoracic echocardiography at birth (Figure 38.2). The characteristic echocardiographic features of HLHS include (1) atresia or stenosis of the aortic and mitral valves, (2) left ventricular hypoplasia, (3) hypoplasia of the ascending aorta and transverse arch with or without discrete coarctation, and (4) right ventricular enlargement. Once the diagnosis is established, special attention should be given to the interatrial communication, the ductus arteriosus, tricuspid valve morphology

and function, the distal aortic arch, and right ventricular function. Echocardiography is the primary tool to monitor patients between palliative stages. After stage I palliation, assessment of right ventricular and tricuspid valve function is critical, and also the adequacy of the interatrial communication, any functional abnormality of the pulmonary (neoaortic) valve, and presence of a left superior vena cava. If both a right and left superior vena cava are present, and there is no bridging innominate vein, a bilateral bidirectional caval–pulmonary connection may need to be established. Complications include recoarctation of the aorta at either the proximal or distal end of the anastomosis, and tricuspid regurgitation, either of which can result in ventricular failure (Figure 38.3).

In HLHS, the right ventricle functions as the systemic ventricle and is challenged by increased afterload and increased preload prior to stage 2 palliation. Myocardial ischemia, coronary abnormalities, and additional volume loading from tricuspid regurgitation may contribute to this

burden. A subset of patients with HLHS develop right ventricular failure and are at risk of increased morbidity. Systolic and diastolic function were assessed in children with HLHS to compare ventricular function following stage I palliative surgery with either an aortopulmonary shunt or a right ventricle to pulmonary artery shunt [32]. There were no early significant differences in right ventricular size, shape, or systolic and diastolic function between groups. Regardless of the type of stage I procedure, patients showed a decrease in both systolic and diastolic indices that persisted through stage II palliation months later [32]. Right ventricular mechanical dyssynchrony has been studied in children with HLHS using tissue Doppler imaging and strain derived from vector velocity imaging [33]. Right ventricular mechanical dyssynchrony was common and may contribute to ventricular dysfunction in some patients.

Cardiac catheterization, angiography, and other imaging modalities

Cardiac catheterization is rarely necessary for diagnosis. Angiography may be useful in the infant with critical aortic stenosis and a small but not diminutive left ventricle to assess the severity of left-sided obstruction or left ventricular hypoplasia if biventricular repair is contemplated. Interventional cardiac catheterization, with an atrial septostomy or blade septectomy, may be necessary for urgent relief of severe interatrial obstruction. Cardiac catheterization may be performed postoperatively to assess hemodynamics, patency of an aortopulmonary shunt, or other confounding anatomic features. Cardiac catheterization and angiography are essential for complete functional and anatomic assessment before stage II palliation (Glenn). Cardiac catheterization is done to assess stenoses, hypoplasia, or deformity of the pulmonary arteries, for direct or indirect measurement of pulmonary artery pressures, and to assess recurrent coarctation of the aorta and, if necessary, perform balloon dilatation of the aortic obstruction. Before stage III (Fontan), cardiac hemodynamic and angiographic studies are performed to determine pulmonary artery pressure, any possible deformity or obstruction of the pulmonary arteries, tricuspid valve competency, and right ventricular function. Major systemic venous collaterals that may be associated with obstruction of the cavopulmonary connection or large aortopulmonary collaterals, particularly from the internal mammary arteries, may require interventional therapy. The systemic venous collaterals may steal or direct blood away from the lungs. Aortopulmonary collaterals increase pulmonary blood flow and subsequent right ventricular volume overload and also pulmonary congestion. Large collaterals are occluded at the time of cardiac catheterization by metal coils or other devices.

Currently, there is a limited role for alternative imaging modalities. CT and MRI may be used to delineate preoperative associated CVM or elucidate complex postoperative anatomy. Ultimately, MRI may have a role in comprehensively and longitudinally evaluating right ventricular function.

Management

General considerations

The management of infants with HLHS varies significantly among physicians, institutions, and countries. If the diagnosis is made in the early prenatal period, termination of pregnancy may be an acceptable option for some families and is the preferred option in many European countries. Once the infant is born, some parents may elect to provide supportive care only. This decision is highly individualized and depends on the family, physician, and available services for care of these patients. Supportive care was much more prevalent in the United States previously than it is today. Options are discussed with the family and the recommendation, in the majority of centers, is staged palliative reconstructive surgery (Table 38.3). The ethical and economic dilemmas posed by HLHS infants are societal issues that require the cooperation of families, physicians, insurers, and various government institutions. The ethical issues raised in the management of these infants include the cost and potential benefits of treatment in an era of limited resources, potential distress and suffering of the infant and family associated with multiple major cardiac operations, and uncertain long-term prognosis.

Fetal management

Based on the observation that aortic stenosis is part of the natural history of HLHS, there has been enthusiasm for *in utero* balloon valvoplasty of the aortic valve in select patients who are predicted to evolve into HLHS. The fetal cardiology group at the Children's Hospital Boston has reported technical success in relieving aortic stenosis in second trimester fetuses, and in some patients preventing progression to HLHS [34]. Although this pertains only to a subset of HLHS, in most patients fetal severe aortic stenosis progresses to HLHS. The benefits of preserving a two-ventricle circulation balance the considerable risks of intervening during gestation, including fetal death and preterm labor (see Chapter 16).

Medical management

After establishing a diagnosis by echocardiography, the initial steps in managing an infant with HLHS include maintaining ductal patency by prostaglandin E_1 infusion and stabilizing hemodynamics before stage I palliation. Mechanical ventilation and inotropic support are required in some patients. Sedation is typically needed, and some patients benefit from increasing the hematocrit through blood transfusion. The focus of medical management is optimizing the balance

Associated genetic syndrome
Intact/restrictive atrial septum
Birth weight less than 2.5 kg
Aortic atresia, mitral stenosis subtype
Ascending aorta dimension <2 mm
Moderate plus tricuspid regurgitation
Prematurity (separate from weight)

between pulmonary (Qp) and systemic (Qs) blood flow, and the general goal is to reduce pulmonary blood flow and right ventricular volume load [35]. Estimating Qp/Qs can be done using the arterial saturation (SaO_2), systemic venous saturation (SvO_2), and pulmonary venous saturation ($SpvO_2$) as follows:

$$Qp/Qs = (SaO_2 - SvO_2)/(SpvO_2 - SaO_2)$$

Optimal oxygen delivery occurs when Qp/Qs = 1 and the arterial venous oxygen saturation difference is 25%. This occurs when SaO_2 = 75% and SvO_2 = 50%, assuming fully saturated $SpvO_2$. Although SvO_2 can vary, confounding interpretation of SaO_2, one strategy to promote patient stability is to use inspired carbon dioxide, which increases pulmonary vascular resistance and consequently increases systemic oxygen delivery [36]. Recently, near-infrared spectroscopy (NIRS) has been used to monitor somatic and cerebral tissue oxygenation and to provide an estimate of SvO_2 [37]. Stage I operative risk factors have been identified (Table 38.4).

Surgical management

HLHS is uniformly fatal without neonatal surgery. The introduction of prostaglandin E_1 to maintain patency of the ductus arteriosus in the 1970s prepared the way for surgical intervention, including staged reconstructive procedures and cardiac transplantation (Figure 38.4). The first successful reconstructive procedure, performed by Norwood *et al.* in 1983 [38], involved connecting the right ventricle to the

systemic circulation by the main pulmonary artery and restricting pulmonary blood flow by creating an aortopulmonary shunt. Stage I palliation may also proceed with a right ventricle to pulmonary artery shunt instead of an aortopulmonary shunt [39]. Alternatively, stage I palliation may be deferred by use of the Hybrid procedure [40]. A second or intermediate stage, modeled after the operation proposed by Glenn in 1958 [41], is subsequently performed, creating a superior vena cava to pulmonary artery connection and eliminating the shunt. In a third stage, the remaining systemic venous flow is connected to the pulmonary artery by the Fontan procedure, introduced in 1971 to treat tricuspid atresia [42]. There have been numerous modifications of each stage. Currently, the typical surgical course is stage I (Norwood) in the first week of life, stage II (Glenn) at 3–6 months, and stage III (Fontan) at around 2–4 years. The alternative operative procedure, cardiac transplantation, was first successfully performed by Bailey *et al.* in 1986, but is rarely used now due in part to limited donor availability [43].

Stage I palliation (Norwood)

The Norwood procedure is designed to (1) provide unobstructed systemic blood flow to the ascending aorta by dividing the main pulmonary artery and creating an anastomosis between the proximal main pulmonary artery trunk and the ascending aorta (patch augmentation is required to enlarge the ascending aorta and extend it beyond the coarctation); (2) provide pulmonary blood flow by creating an aortic-to-pulmonary artery anastomosis or aortopulmonary shunt (also known as a Blalock–Taussig shunt, typically a Gore-Tex 3.5 mm graft interposed between the right subclavian and right pulmonary arteries); (3) create a large interatrial communication by performing atrial septectomy. Alternatively, a right ventricle to pulmonary artery shunt can be used (also known as a Sano modification, typically a Gore-Tex 5–6 mm graft) instead of the aortopulmonary shunt to establish pulmonary blood flow (Figure 38.4a). This modification may be a particularly attractive option in a small infant. It has the hypothetical advantage that diastolic pressure and therefore coronary perfusion are maintained by eliminating diastolic run-off. Despite mixed results in initial studies, a recent multi-center, prospective clinical trial performed by the Pediatric Heart Network (www.pediatricheartnetwork.com) comparing the aortopulmonary shunt with the right ventricle to pulmonary artery shunt determined that there is improved early survival using the right ventricle to pulmonary artery shunt; however, the long-term effects of a right ventriculotomy in a single right ventricle heart remain unknown [44]. Recently, the so-called Hybrid approach to defer stage I palliation has been used. This innovative procedure combines expertise from cardiothoracic surgery and cardiac catheterization, and can be performed in the operating room or a Hybrid-ready catheterization suite. The procedure entails banding of the branch
Figure 38.4 Staged reconstructive surgical palliation. HLHS patients generally undergo three operations: stage I (Norwood) may use either an aortopulmonary Blalock–Taussig shunt (a) or a right ventricle to pulmonary artery shunt (b), followed by stage II (Glenn) (c) and stage III (Fontan) (d). (Modified from Barron *et al*. *Lancet* 2009;**374**:551–64, with permission.)

pulmonary arteries, stenting of the patent ductus arteriosus, and balloon atrial septostomy [40]. This requires sternotomy without cardiopulmonary bypass, and bridges the patient to stage II palliation. Early results demonstrated that stage II palliation in these patients is far more complicated and carries a higher mortality; however, a few centers have reported early outcomes similar to stage I palliation. This strategy appears to be a good option for the high-risk patient, and trades a simpler initial operation for a more complex second operation that combines aspects of conventional stage I and stage II palliation. This trade may be advantageous in avoiding complex surgery in the neonate. It is unclear whether the Hybrid procedure will be established for routine use, but it is being used more frequently.

Stage II palliation (Glenn)

The second reconstructive operation is a bidirectional Glenn procedure, performed at ~3–6 months of age (Figure 38.4b). The superior vena caval blood flow is directed to the

pulmonary arteries, and the connection between the superior vena cava and right atrium is closed with the placement of a patch. At the same time, the aortopulmonary shunt is ligated. Systemic venous blood from the head and arms now perfuses the lungs to provide oxygenated blood, which then returns to the left atrium and through the atrial septal defect into the right atrium. After mixing with all the deoxygenated blood from the inferior vena cava, it is then pumped by the right ventricle into the aorta. The advantages of this operation are that it removes the right ventricular volume overload from the prior aortopulmonary shunt, tends to protect the pulmonary vascular bed from the development of pulmonary artery hypertension, and increases the diastolic systemic arterial blood pressure. Stage II palliation allows remodeling of right ventricular geometry, reducing stress while normalizing the mass-to-volume ratio of the chamber. It is also during this stage that other associated cardiac problems are corrected, such as tricuspid valve repair for tricuspid regurgitation, pulmonary angioplasty for any pulmonary

artery deformity or stenosis, and, if necessary, further enlargement of a restrictive interatrial defect.

Stage III palliation (Fontan)

The third stage of the physiologic repair is performed at ~2–4 years of age. It involves creating an inferior cavopulmonary connection with a separation between the oxygenated and deoxygenated blood in the right atrium so that blood from the inferior vena cava and also from the superior vena cava flows directly into the pulmonary arteries (Figure 38.4c). The conduit was initially intra-atrial, but recently extra-atrial tunnels have become popular. A small fenestration or connection between the conduit and right atrium is typically left to allow gradual accommodation for the increased venous flow, decompression of the conduit should systemic venous pressure rise excessively, and reduction in the frequency and severity of postoperative pleural effusions and other complications. The fenestration may diminish in size or close spontaneously with time, or it may be closed at cardiac catheterization.

Immediate postoperative management is designed to maintain adequate pulmonary blood flow by hyperoxygenation, hyperventilation, and the development of mild respiratory and metabolic alkalosis. Recently, more emphasis has been placed on adequacy of systemic blood flow, because pulmonary blood flow tends to be relatively constant, coming as it does through a conduit [45]. Systemic oxygen transport is monitored by measuring oxygen saturation in the fixed superior vena cava and manipulating systemic flows accordingly. The transpulmonary pressure gradient is monitored from a central venous line and a line placed in the "left" atrial chamber. An elevated transpulmonary gradient may indicate increased pulmonary vascular resistance or anatomic obstruction. Persistent postoperative pulmonary effusions may require prolonged pleural drainage and adequate fluid replacement therapy. Some patients will eventually need ligation of the thoracic duct or pleurodesis.

Postoperative management

Stage I palliation leads to hemodynamic parameters similar to those that existed preoperatively, with pulmonary blood flow and systemic blood flow closely related to the ratio of pulmonary-to-systemic vascular resistance. Residua following stage I palliation have been identified (Table 38.5). After stage I, there is right ventricular pressure overload, because the right ventricle functions as the systemic ventricle and there is continued volume overload from the aortopulmonary shunt. The pressure overload may be aggravated by such factors as residual coarctation and volume overload complicated by residual tricuspid regurgitation. If the aortopulmonary shunt is large, there may be a decrease in systemic blood flow and perfusion with low diastolic pressure, which may in turn lead to diminished coronary blood

flow. In the immediate postoperative period, pulmonary vasoconstriction with moderate to severe hypoxemia is common and usually resolves with appropriate ventilatory support and maintenance of normal acid–base balance. Extracorporeal membrane oxygenation is occasionally used and is limited to patients with reversible myocardial dysfunction, an unexplained increase in pulmonary vascular resistance, or acute respiratory disease. Intravenous infusion of fentanyl or morphine is used for sedation and analgesia. Parenteral alimentation is started on the second postoperative day, particularly in those at risk for necrotizing enterocolitis. The importance of a well-trained staff and a designated pediatric cardiac intensive care unit cannot be overemphasized as essential for optimal outcome of infants with HLHS. In less seriously ill infants, early feedings are initiated by nasogastric tube and subsequently given orally. Feeding intolerance is common and needs to be treated aggressively.

Interstage monitoring programs vigilantly assess weight gain in addition to SaO_2 and improve survival [46]. A small dose of aspirin (20 mg per day) is administered as an anticoagulant. Angiotensin-converting enzyme inhibitors and diuretics are often started before discharge from the hospital to decrease right ventricular workload and improve pulmonary blood flow. Recently, a randomized clinical trial performed by the Pediatric Heart Network showed that angiotension-converting enzyme inhibitors are not recommended for empiric use [47].

Mortality during and after operation remains fairly high. The mortality is 10–20% in the first stage, 4–30% while awaiting stage II, 0–5% for second-stage surgery, 5–7% while awaiting the third stage, and under 10% for the third stage. As a result, current 10-year survival after all three stages is about 40–60%, although recent results appear to be better [48].

Long-term history of treated adults

There are significant long-term sequelae following stage III palliation for HLHS (Table 38.6). Because the systemic circulation depends on the right ventricle, maintaining normal

right ventricular function is essential. Ischemia and hypertrophy of the right ventricle may in turn lead to fibrosis, which decreases myocardial function. Rhythm and conduction disturbances are often accompanied by symptoms and may be life-threatening. Atrial tachyarrhythmias and sick sinus syndrome increase in frequency with advancing age and require close monitoring, pharmacologic therapy, and not infrequently interventional or surgical therapy. Resistant atrial flutter may require conversion of a classic Fontan to a cavopulmonary tunnel or extracardiac conduit or performance of the maze procedure alone or combined with epicardial pacemaker implementation.

Protein-losing enteropathy develops in ~4–13% of patients who have had a Fontan procedure for univentricular heart and often presents with abdominal pain, diarrhea, or peripheral edema. It occurs on the average of approximately 3 years after the Fontan procedure with the development of albuminemia, malnutrition, and a compromised immune state. The loss of albumin depletes intravascular volume and, when coupled with a higher central venous pressure, predisposes the patients to thromboses and strokes. Protein-losing enteropathy in these patients is difficult to treat. Diet alone and periodic albumin replacement may be effective in mild or early enteropathy. Steroids may induce remission in some patients, but are often discontinued because of side effects. Subcutaneous heparin has been effective in many patients. Cardiac transplantation when necessary is also effective.

Neurodevelopmental abnormalities are one of the greatest long-term concerns in children with HLHS. There is both imaging and histopathologic evidence that brains from fetuses and newborns with HLHS are abnormal *before* surgery [14,49,50]. Reported associated congenital CNS malformations include agenesis of the corpus callosum, holoprosencephaly, microcephaly, Arnold–Chiari malformation, and immature cortical mantle. These abnormalities may predispose the patient to acquired CNS abnormalities, including periventricular leukomalacia, cerebral necrosis, intracranial hemorrhage, and cerebral ischemia or infarction. In addition, the compound effects of chronic cyanosis and multiple major operations requiring cardiopulmonary bypass in early childhood are known to predispose to developmental delay. Although most stage III survivors demonstrate normal intelligence and

communication skills, a significant proportion demonstrate cognitive, motor, and behavioral deficits in late childhood and adolescence that may adversely impact quality of life.

Introduction

The univentricular heart [1], single ventricle or "common" ventricle [2,3], accounts for ≤2% of congenital cardiac defects [4], predominating in males by a factor of 1.5–2 [2,5]. For many years, the definition of a univentricular heart has been disputed by various authors [1,3,6,7], differing in terminology and characterization criteria. In 1964, Van Praagh *et al.* [2] defined single ventricle as the absence of the sinus portion of a ventricular chamber, excluding tricuspid and mitral atresia. In contrast, Anderson *et al.* [1] and Shinebourne *et al.* [8], basing their definition on the anatomy of the atrioventricular valves [9] and the atrioventricular connections, rather than ventricular morphology *per se*, included hearts with one valve and >50% of the second valve, or >75% of a common atrioventricular valve, entering one ventricle [8–10]. Therefore, they included as univentricular hearts the single ventricle, the double-inlet ventricle with overriding atrioventricular valve of >50%, the unbalanced common atrioventricular canal [11], tricuspid atresia, and mitral atresia [8,9]. Because most of these hearts have two ventricles, although one is rudimentary or hypoplastic, single ventricle seemed an inappropriate term. Therefore, the term univentricular atrioventricular connection [12] was proposed when two atrioventricular valves (double inlet), one common atrioventricular valve (common inlet), and one single atrioventricular valve (single inlet) are connected completely or in their greater component to a certain ventricle (Figure 39.1). The second or additional ventricular chamber can be hypoplastic when it has an inlet portion (<50% of an atrioventricular valve or <25% of a common atrioventricular valve), including the overriding atrioventricular valves, or a rudimentary chamber in its absence. When the rudimentary chamber is superior, it is morphologically a right ventricle (thick trabecular component); when it is posteroinferior, it is morphologically a left ventricle (fine trabeculated component). The concept of single ventricle by Van Praagh *et al.* is based on morphology of the ventricle itself rather than surrounding structures and thus appears more scientifically sound. However, in clinical practice, the concept of single ventricle by Anderson *et al.* is often considered more practical and therefore is used more commonly.

A univentricular heart can be classified morphologically [13] as follows (Figures 39.1 and 39.2):
 I Single ventricle, with two subtypes
   A Single left ventricle, due to agenesis of the right ventricular inlet
   B Single right ventricle, due to agenesis of the left ventricular inlet
II Unbalanced ventricles with a dominant ventricular chamber, which can have either
   A Dominant left ventricle (hypoplastic right ventricular inlet) or
   B Dominant right ventricle (hypoplastic left ventricular inlet).
According to Anderson *et al.* [1], unbalanced ventricles have >1.5 atrioventricular valve rings or >75% of a common atrioventricular valve ring aligned to a dominant right or left ventricle; the other atrioventricular valve or portion of it is aligned with a hypoplastic right or left ventricle.

Embryology

Comparative morphologic studies [14] suggest that single ventricle in humans is not an evolutionary phylogenetic regression of the human heart towards the single ventricle present in amphibian, fish, and lower reptiles but rather
Figure 39.1 Schematic classification of univentricular atrioventricular connection. Atretic atrioventricular connection: tricuspid atresia (a) and mitral atresia (b). Single ventricle: single left ventricle IA with rudimentary bulboventricular outflow chamber in anterosuperior position (right ventricle) (c); single right ventricle with common atrioventricular valve and atrial dextroisomerism (d). Unbalanced ventricles: dominant right ventricle with hypoplasia of the left ventricle, common atrioventricular valve, and atrial dextroisomerism (e); dominant left ventricle with hypoplastic right ventricular inlet (f). RA, right atrium; LA, left atrium; LV, left ventricle; RV, right ventricle; VOC, ventricular outlet chamber.

results from defective cardiac ontogenesis. Once cardiac looping is complete, the internal structure of the heart still consists of a single convoluted tube including atria, ventricle, bulbus cordis, and truncus arteriosus. The morphologically left ventricle is known to be derived from the ventricle of the bulboventricular loop [14]. By Streeter's stages XI–XV, the atrioventricular canal of the embryo opens entirely into the left ventricle. Thus, common inlet and double-inlet left ventricle are potentially present in human development and may represent an arrest at this stage.

The morphologic aspects of the embryogenesis of single ventricle are still controversial [1,7,13,15]. According to Van Praagh et al. [13], in single left ventricle, there is agenesis of the right ventricular inlet; the right ventricle fails to evaginate from the ventricle of the bulboventricular loop, and the ventricular septum shifts toward the side of the absent right ventricle (anterior and to the right in a d-loop, anterior and to the left in an l-loop). As the ventricular septum moves beneath the infundibulum, it can create the picture of an infundibular outlet chamber. In a single or dominant right ventricle, the absent or poorly developed left ventricle shifts the ventricular septum posteriorly and to the left in a ventricular d-loop or posteriorly and to the right in an l-loop. In these anomalies, the location of the ventricular septum away from the infundibulum generally prevents the development of an infundibular outlet chamber.

Others have suggested that double-inlet left or right ventricle results from an abnormal shift of the atrioventricular canal septum by either growth failure or excessive rightward shift. Thus, some examples of straddling atrioventricular valve can be explained as a lesser degree of abnormal positioning of the atrioventricular canal relative to the ventricular chamber [1,7,15] (see Chapter 1).

Pathologic anatomy

An anatomico-clinical classification of univentricular hearts according to their atrioventricular connection is shown in Figure 39.2.

On the basis of a segmental approach to diagnosis [8,10], a pathologic study described 22 hearts with univentricular atrioventricular connection from a total of 196 congenital heart defects [16]; of the 22, six were single ventricles, six were unbalanced ventricles (four with dominant right ventricle and two with dominant left ventricle), five had classic tricuspid atresia, and five had mitral atresia.

Tricuspid atresia constitutes a typical anatomico-clinical entity among the hypoplastic right ventricles. Similarly, mitral atresia belongs to the hypoplastic left heart variants – although it may coexist with a large left ventricle. In both entities, the atrial septum is aligned normally to the interventricular septum at the level of the crux of the heart. This feature allows their echocardiographic characterization. Mitral and tricuspid atresia are not considered in this chapter (see Chapters 35 and 38). However, diagnostic and management approaches are shared by all these lesions.

Single ventricle, with double inlet or with common inlet

On the basis of a pathologic study of 60 hearts, single ventricle was classified by Van Praagh et al. [2] into four types (Figure 39.3):

• Type A, single morphologically left ventricle, characterized by numerous fine apical trabeculations, obliquely oriented. The papillary muscles originate from the ventricular free wall, into which two atrioventricular valves drain. An infundibular outlet chamber of superior position is separated from the ventricle by the bulboventricular septum and connected to it by the bulboventricular foramen.

• Type B, single morphologically right ventricle, characterized by thick, few, coarse, and straight apical trabeculations, with septal band and moderator band extending to the papillary muscle of the conus; the atria drain through one or two atrioventricular valves.

• Type C, common ventricle, with severe deficiency of the interventricular septum.

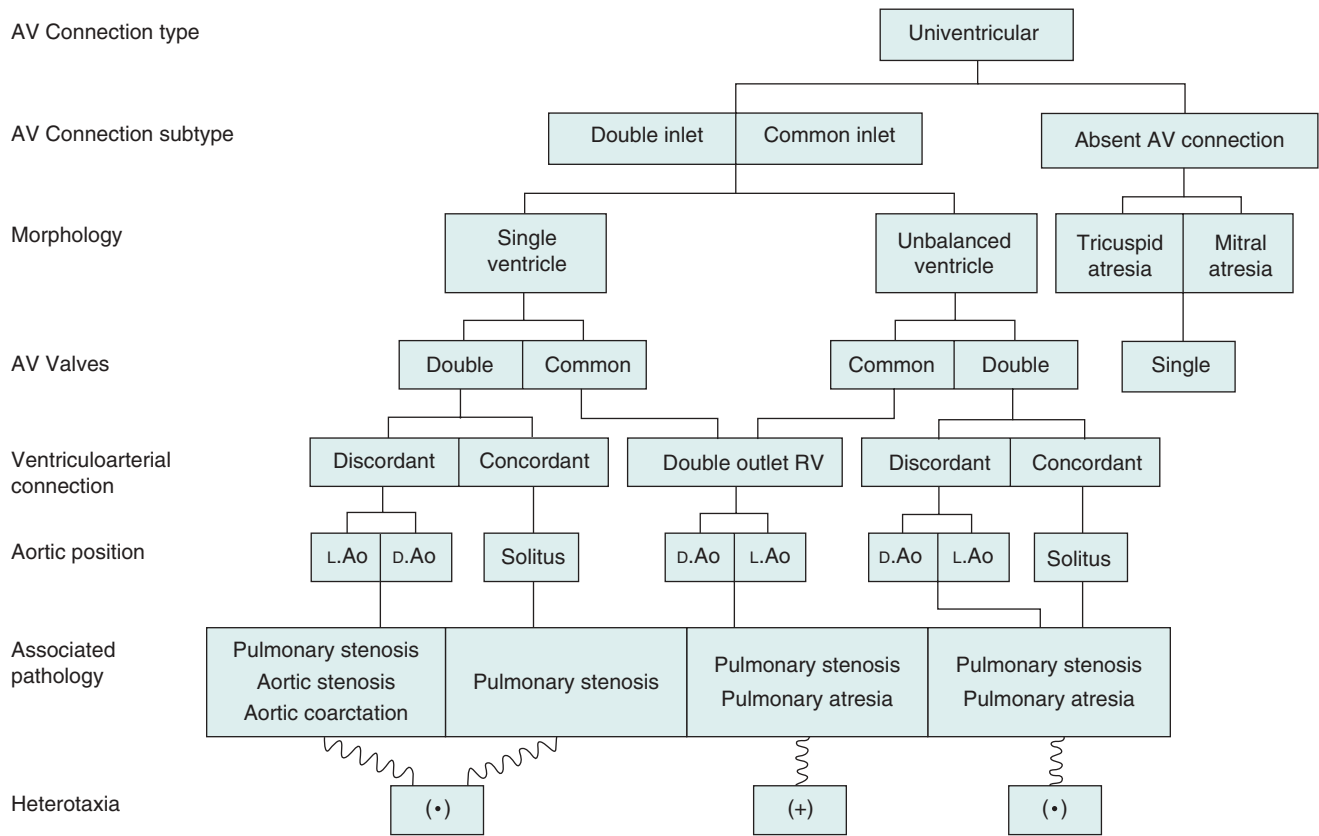
• Type D, undetermined ventricle (diagnosed as neither left nor right ventricle).


Figure 39.2 An anatomico-clinical classification of univentricular hearts according to their atrioventricular (AV) connection. Ao, aorta; RV, right ventricle.

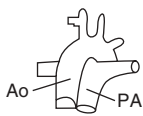
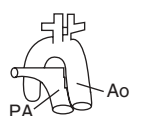
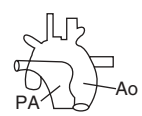
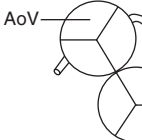
With the segmental approach, single ventricle was classified according to its arterial relationships: I, normal or solitus; II, d-aorta anterior; III, l-aorta anterior; IV, l-aorta posterior (inversus). In addition, the ventricular loop was differentiated as dextro (d) or levo (l), according to the ventricular situs. The atrioventricular connections, the ventriculoarterial relationships (transposition, double outlet, or single outlet), and any obstruction at the pulmonary or aortic level were also determined.

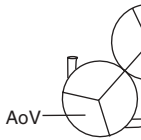
The original type C [2] is not currently considered a form of single ventricle because of having two well-developed ventricles with absent or extremely hypoplastic interventricular septum [13]. Type D is considered to be a single right ventricle not adequately identified [13].

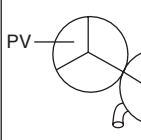
Single left ventricle


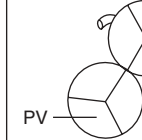


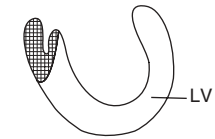


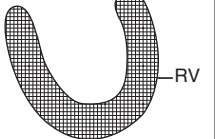


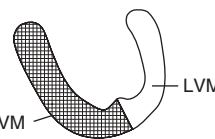


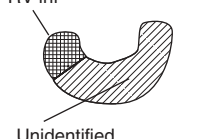


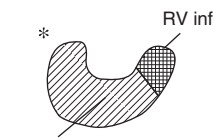


Single left ventricle (Figure 39.4) accounts for 80% of single ventricles [2,13,17], 90% of which have an infundibular outlet chamber and discordant ventriculoarterial connections (transposition). Ventricular l-loop with l-transposition and left outlet chamber occurs in 55% of patients; ventricular d-loop with d-transposition and right-sided infundibular outlet chamber is less common (35%) (Figure 39.4a). The remaining 10% have concordant ventriculoarterial connection










with right-sided infundibular outlet chamber and normally related great arteries (Holmes heart [18]).

The bulboventricular foramen is restrictive in 40% of the patients with discordant ventriculoarterial connection, causing subaortic stenosis, and in 90% of those with concordant ventriculoarterial connections (Holmes heart), causing subpulmonary stenosis. Coarctation of the aorta is associated in 15% of the patients with type IA and coexists with subaortic stenosis. Pulmonary stenosis or atresia occurs in 40% of patients.

There are usually two atrioventricular valves, right and left sided. The valve in contact with the bulboventricular septum is anatomically a tricuspid valve, and that related to the free wall of the ventricle without attachments to the septum is anatomically a mitral valve. Fibrous continuity commonly exists between the atrioventricular valves and the posterior semilunar valve. The atrioventricular valves appear "normal" in 70% of the patients but can be dysplastic with significant regurgitation (15%), more frequently of the left-sided valve. In 15% of patients, the atrioventricular valves are stenotic or even imperforate, particularly the right one.

When the infundibular outlet chamber is left sided and the ventriculoarterial connection is discordant (type IA III), the left coronary artery is usually dominant [17]. Close to its

origin in the posterior and leftward aortic cusp, the left coronary gives origin to a left delimiting artery that outlines the left bulboventricular septal groove. The right coronary originates in the right aortic sinus and runs in the right atrioventricular groove, giving origin to the right delimiting artery and two to six parallel delimiting arteries that cross the anterior surface of the heart, at the site of ventriculotomy for a ventricular septation procedure. When the infundibular chamber is right-sided and the ventriculoarterial connection is concordant, the delimiting arteries also course around the hypoplastic infundibular chamber.

In double-inlet single ventricle, the conduction system is characterized by an accessory atrioventricular anterolateral node [19,20] localized in the floor of the right atrium, at the acute anterolateral margin of the right atrioventricular ring. Through a nonbranching long bundle, it penetrates the ring, reaches the right parietal wall of the ventricle, and passes towards the rudimentary outlet chamber, following its right edge. If the infundibular outlet chamber is left sided, the bundle crosses the outflow tract of the main chamber

anteriorly towards the outlet chamber, immediately anterior and in proximity to the ring of the posterior great artery. If the outlet chamber is right sided, it crosses at the inferior and right edge of the bulboventricular foramen (Figure 39.5).

The location of the sinoatrial node depends on the atrial situs, which is solitus in most patients, rarely ambiguous, and inversus in 1% [21].

Single right ventricle

A single right ventricle is present in 20% of patients with single ventricles [2,13,22]. This includes examples of double-outlet single right ventricle with or without subaortic or bilateral conus, with anterior aorta (subaortic conus) or side-by-side great vessels.

More than 90% of the patients have associated pulmonary stenosis or atresia. Among other associated anomalies are common atrioventricular valve, ambiguous atrial situs [23,24], ostium primum atrial septal defect or common atrium, double-outlet right ventricle, anomalies of systemic venous return (interrupted inferior vena cava with azygos

continuation in patients with polysplenia), inferior vena cava ipsilateral to the descending aorta (in patients with asplenia), double superior venae cavae, unroofed coronary sinus, and anomalous pulmonary venous connections of the extracardiac variety (asplenia) or at cardiac level (polysplenia) (see Figure 39.2) [24].

Unbalanced ventricles

We exclude in this chapter the overriding atrioventricular valves, when the overriding into the contralateral ventricle is <50% of an atrioventricular valve or <75% of a common atrioventricular valve [25], as these are considered as biventricular hearts. An unbalanced ventricle with either a dominant left ventricle [5](IIA) or a dominant right ventricle (IIB) (see Figures 39.1, 39.2, and 39.4) differs from a single ventricle [2,5] in that it has two ventricular inlet portions [26], resulting in an unbalanced biventricular heart, but with a univentricular atrioventricular connection. These are regarded as univentricular hearts. One ventricle is hypoplastic or secondary, and the other is dominant or major. There can be two atrioventricular valves, a common atrioventricular valve [27], or a single patent valve with an imperforate second atrioventricular valve, aligned to both ventricles, although predominantly to the dominant one.

Malalignment between the interventricular septum and the atrial septum, with an abnormal atrioventricular septal angle of 30–90° (normal 10°), has been described [28].

Among patients with unbalanced ventricles, 60% [5] have an unbalanced common atrioventricular valve [11] with either a dominant right ventricle (type IIB, 71%; see Figure 39.4b) or, less frequently, a dominant left ventricle (type IIA, 29%) [29]. They are commonly associated with heterotaxia, often asplenia syndrome, and a large ostium primum atrial septal defect or a common atrium [23,24], and other associated anomalies such as double-outlet right ventricle and pulmonary stenosis or atresia.

About 30% of patients with unbalanced ventricles have a dominant left ventricle (type IIA) with a conoventricular septal defect extending into the inlet septum. The atrioventricular valves are at the same level [5] with overriding of >50% of the tricuspid valve and insertion into an anomalous papillary muscle from the free wall of the left ventricle (Figure 39.6). The remaining 5–10% have a dominant right ventricle (type IIB) with overriding and straddling of the anterosuperior portion of the anterior leaflet of the mitral valve. The anterior mitral valve leaflet, commonly with a cleft, inserts on the anterior papillary muscle of the right ventricle through an anterior ventricular septal defect secondary to malalignment of the conal and anterior muscular septum.

When there are two atrioventricular valves, the ventriculo-arterial connection is discordant in 70% of patients [26] and occasionally associated with superoinferior ventricles. Double-outlet right ventricle occurs in a few patients. Rarely, the

(a)   Minimal

(b)   Moderate

(c)   Extreme
Figure 39.6 Illustration of the three grades of straddling of one atrioventricular valve. (Reproduced from Barra Rossi *et al.*, *Rev Lat Cardiol Cir Cardiovasc Infant* 1986;**3**:171.)

ventriculoarterial connection is concordant. In an unbalanced ventricle, the atrioventricular valves are commonly abnormal [5]. There may be a dysplastic tricuspid valve with insufficiency, a cleft or stenotic mitral valve, or a common atrioventricular valve. The last is common in patients with heterotaxia and unbalanced common atrioventricular valve into a dominant right ventricle [24–26,28,29].

Heterotaxia is common in patients with unbalanced ventricles (60%) and rare in patients with single ventricle (10%). When present, more commonly it is associated with a single right ventricle [5,24,29].

Hemodynamics

Hemodynamic patterns in patients with a univentricular heart [30–34] depend mostly on the presence or absence of obstruction to outflow into the aorta or pulmonary artery, the morphology and function of the single or dominant

ventricle, the type of atrioventricular connection, and the function of the atrioventricular valves.

Pulmonary blood flow

Patients without pulmonary stenosis [34] have increased pulmonary blood flow with a high Qp/Qs (≥3) and signs of congestive heart failure that appear during the first weeks of life. Systemic oxygen saturations approximate 90% without significant clinical cyanosis. When Qp/Qs approaches 2, they may present with mild cyanosis, with oxygen saturation approaching the mid-80s. These patients are generally well and compensated hemodynamically. Patients with moderate pulmonary stenosis and Qp/Qs approaching 1 have cyanosis with oxygen saturations of ~75–80%. When there is severe pulmonary stenosis and Qp/Qs is <1, their cyanosis may become extreme with saturations of 60–70% or less (Figures 39.7 and 39.8) Patients with coexisting pulmonary atresia present in the newborn period when the patent ductus closes spontaneously, as in other ductus-dependent lesions.

Ventricular and atrioventricular valve morphology

Although the effect of anatomy on function is not always predictable, when the single or dominant ventricle is anatomically a left ventricle, ventricular dysfunction is less common and tends to develop later. When the single or dominant ventricle is anatomically a right ventricle, however, it may perform adequately initially but with volume and pressure overload is more prone to evolve into a dilated myopathy because of mismatch between the ventricular mass and volume. This occurs commonly with progressive atrioventricular valve regurgitation. The clinical scenario resembles that in other patients with a systemic right ventricle, such as those with corrected transposition or transposition of the great arteries after the Senning or Mustard procedure. Abnormal and dysplastic atrioventricular valves can also be regurgitant, even without pressure or volume overload, and this may trigger early ventricular dysfunction.

Rarely, a stenotic or imperforate atrioventricular valve is associated with a restrictive atrial septal defect, causing pulmonary edema early in life and requiring emergency intervention to allow left atrial decompression and adequate mixing.

Systemic blood flow

In single left ventricle, obstruction to systemic blood flow is typically due to subaortic obstruction as a consequence of a progressive and relative decrease in the size of the bulboventricular foramen [31]. It can also occur acutely after a sudden decrease in preload and ventricular volume when a partial right-sided heart bypass operation is performed (bidirectional Glenn), in patients after pulmonary artery banding [32,35,36], or when preload normalizes in patients after total right-sided heart bypass operation [36]. Associated arch obstruction in patients with subaortic stenosis can be
Figure 39.7 Hemodynamic graph indicating relationship between systemic (*Q*s) and pulmonary (*Q*p) blood flow in a hypothetical patient with single ventricle after initial neonatal palliation with an arterial oxygen saturation of 75%. In the absence of lung disease, a balanced *Q*p/*Q*s of 1 is likely present. AO, aortic oxygen saturation; MV, mixed venous or systemic venous oxygen saturation; PA, pulmonary artery oxygen saturation; PV, pulmonary vein oxygen saturation.

severe. If there is severe arch hypoplasia, patients are ductus dependent and present similarly to neonates with hypoplastic left heart syndrome.

Natural history

Most patients with single ventricle develop symptoms during the first weeks or months of life. Those with increased pulmonary blood flow show signs of congestive heart failure and pulmonary hypertension, whereas those with decreased pulmonary blood flow and pulmonary stenosis present with

cyanosis. Without treatment by operation, death occurs in infancy in 64% of these patients; more than half die during the neonatal period [37].

Patients with increased pulmonary blood flow [33] develop permanent pulmonary hypertensive vascular changes after the first year of life. This leads to a decrease in the *Q*p/*Q*s ratio and congestive heart failure, followed by progressive chronic cyanosis.

Among adult survivors without surgical intervention, 75% have pulmonary stenosis of moderate degree, and the remaining 25% have pulmonary hypertension with various levels of hypertensive pulmonary arteriopathy [38,39]. Most have congestive heart failure and are classified as New York Heart Association class II. They typically have a single left ventricle with two well-functioning atrioventricular valves, situs solitus, nonrestrictive subaortic bulboventricular foramen, and sinus rhythm. Complete heart block develops in 20% of these patients, requiring a pacemaker [39].

Progressive regurgitation of the atrioventricular valves is poorly tolerated in patients with univentricular heart, especially with a single or dominant right ventricle [35].

Single ventricle can be classified into types A and C, according to the presence or absence of a rudimentary outlet chamber [33,34]. Patients with type C have a poor prognosis, with 50% mortality by 4 years after diagnosis, compared with a 50% mortality at 14 years after diagnosis for patients with type A. The cause of death in patients with type A can be congestive heart failure, arrhythmia, or sudden death [39]. Patients with unbalanced ventricles have an even worse prognosis owing to the frequent association with heterotaxia [25], higher incidence and severity of their pulmonary stenosis, dominant right ventricle, and regurgitation of the atrioventricular valves that can lead to ventricular dysfunction [35].

History and physical examination

Pulmonary stenosis and limited pulmonary blood flow

Pulmonary stenosis occurs in 60% of the patients, who develop clinical manifestations similar to those of patients with tetralogy of Fallot with or without pulmonary atresia. Rarely, the pulmonary stenosis is mild, and the patient may be acyanotic.

In these patients, cyanosis tends to be moderate to severe; clubbing is evident in older patients. Patients rarely have thoracic deformities during infancy, but may later manifest scoliosis. The precordial activity is commonly normal, but patients with coexisting l-transposition may have a left superior parasternal lift. The peripheral pulses are usually normal, unless there is a coexisting coarctation of the aorta. There is a systolic ejection murmur, the intensity and duration of which correlate directly with the amount of pulmonary blood flow and inversely with the severity of the
Figure 39.9 Electrocardiograms in patients with single left ventricle without pulmonary stenosis. (a) Type IA III, 28 days old, with QRS axis of 105° and counterclockwise loop, QR in V_4R, and no q waves in left precordial leads. (b) Type IA II, 45 days old, with QRS axis of 45°, rS in V_1, and R in V_6.

pulmonary stenosis and level of cyanosis. The absence of a systolic ejection murmur suggests severe pulmonary stenosis or atresia. A continuous murmur from a patent ductus arteriosus or a collateral may be heard in the pulmonary areas. The second heart sound is commonly loud, single (aortic component), and maximal at the upper left sternal border, particularly in patients with l-transposition.

Without pulmonary stenosis and increased pulmonary blood flow

About 40% of patients present similarly to those with an unrestrictive ventricular septal defect, increased pulmonary blood flow, and pulmonary hypertension. These patients develop congestive heart failure early in life with dyspnea, retractions, and poor weight gain. Cyanosis in infancy is minimal or absent. They more commonly have thoracic deformities and a hyperdynamic precordium. The second heart sound is loud and single. An S_3 gallop and a mitral mid-diastolic rumble can be heard in the apex. When a systolic thrill appears at the base and suprasternal notch, subaortic stenosis secondary to a restrictive bulboventricular foramen in types A III and A II should be suspected. On auscultation in such patients, there is a harsh, loud systolic ejection murmur at the base and midprecordium with radiation to the neck. A soft systolic ejection murmur in the midprecordium with radiation to the axilla and the back represents relative pulmonary stenosis. With coarctation of the aorta, the femoral pulses are diminished or absent.

More severe pulmonary edema and congestion than are accountable for by the amount of pulmonary blood flow or ventricular dysfunction suggest either severe stenosis or an imperforate left atrioventricular valve with restrictive atrial septal defect or anomalous pulmonary venous connections with obstruction, particularly in patients with asplenia.

Electrocardiography

Patients with single left ventricle, leftward bulboventricular outlet chamber, and ventricular l-loop (type IA III) have an inverted initial activation with q waves in the right precordial leads (qRS or qR in V_1) and no q waves in the left precordial leads (RS in V_6). Their QRS axis in the frontal plane is inferior and rightward, simulating left posterior hemiblock with clockwise loop [21] and qR in II, III, and aVF (Figure 39.9a). With time, complete atrioventricular block may develop [33]. Patients with single left ventricle with rightward outflow chamber and ventricular d-loop (types IA II or IA I) [40–42] have an electrocardiogram similar to tricuspid atresia, although generally without left anterior hemiblock. The precordial leads show an rS in V_1 and tall R waves in the left precordial leads consistent with left ventricular hypertrophy, with or without septal depolarization q waves (qR or R in V_6, due to abnormal initial activation directed anteriorly and to the left) (Figure 39.9b). In the frontal plane, the QRS axis is often in the left inferior quadrant.

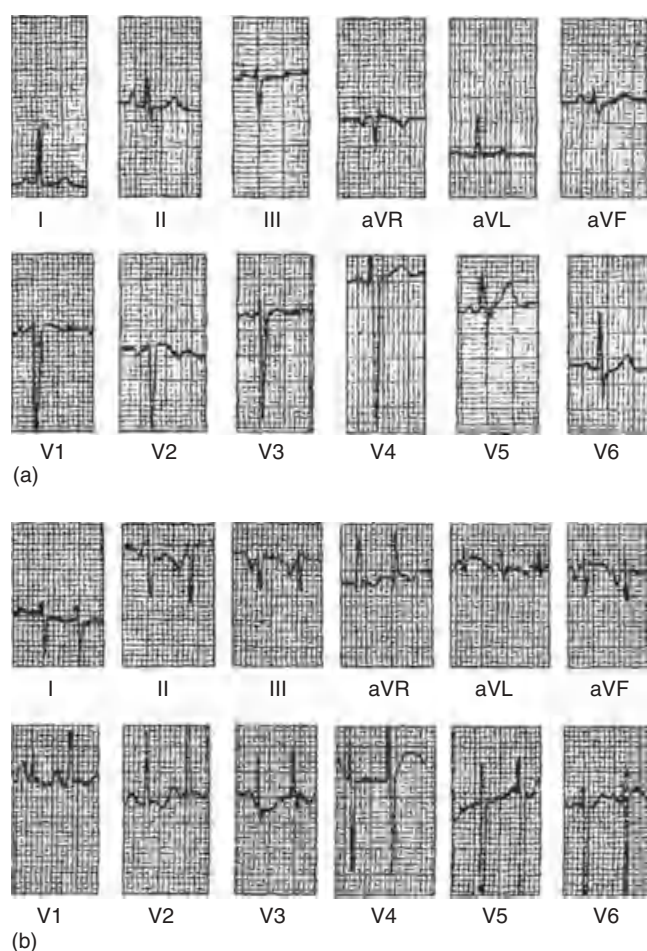
Patients with single right ventricle (type IB) have signs of right ventricular hypertrophy (R, qR, or rsR'). The QRS axis is superior in the frontal plane with a counterclockwise loop. Rarely, the electrocardiogram may show rS waves in all the precordial leads. Patients with unbalanced ventricles commonly have a left anterior hemiblock pattern with signs of left ventricular hypertrophy when the left ventricle is dominant (type IIA). If there is a dominant right ventricle (IIB), the electrocardiogram most commonly shows right ventricular hypertrophy (Figure 39.10).


Figure 39.10 Electrocardiograms from patients with unbalanced ventricles. (a) Type IIA with pulmonary stenosis: left anterior hemiblock and absent right ventricular forces in a 2-year-old patient with a double-inlet dominant left ventricle. (b) Type IIB with pulmonary stenosis: low atrial rhythm, left anterior hemiblock, and right ventricular hypertrophy in a 1-month-old patient with polysplenia with interrupted inferior vena cava and common atrioventricular canal with a dominant right ventricle.

Patients with heterotaxia and asplenia syndrome or dextroisomerism can have two sinus nodes, and those with polysplenia or levoisomerism may lack a sinus node and have a low atrial rhythm. However, the sinus node coincides with the anatomic atrial situs in most patients with asplenia [29]. Congenital complete atrioventricular block in fetal life is associated with levoisomerism and a poor prognosis [43].

Imaging studies

Chest radiography

Patients can be characterized by chest radiography [4,44–46] as follows:

- patients with pulmonary stenosis, normal cardiac size, and diminished pulmonary vascular markings; or
- patients without pulmonary stenosis, severe cardiomegaly (cardiothoracic ratio >65%), and increased pulmonary arterial markings due to high flow or pulmonary venous congestion (pulmonary venocapillary hypertension secondary to congestive heart failure).

An atypical chest X-ray finding may be the first indication of a complex cardiac anomaly, such as a univentricular heart, in a patient who otherwise shows clinical signs of an unrestrictive ventricular septal defect or tetralogy of Fallot (Figure 39.11).

Patients with single ventricle typically have a cardiac silhouette with abnormal superior mediastinal densities, suggesting abnormal position and orientation of the great vessels [4,44–46]. Patients with normally related great arteries often show a "triad of densities" in the superior mediastinum which include in the frontal view ascending aorta, transverse aortic arch, proximal descending aorta, and pulmonary trunk [46]. The lack of an ascending aorta on the right and its presence on the left can indicate l-transposition (see Figure 39.11). A narrow superior mediastinum is commonly seen with d-transposition. The left cardiac border can appear abbreviated because of a bulge in the upper third from an inverted ventricular outlet chamber. A notch indicates the edge of the rudimentary outflow chamber located leftward and superiorly [46] A left anterior oblique projection demonstrating a hypoplastic right ventricle and enlargement of the left ventricle, supports a diagnosis of single left ventricle with outflow chamber.

An unbalanced complete atrioventricular canal can be suspected on chest radiography in patients with associated abdominal and cardiac malpositions, such as dextrocardia or mesocardia, suggesting heterotaxia. Dextroisomerism is more common in these patients and an unbalanced canal with dominant right ventricle with absent or hypoplastic left ventricle and double-outlet right ventricle is usually found.

Progressive cardiomegaly which develops in an older patient suggests the onset of dilated myopathy. Signs of pulmonary venous hypertension out of proportion to the amount of pulmonary blood flow can be observed with regurgitation or stenosis of the left atrioventricular valve with a restrictive atrial septal defect or anomalous pulmonary venous connection with obstruction, most likely in patients with asplenia.

Cardiovascular magnetic resonance (CMR)

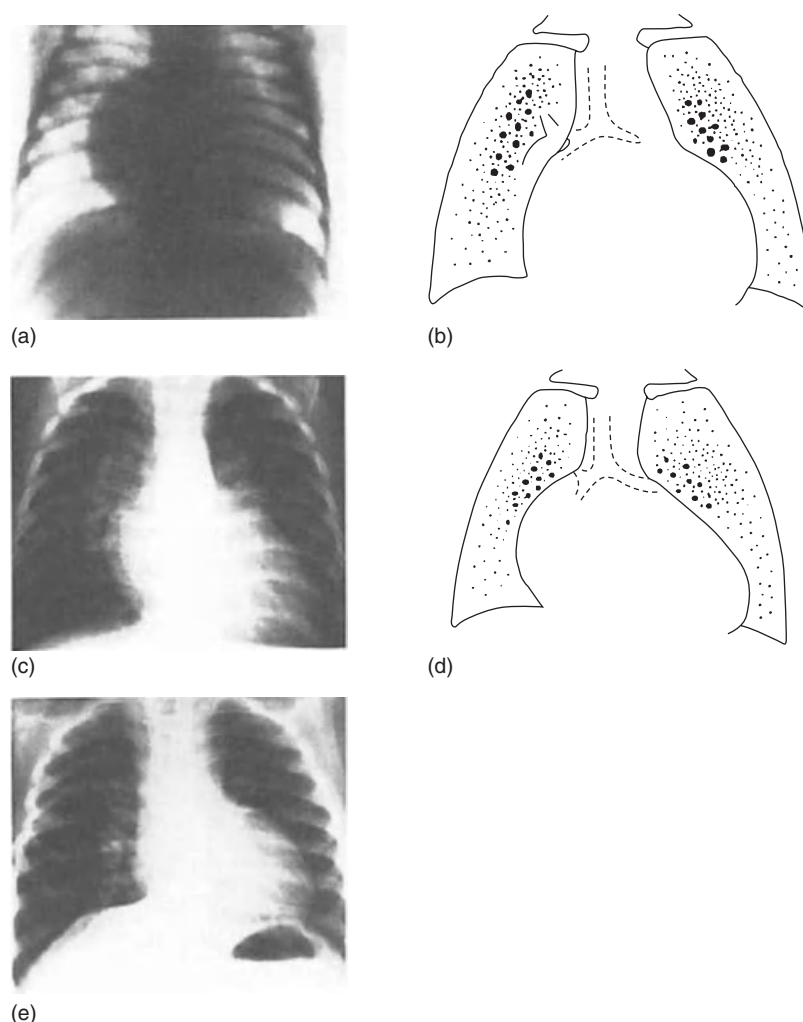
CMR has become a powerful diagnostic tool [47], complementary to echocardiography, and it can replace diagnostic cardiac catheterization. It provides anatomic and functional information in addition to tissue characterization. It is considered the gold standard for evaluating ventricular volumes, mass, and ejection fraction [48,49]. The measurements can be made without assuming a certain geometric ventricular shape, which is highly advantageous


Figure 39.11 Chest radiographs and schematic X-ray drawings in patients with single ventricle. (a, b) Newborn with no pulmonary stenosis and congestive heart failure. (c, d) Infant with no pulmonary stenosis and congestive heart failure, d-transposition. (e) A 3-year-old child with pulmonary stenosis and l-transposition.

in patients with single ventricle as often ventricular shape is atypical. A limitation is that CMR cannot quantify pulmonary artery pressure or ventricular end diastolic pressure. In addition, particularly in young children, sedation or anesthesia is needed.

The protocol includes dark blood sequences (T1 and T2 weighted), bright blood sequences (cine-CMR or cine-loop), phase-contrast velocity mapping, gadolinium-enhanced 3D magnetic resonance volumetric angiography, 3D reconstruction (3D contrast MR angiography), and delayed enhancement (late gadolinium-enhanced CMR) for evaluating myocardial viability. Myocardial wall mechanics can be evaluated using tagging techniques [50].

The CMR evaluation in patients with single ventricle can be complex given the highly variable anatomic substrate (Figure 39.12). Prior to an operation, CMR can identify patient risk factors. Although many centers continue to perform elective cardiac catheterization in all patients before bidirectional Glenn and Fontan procedure, some only study

invasively those with risk factors [51] which have been identified by CMR.

In preparation for upcoming surgical staging, CMR allows the evaluation of chronic lung disease, heterotaxy, atrioventricular valve regurgitation, ventricular dysfunction, aortic regurgitation, pulmonary artery or vein stenosis or distortion, and systemic venous anomalies, all of which are considered high risk factors. Thus, CMR may indicate the need for a modified surgical procedure or an interventional cardiac catheterization [52]. The anatomic definition by CMR (Figure 39.13) confirms the underlying diagnosis, following the segmental analysis [52], especially focusing on the pulmonary vasculature to rule out hypoplasia, stenosis, compression, and distortion. The functional evaluation allows determination of ventricular volume, mass, and ejection fraction (Figure 39.14).

The development of veno–veno collaterals can be identified and systemic venous flow can be studied (Figures 39.15 and 39.16).
(a)
(b)

Figure 39.12 (a) Transverse image obtained by magnetic resonance in a patient with unbalanced ventricles (IIB) with a common atrioventricular canal and right ventricular dominance of >75% of the common atrioventricular valve aligned with the right ventricle. Note the hypoplastic posterior left ventricle. (b) Cine magnetic resonance imaging in a coronal plane of a total cavopulmonary anastomosis through a right-sided intra-atrial lateral tunnel showing widely patent anastomoses. Note direct anastomosis of the superior vena cava (SVC) to the right pulmonary artery (APD) and anastomosis of the inferior vena cava (IVC) to the right pulmonary artery through the intra-atrial tunnel (TUNNEL).

The position of the aorta or neoaorta relative to the sternum can be demonstrated, which is helpful prior to a repeat sternotomy (Figure 39.17).

Figure 39.13 Three-dimensional contrast MR angiography demonstrates interruption of the inferior vena cava with azygos continuation following bidirectional Glenn procedure or Kawashima. In a posterior view two arches are demonstrated (aortic and azygos).

Pleural or pericardial effusions can be quantified. Flow studies using phase-contrast velocity mapping allow one to evaluate flow dynamics in arteries and veins [53] and determine the relationship between both right and left pulmonary blood flow and also the Qp/Qs.

Following total right heart bypass or modified Fontan procedure, a similar protocol to that used post-Glenn is selected, incorporating some additional sequences and cuts [54].

In patients with an atriopulmonary anastomosis [55], the right atrial dimensions are assessed in addition to the usual pattern of slow flow (smoke-like) within the chamber (Figure 39.18), the presence of any thrombus (Figure 39.19), and anatomic features in addition to flow dynamics within the systemic veins and pulmonary arteries [56] and veins (Figures 39.20 and 39.21). Similarly, flow patterns and anatomy are addressed in patients with lateral tunnel Fontan or extracardiac conduits (Figures 39.22 and 39.23) [57,58]. A fenestration can be visualized and sized.

In assessing the distribution of pulmonary blood flow, lung scintigraphy has been traditionally considered the gold standard. However, its value in patients with single ventricle following surgical palliation can be limited, as the results are highly dependent on the site of injection (upper or lower extremity) and streaming flow patterns. Such limitations can be overcome with CMR, which allows determination of the relationship of right versus left pulmonary blood flow based on flow velocities. In addition, CMR allows quantification of aortopulmonary collateral flow via plane phase-contrast velocity mapping [59].

It is important to address ventricular function by CMR by determining myocardial fibrosis by delayed enhancement,
Figure 39.14 MR angiography in patient with single left ventricle after systemic to pulmonary artery shunt. Short-axis cuts from the ventricular apex to the base allow evaluation of ventricular volumes, ejection fraction, and ventricular mass.

as this information cannot be provided by any other diagnostic test with equivalent accuracy. CMR with the PAMM (spatial modulation of magnetization) technique [60,61] has allowed the study of right ventricular regional wall motion and strain analysis in patients at different stages of single ventricle surgical palliation. With this method, it is possible to compare ventricular mechanics in patients with a single ventricle with those in patients with a systemic right ventricle and to study ventriculo-ventricular interactions. In both groups, there were abnormalities in regional myocardial strain, twisting motion, and regional radial motion. In patients with a univentricular right heart, the lack of

ventriculo-ventricular interaction determined by inferior wall paradoxical systolic wall motion is different from that observed in patients with a Senning operation, in whom paradoxical septal motion occurs.

The abnormalities in ventricular mechanics and geometry secondary to stress, strain, and regional twist in univentricular hearts with a right ventricular anatomy are similar to those in hearts with a left ventricular anatomy [57]. Such changes in ventricular mechanics generate a regional increase in oxygen consumption, which may play a role in the development of ventricular dysfunction.

(d)
Figure 39.19 Single left ventricle, pulmonary atresia status post-atriopulmonary anastomosis. Spin-echo dark blood axial cut (a), with hyperintense signal in the right atrium (RA), due to slow flow demonstrates severe right atrial dilation with a round image consistent with intracavitary thrombus (T). Coronal cut spin-echo (b) with filling defect due to thrombus surrounded by slow flow with hyperintense signal. Coronal cut MR angiogram (c) shows ovoid thrombus (50 × 60 mm) surrounded by white blood. (d) Single left ventricle status post-extracardiac conduit. 3D contrast MR angiography demonstrates in coronal partition filling defect at main pulmonary artery stump consistent with thrombus (20 × 17.5 mm) which does not enhance with gadolinium (arrow). T, thrombus; *, coronary sinus.

Echocardiography

Two-dimensional echocardiography allows sequential determination of thoracoabdominal situs, atrioventricular and ventriculoarterial alignments and connections, morphology and function of the single ventricle or dominant ventricle and atrioventricular valves, position of the infundibular outlet chamber and size of the bulboventricular foramen, and associated cardiac defects.

The thoracoabdominal situs is determined from a subxiphoid window, in a transverse view at the level of the twelfth thoracic vertebral space, by analyzing the location of the inferior vena cava and the descending aorta relative to the spine. A second superior vena cava and communicating
Figure 39.20 Following atriopulmonary anastomosis, a giant right atrium is documented with compression of the right upper pulmonary vein (RSPV) (arrow).

Figure 39.22 3D contrast MR angiographic reconstruction with surface rendering in a patient with single left ventricle with a history of bilateral bidirectional Glenn procedures followed by Fontan completion demonstrates stenosis at the distal anastomosis of the extracardiac conduit.

Figure 39.21 Inferior vena cava flow curves showing a biphasic pattern with a large systolic (S) and a small early diastolic peak (D), and retrograde flow in late diastole (A).

vein can be investigated from a high parasternal view. From an apical four-chamber view, scanning from posterior to anterior, the atrioventricular connection is demonstrated [5,62–66]. Patients with a single ventricle can have either two atrioventricular valves positioned at the same level (Figure 39.24) [5] or, rarely, one common atrioventricular valve aligned to the only ventricular chamber. In a short-axis

view, the morphologic aspects of each valve can be analyzed, including the number of leaflets and their attachments and relationship to each other (Figure 39.24). In addition, the position of the infundibular outlet chamber can be determined; it is always superior in patients with single left ventricle (Figure 39.24). The morphologic character of the ventricle can also be diagnosed by echocardiography, by finding either left ventricular thin trabeculations or right ventricular thick trabeculations and moderator band.

From parasternal long-axis, subxiphoid long-axis, and oblique views, the ventriculoarterial relationship is identified. Patients with single left ventricle most commonly have a posterior pulmonary artery and an anterior aorta arising from the infundibular outlet chamber (Figure 39.24). In patients with a Holmes heart, the pulmonary artery is anterior and aligned to the infundibular outlet chamber. The aorta is posterior, aligned to the single left ventricle, and has fibrous continuity with the atrioventricular valve.

From these projections, the size of the bulboventricular foramen is determined [64] by the ellipse formula, $\pi D_1 D_2/4\,\mathrm{m}^{-2}$, where D_1 and D_2 are the major and minor diameters of the ellipse. A measurement of $<2\,\mathrm{cm}^2\ \mathrm{m}^{-2}$ is consistent with a restrictive bulboventricular foramen. Although the gradient may be underestimated by continuous-wave Doppler study, color Doppler examination may localize the site of turbulent flow and the highest gradient. If the Doppler gradient is $>1.5\,\mathrm{m\ s}^{-1}$, the bulboventricular foramen is considered to be restrictive [64].

(a)

(b)
Figure 39.23 Anterior (a) and posterior (b) view of 3D contrast MR angiographic reconstruction with surface rendering in a patient with a history of atriopulmonary anastomosis. A markedly dilated right atrium is demonstrated with normal pulmonary artery branching pattern and development.

The morphologic features of the ventricular septal defect in patients with unbalanced ventricles and dominant left ventricle (type IIA) can be determined from an apical four-chamber view. Conoventricular septal defects extend to the inlet septum when there is additional malalignment of the ventricular septum to the atrial septum. In such patients, the atrioventricular valve and >50% of the second one or >75% of a common atrioventricular valve are aligned to the left ventricle (Figure 39.25). Patients with dominant right ventricle (type IIB) and common atrioventricular valve also have a primum atrial septal defect.

An unbalanced common atrioventricular canal is best diagnosed from an apical four-chamber view (Figure 39.25). From a parasternal short-axis view, a small component of the atrioventricular valve ring is identified aligned to a hypoplastic left ventricle. A double-outlet right ventricle can be diagnosed from a subxiphoid projection.

The maximal instantaneous gradients at aortic, subaortic, pulmonary, and subpulmonary levels are examined with continuous-wave Doppler study. The function of the atrioventricular valves is examined by color Doppler study.

The single ventricle differs from the normal left ventricle that resembles an ellipse. Hence it is not amenable to geometric assumptions and, therefore, functional assessment has been only qualitative and subjective. The myocardial performance index (MPI or Tei index) [67] is a Doppler-derived index of ventricular function that is independent of geometric constraint. It has been used for evaluating patients with single ventricle [68,69].

However, accurate assessment of ventricular function in single ventricle must rely on three-dimensional reconstruction, which can be done using two orthogonal views of the subcostal sagittal and coronal planes. This technique has been used to evaluate effects of resynchronization therapy with multisite pacing in univentricular hearts [70].

Transesophageal echocardiography

This is particularly indicated in patients with poor echocardiographic windows, or as part of the intraoperative and perioperative assessment Patients with single ventricle particularly benefit from this diagnostic tool when there is a need to rule out intracardiac thrombus prior to cardioversion or following a stroke or transient ischemic attack.

A high horizontal plane allows anatomic determination of the atrial appendages and atrioventricular connections. A transgastric short-axis view allows verification of the atrioventricular connections and gradients across the ventricular outflow tracts.

Catheterization and angiography

Diagnostic cardiac catheterization

Cardiac catheterization and angiography in patients with single ventricle [33,71–73] or unbalanced ventricles [74,75] provide anatomic and hemodynamic information

(a)

(b)

(c)
Figure 39.24 (a) Echocardiogram performed in a patient with {S,D,D} double-inlet left ventricle and d-malposed great arteries and subaortic infundibular outlet chamber. On apical four-chamber view, the two AV valves are demonstrated situated at the same level. (b) They can also be visualized opening "en-face" from subxyphoid view (*). (c) The anatomy of the bulboventricular foramen is demonstrated on subxyphoid view (arrow). There is a subaortic infundibular outlet chamber (*). LA, left atrium; LV, left ventricle; RA, right atrium.

necessary for management. Diagnostic anatomic data, which corroborate the results of noninvasive diagnostic tests, include the following:

1 Atrial situs.

2 Systemic venous connections (an additional superior vena cava, innominate vein, site of entry of the inferior vena cava and hepatic veins, interrupted inferior vena cava with azygos continuation).

3 Pulmonary venous connections.

4 Atrioventricular valves and connections [74]. These can be recognized by cineangiocardiography, through demonstration of anterograde flow through the atrioventricular valves during atrial injection or, more commonly, ventricular injection (unopacified blood). Valvar morphology can be determined by trapping of contrast material underneath the valve leaflet, by delineating the valve ring, or from the configuration of the closed valve after ventricular opacification or as a curved or lineal tangential defect if the valve is
Figure 39.25 In apical four-chamber view the echcocardiogram demonstrates unbalanced common atrioventricular canal with dominant right ventricle (RV) and a hypoplastic left ventricle (*).

stenotic. A large valve annulus suggests either single or common atrioventricular valve, whereas when it is small, a hypoplastic or stenotic valve is likely. The relationship of the atrioventricular valves to the semilunar valves and degree of development of the conal septum (mitral to aortic continuity rules out subaortic conus) are delineated by a ventriculogram. A gooseneck deformity on a left ventriculogram is diagnostic of an atrioventricular septal defect [74].

5 Morphologic aspects of the single or dominant ventricle, infundibular outlet chamber, and hypoplastic rudimentary ventricle. A left ventriculogram in four-chamber view demonstrates the absence of the posterior ventricular septum in single left ventricle (type IA) (Figure 39.26) or a malaligned interventricular posterior septum in unbalanced ventricles with a dominant left ventricle (type IIA) (Figure 39.27).

6 Pulmonary or systemic obstruction (restrictive bulboventricular foramen, stenotic pulmonary or aortic valve).

7 Ventriculoarterial alignments and connections.

8 Anatomy of the pulmonary arteries (size of central pulmonary arteries, Nakata index [75] and McGoon ratio [76], arborization abnormalities and branch pulmonary artery stenosis, washing out of contrast medium by competing flow from aortopulmonary collaterals, pulmonary transit time, and arteriovenous fistulas).

9 Aortic arch anatomy, branching abnormalities, and any aortopulmonary collaterals.

10 Ventricular function (ejection fraction) and ventricular geometry (mass/volume relationship).

After any surgical procedure, a diagnostic cardiac catheterization is performed to rule out sequelae from prior operations, including acquired pulmonary artery stenosis at the site of previous shunt or pulmonary artery banding, pulmonary arteriovenous fistulas in patients with partial right ventricular bypass (classic Glenn, bidirectional Glenn, or Kawashima

operation) [77], cavocaval or cavoportal [78] decompressing venous collaterals after partial right-sided heart bypass, sources of right-to-left shunt after a total right-sided heart bypass through fenestration, interatrial communications [79], and baffle leaks or left-to-right shunts by aortopulmonary collaterals [80].

Before a second- or third-stage palliation, a complete hemodynamic study is performed. To obtain accurate and complete data, two pressure transducers must be used to record the transpulmonary gradient by simultaneous recording of pulmonary artery and pulmonary venous, left atrial, or ventricular end-diastolic pressures. Ideally, oxygen consumption should be measured and the patient should be in stable hemodynamic condition, preferably well sedated but breathing spontaneously, with normal arterial pH to avoid a falsely elevated estimated pulmonary vascular resistance. Oversedation should be avoided, given that retention of CO_2 and secondary respiratory acidosis increase the pulmonary vascular resistance, and airway obstruction leads to significant variability in intracardiac pressures. With the difficulties in achieving perfect sedation in some age groups, many authorities favor the use of general anesthesia, selecting drugs that minimally affect cardiovascular performance and performing the hemodynamic measurements at the time when the patient is relatively lightly anesthetized. Two sets of hemodynamic data should be collected and be consistent. Because major management decisions depend on the hemodynamic data, these should be collected with the utmost precision and accuracy. As a result, pulmonary arterial pressure, pulmonary vascular resistance, Qp/Qs ratio, and functional data evaluating ventricular mechanics (ventricular end-diastolic pressure, preload, and afterload) will be determined and/or calculated. A pulmonary vascular resistance <3 mmHg l^{-1} min^{-1} m^{-2} is required for successful surgical staging (see discussion about hematocrit and viscosity in Chapter 10).

With advances in noninvasive imaging, particularly CMR, some have adopted the practice of not performing routine cardiac catheterizations before surgical staging in patients who have a benign clinical course and no risk factors identified on echocardiography and CMR [51]. This approach remains controversial, as CMR does not provide complete hemodynamic data, often requires anesthesia, and not all cardiac centers have the necessary congenital cardiac CMR expertise to address accurately all potential risk factors for surgical staging.

Interventional cardiac catheterization

Patients with a univentricular heart may require a transcatheter intervention early in their course and before the initial surgical procedure if they have a restrictive atrial septal defect and left atrial outlet atresia or stenosis. Transcatheter creation of a new atrial septal defect with septostomy and balloon septoplasty may decompress the left

atrium with significant improvement of hemodynamics, reduction in pulmonary venous congestion, and pulmonary vascular resistance. Patients with ductal-dependent lesions have been managed by stent placement in the ductus arteriosus [81]. This can be done to provide either an aortopulmonary shunt in patients with ductal-dependent pulmonary blood flow, or systemic blood flow in those with ductal-dependent systemic perfusion. Indeed, an accepted management option is to perform a *hybrid procedure* in patients with a single ventricle as an alternative to a Norwood procedure. Bilateral pulmonary artery banding and stent implantation in the patent ductus arteriosus are performed as a single procedure jointly by a surgeon and an interventional cardiologist. Some centers have pioneered this approach [81] and use it as a first-line therapy for neonates s with hypoplastic left heart syndrome and variants. Others use this approach only in high-risk patients (those who are born prematurely, with multiple congenital anomalies, significant ventricular dysfunction, or atrioventricular valve regurgitation, etc.).

Patients with severe pulmonary stenosis or atresia may have pulmonary arteries that are inadequate to allow future second- and third-stage surgical palliation. Transcatheter pulmonary artery rehabilitation through serial balloon dilatation procedures may be the only option for these patients to become candidates for either staged single ventricle palliation or heart transplantation.

If a source of potentially detrimental postoperative right-to-left or left-to-right shunting is identified during cardiac catheterization, transcatheter closure is indicated [82] to avoid excessive cyanosis or paradoxical embolus. Examples are a small, persistent, left superior vena cava draining to the coronary sinus (in the absence of coronary sinus ostia stenosis or atresia), other potential decompressing venous connections (particularly in patients with heterotaxia), and significant aortopulmonary collaterals.

Following the various stages of surgical intervention for single ventricle, interventional cardiac catheterization plays a key role in optimizing hemodynamics, particularly in symptomatic patients. Many abnormalities are amenable to transcatheter treatment (Table 39.1). Sometimes, emergency cardiac catheterization in the immediate postoperative period is needed in a severely compromised patient to create a new or augment a baffle fenestration [83], close a baffle leak, or dilate or stent a stenotic vessel.

Interventional catheterizations are also performed later postoperatively. Catheter interventions may be on either the primary defect or on a coexisting cardiac abnormality. Examples are coil embolization of a small, persistent, left superior vena cava or aortopulmonary collaterals [80,82], balloon dilatation of peripheral pulmonary artery stenosis, and rarely pulmonary valvotomy or balloon dilatation of a native coarctation in selected high-risk surgical patients. Interventions may be performed on postoperative

Table 39.1 "Abnormalities" in the total right-sided heart bypass circulation.

Type	Manifestation	Characteristics
Obstructions	Ventricular pressure overload	Cardiac: outflow tract obstruction, aortic valve stenosis
		Systemic arterial: arch obstructions, systemic hypertension
	Systemic venous pressure overload	Systemic venous: baffle stenosis
		Pulmonary arterial: branch pulmonary artery stenosis, high pulmonary vascular resistance
		Pulmonary venous: stenosis of pulmonary veins (intrinsic or extrinsic by compression)
Shunts	*Right-to-left shunt*	Cardiac: fenestration, interatrial communications, decompressing
	Cyanosis	veins to left atrium
		Systemic venous: decompressing venous collaterals
		Pulmonary atrial: arteriovenous malformations
	Left-to-right shunt	Cardiac: residual anterograde flow into main pulmonary artery,
	Ventricular volume overload	patch leak in atriopulmonary anastomosis with tricuspid valve patch
		Systemic arterial: aortopulmonary collaterals, residual patent ductus arteriosus or surgical grafts
Pump failure or dysfunction		Cardiomyopathy causing systolic or diastolic dysfunction, arrhythmias, atrioventricular valve insufficiency

abnormalities [82–85], such as branch pulmonary artery balloon dilatation or stent placement at a prior shunt insertion site, coil embolization of a patent aortopulmonary shunt and acquired aortopulmonary collaterals after prior thoracotomy, transcatheter closure of residual anterograde flow through the pulmonary valve, coil embolization of decompressing venous collaterals, transcatheter closure of fenestration or baffle leaks, and balloon dilatation of postoperative coarctation (Table 39.2; see also Table 39.1).

The role of interventional cardiac catheterization as adjunct to operation is clearly illustrated by transcatheter closure of a baffle fenestration after a total right-sided heart bypass procedure [84.85]. A complete hemodynamic study is performed, including test balloon occlusion of the fenestration, and if well tolerated (see Table 39.2), transcatheter closure is performed.

Management

In a normal biventricular circulation, the right ventricle allows an increase in the cardiac output with exercise without a rise in systemic venous and ventricular end-diastolic pressures [86]. Ventricular septation developed 165 million years ago, when the right ventricle appeared in reptiles and birds and allowed adaptation to air breathing, aerobic exercise, and flying [87]. Patients with univentricular circulation after total right heart bypass lack this important mechanism of adaptation to aerobic exercise.

In managing patients with univentricular hearts, the initial objective is to protect the pulmonary vasculature and

ventricular function, keep pulmonary artery pressures low, and allow adequate systemic oxygen saturation (≥80%). Early in life, this can be achieved at the original palliative surgery by a pulmonary artery banding or a Blalock–Taussig shunt (Table 39.3), according to the underlying anatomic substrate. Stent implantation of a ductus is an alternative to an aortopulmonary surgical shunt; the intermediate and long-term results are not well known [88].

Three different types of "corrective" operations have been proposed for these patients. Theoretically, ventricular septation [89] would be ideal, although it is possible only in rare anatomic types with two normal atrioventricular valves with adequate distribution of papillary muscles and attachments to allow partitioning. The technical difficulties and high early and late mortality have restricted ventricular septation to patients with both ideal anatomy and major risk factors that contraindicate a right-sided heart bypass procedure. Ventricular septation has been performed in patients with univentricular heart type IA III, normal atrioventricular valves, nonrestrictive bulboventricular foramen, no prior palliative operations, chronic cyanosis, and severe polycythemia. An additional requirement is a diastolic ventricular volume 250% larger than a normal left ventricle [89]. This procedure is also possible in patients with common ventricle (type C of Van Praagh *et al.* [2]) because there are two well-developed ventricles with a markedly deficient interventricular septum.

The most common surgical approach is staged surgical palliation by a partial (bidirectional Glenn procedure) or total (Fontan–Kreutzer procedure) right heart bypass operation.

Table 39.2 Suggested sequential steps for transcatheter fenestration closure.

Step	Procedure[a]
1	Determine RA or PA and AO saturations and pressures at baseline
2	Test balloon occlusion for 10 min
3	Determine RA or PA and AO saturations and pressures during balloon occlusion of the fenestration (after 10 min)
4	If RA pressure >16 mmHg and CI decreases to <2 l min^{-1} m^{-2}, the fenestration is left open. If RA pressure <16 mmHg and CI >2 l min^{-1} m^{-2}, the fenestration may be closed

[a]AO, aorta; CI, cardiac index; PA, pulmonary artery; RA, right atrium.

As a last option, some patients with univentricular heart may undergo cardiac transplantation, if unsuitable for staged surgical palliation or after a failed the surgical approach.

Surgical management

Initial palliative surgery

Neonates with coexisting severe pulmonary stenosis or pulmonary atresia who present with marked hypoxia (PO_2 < 30 mmHg) require prostaglandin E_1 to maintain ductal patency and increase blood flow to the pulmonary vasculature until a permanent source of pulmonary blood flow is established either surgically by an aortopulmonary shunt, or via a transcatheter approach with stenting of the ductus arteriosus. A modified Blalock–Taussig shunt with a Gore-Tex graft

positioned between a subclavian artery and the ipsilateral pulmonary artery is the most widely used type of shunt. Similarly, those with aortic arch hypoplasia or severe coarctation require prostaglandin infusion until arch reconstruction can be performed.

Neonates with increased pulmonary blood flow, elevated pulmonary artery pressures, and congestive cardiac failure need manipulation of the pulmonary vascular resistance to maintain an adequate preoperative Qp/Qs ratio, allowing sufficient systemic perfusion while limiting pulmonary blood flow [34,90]. This may be achieved either by use of a closed hood [91], to increase inspired PCO_2 and pulmonary vascular resistance, or by hypoventilation using mechanical ventilation, sedation, and paralysis. This can be achieved in some patients by a low inspired FiO_2 (<21%). Supplemental oxygen and hyperventilation should be avoided, as should any factor that could lower the pulmonary vascular resistance. Once patients are hemodynamically compensated, an initial palliative operation is performed (see Table 39.3). When pulmonary artery banding is indicated, this is achieved narrowing the pulmonary trunk to a luminal diameter of 21 mm + 1 mm kg^{-1} body weight [92]. By intraoperative pressure measurement, the distal pulmonary artery pressure should be ~50% of the systemic pressure. If the oxygen saturation drops to <80% or the patient develops bradycardia in the operating room, the band should be loosened. If the banding is unsuitable because of marked cyanosis (PO_2 <30 mmHg), persistent high pulmonary blood flow (oxygen saturation >85%, or high pulmonary venous flow velocity measured by echocardiography >0.7 m s^{-1} and transmitral flow E >1 m s^{-1}), a second procedure to revise the banding is indicated.

Table 39.3 Management algorithm for patients with univentricular heart.

Ductus dependent	Pulmonary obstruction	Systemic obstruction	Primary procedure	Secondary procedure	Final procedure
YES	YES	NO	BTS PDA stent	BDG BDG	
	NO	YES	Arch repair + PAB (#) Norwood Hybrid procedure	BDG Comprehensive stage II + BDG	Complete right heart bypass or Fontan

	NO	YES	Arch repair + PAB DKS/BTS	BDG	
		NO	PAB	BDG	

(#) if isolated aortic arch obstruction
BDG, bidirectional Glenn operation ; BTS, Blalock-Taussig shunt, usually of modified type; DKS, Damus-Stansel-Kaye operation; PAB, pulmonary arterial band; PDA, patent ductus arteriosus.
Figure 39.28 Damus–Kaye–Stansel anastomosis for single ventricle and subaortic stenosis. (a) The pulmonary artery (PA) is transected proximal to the bifurcation. An appropriately positioned and sized incision is made in the ascending aorta. (b) The distal end of the pulmonary artery is oversewn, and the proximal end of the pulmonary artery is anastomosed to the opening in the aorta. (c) An appropriately shaped hood (Dacron tube, pericardium, allograft, or Gore-Tex) is added to the anastomosis. AO, aorta; LV, left ventricle; RA, right atrium; RV, right ventricle. (Reproduced with permission from Park, *Pediatric Cardiology for Practitioners*, 3rd edn, Mosby, St. Louis, 1996, p. 234.)

Currently, the early operative mortality for the initial palliative procedures in neonates is <5%, but varies from 2.7 to 17%. according to the extent of procedures performed [90,93]. If an aortopulmonary shunt is performed after the neonatal period, the mortality is significantly lower than when aortic arch reconstruction or a Damus–Kaye–Stansel-type anastomosis is required.

After pulmonary artery banding, the reduction in the ventricular volume can decrease the size of the bulboventricular foramen, and subaortic stenosis may develop. This occurs in >73% of patients with coexisting transposition [94], for whom pulmonary artery banding should be avoided whenever there is a significant risk for development of subaortic stenosis.

In the intermediate and long-term follow-up of patients after the initial palliative procedure, ventricular dysfunction may become significant [95]. The increase in preload relative to the ventricular volumes at end-systole and end-diastole (2.5–3 times normal) reduces the long-axis/short-axis relationship (normal, 1.9:1).As a result, the ventricle becomes rounder, the end-systolic stress (afterload) increases, and ventricular function, mass/volume relationship, and ventricular contractility are reduced [95].

Second-stage palliative surgery: partial right-sided heart bypass (bidirectional Glenn procedure)

A partial right-sided heart bypass can be performed by a right cavopulmonary anastomosis, as proposed by Glenn [96] in 1958 and Bakulev and Kolesnikov [97] in 1959. Hopkins *et al.* [98] extended this concept in 1985 to a bidirectional cavopulmonary connection.

This operation can be performed with standby cardiopulmonary bypass, except when other intracardiac procedures are performed concomitantly, for example, atrioventricular valvoplasty, augmentation of the bulboventricular foramen,

Damus–Kaye–Stansel procedure (Figure 39.28), or branch pulmonary arterioplasty.

To optimize pulmonary blood flow distribution, the cavopulmonary anastomosis should be placed as centrally as possible. An end-to-side anastomosis is performed with readsorbable suture, interrupted in four quadrants. The azygos and or hemiazygos veins, when present, are always divided.

Pulsatility can be allowed by leaving anterograde flow across a restrictive open pulmonary outflow tract or a patent modified Blalock–Taussig shunt, predominantly perfusing the contralateral lung [99]. When anterograde flow is retained, a pulmonary artery band is adjusted over a 3 mm Hegar bougie to control the amount of pulmonary blood flow.

Pulmonary artery branch plasty can be performed with untreated autologous pericardium. In patients who require pulmonary arterioplasty, it is preferable to leave a source of pulsatility. To correct a restrictive bulboventricular foramen, a Damus–Kaye–Stansel procedure or a partial resection of the bulboventricular foramen may be performed (see Figure 39.28). Atrioventricular valve regurgitation is a difficult problem and is considered a significant risk factor, probably because of its association with ventricular dysfunction. When two atrioventricular valves are present, one of which is normal in size and function, closure of the regurgitant one may be considered, in association with resection of the atrial septum. A valve ring annuloplasty can be performed in the remaining atrioventricular valve to avoid its dilatation secondary to ventricular enlargement. If there is an insufficient single or common atrioventricular valve, an attempt at valvoplasty or even valve replacement may be undertaken. In patients with both right and left superior venae cavae without a significant communicating vein, cavopulmonary anastomosis should be performed bilaterally. Around 3 months of age, after cardiac catheterization and angiocardiography to identify risk factors for right-sided heart bypass (Table 39.4), a bidirectional cavopulmonary

Table 39.4 Risk factors for a total right-sided heart bypass operation: proposed incremental risk scale[a].

Risk factor	No incremental risk	Moderate increase in risk	High risk
Age (years)	<2[b]	<1.5	<1
Mean PA pressure (mmHg)	<15	15–18	≥18
McGoon index[c]	>2.4	1.8–2.4	<1.8
Pulmonary vascular resistance (PVR) (Wood units)	<2	2–3	>3
Transpulmonary gradient (mmHg)	<6	6–12	>12
Ventricular end-diastolic pressure (VEDP) (mmHg)	<10	10–14	>14
Ejection fraction	>60	45–60	<45
AV valve insufficiency	None or mild	Moderate	Severe
Heterotaxia	No heterotaxia	Polysplenia	Asplenia
History of PA banding	No PA banding	Yes	PA band associated with branch PA stenosis
Mayo Clinic index[d]	<2	2–4	>4
Nakata index[e]	>250	250–200	<200
PA stenosis	None	Mild to moderate	Severe
Restrictive BVF	No restriction	Mild (<30 mmHg)	Moderate to severe (>30 mmHg)
Left AV valve	Normal	Stenosis	Atresia valve

[a]AV, atrioventricular; BVF, bulboventricular foramen; PA, pulmonary artery.
[b]According to institutional preferences, this age may be variable. At the Buenos Aires Children's Hospital, the cutoff age between low and moderate risk is considered to be 4 years.
[c]McGoon index: [RPA (mm) + LPA (mm)]/descending aorta at the diaphragm (mm).
[d]Mayo Clinic index: [PVR (Wood units) + VEDP (mmHg)]/[Qp (l min^{-1} m^{-2}) + Qs (l min^{-1} m^{-2})].
[e]Nakata index: RPA + LPA (mm^2 m^{-2}).

anastomosis is performed. Severe high-risk factors, such as Nakata index <120 mm^2 m^{-2}, severe ventricular dysfunction, and severe peripheral pulmonary artery stenosis with distal hypoplasia, may contraindicate the operation.

After partial right-sided heart bypass, there is a more efficient pulmonary blood flow, as the Qp becomes effective blood flow (Qe), allowing adequate systemic oxygen saturation (80–85%) and a reduction in preload and atrial filling pressures [100]. An aortopulmonary shunt, which requires a Qp/Qs ratio >2 to keep oxygen saturation above 80%, is replaced by a hemodynamically advantageous system that allows adequate oxygen saturations, a Qp/Qs ratio of <1, without recirculation of blood [101], while reducing the ventricular volume load and preserving ventricular function [102,103]. Long-standing ventricular volume overload with an aortopulmonary shunt can lead to dilated myopathy and ventricular dysfunction [35,104], particularly with a single right ventricle and/or atrioventricular valve insufficiency. The change in ventricular geometry after a bidirectional Glenn anastomosis (decrease in ventricular volume and increase in the ventricular mass/volume ratio) results in an immediate 25% reduction in the area of the bulboventricular foramen [105]. This frequently produces subaortic stenosis

in patients with transposition [94]. Similarly, after a total right-sided heart bypass [105], the change in ventricular geometry causes a 40% reduction in the bulboventricular foramen size.

A bidirectional Glenn anastomosis is pulsatile with additional pulmonary blood flow from a shunt or anterograde flow across the pulmonary valve. In these situations, systemic oxygen saturation tends to be higher at the expense of increased ventricular volume and higher pulmonary artery pressures. A pulsatile bidirectional Glenn anastomosis is particularly indicated for patients with small or stenotic pulmonary arteries, in whom a simultaneous pulmonary arterioplasty is performed.

If there is significant atrioventricular valve regurgitation and depressed ventricular function, or if the intraoperative superior vena caval pressure is >14 mmHg, any source of pulsatility should be eliminated, The technique described by Kawashima *et al.* [106] can be employed in patients with heterotaxia, interrupted inferior vena cava, and azygos or hemiazygos continuation. After this operation, all systemic venous return, except from the hepatic veins, is directed to the pulmonary arteries. This should be considered a partial right-sided heart bypass operation, because the hepatic

venous flow is still excluded from the pulmonary circulation.

Lung perfusion scan

The distribution of pulmonary blood flow after a cavopulmonary connection is preferentially to the ipsilateral pulmonary artery [107,108]. On lung scintigraphy, with upper extremity intravenous isotope injection, both the pulsatile and nonpulsatile bidirectional Glenn procedures show dominant perfusion of the ipsilateral pulmonary artery, and this is reproduced during exercise. With time, this distribution could lead to relative hypoplasia of the contralateral pulmonary artery [109]. Other late complications after a bidirectional Glenn anastomosis include the development of pulmonary arteriovenous microfistulas [77,110] 50–100 μm in diameter, particularly in the lower lobes, which are the best-perfused areas. The absence of hepatic blood flowing into the pulmonary circulation has been postulated in their pathogenesis [77]. An additional source of pulmonary blood flow providing pulsatility in addition to blood flow that has passed through the liver may prevent the development of these fistulas. A larger volume of pulmonary blood flow and the pulsatility may also play a role in pulmonary arterial growth [102,111,112]. Therefore, some prefer a pulsatile bidirectional Glenn anastomosis [99] with a controlled source of pulmonary blood flow, maintaining the mean pulmonary artery pressure at <15 mmHg and the pulsatility amplitude at <5 mmHg higher than the mean pulmonary artery pressure.

Doppler flow dynamics

The echocardiographic evaluation of superior vena cava and pulmonary artery flow dynamics in a bidirectional Glenn procedure demonstrates [108,113] continuous laminar flow of low velocity (<0.5 m s^{-1}) (Figure 39.29). With an additional source of pulsatile flow, in the contralateral pulmonary artery there may be a low or moderate velocity (1 m s^{-1}), continuous flow (aortopulmonary shunt), or systolic flow (anterograde flow through the pulmonary valve). Doppler evaluation of the superior vena cava may identify (see Figure 39.29) continuous venous flow (hypopulsatile bidirectional Glenn), a reduction in the systolic flow (pulsatile bidirectional Glenn), or retrograde flow during systole (hyperpulsatile bidirectional Glenn) (Table 39.5).

Right-to-left shunts (venous collaterals, arteriovenous fistulas)

The increasing cyanosis in patients after a bidirectional Glenn procedure can be explained by the patient's growth, because the contribution of the head and neck vessels to the total cardiac output diminishes with time [114]. Other common sources of a right-to-left shunts such as decompressing venous collaterals [115,116], particularly in patients with a bidirectional Glenn anastomosis and an elevated pulmonary artery pressure, should be excluded. The incidence of decompressing venous collaterals ranges from 13% [110] to 75% [117].

Contrast echocardiography with fast injection of saline or dextrose solution (3–6 ml) in an upper extremity may show rapid filling of the pulmonary veins, suggesting pulmonary arteriovenous fistulas but decompressing venous collaterals to the pulmonary veins cannot be excluded by this finding. An abnormality in the upper extremity contrast echocardiogram occurs in 15% [117] to 60% [110] of these patients. Arteriovenous fistulas can be suspected from a typical radiographic reticular image in the lower lobes, which extends to the periphery. After a Kawashima operation [118], there is evidence of a right-to-left shunt with oxygen saturations of ~90% initially, with subsequent progressive cyanosis attributed to the development of pulmonary arteriovenous fistulas [80,110,118]. The progressive right-to-left shunt also results from decompressing venous collaterals, in particular with anomalous cavoportal connections [119], which become more prominent with time. In these patients, transcatheter embolization may be therapeutic.

The Doppler evaluation of the lower pulmonary venous flow during inspiration demonstrates continuous flow (>0.5 m s^{-1}) that decreases markedly in expiration (Figure 39.30), probably because of collapse of the microfistulas because of increased intrathoracic pressure. Diagnosis of pulmonary arteriovenous fistulas is confirmed by cardiac catheterization. Pulmonary angiograms demonstrate dilated terminal arteries, absent capillary phase, early pulmonary venous opacification, and dilated pulmonary veins. Oximetry reveals desaturation of the pulmonary veins that is not corrected with administration of oxygen. There are few therapeutic options for patients with pulmonary arteriovenous malformations. A brachial or axillary arteriovenous fistula can be performed to increase the pulmonary blood flow and allow blood from the liver to be incorporated in the pulmonary circulation [120,121]. Regression after liver transplantation in patients with liver disease [122] and after complete right-sided heart bypass [123] supports the hypothesis that pulmonary arteriovenous fistulas can be reversible with incorporation of hepatic blood flow.

Exercise capacity

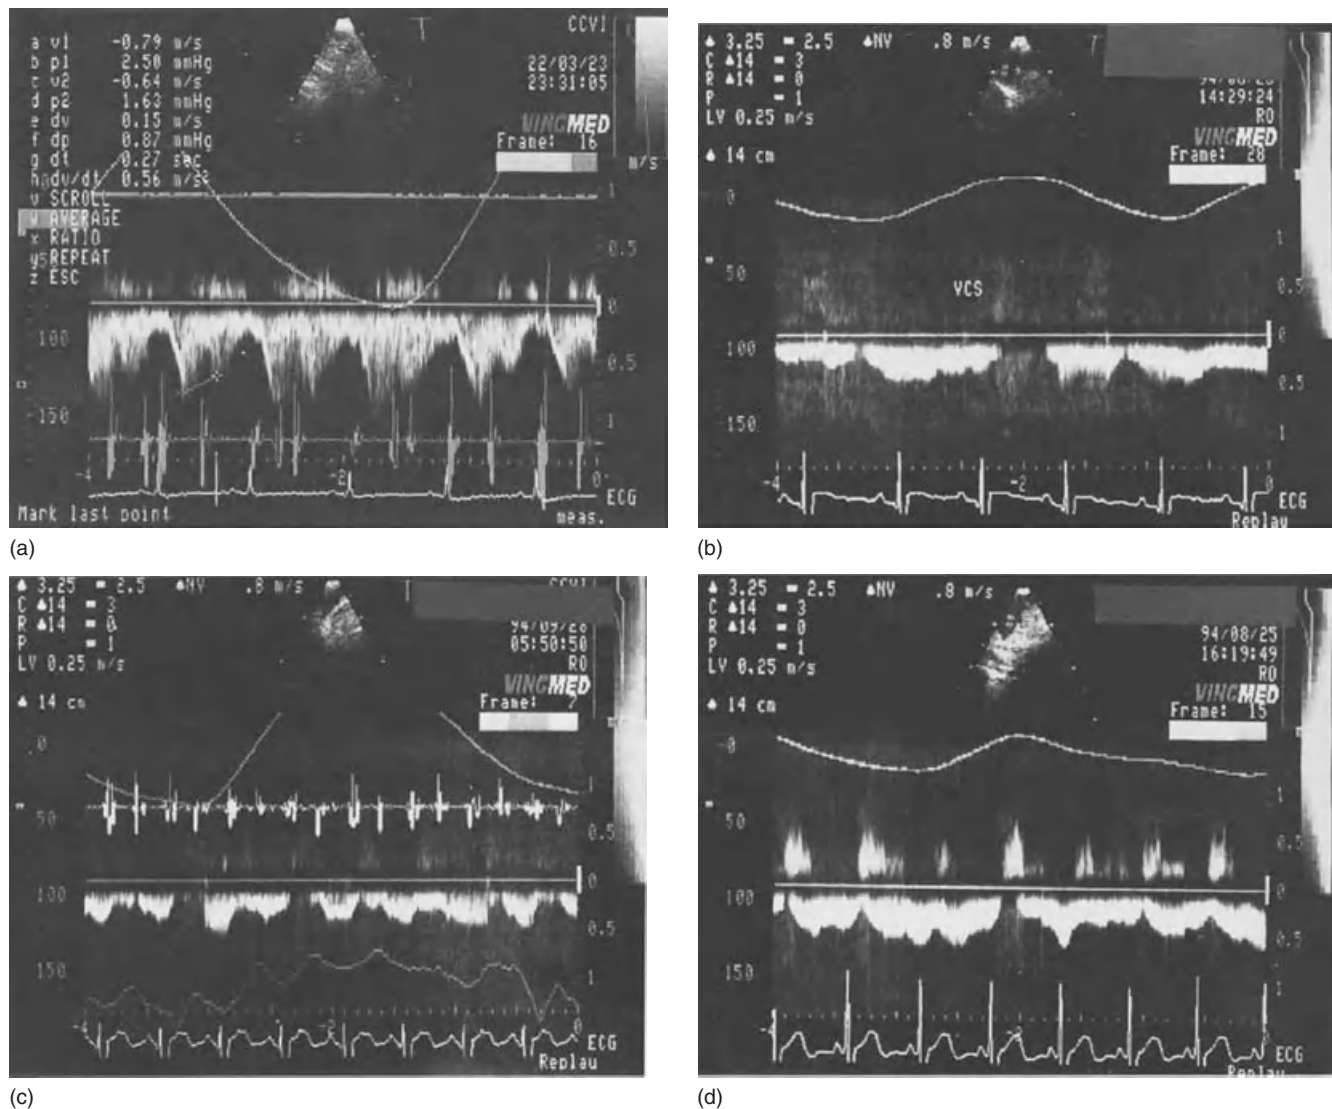
Patients with partial right-sided heart bypass, whether pulsatile or not [124], have markedly depressed exercise capacity (48% of estimated functional capacity) directly related to the level of systemic desaturation [124]. The chronotropic response is normal, as it is in cyanotic congenital heart defects [125]. Exercise stress testing demonstrates that even with an adequate resting systemic saturation (>85%), marked desaturation (<70%) develops with exercise.


Figure 39.29 Two-dimensional Doppler flow dynamics in superior vena cava. (a) Normal, anterograde biphasic with increase at early inspiration. (b) Nonpulsatile bidirectional cavopulmonary anastomosis, with continuous flow and inspiratory increase in velocity. (c) Pulsatile bidirectional cavopulmonary anastomosis, anterograde flow with systolic slowing. (d) Hyperpulsatile bidirectional cavopulmonary anastomosis, with retrograde systolic flow in superior vena cava.

Definitive palliative surgery: total right heart bypass (Fontan–Kreutzer procedure)

A total or complete right heart bypass directs all systemic venous return into the pulmonary arteries in the absence of a ventricular pump. The operation was first performed by Fontan and Baudet in 1971 [126] for tricuspid atresia IB with the concept that the thickened atrium could be "ventricularized" [127]; they inserted inlet and outlet valves in the atrium. In the same year, and unaware of Fontan and Baudet's reported experience, we performed a total right-sided heart bypass in Argentina [128]. Even in that early experience, valves in the inferior or superior venae cavae

were avoided by our group. What is now known as a fenestrated Fontan procedure [85,129] was first performed in Argentina in 1971 by leaving a residual 6 mm atrial level communication to serve as a pop-off valve. We performed the atriopulmonary connection with a different hemodynamic concept to that of Fontan and Baudet, as we considered the right atrium to be a compliant chamber without any significant pump function and that the suction force of the system would be generated by the end-diastolic pressure of the systemic ventricle [130–132].

Multiple modifications of the initial Fontan procedure have been proposed and performed over time (Figure 39.31).

Table 39.5 Flow dynamics by transthoracic two-dimensional echo Doppler in bidirectional cavopulmonary connection.

Flow	Superior vena cava	Pulmonary artery (PA)
Nonpulsatile	Continuous $<0.5\,\mathrm{m\,s^{-1}}$ ↑ Inspiration	Continuous $<0.5\,\mathrm{m\,s^{-1}}$ ↑ Inspiration
Pulsatile	Continuous, decreasing in systole $<0.5\,\mathrm{m\,s^{-1}}$ ↑ Inspiration	Right PA: continuous, $<0.5\,\mathrm{m\,s^{-1}}$, ↑ inspiration Left PA: pulsatile, $>0.5\,\mathrm{m\,s^{-1}}$
Hyperpulsatile	Retrograde during systole Anterograde during diastole ↑ Inspiration	Right PA: continuous Left PA: hyperpulsatile, $>1\,\mathrm{m\,s^{-1}}$

Initially, as described above, the anterior atriopulmonary connections were performed, as reported by Fontan and Baudet [126], Kreutzer *et al.* [128], and Bjork *et al.* [133]. In 1978 the posterior atriopulmonary connection was introduced [55,134], but later improved surgical techniques were developed: the lateral tunnel by de Leval *et al.* [135], Jonas and Castaneda [136], and Puga *et al.* [137] and the extracardial conduit by Puga and co-workers in 1988 [138] and Marcelletti *et al.* in 1990 [139]. Both the lateral tunnel and extracardiac conduit are considered excellent surgical techniques. Although the extracardiac conduit has become the preferred approach at most centers, it remains controversial, and both approaches have excellent reported outcomes [140]. However, follow-up of the extracardiac conduit is shorter than for the lateral tunnel [130]. The lateral tunnel, which tends to produce more arrhythmias, is more often performed in small patients, given the growth potential of the surgical pathway. The extracardiac conduit has less tendency to produce arrhythmias because of the lack of atrial sutures and low-pressure exposure of the sinus node can be performed without an aortic cross-clamp, and for some, the fenestration may be closed without the need for an implantable device [141]. Indeed, at the Buenos Aires Children's Hospital, it is routine to close the fenestration before hospital discharge by adjusting a snare under local anesthesia [141].

Authorities differ about the optimum timing of this procedure. Following a partial right heart bypass, as the systemic oxygen saturation decreases below 80% or the hematocrit rises above 55%, completion to a total bypass (Fontan–Kreutzer procedure) should be considered, irrespective of age. Adults with a single ventricle can undergo total right heart bypass with low morbidity and mortality [142]. After a total bypass, even when performed on ideal patients, the clinical status may deteriorate with time, even with a normal Qp/Qs ratio of 1. This observation reinforces the concept that the procedure is indeed only palliative. The worrisome long-term complications that follow total right heart bypass operations make one reconsider the approach to timing of this palliative surgery.

The complications of pregnancy in patients after a total right heart bypass should be discussed preoperatively with female patients. Limited experience has demonstrated only 45% incidence of live births among 33 pregnancies [143]. The alternative of chronic cyanosis in a palliated partial right heart bypass circulation, however, is not a benign physiology for a pregnancy. A total right heart bypass normalizes oximetry, eliminates shunts, abolishes the risk of brain abscess, and establishes a series circulation but with only a single systemic ventricular pump.

In the long-term follow-up of patients with total right-sided heart bypass [144–154], poor results have been reported for patients with heterotaxia, low age at operation, weight <15 kg, elevated pulmonary artery pressure, atrioventricular valve dysfunction, and right atrial pressure >20 mmHg or left atrial pressure >10 mmHg in the early postoperative period [147,148,153].

Typically following cardiac catheterization and cineangiography or alternative noninvasive testing to determine risk factors for a total right heart bypass (Table 39.6; see also Table 39.4), patients undergo a total cavopulmonary anastomosis [101,135] with lateral intra-atrial tunnel, extracardiac conduit, or a cavoatriopulmonary anastomosis [155,156], each of which may or may not be fenestrated [84,129]. The cavoatriopulmonary modification protects the sinus node, allows low pressure in the coronary sinus [157], and permits homogeneous distribution of pulmonary blood flow, because it includes a mixing chamber similar to that in an atriopulmonary anastomosis [107]. The most common technique used currently in the United States is the fenestrated extracardiac conduit.

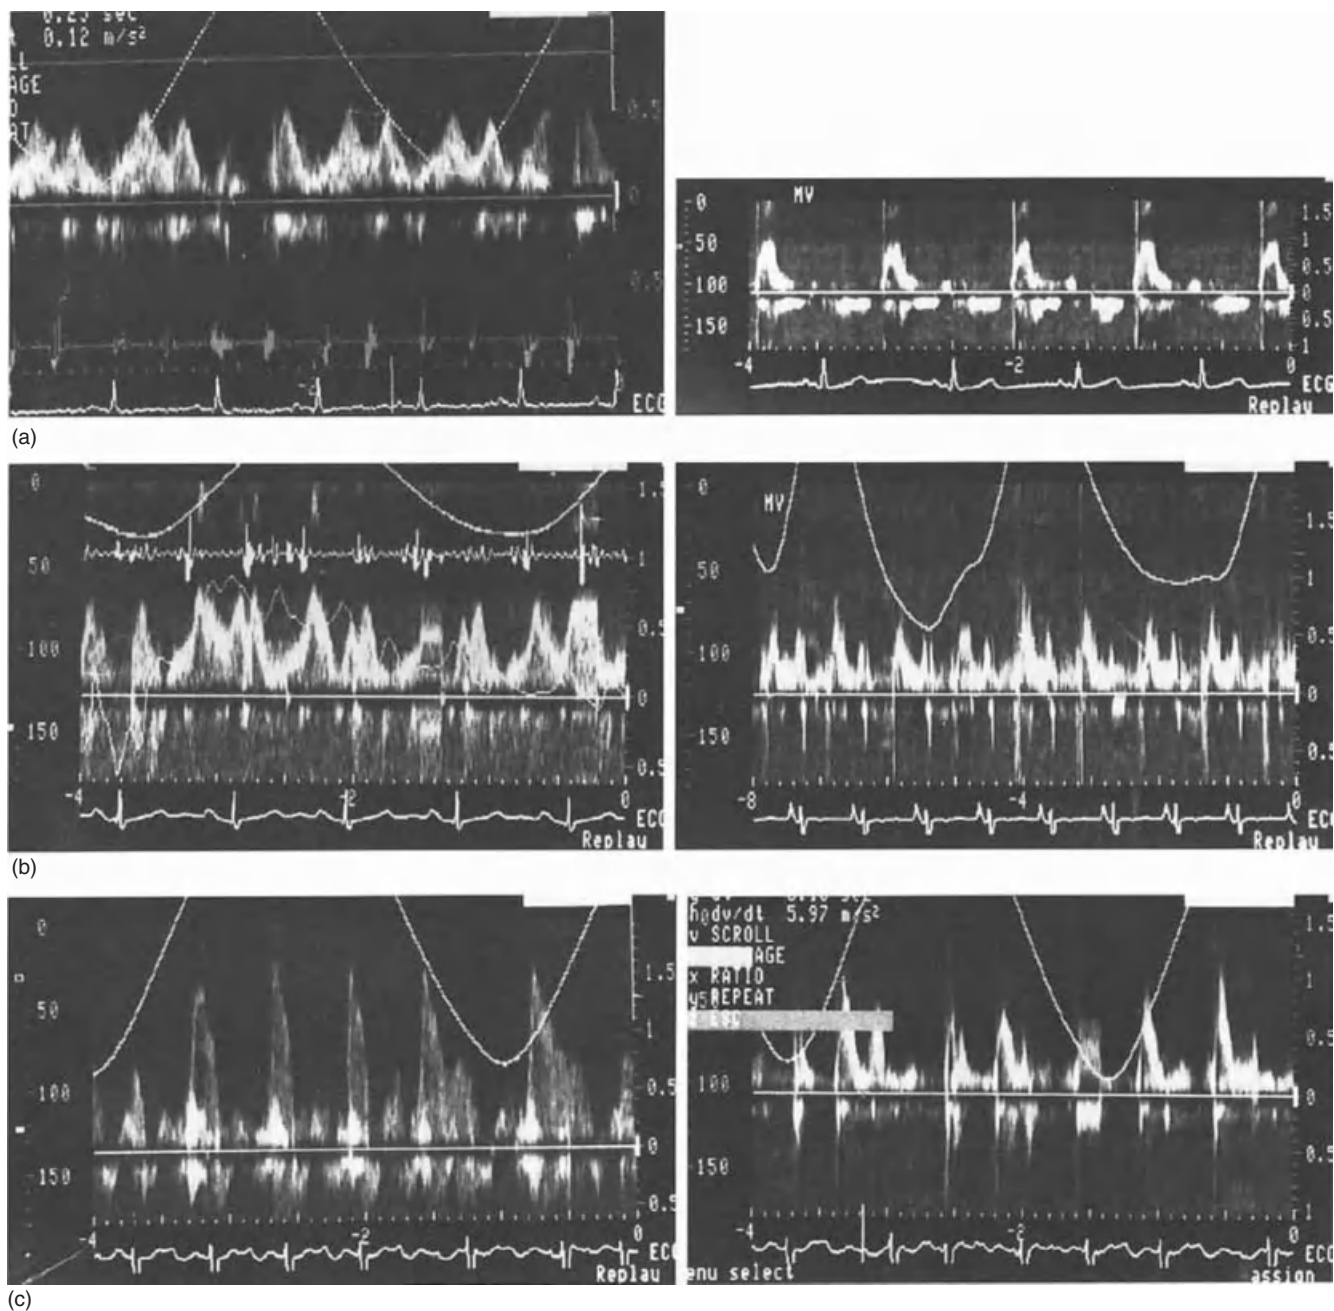
Associated cardiac malformations increase risk factors for a total right-sided heart bypass (see Table 39.4) and demand technical modifications.


Figure 39.30 Flow dynamics by two-dimensional Doppler echocardiography at pulmonary veins (left) and mitral valve (right) in normal (a), atriopulmonary anastomosis (b), and late failure after atriopulmonary anastomosis (c). The pulmonary venous flow in (b) is triphasic anterograde (prodiastolic, telediastolic, and protosystolic), with increase in velocity during inspiration, the same as the transmitral flow. In (c), there are high velocities recorded in pulmonary veins (1.5 m s^{-1}) with a monophasic protodiastolic flow, differing from the transmitral flow velocity (0.7–1 m s^{-1}). Atrial flutter is present.

A staged approach for performing a total right heart bypass has allowed a significant reduction in morbidity [158] by avoiding a sudden change in ventricular geometry. After a total right-heart bypass performed without a prior staging partial bypass procedure, there is a 100% reduction in the ventricular chamber volume and an increase in both ventricular wall thickness and mass/volume ratio [159,160],

which leads to diastolic ventricular dysfunction early postoperatively [160].

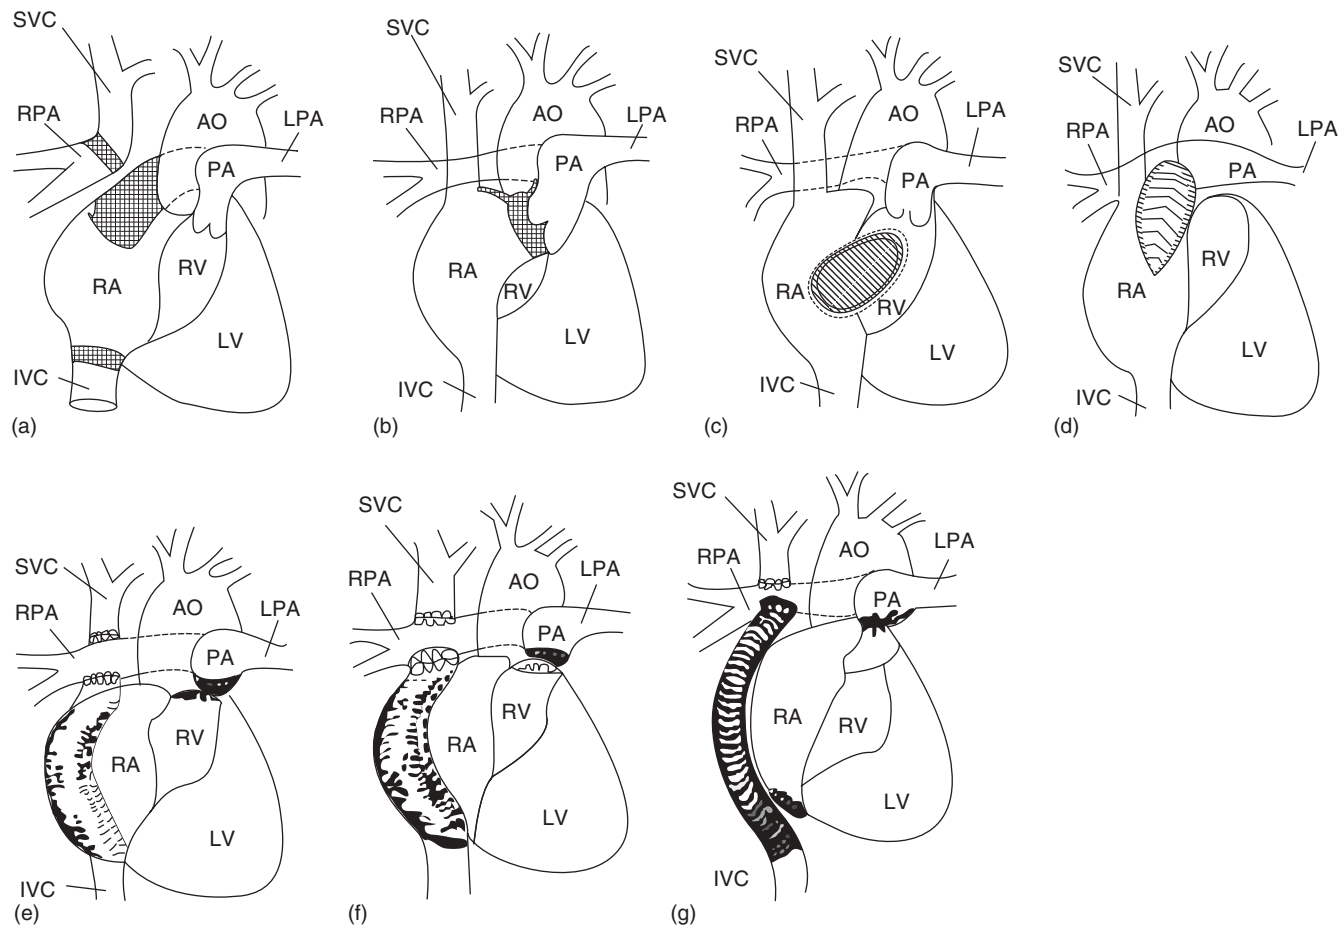
An atriocavopulmonary anastomosis (central tunnel) (Figure 39.32) [155,156] with or without prosthetic material, is an alternative technique for performing a total right heart bypass. It is particularly useful in the conversion of atriopulmonary anastomosis by creating an intra-atrial


Figure 39.31 Modifications of the total right-sided heart bypass operation. (a) The original Fontan procedure [126]: an end-to-end anastomosis of the RPA to SVC, an end-to-end anastomosis of the right atrial appendage to the proximal end of the RPA by an aortic valved homograft, closure of atrial septal defect, insertion of a pulmonary valve homograft into the IVC, and ligation of the main pulmonary artery. (b) Total right-sided heart bypass [128]: anastomosis of right atrial appendage to the main pulmonary artery with its intact pulmonary valve (excised from the RV) after closing the atrial and ventricular defects. A Glenn operation was not performed, and no IVC valve was used. (c) Bjork *et al*. [133] anastomosed the right atrial appendage directly to the RV outflow tract if the pulmonary valve was normal, using a roof of pericardium to avoid a synthetic tube graft. (d) The posterior anastomosis of the RA to the PA [134]. (e, f) Separate anastomosis of the divided SVC to the RPA: insertion of an IVC to SVC intra-atrial baffle (total cavopulmonary connection) with (f) and without (e) fenestration. (g) Extracardiac conduit between the RPA and a bidirectional Glenn operation. AO, aorta; IVC, inferior vena cava; LPA, left pulmonary artery; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava. tunnel. If made of autologous tissue, it is constructed using the patient's own atrial wall, reducing the size of the atrial chamber. The use of native atrial tissue may lead to increased incidence of arrhythmias long term, but allows for growth potential. In addition, a bidirectional cavopulmonary anastomosis is performed. The inferior vena cava is connected through this tunnel to the main pulmonary artery trunk and branches, similarly to performing an atriopulmonary anastomosis. The advantages of this central tunnel technique [156] are excluding the sinus node and coronary sinus from higher pressure [157], growth potential, absence of suture lines near the sinus node and nodal artery, avoiding prosthetic material, and theoretically favorable distribution of inferior

vena cava blood flow to both lungs. The extracardiac conduit technique [118] shares some advantages with the central tunnel technique, such as the absence of atrial suture lines, although it uses prosthetic material, lacks growth potential, and usually causes preferential distribution of inferior vena caval blood flow to the ipsilateral pulmonary artery, depending on the position of the anastomosis. The postoperative electrocardiogram in these patients shows small-amplitude P waves in the right precordial leads, suggesting low right atrial wall stress. The flow dynamics by Doppler evaluation demonstrate presystolic pulsatility in the inferior vena cava.

After atriopulmonary connection, late failures are common, [144], even in patients with ideal preoperative condition

Table 39.6 Choussat's criteria[a].

Age 4–15 years
Sinus rhythm
Normal drainage of caval veins
Normal volume of right atrium
Mean PA pressure ≤15 mmHg
Pulmonary resistance <4 U m^{-2}
Ratio PA/Ao ≥0.75
Normal ventricular function
No impairing effect of shunt

[a]PA, pulmonary artery; Ao, aorta.

according to the original Choussat's criteria (see Table 39.6) [150]. Experience has demonstrated that these criteria should be regarded as only a guide, because the absence of one or more of these factors should not be considered an absolute contraindication to surgery. It is no longer standard to use these criteria to determine candidacy for Fontan completion. Some patients with significant high-risk factors may still benefit from staged palliation even if considered as a bridge to cardiac transplantation.

Postoperative follow-up
As long-term follow-up data become available, more complications and side effects are identified associated with the procedure and specific techniques that have become outdated. The late results of all these procedures indicate that having a total right heart bypass operation has major long-term adverse consequences secondary to chronic venous hypertension. Limited follow-up data are available for patients with the more recent modifications. The mid-term results after extracardiac conduit are favorable, particularly regarding the incidence of atrial arrhythmias [152].

Exercise capacity
Patients with total right-sided heart bypass have mildly diminished functional capacity [124] to ~79% of estimated capacity as determined by ergometry. They have mild desaturation and subnormal chronotropic response [151–165]. Cardiac output does not increase normally [151–163], in part from both reduced pulmonary blood flow and impaired chronotropic and contractile responses to exercise [164]. Minute ventilation and the ventilatory equivalent for oxygen and carbon dioxide remain above normal [165]. In addition, arrhythmias are more frequent with exercise than at rest [161].

Lung perfusion scan
After total cavopulmonary anastomosis, preferential blood flow distribution to the lung ipsilateral to the cavopulmonary connection is commonly observed [107,108,166]. Certain technical modifications allow a more homogeneous distribu-

tion of blood flow that may have an effect on pulmonary arterial growth. Results can be difficult to interpret, however, as they vary according to the site of injection and streaming patterns, with the exception of the atriopulmonary anastomosis where there is a chamber of complete mixing.

Doppler flow dynamics
Hemodynamic failure after total right-sided heart bypass can be detected by Doppler echocardiographic analysis of flow dynamics (Table 39.7) [108].

Complications following total right heart bypass

Among the causes or manifestations of failure following a total right-sided heart bypass procedure are the following.

Increased transpulmonary pressure gradient
The flow dynamics after a total right-sided heart bypass depend on the pressure gradient between the right atrium and the left atrium, the transpulmonary gradient. This gradient should ideally not exceed 6 mmHg. Failure after a total right-sided heart

Table 39.7 Flow dynamics by transthoracic two-dimensional echo Doppler in atriopulmonary anastomosis[a].

Flow	"Normal" function	Dysfunctional
Inferior vena cava	Anterograde biphasic S/D $<0.5\,m\,s^{-1}$ ↑ Inspiration	Anterograde in inspiration Retrograde in expiration
Pulmonary artery	Anterograde biphasic S/D with PS exacerbation $0.5\,m\,s^{-1}$ ↑ Inspiration	Anterograde in inspiration $<0.5\,m\,s^{-1}$ Retrograde in expiration
Pulmonary veins	Anterograde biphasic D > S $<0.6\,m\,s^{-1}$ ↑ Inspiration	Anterograde diastolic $>1\,m\,s^{-1}$ ↑ Inspiration
Mitral valve	E > A $<0.6\,m\,s^{-1}$ ↑ Inspiration	Restrictive E $\geq 1\,m\,s^{-1}$ ↑ Inspiration Gradient VP – MV

[a]A, late diastolic filling; D, diastolic; E, early diastolic filling; MV, mitral valve; PS, presystolic; S, systolic; VP, pulmonary veins.

bypass may be secondary to a rise in the transpulmonary gradient with time. Various factors may contribute to this increase, such as deficient pulmonary arterial growth (Nakata index becoming smaller with time) [167,168] or chronic pulmonary micro- or macro-thromboembolism [169,170]. In these patients, oral anticoagulants should be routinely prescribed.

Giant right atrium

Another long-term complication after total right-sided heart bypass of the atriopulmonary anastomosis variety is the development of a giant right atrium. Commonly atrial arrhythmias and thromboembolic complications are associated, and the right pulmonary veins may be compressed by the posterior right atrial wall (Figure 39.20), which further increases the transpulmonary gradient. Patients benefit from conversion to a lateral tunnel connection [171,172] to increase their functional capacity and release compression of the right pulmonary veins.

Right-to-left shunts

In some patients, failure after a total right-sided heart bypass is characterized by cyanosis. Right-to-left shunting can result from a baffle leak, fenestration, and/or decompressing venous collaterals to pulmonary veins or to cardiac veins. Small interatrial communications can develop and cause cyanosis in the long-term follow-up, particularly in those with atriopulmonary connections [173]. To date, there have been no reports of pulmonary arteriovenous fistulas in patients with atriopulmonary connections or total cavopulmonary shunts with homogeneous distribution of hepatic venous blood flow to both lungs.

Thromboembolism

Patients with single ventricle variants following the Fontan procedure are at an increased risk for thrombosis, with significant morbidity and mortality. Those with atriopulmonary anastomosis can develop atrial flutter and chronic thromboembolism [169,170]. The incidence of thromboembolic complications (3.9%) seems to be independent of the type of connection for total right-sided heart bypass [169]. Systemic embolism can also follow a total right-sided heart bypass, particularly in those with a source of right-to-left shunting (fenestration).

There are anatomic predisposing factors, such as areas of blood flow stasis including in the central pulmonary arteries in patients with prior bilateral Glenn procedure [174], the main pulmonary artery surgical stump [175], a giant right atrium after atriopulmonary anastomosis, a prior Kawashima connection type, thrombogenic foreign material, arrhythmias, ventricular dysfunction, prolonged immobilization, and protein-losing enteropathy [176].

The prevalence of thrombosis following the Fontan procedure has ranged from 17 to 33% using transesophageal echocardiography [177–179]. Retrospective reviews report >15% risk for thrombosis and 1–7% risk for thrombosis-related events [176].

Patients with single ventricle variants may have intrinsic and acquired alterations in thrombophilic factors, which can predispose them to both bleeding and thrombosis [180–182]. Although these findings may explain the incidence of such complications, they have not altered practice guidelines, as typically extensive coagulation laboratory workups are not routinely performed prior to surgical staging.

Controversy continues about thrombosis prophylaxis in patients with single ventricle variants. Limited numbers of publications have addressed this issue. A retrospective observational study by Seipelt *et al.* [183] showed that patients taking either aspirin or warfarin had lower event rates than those without antithrombotic therapy. A study demonstrated that when using solely postoperative aspirin as antithrombotic agent, no thrombotic events occurred at mid-range follow-up (mean follow-up 40 months) [184]. Other studies have suggested that there may be no benefit to thromboprophylaxis [185,186].

In general, antiplatelet therapy with aspirin (3–5 mg kg^{-1} per day) has been recommended after Stage I palliation and also following bidirectional Glenn procedure. Many continue the use of antiplatelet therapy for long-term anticoagulation after Fontan procedure, although some advocate oral warfarin. Some elect a stronger anticoagulation regimen for 3–12 months after Fontan procedure and then continue with antiplatelet therapy alone. Which approach is the best management option with regard to risk–benefit is unknown. The ACC/AHA 2008 Guidelines for the management of adults with congenital heart disease [187] recommend the use of warfarin as a Class I recommendation (level of evidence C) for adult patients who after Fontan procedure have documented atrial shunt (all those fenestrated), atrial thrombus, atrial arrhythmias, or a thromboembolic event.

Arrhythmias

About 37% of patients with total cavopulmonary anastomosis have sinus node dysfunction [188,189]. This may occur from direct damage to the sinus node artery or to the node itself. Sinus node dysfunction can also occur after atriopulmonary connection (12%) and is particularly frequent after bidirectional Glenn or hemi-Fontan procedures [189].

Arrhythmias may occur in the early postoperative period, particularly in patients with high-risk factors and poor postoperative hemodynamics. Among these, atrial arrhythmias, junctional ectopic tachycardia, and even ventricular arrhythmias may develop [190]. Junctional ectopic tachycardia can occur in the immediate postoperative period after total right-sided heart bypass [191], particularly in patients younger than 3 years, and has a poor prognosis.

Supraventricular tachycardia seems to be less frequent in patients with total cavopulmonary connection than in those with atriopulmonary connection, although the follow-up periods are not comparable [191].

Protein-losing enteropathy

This serious complication of chronic venous hypertension occurs in >11% of the patients [148]. They present with hypoproteinemia, hypoalbuminemia, chronic edema, pleural effusions, ascites, pericardial effusions, and increase of fecal α_1-antitrypsin. Clearance of α_1-antitrypsin is currently the best method of evaluating protein-losing enteropathy.

Various management options have been considered for such patients, including steroid treatment, low molecular weight heparin, selective pulmonary vasodilator therapy, fenestration creation, heart transplantation, and Fontan takedown.

Plastic bronchitis

Another rare manifestation of failure after a total right-sided heart bypass has been chyloptysis and expectoration of bronchial casts, a rare, life-threatening complication of uncertain physiopathology [192,193]. However, procedures which decrease venous pressures may result in its resolution. In addition, cardiac transplantation is also generally therapeutic. The presentation is variable, typically during late follow-up, but may happen early. Manifestations include a chronic productive cough, which progresses to severe life-threatening airway obstruction. Patients cough bronchial casts that are acellular, made of mucin, fibers, and few mononuclear cells.

Liver disease

As more patients survive for many years after a single ventricle repair, the effects of long-term passive congestion of the liver are being reported. Apart from frequent disturbances of liver enzymes and clotting factors produced by the liver, established cardiac cirrhosis has been observed in 10–30% of patients, and hepatic adenoma and carcinoma have been reported [194–199]. There is some concern that these complications may develop more often with time, and evaluating the liver may need to be done more frequently.

General complications and management

Clinical failure after a total right-sided heart bypass is managed according to the specific hemodynamic abnormality or manifestation of failure. Anticongestive medications, afterload-reducing agents, and oral anticoagulants are widely used. Cardiac catheterization and potential transcatheter interventions should always be performed. Invasive evaluation of arrhythmias with possible ablation, in addition to medical management, may be beneficial [200]. Some patients improve after conversion from one form of total bypass to another with more favorable hemodynamics [172,201]. Other patients can only be either reverted to a partial right-sided heart bypass or referred for cardiac transplantation.

40 Pulmonary Atresia with Intact Ventricular Septum

Henry Chubb & Piers E. F. Daubeney

Royal Brompton Hospital, London, UK

Epidemiology and genetics

Pulmonary atresia with intact ventricular septum (PAIVS) is a relatively rare cardiac anomaly, accounting for ~3% of congenital heart disease, with an incidence of 7–8 per 100 000 live births. In the current era of fetal diagnosis (and in some countries the parental option for termination), the incidence has fallen to ~4.5 per 100 000 live births in the United Kingdom and Sweden [1–4]. There is no significant geographical variation and both sexes are equally affected. Several familial clusters of PAIVS have been noted [5–7], but most instances are sporadic with no genetic cause identified.

Pathogenesis

The pathogenesis of PAIVS is controversial [8]; developmentally, the disease is restricted to the right ventricle (RV), tricuspid valve (TV), and pulmonary valve (PV). Often critical pulmonary stenosis has progressed to pulmonary atresia *in utero* [2,9,10], but the etiology of the initial stenosis and subsequent atresia is incompletely understood.

More than one primary pathology may ultimately present with PAIVS [8]. There are those with a severely regurgitant TV, in whom the RV becomes severely dilated. Early in development the PV is patent, but acquired functional atresia develops because of reduced forward flow through the RV outflow tract from poor RV function and severe TR. The functional atresia progresses to anatomic atresia of the PV [11].

The remaining forms that present with a hypoplastic RV may be caused by two different pathologies. Histologic findings suggest that patients with large RV to coronary artery connections (RVCACs – see below) have a different intraventricular pathology compared with those without RVCACs. The latter are more likely to have significant endocardial fibroelastosis (EFE) [12,13]. The implication is that RVCACs may steal forward flow from the RV, thus reducing the anterograde flow across the PV, so that the RVCACs are thought to be part of the cause rather than the effect: there are reports of RVCACs forming even with severe TR [14]. In those without RVCACs, the EFE appears to be related to persistently high intraventricular pressure, and the atresia of the pulmonary valve appears to be the primary event.

Morphology

By definition, there is anatomic atresia of the pulmonary valve and an intact ventricular septum, although patients with a coexisting small restrictive muscular ventricular septal defect present in a very similar manner. The atrial situs is normal or solitus, with concordant atrioventricular and ventriculoarterial connections and a left-sided aortic arch in almost all patients [1,15,16], although PAIVS has been associated with congenitally corrected transposition of the great vessels [17–19].

In the majority of patients, the cardiac morphology can be classified within a spectrum as outlined in Table 40.1; the minority with a dilated right ventricle form a separate group.

Pulmonary valve

In 75% of patients, the atresia of the PV is membranous [1] (Figure 40.1). In the remaining 25% of patients. the atresia is muscular, with implications for catheter-based interventions.

Table 40.1 Spectrum of cardiac morphology in patients with pulmonary atresia and intact ventricular septum.

	Dilated RV	Mild RV hypoplasia	Moderate RV hypoplasia	Severe RV hypoplasia
RV morphology	Huge and thin-walled	Tripartite	"Bipartite"	"Unipartite"
Timing of closure of PV *in utero*	Any	Late	⇒	Early
Tricuspid valve	Large ($z > 0$)	Normal/small ($z = 0$ to -2)	Very small ($z = -2$ to -5)	Tiny ($z < -5$)
Angle of arterial duct	Obtuse/ acute	Obtuse	Obtuse/acute	Acute
RVCACs[a]	Not present	Not present/ mild	Mild/major	Major/ RVDCC[a]

[a]RVCAC, right ventricle to coronary artery connection; RVDCC, right ventricular-dependent coronary circulation.

In those with muscular atresia, the RV is usually small, with fibrous valve tissue above the level of the muscular obstruction. One patient was reported with an atretic RV infundibulum and a patent PV situated above it [20].

For those with membranous PV atresia, the PV morphology is of two distinct types. With a lower pressure RV (as with severe TR), prominent commissural ridges meet at the center of the thickened valve. In contrast, those with a higher pressure RV have less prominent commissural ridges and a smooth, thin, central portion of the valve [9,15]. The valve is usually tricuspid, although bicuspid variations have been described [21].

Tricuspid valve

The tricuspid valve (TV) is always abnormal [22]. The leaflets are often thickened, with short chordae tendineae and small papillary muscles, tethering the leaflets and reducing mobility. The TV annulus is usually small, and the largest population-based study of 182 patients found a mean tricuspid valve z-score of -5.2 (interquartile range -8.4 to -2.6) [1]. The z-scores calculated for the same valve vary depending on the z-score algorithm used and whether the normal data were derived from echocardiograms or postmortem specimens (Figure 40.2) [23–26]. Not all studies
Figure 40.2 The z-score for the tricuspid valve (TV) annulus calculated from the most commonly used z-score algorithms in the literature [23–26]. The z-score is calculated for a neonate of typical body surface area (BSA) of 0.21 m². Note that the Rowlatt study [26], although widely used, is based on a postmortem series. The reason why Daubeney *et al.*'s data [23] have a steeper curve is the smaller spread of their normal data and hence smaller standard deviation.

Figure 40.3 Chest radiograph from a patient with pulmonary atresia and intact ventricular septum with severe tricuspid regurgitation.

report the algorithm used to calculate z-scores, so comparisons between studies should be interpreted with caution.

Patients with a significantly regurgitant TV have a poor prognosis. An Ebstein-type malformation of the tricuspid valve has been reported in 10% [1,27] to 37% [28] of patients, and an unguarded tricuspid orifice may occur [28–30]. The severe regurgitation can produce the so-called "wall-to-wall" heart [11] (Figure 40.3), with a near total absence of the myocardium and a paper-thin ventricular wall resembling Uhl's anomaly [31]. In this form of PAIVS, the pulmonary arteries are frequently hypoplastic [1].

Right ventricle

The RV morphology ranges from a severely hypoplastic and hypertrophied ventricle to a huge dilated thin-walled cavity. The RV has been described as tripartite (containing inlet, outlet, and apical components), bipartite (containing inlet and outlet components), or unipartite (inlet component only) (Figure 40.4). In reality, however, the three components are always present, but may not be identified because of intracavity muscle overgrowth. The occurrence of each type at birth is tripartite(59%), bipartite(34%), and unipartite(7%) [1].

The myocardium is generally abnormal. There is myocardial disarray with fibrosis and reduced numbers of myocytes, especially with the smaller RVs [32,33]. The moderator band and papillary muscles are often poorly

defined, and in ~25% there is significant endocardial fibroelastosis (EFE). EFE is rarely significant if there are RVCACs, but they may coexist [12,34]. Ventricular function may be further compromised by frank ischemia, infarction, and myocardial rupture, due to the abnormal coronary circulation in some (see below), and changes may involve left ventricular myocardium of the left ventricle by the time of birth [35].

Pulmonary arteries

The pulmonary arteries are usually normal in size and confluent. They are hypoplastic in about 9% of patients, particularly with significant RV dilatation. Rarely, the arteries are not confluent and supplied by separate ducts [36], or there may be aortopulmonary collaterals [1].

Arterial duct

When the RV is well formed, the arterial duct is usually normal and creates an obtuse angle at its junction with the distal aorta [1]. The more hypoplastic the RV, the more likely the duct is to be longer, more tortuous, and to join the aorta proximally and at an acute angle [1,2,9,37,38] (Figure 40.5). The earlier closure of the pulmonary valve in fetal life correlates with a more acute angle of ductal insertion into the aorta [9].

Coronary arteries

Abnormalities of the coronary circulation in PAIVS vary and can confuse the clinician. They are the most important determinants of long-term outcome [39]. The changes in the coronary circulation of a hypertensive right ventricle represent a continuum, ranging from clinically unimportant myocardial sinusoids, through right ventricular coronary connections (RVCACs), to a right ventricular-dependent coronary circulation (RVDCC) [27]. Some have attempted to grade these connections (Table 40.2).

Nomenclature varies, with the term "RV coronary artery connections" (RVCACs) used synonymously with "coronary artery fistulas" and even "myocardial sinusoids." The first two terms are generally held to be equivalent, but we concur with Freedom *et al.* that the use of the term "sinusoids" to describe these connections is incorrect [12]. Gittenberger-de Groot and co-workers have drawn a distinction between effectively blind-ending "myocardial sinusoids" that may connect to the myocardial capillary bed and "ventricular–coronary connections" that are direct communications with the coronary arteries (Figure 40.6a and b) [34,42,43]. Only
Figure 40.4 Spectrum of pathology in pulmonary atresia with intact ventricular septum. Right ventricular (RV) angiograms showing (a) dilated thin-walled RV and right atrium (RA) with severe tricuspid regurgitation and membranous pulmonary atresia (anteroposterior view); (b) so-called tripartite RV with membranous atresia (lateral view); (c) so-called bipartite RV with membranous atresia, with some RV-to-coronary fistulas (lateral view); (d) tiny so-called unipartite RV with muscular atresia and RV-to-coronary fistulas with retrograde filling of the aorta (lateral view). Figure 40.5 Ductal angle in pulmonary atresia with intact ventricular septum. (a) Echocardiogram showing normal obtuse angle of duct to descending aorta (>90°) in a patient with a tripartite RV and membranous pulmonary atresia. (b) abnormal acute angle duct (<90°) in a patient with "unipartite" RV and muscular pulmonary atresia. Ao, aorta; DAO, descending aorta; LA, left atrium. (Reproduced from Daubeney *et al. J Am Coll Cardiol* 2002;**39**:1670–9, with permission from the *Journal of the American College of Cardiology.*)

Table 40.2 Grading of connections.

Grade	RVCAC[a]	RVDCC[a]	Frequency (range) (%)[b]
0	Nil	No	46 (25–55)
1	Small and insignificant	No	18 (8–21)
2	Significant, filling the aortic root from RV injection	Possible	20 (18–23)
3	Associated with one interruption in a major coronary artery	Yes	10 (4–20)
4	Associated with interruptions in two major coronary arteries	Yes	5 (2–15)

[a]RVCAC, right ventricle to coronary artery connections; RVDCC, right ventricular-dependent coronary circulation.
[b]Frequency was calculated from review of a total of 511 patients, although exact definitions vary between observers [1,27,40,41].

in the latter would histologic abnormalities of the coronary system be expected to occur [12,34,44].

Typically, the RVCACs connect to branches of either the right coronary artery (RCA) or the left anterior descending artery (LAD). Reversed turbulent flow from the hypertensive RV disturbs the formation of the normal coronary vasculature. These effects range from mild intimal and medial thickening, with a normal-sized lumen, to complete loss of the normal arterial wall morphology, with replacement by fibrocellular tissue that causes severe stenosis or obliteration of the arterial lumen [12,34] (Figure 40.7). Macroscopically, stenoses and even interruption of the epicardial coronary arteries may develop, and occasionally the RVCACs become dilated and ectatic [1] (Figure 40.8). The affected coronary arteries are usually the proximal LAD and distal RCA [1,27,40] adjacent to the RV. Rarely, the circumflex artery is involved [1,14].

Right ventricular-dependent coronary circulation (RVDCC)

The most severe disruption of the native coronary arteries can cause an RVDCC. This occurs when the coronary artery blood supply depends upon maintaining systemic or suprasystemic RV pressures. An RVDCC is present when there is:

- coronary ostial atresia
- interruption of a single major coronary artery
- significant stenosis of a single major coronary artery
- markedly ectatic coronary artery connections sufficient to cause severe coronary steal if the RV were decompressed [1,12,45].
(a)
(b)

Figure 40.6 (a) The angiocardiographic appearance of spongy myocardium with extensive myocardial sinusoids (arrows) is demonstrated by this lateral right ventriculogram. (b) Ventriculocoronary connections between a diminutive right ventricle and both coronary arteries. Frontal right ventriculogram demonstrates opacification of both right and left coronary arteries. The curved black arrow notes the ventriculocoronary connection. The right coronary artery (black arrows) is also opacified and shows minimal luminal irregularities. The left anterior descending coronary artery shows multiple levels of stenosis (white arrows). AO, aorta; RV, right ventricle. (Reproduced with permission from Freedom *et al. Congenital Heart Disease: Textbook of Angiocardiography*. Armonk, NY: Futura Publishing, 1997, pp. 617–62.)

Some have more stringent criteria for defining RVDCC, requiring the involvement of two coronary arteries [40,46], but this seems excessive. Ultimately, the absence of an RVDCC in the presence of RVCACs can only be confirmed if decompression of the RV is tolerated by the coronary
Figure 40.7 Cross-section of the anterior descending coronary artery demonstrates virtual luminal occlusion by myointimal hyperplasia in this neonate with, in retrospect, a right ventricular-dependent coronary circulation. (Reproduced with permission from Freedom *et al. Congenital Heart Disease: Textbook of Angiocardiography*. Armonk, NY: Futura Publishing, 1997, pp. 617–62.)
Figure 40.8 Various types of right ventricular-dependent coronary circulations in pulmonary atresia and intact ventricular septum. (a) Absent connections between coronary arteries and aorta; (b) multiple connections with proximal right coronary artery narrowing and left anterior descending interruption; (c) severe ectasia of both right and left coronary arteries with ventriculocoronary connections; (d) multiple ventriculocoronary connections with origin of left coronary artery from pulmonary artery. circulation, and the intra-procedure ECG is a sensitive barometer of this measure [47].

The proportion of patients with an RVDCC varies between 7.6% [1] and 23% [8,12]. Once a diagnosis of RVDCC has

been established, the implications for the management are profound.

Left-sided structures

Although PAIVS is considered a pathologic condition of the right heart, it has important implications for left-sided heart development as a consequence of the disruption of the myocardium of the left ventricle and its coronary blood supply [35]. Additionally, the hypertensive RV may create a convex distortion of the LV septum, forming a subaortic bulge (Figure 40.9a–c). There is a relatively high proportion of coexisting LV and outflow tract abnormalities (8% in one population study [1]), aortic stenosis [48,49], and coarctation of the aorta [50,51].

Conduction system

The cardiac conduction system is generally normal [52], although Wolff–Parkinson–White syndrome has been reported [29,53].

Rare associated anomalies

Associated anomalies are rare and a large retrospective postmortem review found no significant associated extracardiac anomalies [54]. PAIVS has been associated with trisomy 21 [2], trisomy 18 [41,55], and 22q11 deletion [56].

Clinical presentation

Fetal diagnosis
PAIVS is increasingly being diagnosed in fetuses. The diagnosis is suspected from asymmetry on a four-chamber view, and features of critical pulmonary obstruction can be seen as early as 12 weeks' gestation [36]. Since an association with chromosomal or extracardiac abnormalities is rare, decisions regarding continuation of pregnancy are generally based on the malformation's severity. Gardiner *et al.* [10] formed a set of parameters that predict a final biventricular circulation with a sensitivity of 92% and a specificity of 100%, and other groups have reported similar results [57,58] (see Chapter 16). RVCACs can be detected *in utero* in some patients [10,44,59]. In the United Kingdom, the termination rate for antenatally diagnosed PAIVS was ~60% in the early 1990s [2].

When the pregnancy is continued, in a few centers *in utero* pulmonary valvoplasty is considered in selected patients (discussed later). At birth, appropriate plans can be put in

(a)

(b)

(c)
Figure 40.9 (a) Echocardiographic apical four-chamber view. A subaortic bulge is seen in this patient with a bipartite RV. (b) Convex septal bulge in a patient with a small and hypertensive RV. This septal bulge produces the substrate for LV outflow tract obstruction after volume-reducing surgery such as bidirectional cavopulmonary connection or a Fontan-type procedure. (c) Left long axial oblique left ventriculogram demonstrates the convex septal bulge (arrows) promoting dynamic left ventricular outflow tract obstruction. AO, aorta; LV, left ventricle; MV, mitral valve. (Parts (b) and (c) reproduced with permission from Freedom *et al. Congenital Heart Disease: Textbook of Angiocardiography.* Armonk, NY: Futura Publishing, 1997, pp. 617–62.)

place for a neonate with a duct-dependent lesion; the degree of hypoxia prior to intervention is generally much reduced in patients with an antenatal diagnosis, but so far there is no proven survival benefit [2,60].

History and examination

The initial presentation of an undiagnosed neonate with PAIVS is typically with cyanosis when the duct begins to close soon after birth, usually within the first 48 h. On

examination, the first heart sound is normal, the second heart sound single and soft, and there is no ejection click. A ductal murmur may be audible at the left upper sternal edge, or a soft blowing pansystolic murmur at the left lower sternal edge from tricuspid regurgitation. The peripheral pulses are generally good, unless the atrial septal defect is severely restrictive, with normal four-limb blood pressures and saturations low but equal in all extremities.

The presentation in neonates with severe tricuspid regurgitation is considerably different. The left side of the chest may be bulging, with a rocking precordium and systolic thrill, accompanying the loud pansystolic murmur. Heart failure is often conspicuous, with significant hepatomegaly. Respiratory distress or ventilatory difficulties may result from hypoplastic lungs.

Electrocardiogram and chest X-ray

The EKG in most neonates with PAIVS reflects the small right ventricle. The rhythm is generally normal sinus. The P waves are tall and peaked, reflecting right atrial hypertrophy. The mean frontal QRS axis is less rightward than in most neonates, between +30° and +90°. In the chest leads, there is a more adult-type pattern with an rS waveform in the right precordial leads (V4R and V1) and a pure R wave in the left precordial leads (V5 and V6). There may be markers of left ventricular hypertrophy, but EKG evidence of right ventricular hypertrophy is rare despite the RV muscle bulk. Occasionally, ST-T changes reflect myocardial ischemia.

The chest X-ray shows a relatively normal cardiothoracic ratio, except in those with a "wall-to-wall" heart. The right atrial border is prominent. The pulmonary vascular markings are diminished. The aortic arch is generally left sided.

Echocardiography

Echocardiography remains the most important imaging modality in the diagnosis of PAIVS. In such a heterogeneous condition, all morphologic features of the heart must be systematically evaluated to optimize management [61].

Atrial septal defect

The ASD is usually unrestrictive in a term neonate. The size and flow across the ASD should be defined. The right atrium is generally enlarged.

Tricuspid valve

The size of the tricuspid valve annulus should be measured from the four-chamber view in early diastole to allow comparison with published z-scores [23–25]. The anteroposterior diameter can be evaluated on a modified long-axis parasternal view, but it should not be used as a measurement for z-score calculation. The tricuspid valve is frequently dysplastic and small. With severe right ventricular

hypertrophy it may be difficult to evaluate the subvalvar apparatus. A short-axis sweep, from either a parasternal or subcostal view, should define the valve's morphology, particularly of the septal leaflet.

Right ventricle

The RV often looks smaller on echocardiography than its true size, as the intertrabecular spaces appear obliterated. Surrogate markers of RV size, such as TV annulus, are often used and have been well validated [62–64]. Some advocate RV length as a more accurate marker of RV size [61], although it may be difficult to define because of thick apical trabeculations. From a four-chamber and a modified oblique subcostal view, the inlet, apical, and infundibular portion of the RV can be assessed. This allows classification of the RV as "unipartite," "bipartite," or "tripartite." The RV systolic pressure is usually suprasystemic, and can be estimated from the velocity of the TR jet. There may occasionally be a small, insignificant muscular VSD, which is unmasked after RV decompression.

Pulmonary valve and branch pulmonary arteries

The size and morphology of the PV are generally evaluated from the short-axis parasternal view, and measurements for calculation of z-scores should be made from that position. It may be difficult to differentiate critical pulmonary stenosis from pulmonary atresia. The only clue about valve patency may be a few pixels of regurgitation on color flow evaluation. In patients with severe TR and poor RV function, particularly those with a "wall-to-wall" heart, differentiation of anatomic atresia from functional atresia of the PV may be difficult. Again, regurgitation is the most sensitive measure of patency of the PV.

The main pulmonary artery and branch pulmonary arteries are generally confluent and of good size. Rare anomalies should be excluded.

Coronary arteries

Significant RVCACs may be found on color Doppler evaluation. The Nyquist limit should be set low, ~40–60 cm s^{-1} [65], and at high sensitivity. Transmural color Doppler flow may be seen from RV cavity to coronary arteries during systole with reversed flow in diastole. The flow within RVCACs may be confused with flow within the deep trabeculations of the RV, but can be differentiated as the flow in the trabeculations should be towards the RV chamber in systole. The most useful view is a subcostal long-axis view, but four-chamber and short-axis parasternal views may also be helpful.

The origins of the coronary arteries at the aortic root should also be evaluated. z-Score algorithms are widely available for measurements of coronary arteries at significant positions, and an increased z-score ($> +2$) should arouse suspicion of RVCACs if not already identified (Figure 40.10).
Figure 40.10 A large right coronary artery (solid arrows) arising from the aortic root should lead to a search for RVCACs. Left coronary artery shown by dotted arrows. (Courtesy Dr J. Simpson, Evelina Children's Hospital, London.)

Color and pulsed-wave Doppler evaluation of the coronary flow close to the coronary orifice should also be employed. Retrograde systolic or bidirectional flow suggests significant RVCACs [66,67].

Stenoses of the native epicardial coronary arteries are more difficult to identify, unless they occur in a region of the coronary artery that is well visualized. Occasionally, atresia of the coronary orifice may occur [68,69], and if a coronary orifice cannot be identified on transthoracic echocardiography this should be evaluated with another imaging modality.

Left heart structures

LV wall motion abnormalities should lead to a search for RVCACs, if not already identified [65]. The LV length and MV annulus should be measured to compare with the size of right heart structures, Aortic stenosis and coarctation should be excluded.

Diagnostic cardiac catheterization

The role of diagnostic catheterization in PAIVS has evolved. Catheter pulmonary valvotomy is now established as a common management technique for those with favorable anatomy and angiography is routinely performed during the procedure [70].

For those patients not undergoing catheter intervention, selective angiography remains the way to define the coronary anatomy. At some centers, all patients with PAIVS undergo cardiac catheterization [14,27]. Finding RVCACs alone does not contraindicate RV decompression of the right ventricle. Therefore, at other centers, diagnostic cardiac catheterization is reserved for those most likely to have an RVDCC. This includes patients with the smallest right ventricles; for those determined suitable for only a univentricular repair, it may be appropriate to perform the angiography later in these patients, before a bidirectional cavopulmonary anastomosis [36].

Angiography should include a RV angiogram, to define the form and function of the RV and the presence of RVCACs. Aortic root angiography should be performed in the same planes to establish the relationship of the RVCACs and the native epicardial coronary anatomy [71,72]. Angiograms require extensive experience in reviewing normal coronary anatomy and should be interpreted by the most experience operator available [27]. If a large RVCAC is identified but there is no retrograde flow into the aorta, dense opacification of the aortic root is required to rule out an interruption of the coronary artery [71–73].

Hemodynamic evaluation usually shows a right atrial pressure slightly higher than the left, and suprasystemic RV pressure.

Other imaging modalities

Computed tomography (CT) and magnetic resonance imaging (MRI) techniques have not been established in the routine evaluation of a neonate with PAIVS. Newer CT multidetector techniques, such as Flash spiral mode, can provide increasingly detailed coronary artery anatomy in neonates. They have not been validated, however, in the unusual anatomy that exists in PAIVS.

Table 40.3 Parameters suggested by investigators to determine treatment pathway[a].

Parameter[b]	Biventricular route	Borderline	Univentricular route
TV z-score [64]	>−2.5	−2.5 to −5	<−5
RV morphology [85]	Tripartite	Bipartite	Unipartite
RVDI [86]	>0.35	<0.35	<0.35 *and* muscular atresia
Presence of RV infundibulum [87]	Yes	Small and narrow	No
RVCACs	Nil/minor	Minor/major	RVDCC
Treatment at presentation	RF perforation or closed surgical valvotomy	RF perforation or surgical valvotomy/ RVOT patch *and consider* PDA stent/BTS	Palliative procedure – BTS ± BAS

[a]RVDI, RV development index {calculated as [RVEDV (%N) × TVD (%N) × RVOD (mm) × 10^{-5}]/BSA (m^2), where BSA, body surface area};%N, percentage of normal, RVEDV, RV end diastolic volume, RVOD, RV outflow diameter, TVD, TV diameter, RVCAC, RV to coronary artery connections; RVDCC, RV-dependent coronary circulation; RVOT, RV outflow tract; BTS, Blalock–Taussig shunt; BAS, balloon atrial septostomy.
[b]Note TV z-score is highly dependent upon z-score algorithm, and some investigators do not report which algorithm has been used.

MRI may play a future role in evaluating the hypoplastic RV, paralleling studies of the hypoplastic left heart. Currently, MRI is not used routinely to evaluate ventricular volumes and function of neonates.

Initial management

Fetal intervention

A fetal diagnosis of PAIVS is made in 30–70% of patients with PAIVS [60], depending upon the resources for fetal diagnosis. Fetal intervention is available in some centers, but the worldwide experience of *in utero* valvoplasty remains extremely small [74–77] (see Chapter 16). Limited evidence suggests that valvoplasty may improve RV growth *in utero* and the later chances of a biventricular outcome. Patients should be considered for the procedure only if they are at the severe end of the disease spectrum, likely to receive a univentricular repair without intervention and without significant RVCACs that would prevent RV decompression postnatally [10,74]. In 2006, the UK National Institute for Health and Clinical Excellence (NICE) issued guidelines on percutaneous fetal balloon valvoplasty [78], but noted that evidence is lacking for this procedure.

Treatment algorithms

At birth, the neonate has a duct-dependent pulmonary circulation. Therefore, the infant should be maintained on a prostaglandin E$_1$ infusion to maintain duct patency. In patients with severe RV hypoplasia and the greatest likelihood of possessing an RVDCC, good right-sided filling pressures and a high RV pressure must be maintained. Once the RVDCC is compromised, it is difficult to resuscitate these patients as extracorporeal membrane oxygenation (ECMO) generally reduces RV pressure, and cardiopulmonary resuscitation is also less effective than in most other neonates [79].

Once stabilized and evaluated, the best treatment pathway is selected on an individual basis according to RV and coronary anatomy. The management protocol for neonates remains controversial. Centers that achieve a balance of biventricular and univentricular pathways for patients generally have the best survival outcomes [80].

With the exception of those patients with an RVDCC or a severely regurgitant TV, it is becoming more widely accepted that most patients with membranous atresia and a tripartite and possibly bipartite ventricle should undergo RV decompression. [64,81]. This entails establishing forward flow through the RV, even if hypoplastic. There are several factors to be considered. First, the RV growth potential and regression of RVCACs following decompression are difficult to predict [1,62,81,82]. Second, LV function in a univentricular circulation is hampered by the adjacent hypertensive RV [83]. Third, in some patients, RVCACs progress postnatally to an RVDCC when the RV is not decompressed [1]. The risks of a more technically demanding procedure increase with the smallest RVs, and risk–benefit assessment must be individualized for each patient [84]. Table 40.3 illustrates the parameters suggested by various investigators to delineate the borderline heart anatomy.

Forward flow can be established by either catheter or surgical intervention. The RV of patients with borderline anatomy is often incapable of supplying the entire pulmonary circulation after creating forward flow. In these patients, the pulmonary blood flow can be augmented by one of three methods: continued prostaglandin E$_1$ infusion, stenting the arterial duct, or creating a systemic to pulmonary shunt. In those patients with the smallest RV, the atrial septal defect is often enlarged in the initial procedure [64]. The patient then requires careful evaluation at each follow-up as biventricular, one-and-a half ventricle, and univentricular outcomes all remain possible.

Catheter intervention

Transcatheter laser-assisted balloon pulmonary valve dilatation in pulmonary valve atresia was first described in 1991 [88]. Over the last two decades, significant progress has been made in terms of safety and technical limitations [89–96], and catheter pulmonary valvotomy now forms the mainstay of treatment for PAIVS in many centers for patients with favorable anatomy [8,36,97,98]. Results of the procedure are good, and may be better than in primary surgical intervention [97,99–103]. Comparison with surgical results is difficult, because patients selected for catheter valvotomy tend to have the most favorable anatomy [102].

Techniques for catheter perforation of the pulmonary valve include the use of mechanical force [104], laser energy, and radiofrequency energy (Figure 40.11a–e). The first two have been largely replaced by the last. The equipment required to produce radiofrequency energy is safer and more readily available than laser equipment, and is often already used in laboratories performing electrophysiologic procedures. Some use both arterial and venous access, with catheters "kissing" across the atretic pulmonary valve prior to perforation [70], whereas others use only venous access [105]. The greatest risk of the procedure is that the wire may burn through the pulmonary trunk, causing cardiac tamponade. Once the wire has been safely positioned across the atretic valve, a balloon is passed over the wire and the valve is dilated. Forward flow can be seen on subsequent RV angiography. The catheter technique is increasingly difficult with smaller patients and smaller RVs, and a hybrid procedure may be used in the highest risk patients. Direct access to the right ventricle is obtained via a small subxiphisternal incision and a transventricular sheath is placed to provide optimum position and stability for radiofrequency perforation of the valve [106,107].

At the end of the procedure, the arterial duct may be stented, if the pulmonary blood flow needs to be augmented for the first few months of life [90,108,109]. If such an approach is planned, the prostaglandin infusion should be stopped at the beginning of the catheter valvotomy to allow the duct to constrict and allow safe stent placement [70]. After opening the pulmonary valve, the RV becomes smaller, thus demonstrating the need for the stent [110]. The long-term results of this approach are unknown.

Surgical intervention

Operative management as the initial procedure has progressively become reserved for patients with the most severe forms of PAIVS, particularly at centers with the facility to perform catheter valvotomy. In patients in whom RV decompression is not contraindicated, a closed pulmonary valvotomy is performed or the right ventricular outflow tract (RVOT) is enlarged with a patch [47,62,65,80,81,84,85,98]. A Blalock–Taussig or central shunt is then created to supplement pulmonary blood flow in all patients except those with the most favorable anatomy. In patients assumed to follow a univentricular pathway, a balloon atrial septostomy is performed before creating the shunt [16,36].

Those who advocate a more aggressive approach towards achieving a biventricular repair also ligate the RVCACs in the initial procedure [65,81]. In this technique, the RVCACs are identified from preoperative echocardiography and angiography, and monitored in real time during the operation by both surface and transesophageal echocardiography. The RVCACs are trial occluded and the operators monitor for EKG and wall motion abnormalities. If the trial occlusion is well tolerated, the RVCAC is ligated. The aim is for patients with borderline RVDCC to progress to a biventricular circulation. In addition, this surgical procedure allows for tightening the ASD and encouraging forward flow through the TV and an increase in RV volume. Alternatively, those patients with significant RVCACs but without an RVDCC may undergo thromboexclusion of the RV [39,111], to protect the LV from the effects of a suprasystemic RV. From that point onwards, a univentricular outcome is mandated.

For patients with a proven RVDCC, the options are more limited. The RV cannot be decompressed, and the initial procedure is to create a systemic to pulmonary shunt [40,47]. Thereafter, the treatment pathway is towards a Fontan circulation, but thromboexclusion should not be performed [39].

The surgical treatment of those patients with severe tricuspid regurgitation is very different, and is similar to that for severe Ebstein's malformation. Rarely it is possible to repair the tricuspid valve, aiming for a biventricular repair. However, in most patients a univentricular outcome is pursued, and frequently a Starnes procedure [112] is appropriate. In this procedure, the tricuspid valve is closed with autologous pericardium and a 4 mm aortopulmonary shunt is placed.

Transplantation

The patients at the most severe end of the spectrum of RVDCC are those with aortocoronary atresia (Figure 40.12). This malformation is incompatible with life, with no survivors reported [47,68], except for one patient who had a direct collateral vessel from the descending thoracic aorta connecting with the coronary circulation [69]. These patients should be put forward for early transplantation if appropriate. Bridging the patients to transplant is difficult as they are not good candidates for ECMO: the right ventricle must remain filled and pressure loaded at all times. There is only a single report of a successful transplant performed for this pathology [113].

Late management and prognosis

The aim is to separate the pulmonary and systemic circulations, abolish cyanosis, and close systemic to pulmonary or pulmonary to systemic shunts. This may be achieved in a biventricular,
Figure 40.11 Catheter-based therapy for pulmonary atresia and intact ventricular septum using radiofrequency-assisted perforation of the atretic pulmonary valve. (a) Cranially tilted frontal right ventriculogram shows atresia (arrow) of the pulmonary valve. (b) Lateral pulmonary angiogram shows an imperforate pulmonary valve. (c) The Judkins right coronary artery catheter is introduced anterograde from the femoral vein to the right ventricular (RV) outlet (three arrows). After an application of radiofrequency energy to the atretic valve, a wire has been advanced into the pulmonary artery (PA). The pulmonary valve sinus has been marked by a wire introduced retrograde through the ductus arteriosus (single arrow). (d) The wire is advanced from the RV, through the PDA, and into the descending aorta to allow a balloon (black arrow) to be introduced across the perforated pulmonary valve for valvotomy. (e) After valvotomy, right ventricle–pulmonary artery continuity is clearly established with less tricuspid regurgitation. PDA, patent ductus arteriosus; RA, right atrium. (Reproduced with permission from Freedom *et al. Congenital Heart Disease: Textbook of Angiocardiography*. Armonk, NY: Futura Publishing, 1997, pp. 617–62.)

one-and-a-half ventricle or univentricular circulation. Where not possible, the circulation remains mixed [114].

Biventricular pathway

A single procedure is rarely sufficient, and further interventions are frequently required for eventual biventricular outcome [36,99,100].

- *Residual pulmonary stenosis:* Balloon dilatation should be considered for a gradient greater than 50 mmHg or symptoms of dyspnea or presyncope.
- *Cyanosis:* Residual cyanosis (saturations <90%) represents a residual atrial right-to-left shunt. Early postoperation (<3 months), it may be necessary to augment the pulmonary blood flow with a systemic to pulmonary shunt or stenting of the arterial duct if still patent. Later following operation (>1 year), it is necessary to decide if the RV can support the entire pulmonary blood flow. If the RV is capable, the ASD should be closed, either surgically or by device. Trial occlusion of the ASD reduces the risk of misjudging the RV potential. If the RV is small and restrictive but with good function, an RV overhaul, which enlarges the RV cavity, should be considered [115]. If the RV remains very small and has little prospect of supporting the entire pulmonary blood flow, a one-and-a-half ventricle pathway may be indicated (see below). MRI may help assess RV size and function.
- *Closure of shunts:* Systemic-to-pulmonary shunts and arterial duct stents may close spontaneously. If they remain patent

into childhood, they should be closed, usually by a catheter technique.

- *Late concerns:* The course resembles that of repaired tetralogy of Fallot. The pulmonary valve is frequently regurgitant, and may require replacement, either percutaneously or surgically. The dysplastic tricuspid valve may require repair.

Growth of the right ventricle

Evidence of RV growth in patients with a biventricular circulation is controversial. Growth implies that the z-scores of markers of RV size increase over time. Following surgical intervention, some groups have reported RV catch-up growth, particularly in those with the smallest RVs [63,82,116,117]. Follow-up studies of patients who have undergone catheter valvotomy have not shown convincing evidence of RV growth [100,118].

One-and-a-half ventricle pathway

In a one-and-a-half ventricle circulation, the superior vena cava drains directly to the pulmonary arteries via a bidirectional cavopulmonary anastomosis (CPA), while the inferior vena cava drains to the RV providing pulsatile blood flow to the lungs [119–122]. The atrial septal defect is closed. The cavopulmonary anastomosis is often combined with an RV overhaul procedure [115,121]. Although this approach provides some physiologic advantages, there is little evidence that long-term outcome in terms of exercise tolerance or freedom from arrhythmia is improved compared with a univentricular circulation [121,122].

Univentricular pathway

The Fontan circulation in patients with PAIVS is generally completed within the first 4 years of life. The complications of a univentricular circulation are the same as for other patients with a single ventricle circulation, and described in Chapter 39. Chronic low cardiac output and elevated systemic venous pressures create long-term concern about thrombotic events, arrhythmias, and protein-losing enteropathy [123].

There is a detrimental effect of the hypertensive RV adjacent to the LV [83] causing abnormal septal wall motion and convexity into the LV outflow tract resulting in subaortic obstruction [1,124]. Therefore, with a Fontan circulation RV thromboexclusion should be considered [39].

Right ventricular-dependent coronary circulation

Cardiopulmonary bypass (CPB) has a higher risk in patients with RVDCC because of the requirement to ensure adequate RV filling throughout the procedure [79]. With careful monitoring throughout CPB, the overall mortality is broadly comparable to that for other patients with PAIVS undergoing a Fontan procedure (19%) [47].
Figure 40.12 Retrograde aortogram shows dense opacification with atresia of the origins of both coronary arteries in a patient with pulmonary atresia with intact ventricular septum. AO, aorta. (Reproduced with permission from Freedom *et al. Cardiol Young* 2000;**10**:60–3.)

Table 40.4 Illustration of survival rates for children born with PAIVS reported in the largest long-term studies.

Study	No. of patients[a]	Median length of follow-up (years)	RVDCC (%)	Biventricular outcome (%)	Catheter valvotomy (%)	Survival at latest follow-up (%)
Daubeney et al. (2005) [16]	168	9	4.2	32	24	70
Ashburn et al. (2004) [80]	408	10.3	5	33	Nil	59
Ekman Joelsson et al. (2001) [4]	77	6	9[b]	41	Unknown	68
Hanley et al. (1993) [63]	171	4	9	32	0	64
Moller (2010) [125]	1039	1	Unknown	Unknown	14	80

[a]Number of patients includes only those put forward for intervention.
[b]Includes "significant RVCACs."

Prognosis

The prognosis for patients with PAIVS is difficult to compare across studies because of its heterogeneity and the wide range of approaches used by different institutions. Table 40.4 shows the cumulative experience of the largest multicenter and population-based studies: overall survival into adolescence is ~60–70%. Studies universally report excellent survival after the first year of life.

The overall quality of life for survivors with PAIVS has been found to be good, with no significant difference between a univentricular or biventricular circulation [126]. Exercise tolerance is universally decreased, and there is only a minor, if any, increase in exercise tolerance for those with biventricular compared with univentricular circulation [127,128].

Long-term concerns include tachyarrhythmia, but there are few data about patients with PAIVS in adulthood. Sudden death due to arrhythmia and atrial arrhythmias have been reported, but the overall incidence appears low [39,121,129]. As expected, the RV remains restrictive in later life [130]. Life-long surveillance is mandatory for all patients with PAIVS, but special care should be given to those with significant RVCACs and RVDCC, where evidence of progressive myocardial ischemia, LV dysfunction, and malignant ventricular arrhythmia should be sought [131,132].

Pregnancy

Successful pregnancies have been reported in women with PAIVS following biventricular repair [133]. Close supervision is required, preferably in an obstetric unit with expertise in the requirements of congenital heart disease patients.

Tetralogy of Fallot and Pulmonary Atresia with Ventricular Septal Defect

Andrew Redington

University of Toronto and Hospital for Sick Children, Toronto, ON, Canada

Introduction

Tetralogy of Fallot is the commonest of the cyanotic congenital heart diseases and, in its simplest form, was one of the first to be successfully treated by palliative (the classical Blalock–Taussig shunt in 1945) and then open-heart surgery over 50 years ago. The survivors of these ground-breaking procedures are entering late middle life, and already there are more adults than children with the disease.

The term tetralogy of Fallot is often used as an umbrella diagnosis that includes those with abnormal ventriculo-arterial connections (tetralogy of Fallot with double-outlet right ventricle), and particular associated features (e.g., tetralogy of Fallot with pulmonary atresia, with and without major aortopulmonary collateral arteries, tetralogy of Fallot with absent pulmonary valve syndrome).

Anatomy

The fundamental abnormality that characterizes the disease is anterior and cephalad deviation of the outlet septum (Figure 41.1). The secondary effects of this singular abnormality are the creation of a ventricular septal defect (VSD), aortic override, and right ventricular outflow tract obstruction and hypertrophy [1–3].

Right ventricular outflow tract obstruction

The hallmark of the right ventricular outflow tract obstruction in tetralogy of Fallot is infundibular stenosis. This is due to many factors, the most important of which is the anterior cephalad deviation of the outlet septum [2]. Outlet obstruction is further aggravated by hypertrophy of the outlet septum, the anterior limb of the septomarginal trabeculation, and the septoparietal trabeculations. Indeed, in the absence of these coexisting abnormalities, the degree of outflow tract obstruction resulting from the malaligned outlet septum alone may be minimal or none, the intracardiac anatomy of the "Eisenmenger VSD" being almost indistinguishable from that of tetralogy of Fallot, except for the subpulmonary stenosis. [2]

The right ventricular outflow tract obstruction, however, is not limited to the infundibular region. In most patients, the pulmonary valve is stenotic, the pulmonary valve annulus itself can be hypoplastic, and supravalvar obstruction may be present at the level of the sinotubular ridge and extend to involve the pulmonary trunk. The branch pulmonary arteries can be diffusely small or may have focal areas of narrowing, most commonly at their origins, but also involving the lobar and segmental divisions. Obstruction is commonly in the proximal left pulmonary artery at the juxtaductal or juxtaligamental site. Delineating the sites of right ventricular outflow tract obstruction is important for planning repair.

Ventricular septal defect

The VSD in patients with tetralogy of Fallot is usually large and unrestrictive. In most patients, the VSD is perimembranous, with the central fibrous body forming the inferior border and the conduction system running adjacent. In approximately 20% of patients there is a muscular posteroinferior rim (Figure 41.1) [3]. Controversy remains as to whether tetralogy of Fallot can coexist with a doubly committed VSD. The hallmark of the doubly committed VSD is fibrous continuity of the leaflets of the aortic and pulmonary valves. This implies absence of the muscular outlet septum, which then clearly cannot be deviated anterior and cephalad. Nonetheless, there exists a group of children with identical anatomy and physiology to that of "classical" tetralogy, but who possess a

Figure 41.1 An anatomic specimen from tetralogy of Fallot. Note the hypertrophied outlet septum (OS), which is malaligned with respect to the rest of the septum. Consequently there is aortic override (AO), and right ventricular outflow tract obstruction with hypertrophied septoparietal trabeculations (SPT). Note that in this case there is a muscular postero-inferior rim (*) to the ventricular septal defect (VSD), separating the tricuspid valve (TV) leaflet from the aortic valve. Original image kindly supplied by Professor RH Anderson.
Figure 41.2 Aortogram in a long-axis oblique/cranial projection. The left anterior descending (LAD) coronary artery can be seen arising from the proximal right coronary artery (RCA) with a course that traverses the right ventricular outflow tract. CIRC, circumflex coronary artery.

doubly committed defect (sometimes described as the South American Tet, the Mexican Tet, the Asian Tet, etc.). As an accommodation, some suggest that the "fibrous component" of the outlet septum does indeed persist in these patients (a small ridge of fibrous tissue is often seen separating the semilunar valve leaflets), thus allowing the diagnosis of tetralogy.

Although most patients have a single large defect, additional muscular VSDs may be found.

Aortic override

The degree of aortic override varies considerably. It should be remembered that tetralogy of Fallot is a diagnosis, whereas double-outlet right ventricle defines a ventriculo-arterial connection, and the two may coexist. If the degree of override is >50%, then the designation of tetralogy of Fallot with double-outlet right ventricle may be made. This is sometimes, but not always, associated with a bilateral infundibulum

(associated muscular separation of the mitral and aortic valve leaflets). The latter is neither required for the definition of double-outlet connection (it may occur in the setting of a clearly dominant connection of the aorta to the left ventricle) nor excludes the diagnosis of tetralogy of Fallot.

Associated anatomic features

Several anatomic features frequently associated with tetralogy of Fallot can have considerable clinical and therapeutic implications. Atrial communications are fairly frequent and usually at the fossa ovalis as either a patent foramen ovale or more rarely a true secundum atrial septal defect. Approximately 25% of patients have a right-sided aortic arch that can alter the approach to a palliative shunt. Tetralogy of Fallot may coexist with atrioventricular septal defect (AVSD), and should be especially considered in children with Down syndrome. A primum component may not be present in these, and under such circumstances the clue to the presence of an AVSD is a trileaflet left atrioventricular valve on echocardiographic imaging. Straddling atrioventricular valve is a rare associated feature. Abnormalities of the coronary arteries, such as the left anterior descending coronary artery arising from the right coronary artery, occur in ~4% of patients (Figure 41.2). This anomaly is exceedingly important to recognize, as the left anterior descending coronary then crosses the right ventricular outflow tract, and failure to identify this vessel can result in its inadvertent transection during outflow tract repair. Occasionally, significant systemic-to-pulmonary collaterals are present even when the outflow tract is patent. This is commonly associated with discontinuous branch pulmonary arteries or bilaterally diminutive central pulmonary arteries.

Tetralogy of Fallot with absent pulmonary valve

Tetralogy of Fallot with absent pulmonary valve affects 2–10% of patients with intracardiac anatomy typical of tetralogy of Fallot, but characterized by the absence of a

functioning pulmonary valve [3]. The pulmonary annulus is usually small with vestigial pulmonary valve leaflets, resulting in some degree of stenosis and severe regurgitation. The anatomic hallmark of this lesion is aneurysmal dilatation of the main and branch pulmonary arteries, particularly the right, which may result in bronchial compression and airway compromise that can be life-threatening. The arterial duct and/or ligament is usually absent, and this feature has been implicated in the pathogenesis of the disease. The physiology varies considerably, but the early management depends primarily on the severity of the airway disease.

Tetralogy of Fallot with pulmonary atresia

This variant can be considered at the most severe end of the spectrum of tetralogy of Fallot, and occurs in 11–24%. The intracardiac anatomy is identical with that of classic tetralogy of Fallot with a large outlet VSD, an overriding aorta, normal or near-normal sized right and left ventricles, and normal atrioventricular valves. The outflow tract anatomy is variable, however, ranging from valvar atresia alone to muscular atresia beneath a usually small pulmonary trunk arising in the usual position, and to muscular atresia with absence of the pulmonary trunk (single-outlet connection) [3,4]. As a result, the pulmonary artery anatomy is much more variable. In the least complex form, the main pulmonary artery is supplied by the arterial duct. These patients are currently managed by complete repair in the early neonatal period. At the other end of the spectrum, the central pulmonary arteries are either absent or diminutive, and the segmental pulmonary blood flow is supplied by multiple aortopulmonary collateral arteries (MAPCAs). These MAPCAs arise usually from the descending thoracic aorta, but occasionally from the innominate or subclavian arteries or the upper part of the aortic arch; rarely they arise from the abdominal aorta. MAPCAs can supply multiple bronchopulmonary segments in either a unifocal manner or with a multifocal distribution of pulmonary blood flow to different segments by the central pulmonary arteries and the MAPCAs. Careful delineation of the segmental blood supply is required prior to surgical management. Although advanced imaging techniques (CT and MRI) are able to define the anatomy of the MAPCAs and central PAs, there remains an important role for cardiac catheterization and angiography, to define the nature of the segmental connections in the more complex patients.

Incidence

Tetralogy of Fallot occurs in 3–5/10 000 live births (see Chapter 19) and is among the three or four most common cardiac lesions requiring cardiac catheterization or operation

Table 41.1 Conditions associated with tetralogy of Fallot.

Trisomy 21 (Down)
Velocardiofacial (Shprintzen)
22q11 deletion or CATCH-22[a] syndrome
Goldenhars
Thrombocytopenia absent radius
CHARGE[b]
VATER[c]/VACTERL[d]
Fetal alcohol
Pierre Robin
Associated organ abnormalities
Include tracheoesophageal fistula, imperforate anus, hydrocephalus, omphalocele

[a]CATCH-22 = cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia, and abnormality of chromosome 22.
[b]CHARGE = coloboma, heart disease, atresia choanae, retarded growth and development, genital abnormalities, ear anomalies.
[c]VATER = vertebral defects, anal atresia, tracheoesophageal fistula, renal defects, and radial upper arm dysplasia.
[d]VACTERL = VATER + cardiac and limb anomalies.

in the first year of life [5–7]. It is slightly more common in males than females and is associated with chromosomal abnormalities in ~11% of patients, nonchromosomal syndrome complexes in ~8%, and problems of other major organs in ~16% (Table 41.1). A microdeletion of chromosome 22q11 may be present in 20–30% of patients with tetralogy of Fallot, with higher values if there is also pulmonary atresia [8–11]. This same chromosome is involved in DiGeorge syndrome and abnormalities considered previously such as the velocardiofacial syndrome (Shprintzen syndrome).

The recurrence risk for tetralogy of Fallot in families with one affected child is probably 2–5%. For mothers who have tetralogy of Fallot, the transmission risk for congenital heart disease in offspring is probably 5–10%; for fathers with tetralogy of Fallot, the transmission risk is ≤5 [12].

Natural history

Fallot's prediction [13] that ~75% of older cyanotic children would have tetralogy of Fallot was true before the advent of cardiac surgery. This lesion has the best untreated outcome of any cyanotic malformation, although the median age at death in different series has ranged from age 4 to 12 years [14,15]. Only ~10% of untreated patients live beyond 20 years [15–18], and they have neither pulmonary atresia nor absent pulmonary valves. Fewer than 5% survive to age 40 years [19]. Most long-term survivors had only mild cyanosis, although they are still at risk of many of the complications of

chronic cyanotic heart disease (see Chapter 52). In addition, ventricular tachycardia occurs with increasing frequency as they age [20].

About half of the patients with tetralogy of Fallot and absent pulmonary valve die before 1 year of age [3], mainly because of airway complications. The remainder continue to be mildly cyanotic for 5–20 years but die prematurely because of right ventricular failure caused by volume overload.

About half of the patients with tetralogy of Fallot and pulmonary atresia die before 1 year of age, and presentation with severe cyanosis and small MAPCAs is ominous [3,21]. The amount of pulmonary blood flow governs the outcome for the remainder, with some patients able to survive unoperated into adulthood.

Physical examination and clinical presentation

The clinical presentation of patients with tetralogy of Fallot depends primarily on the degree of right ventricular outflow tract obstruction. Presentation can range from a profoundly cyanotic newborn with ductus-dependent pulmonary circulation to an asymptomatic child with adequate pulmonary flow presenting with a murmur. Because of this wide spectrum of presentation, the physical findings vary widely. Relatively few are cyanotic at birth, but most become cyanotic by 3 months of age.

Inspection often reveals an apparently healthy infant or child, although major extracardiac anomalies, such as hypospadias, cleft lip and palate, pectus carinatum, and other bony abnormalities, can be seen [22]. Cyanosis is present to varying degrees and can be best appreciated in the mucous membranes or nail beds. The degree of cyanosis depends not only on the amount of right-to-left intracardiac shunting, but also on the hemoglobin concentration. To appreciate cyanosis, there must be approximately 3–5 g dl^{-1} of desaturated hemoglobin in arterial blood; this quantity is easier to achieve at higher hemoglobin concentrations. Therefore, the relatively erythrocytotic neonate may appear more cyanotic shortly after birth than at a few months of age during the period of normal postnatal physiologic anemia.

The level of cyanosis in a given individual also varies with activity and metabolic rate. Fever and exercise increase the level of cyanosis, both from the decreased systemic vascular resistance and from a resultant increase in right-to-left shunting, and also increased oxygen consumption by the tissues, with a resultant fall in mixed venous saturation.

Although rarely observed in "developed" countries, older children with unrepaired tetralogy of Fallot often squat. This position is thought to improve systemic saturation by increasing the systemic vascular resistance by kinking the large arterial vessels in the legs. The increased systemic resistance

shifts the biventricular output such that more blood flow enters the lungs across the pulmonary outflow obstruction, and forms the basis of the "knee–chest" positioning recommended for the early treatment of hypercyanotic spells in younger children.

Tetralogy spells or hypercyanotic spells are periods of severe cyanosis associated with hyperpnea, tachypnea, and agitation that can result in coma. They begin between 3 months and 2 years of age, and occur more commonly in the mornings, during the summer months, and during intercurrent illnesses. The episodes are usually self-limited and usually last 15–30 min, but they can be prolonged. The hypoxemia can be severe enough to alter mental status and even result in death. The physiologic basis for these episodes remains obscure, although a number of hypotheses have been proposed, including increased infundibular contractility or spasm, peripheral vasodilatation, hyperventilation, and stimulation of right ventricular mechanoreceptors [23]. The lack of a "sphincter-like" orientation of the muscles of the right ventricular outflow tract, and the occurrence of almost identical spells in the setting of a doubly committed VSD (and hence no infundibulum), make the popular characterization of "infundibular spasm" unlikely, and treatment is directed at modifying the SVR and mixed venous oxygen saturation, not the putative spasm. A child admitted with one of these spells should be diagnosed rapidly and clinically. Diagnostic investigations are not required. The combination of hyperpnea, deep cyanosis, and normal air entry into lung fields (thus excluding a foreign body in the airways) is pathognomonic. Some infants have minor spells with inconsolable irritability and only a slight increase in cyanosis. They are often erroneously diagnosed as having colic and, when severe, may even have been diagnosed as having seizures.

Clubbing of the fingers and toes develops in patients with chronic cyanosis. Although usually seen in older patients, it can develop in infancy. Clubbing resolves with restoration of normal systemic oxygen saturation after complete repair.

In a preoperative patient, the jugular venous pulsations are usually normal, although difficult to evaluate in infants. The right ventricle remains relatively compliant with normal or only mildly elevated diastolic pressures, and significant tricuspid regurgitation is uncommon. Thus the *a* and *v* waves in the jugular pulse are usually normal.

The peripheral pulses are usually normal, and accentuated pulses should suggest a large patent ductus arteriosus or significant aorticopulmonary collateral arteries. The precordial impulse can be normal, but usually a right ventricular parasternal lift can be appreciated. Hepatomegaly is unusual.

Auscultation reveals a normal first sound and a single second (aortic) sound that is loudest at the mid-left sternal border. With significant right ventricular outflow tract obstruction and low pulmonary arterial pressures, the pulmonary component of the second heart sound is usually

inaudible. Occasionally, if the outflow tract obstruction is not severe, splitting of the second heart sound can be appreciated. Third and fourth heart sounds are uncommon. An early systolic ejection click can be heard at the left mid-to-upper sternal border caused by the dilated ascending aorta and the increased systemic blood flow.

The murmur in patients with unrepaired tetralogy of Fallot is generated by the right ventricular outflow obstruction. The VSD is large and unrestrictive, and the right-to-left shunt does not produce a murmur. The murmur is classically described as a low-pitched, systolic crescendo/decrescendo ejection murmur best heard at the left mid-to-upper sternal border with radiation to the back. However, it is not uncommon for the murmur to resemble that of plateau quality, best heard at the left mid-to-lower sternal border. In these patients, one needs to rely on other physical findings such as cyanosis or a single second heart sound to suspect the diagnosis of tetralogy of Fallot. In an acyanotic neonate, the murmur caused by the left-to-right shunt across a small VSD is difficult to separate from the murmur of infundibular stenosis, and it is easy to misdiagnose the infant. The distinction can be made clinically in most infants; a neonate with tetralogy of Fallot will have a forceful right ventricular lift and usually a loud and single second heart sound.

Unlike pulmonary valve stenosis with an intact ventricular septum in which the intensity and length of the murmur increase with increasing obstruction, the murmur in tetralogy of Fallot diminishes with worsening obstruction. This is because the intensity of the murmur is related not only to the degree of obstruction, but also to the amount of flow across the obstruction. In tetralogy of Fallot, as the right ventricular outflow tract obstruction progresses, the right ventricular systolic output is preferentially shunted across the VSD and into the systemic circulation. The flow across the right ventricular outflow tract is reduced, resulting in a softer murmur. This phenomenon is best demonstrated by a tetralogy spell, during which the outflow obstruction can become so severe that the murmur becomes inaudible while the patient becomes progressively more cyanotic.

Diastolic murmurs are rarely heard in an unoperated patient with tetralogy of Fallot. A continuous murmur in the left infraclavicular region suggests a patent arterial duct. Very rarely a right-sided duct results in a continuous murmur in the right infraclavicular region. Continuous murmurs heard in the posterior lung fields raise concern about significant aorticopulmonary collaterals. An early diastolic murmur along the left sternal border is one of the hallmark findings in tetralogy of Fallot with absent pulmonary valve.

The physical examination in a postoperative patient depends on the type of procedure performed. Palliation with a systemic shunt produces a continuous murmur similar to a patent duct. Appreciation of this murmur in the immediate postoperative period may be difficult because of a ventilator or other competing noises. In this situation, auscultating with the bell of the stethoscope briefly applied to the end of the endotracheal tube often allows appreciation of the murmur because of the proximity of the shunt to the bronchi.

After complete repair of tetralogy of Fallot, a variety of physical findings can be found. On inspection, cyanosis should be absent and clubbing should resolve with time. If tricuspid regurgitation has developed, a prominent *v* wave can be appreciated in the jugular pulsations. Depending on the degree of pulmonary insufficiency and residual outflow tract obstruction, one can palpate a right ventricular parasternal lift. On auscultation, the first heart sound remains normal. The second heart sound frequently remains single. When, however, the pulmonary valve is partially or completely intact, or a valved conduit is used, the second heart sound can split normally with respiration or, if there is right bundle branch block, is widely split. It varies with respiration, but the split persists during expiration. Frequently, an ejection systolic murmur is present at the left mid-to-upper sternal border from mild residual right ventricular outflow obstruction. A louder ejection murmur should raise concern about more significant obstruction. During follow-up, long systolic ejection murmurs that are best appreciated at the left upper sternal border or in either the axilla or the back indicate branch pulmonary artery stenosis and usually warrant further investigation. A blowing, pansystolic murmur from a small residual VSD or tricuspid regurgitation may be heard at the left lower sternal border. A low-pitched delayed diastolic decrescendo murmur at the mid-left sternal border is common and results from pulmonary regurgitation caused by relief of the right ventricular outflow obstruction. This diastolic murmur should be differentiated from the high-pitched early diastolic decrescendo murmur at the left sternal border generated from aortic regurgitation. This latter murmur is not expected unless patients have had long-standing pulmonary atresia with a dilated aortic root, and it also warrants further evaluation. Most patients with satisfactory surgical results have soft systolic/diastolic to-and-fro murmurs of mild pulmonary stenosis and regurgitation along the mid-to-upper left sternal border.

Absent pulmonary valve

This is characterized by severe dilatation of the pulmonary arteries with mild pulmonary stenosis and severe pulmonary regurgitation. The dilated pulmonary arteries can compress the bronchi and result in life-threatening airway compromise as early as the immediate newborn period. Standard airway support, such as endotracheal intubation and mechanical ventilation, is sometimes only partially effective. Positioning the infant prone improves airway compromise by removing bronchial compression and can be life-saving.

Alternatively, if these infants do not have significant airway compromise, they are more apt to develop congestive

heart failure as their right ventricular outflow obstruction is less severe and left-to-right shunting with pulmonary overcirculation is possible. These infants may be intensely cyanotic at birth, but then after a few days, as pulmonary vascular resistance decreases and pulmonary blood flow increases, cyanosis is often mild or absent. On palpation, a prominent precordial impulse with a right ventricular lift is common, and a thrill may be present. Hepatomegaly can accompany other signs of congestive heart failure. On auscultation, the first heart sound is normal, and the second heart sound is single. Third or fourth sounds can be heard. There is a characteristic prominent systolic/diastolic to-and-fro murmur ("sawing wood" murmur) heard along the left sternal border. The murmur is often fairly loud. The systolic component is an ejection quality murmur generated by the pulmonary stenosis, and the diastolic component is a low-pitched decrescendo murmur generated from the severe pulmonary regurgitation.

Postoperatively, these patients may still have significant airway compromise. Depending on the type of repair, physical findings on cardiac examination often resemble those in other patients with tetralogy of Fallot.

Tetralogy of Fallot with pulmonary atresia

Auscultation reveals a single second heart sound and usually a continuous murmur from the arterial duct or MAPCAs. Occasionally, patients have no audible murmur, and, conversely, patients rarely can have loud continuous murmurs (predominantly over the back) and bounding pulses when pulmonary blood flow is unrestrictive and congestive heart failure can ensue.

Patients with a balanced degree of pulmonary flow and soft murmurs may escape detection in the neonatal period and be recognized only as their cyanosis becomes apparent, or physical examination becomes significant in terms of murmur or prominent precordial ventricular impulse.

Diagnosis

An acyanotic neonate with tetralogy of Fallot must be distinguished from an infant with a simple VSD (see earlier). If cyanotic, the infant needs to be distinguished from infants with other forms of cyanotic heart disease with pulmonic stenosis, including double-outlet right ventricle, transposition of the great arteries and a VSD, single ventricle, and tricuspid atresia with normally related great vessels. Each of these has distinctive echocardiographic features. Tricuspid atresia has a characteristic electrocardiogram, and all these entities are much less common than tetralogy of Fallot.

The diagnosis of tetralogy of Fallot is aided by electrocardiography and chest radiography. The electrocardiogram is

Figure 41.3 Posteroanterior radiograph showing the tetralogy of Fallot. The apex of the heart is elevated, resulting in a boot-shaped configuration (open arrows). The heart is not enlarged, and the pulmonary vasculature is at the lower limits of normal, suggesting a mild form of tetralogy of Fallot. There is displacement of the superior vena cava (arrows) by a right-sided aortic arch, which also displaces the esophagus towards the left (black arrow).

useful because it always shows right ventricular hypertrophy. In addition, right atrial enlargement and right-axis deviation are also usually present. Left-axis deviation should raise the possibility of an associated atrioventricular septal defect. Biventricular hypertrophy may be seen in patients who have so-called pink tetralogy with increased pulmonary blood flow. In a neonate, the first or only sign of right ventricular hypertrophy can be an upright T wave in lead Vi or V_4R after 3 days of age. As the child gets older, typical signs of right ventricular hypertrophy are present: right axis deviation, increased anterior (large R waves, or an rR' pattern or a QR pattern in V1) and rightward (large S in V6) forces, and upright T waves in V1.

The chest radiograph of the typical patient shows normal visceroatrial situs, a tilted-up apex, a concave main pulmonary artery segment, and normal to decreased pulmonary vascularity. The heart is usually not enlarged (see Figure 41.3). A right-sided aortic arch can be identified in ~25% of patients with tetralogy of Fallot.

Patients with tetralogy of Fallot and absent pulmonary valve usually have an enlarged heart and markedly enlarged main, right, and left pulmonary arteries. Frequently, lung hyperinflation and tracheobronchial compression occur (see Figure 41.4).

The electrocardiogram and chest radiograph in patients with co-existing pulmonary atresia are usually identical with those found in patients with simple tetralogy of Fallot.
Figure 41.4 Posteroanterior radiograph of tetralogy of Fallot and absence of the pulmonary valve. Typically the right pulmonary artery shows massive dilatation (arrows). The heart is markedly enlarged because of the increased stroke volume of the right ventricle. Dilatation of the left pulmonary artery may occur but is much less common.

Figure 41.5 Echocardiogram showing a four-chamber image of a fetus with tetralogy of Fallot at 32 weeks' gestation, demonstrating large ventricular septal defect (arrow). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

The rare patient with increased pulmonary blood flow caused by a large ductus or a large collateral can show an enlarged heart with increased vascularity and hyperinflated lung fields.

Echocardiography

Two-dimensional echocardiography and Doppler echocardiography usually completely define the diagnosis of tetralogy of Fallot, both prenatally and postnatally. Tetralogy of Fallot has been diagnosed as early as 14 weeks' gestation using transvaginal ultrasound.[24] This lesion, however, continues to evolve through mid and late gestation [25–28]. Serial studies of the embryo and fetus with tetralogy of Fallot are essential in preparing families for the postnatal course of these infants. Early in gestation, the large malalignment perimembranous VSD and aortic override can be seen. Anterior deviation of the outlet septum is also apparent. By mid-gestation, there is considerable variation in the size of the main pulmonary artery, ranging from normal to hypoplastic. The branch pulmonary arteries are usually of normal size. In the second half of pregnancy, patients with more severe forms of tetralogy of Fallot demonstrate abnormal growth of the main and branch pulmonary arteries, resulting in progressive hypoplasia, and even in loss of anterograde flow. The aorta may be normal or increased in size during mid-gestation, with an increased rate of growth compared with a normal fetus, resulting in the large ascending aorta characteristic of this lesion.

The likelihood of prenatal detection of tetralogy of Fallot during ultrasound screening depends on both the severity of the lesion and the experience of the ultrasonographer. Although the VSD should be seen in the four-chamber view during obstetric screening (Figure 41.5), this lesion has been missed during screening examinations that rely on this view alone. Visualization of the outflow tract views increases the likelihood of prenatal diagnosis of tetralogy of Fallot, although fetuses with a milder forms of this anomaly have relatively normal outflow tract views at mid-gestation. In large prenatal echocardiographic series using multiple imaging planes for comprehensive evaluation, tetralogy of Fallot is one of the more commonly diagnosed lesions, accounting for 4–28% of identified congenital cardiac anomalies. The subset of fetuses with tetralogy of Fallot with absent pulmonary valve are disproportionately represented in prenatal series, almost certainly because the dilated right ventricle and pulmonary arterial tree that characterize this lesion result in their more frequent identification.

During prenatal echocardiographic examination, the characteristic VSD can be demonstrated in the long-axis, sagittal, and four-chamber views. Doppler interrogation of the VSD should be included to rule out the rare restrictive VSD. Short-axis and sagittal views can be used to delineate the right ventricular outflow tract and main and branch pulmonary arteries. Although Doppler interrogation of the right ventricular outflow tract is important in assessing the severity of obstruction postnatally, flow velocities in the parallel fetal circulation are usually in the normal range [28,29]. Doppler interrogation and Doppler color flow mapping can, however, readily demonstrate the to-and-fro flow pattern
Figure 41.6 Echocardiogram showing a parasternal long-axis view of an infant with tetralogy of Fallot, demonstrating a large perimembranous ventricular septal defect, aortic override, and mitral/aortic valve fibrous continuity. AO, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.
Figure 41.7 Echocardiogram showing a subcostal right oblique view in a neonate demonstrating large ventricular septal defect, overriding aorta, tricuspid/aortic valve fibrous continuity, and anterior deviation of the infundibular septum (*). Arrows identify tricuspid valve leaflet. AO, aorta; LV, left ventricle; RA, right atrium; RV, right ventricle.

seen in fetuses with absent pulmonary valve. Sagittal imaging also allows examination of the arterial duct and aortic arch. Fetuses with more severe right ventricular outflow tract obstruction have retrograde ductal flow *in utero* [25,30]. Other evidence of the severe right ventricular outflow tract obstruction includes significant hypoplasia of the main and branch pulmonary arteries and poor growth of the pulmonary arterial tree during the course of serial examinations.

As with all prenatal diagnoses of congenital heart disease, fetuses with tetralogy of Fallot should undergo assessment of fetal karyotype and comprehensive ultrasound examination to rule out extracardiac anomalies. Families should be counseled regarding the *in utero* evaluation of this lesion and the need for serial evaluations. All fetuses with the prenatal diagnosis of tetralogy for Fallot should be delivered at a tertiary care center with appropriate support staff for evaluating and managing these infants.

Postnatally, complete echocardiographic evaluation must include examination of all aspects of anatomy important to management. At most institutions, echocardiography is the primary method of evaluation before operation, with cardiac catheterization reserved for those patients with specific unresolved questions after echocardiographic examination. Elements of anatomy that must be assessed include the anatomic type and boundaries of the VSD, the presence or absence of multiple VSDs, the severity and level of right ventricular outflow tract obstruction, the anatomy of the pulmonary arteries, the anatomy of the aortic arch, the course of the coronary arterial tree, and the presence of associated abnormalities.

The large VSD present in this lesion can be imaged in multiple views. Its relationship to the aorta, the mitral valve, and the large VSD can be seen in the long-axis view (Figure 41.6). The relationship between the defect and the tricuspid valve can be seen in the parasternal short-axis view, in which the potential for extension as a doubly committed defect can also be assessed. The apical four-chamber view usually demonstrates the continuity among the tricuspid, aortic, and mitral valves and also allows assessment of the degree of aortic override. Caudal angulation of the transducer can be used to examine the degree of posterior extension of the defect.

The subcostal right oblique view is perhaps the most useful view to evaluate the VSD and outlet septum (Figure 41.7). Here, the relationship between the tricuspid and aortic valves in infants with a perimembranous defect is well seen. In the rare instances of obstruction of the VSD, the subcostal coronal view allows demonstration of the abnormal or accessory tricuspid valve tissue obstructing the defect and of possible attachments to the infundibular septum [31,32]. This abnormal tricuspid valve tissue can also be imaged in parasternal axis views.

The levels of right ventricular outflow tract obstruction are best assessed in the parasternal short-axis and subcostal views. The prominent septoparietal trabeculations can be seen intruding on the infundibular region in the subcostal coronal view. In the parasternal short-axis and subcostal sagittal views, the anterior and superior deviation of the infundibular septum can be appreciated, and the abnormal pulmonary valve can be seen (Figures 41.8 and 41.9). Measurements of the pulmonary valve annulus are important in predicting the need for transannular patch.

Pediatric Cardiovascular Medicine
Figure 41.8 Echocardiogram showing a diastolic frame from parasternal short-axis view of a 3-week-old infant with tetralogy of Fallot. Tricuspid valve leaflets partially obscure ventricular septal defect (double arrows). Anterior deviation of the infundibular septum and small pulmonary annulus (single arrow) are demonstrated. AO, aorta; LA, left atrium; PA, pulmonary artery; RA, right atrium.
Figure 41.10 Echocardiogram showing a parasternal short-axis view with counter-clockwise rotation from a neonate with tetralogy of Fallot, demonstrating the right coronary artery (single arrow) originating from the right coronary orifice and giving rise to the left anterior descending coronary artery, which crosses the pulmonary outflow tract anteriorly (double arrows). AO, aorta; PA, pulmonary artery; RPA, right pulmonary artery.

Figure 41.9 Echocardiogram demonstrating a subcostal sagittal image from an infant with tetralogy of Fallot and a large ventricular septal defect (double arrows) with aortic override and anterior deviation of the infundibular septum (single arrow). AO, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

The parasternal short-axis view allows evaluation of the pulmonary artery confluence and proximal branch pulmonary arteries; the suprasternal short- and long-axis views also allow verification of the confluent nature of the pulmonary arteries

and visualization of the branch pulmonary arteries more distally. When the pulmonary arteries are not confluent, alternative sources of blood supply can be identified from these views. Assessment of the size and symmetry of the branch pulmonary arteries is important in both the decision regarding the appropriateness of primary repair and the need for patch augmentation of the proximal pulmonary arteries at the time of operation. Despite the multiple levels of right ventricular outflow tract obstruction and the elongated nature of the infundibular obstruction, predicted outflow tract gradients using the modified Bernoulli equation compare favorably with catheterization data [33], allowing verification of the usually low pulmonary arterial pressure.

These same views can be used to assess the right ventricular outflow tract in infants with tetralogy of Fallot and absent pulmonary valve. In these infants, the infundibular obstruction may not be as severe, although there is significant obstruction at the small pulmonary annulus and, in some patients, by dysplastic valvar tissue. There is marked dilatation of the proximal main and branch pulmonary arteries, and Doppler interrogation demonstrates the severe pulmonary insufficiency that characterizes this lesion.

Several groups have described the echocardiographic evaluation of coronary artery anatomy in this lesion [34–36]. Echocardiographic evaluation must demonstrate that no major coronary arteries cross the right ventricular outflow tract (Figure 41.10). The origin and course of the

left and right coronary arteries can be traced in multiple views, although the parasternal long- and short-axis views may be the most helpful. Any concerns regarding abnormal coronary anatomy should be verified angiographically.

Aortic arch anatomy can be demonstrated by echocardiography using suprasternal long- and short-axis views, first to determine the relationship between the trachea and the arch, and then to define the branching pattern. Doppler color flow mapping can be used to exclude a ductus arteriosus or prominent aortopulmonary collaterals.

Complete echocardiographic evaluation must also exclude associated anomalies important in planning the surgical approach. Two-dimensional imaging and color flow mapping in multiple planes must be used to identify an associated atrial septal defect and additional VSDs. Abnormalities of pulmonary and systemic venous connection must be delineated, and rare left-sided lesions, such as mitral valve abnormalities (e.g., straddling) and subaortic obstruction, must also be identified.

Postoperative studies must define residual septal defects and the degree and level of residual outflow tract obstruction. Care should be taken to examine the branch pulmonary arteries distally to identify branch stenosis at the sites of previous shunts or at the juxtaductal site (Figure 41.11). Many patients after transannular patch repair have significant pulmonary regurgitation, which can be assessed either comparing the width of the regurgitant jet to the annulus [37] or assessing the distal extent of the regurgitant jet from the annulus [38]. Although pulmonary regurgitation is generally well tolerated, assessment of right ventricular size and wall motion, and also tricuspid valve function, should be part of all postoperative echocardiographic studies.

Patients with coexisting pulmonary atresia and VSD have similar intracardiac anatomy to classic tetralogy of Fallot. In the absence of anterograde flow from the right ventricle to the pulmonary artery, careful echocardiographic study of the central pulmonary arteries is necessary. Echocardiographic study should define the intracardiac anatomy, evaluate ventricular function, valvar regurgitation, and coronary origins, define the status of central pulmonary arteries, measure the size of the main, right, and left pulmonary arteries, define the presence or absence of either a left- or right-sided ductus arteriosus, and define the site of origin and proximal distribution to right or left lungs of as many MAPCAs as possible. These studies can be difficult and time consuming, with the need for extensive color-flow mapping. A reasonable road map should be obtained before the necessary cardiac catheterization procedures. Intracardiac anatomy should be defined completely so that contrast media can be conserved at catheterization for comprehensive delineation of pulmonary artery origin, distribution, and anatomy.

(a)

(b)
Figure 41.11 Two angiograms from a 22-year-old patient after complete repair in childhood with residual branch pulmonary artery stenosis and right ventricular hypertension. (a) The bilateral branch stenosis is well visualized (long arrows). A small diverticulum of the right ventricular outflow tract (short arrow) is demonstrated. (b) Angiography demonstrated relief of proximal pulmonary artery stenosis.

Computed tomography and magnetic resonance imaging

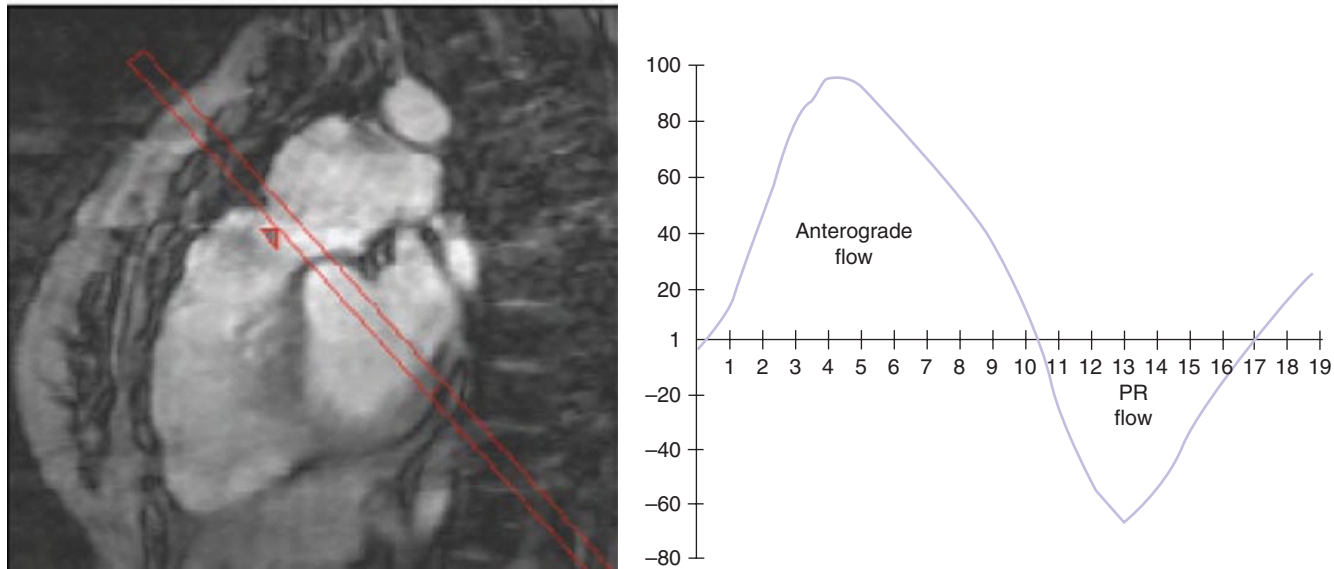
CT scanning is sometimes performed to delineate the anatomy and distribution of the central pulmonary arteries and MAPCAs in those with pulmonary atresia, but in general avoiding ionizing radiation is preferred. Consequently, MRI is more often chosen, particularly as full diagnostic studies can now be performed during postprandial sleep, or with sedation, even in young infants. In postoperative patients,


Figure 41.12 Magnetic resonance image of the right ventricle (left panel), with flow assessment in the right ventricular outflow tract (right panel). Note the anterograde and retrograde flow, the latter quantifiable as the volume of pulmonary regurgitation (PR).

MRI has become the mainstay of assessment of right ventricular function and volumes, particularly as they pertain to decision-making regarding the timing of pulmonary valve replacement. MRI allows the assessment of all aspects of cardiac and extracardiac anatomy, and the basics of RV function (Figure 41.12). Most importantly, it has become the gold standard for assessing pulmonary regurgitation, which, as discussed below, is one of the most important factors in late follow-up.

Medical management

The medical management of a patient with tetralogy of Fallot depends on the clinical presentation. A cyanotic neonate who is duct dependent should be stabilized with prostaglandin E_1 infusion.

In an asymptomatic infant with adequate pulmonary flow and systemic saturation, no initial therapy may be necessary. This infant can be followed as an outpatient with close attention to growth, symptoms, and systemic saturation. If the child develops significant cyanosis or reaches an appropriate size or age, repair can be performed electively. The development of tetralogy spells is an indication for early intervention.

Medical management of hypercyanotic spells is directed towards improving pulmonary blood flow and sustaining mixed venous oxygen saturations (reducing systemic oxygen consumption). Parents should be educated to comfort the child while placing him or her in the knee–chest position to increase systemic afterload and force more blood flow across the pulmonary outflow tract. In a hospital, the patient's airway and breathing should be assessed, the patient placed in the knee–chest position, and 100% oxygen given. Sedation with morphine sulfate ($0.1\,mg\,kg^{-1}$) can be given intravenously (i.v.), or intramuscularly (i.m.) should an intravenous line not be available. Acidosis may develop and should be treated with bicarbonate. An intravenous fluid bolus (5–$10\,ml\,kg^{-1}$) of saline or lactated Ringer's solution ensures adequate right ventricular filling. Should these measures fail, intravenous beta-blockade with propranolol or esmolol slows the heart rate and increases systemic vascular resistance, while decreasing catecholamine stimulation and contractility. Systemic afterload can be increased with alpha-agonists in an effort to force more blood flow through the right ventricular outflow tract. Phenylephrine (Neo-Synephrine) $0.02\,mg\,kg^{-1}$ i.v. or $0.1\,mg\,kg^{-1}$ i.m. is often more rapid and successful than other therapies [39]. Finally, should all measures fail, general anesthesia can reverse the episode or prepare the patient for an emergency aortopulmonary shunt if hypoxemia persists.

In patients with chronic hypoxemia, oral therapy with propranolol (0.5–$1\,mg\,kg^{-1}$ b.i.d.–q.i.d.) can improve oxygen saturations and reduce the risk of hypercyanotic spells. These patients are also at risk for thromboembolic complications, a risk that is highest in patients with coexisting iron deficiency anemia. Close monitoring of both hemoglobin concentration and hematocrit is necessary so mean corpuscular volume can be calculated. The hemoglobin should be approximately one-third of the hematocrit; if less, the patient has iron deficiency anemia. These patients should have an elevated hemoglobin at baseline, and a normal hemoglobin value

may actually represent a relative anemia. Iron deficiency anemia should be treated with supplemental iron.

Whether an infant or young child undergoes initial palliation or complete repair depends on the institution. In the past, the approach was to delay complete repair until later childhood. In the mid-1990s, successful complete repair in early infancy and even the immediate neonatal period was demonstrated, and most large units now reserve palliation (either surgical or by interventional catheterization [40–42]) for very small and/or premature infants, or those with additional abnormalities [43–45]. Elective primary repair is usually performed at 6–18 months of age.

Cardiac catheterization

Cardiac catheterization is now reserved for those with complex additional abnormalities, such as MAPCAs. The catheterization is most commonly performed from a femoral approach where both arterial and venous access is obtained. The left side of the heart can often be reached via an atrial communication so that most of the hemodynamic measurements can be performed with the venous catheter. Pressures and oxygen saturations should be obtained in the superior vena cava, both ventricles, both atria (if there is an atrial communication), and the aorta. If left atrial saturations are low, pulmonary venous saturations should be obtained. Systemic left and right ventricular systolic pressures should be expected, and any variation from this requires further investigation. Ventricular end-diastolic and atrial pressures are often normal or only mildly elevated. A wide systemic pulse pressure should suggest a patent arterial duct or large systemic to pulmonary artery collateral vessels. Saturation values usually demonstrate some right-to-left shunting, which can be at both the atrial and ventricular levels. Evidence of left-to-right shunting may also be found if the pulmonary arteries are entered. Whether to cross the right ventricular outflow tract in a patient who is being prepared for elective repair depends on the operator. The benefit is that pulmonary artery pressures and saturations can be obtained; pulmonary flow, pulmonary resistance, and left-to-right shunting can be calculated. Additionally, branch pulmonary artery stenosis may be further examined, although this may be difficult to assess in the presence of significant proximal obstruction. The benefits must be weighed against the risks, which include arrhythmia, perforation, and hypercyanotic spells, associated with attempts to cross the stenotic outflow tract.

Angiography should be guided by the anatomic questions to be answered. Biplane cineangiography is needed, and the angiograms that provide the most important information for a particular patient should be performed first. This ensures adequate contrast availability, should multiple angiograms of a particular structure be necessary.

With multiple levels of obstruction to pulmonary flow, including infundibular, valvar, supravalvar, and branch

pulmonary artery, an injection of contrast material into the right ventricle is often indicated (Figure 41.11). To visualize the branch pulmonary arteries and their bifurcation better, it is helpful to angle the anteroposterior (AP) camera about 30° cranially with a small amount of left anterior oblique (LAO) rotation. The cranial angulation prevents overlap of the outflow tract on to the pulmonary artery bifurcation. The LAO rotation of the camera improves evaluation of the proximal left pulmonary artery, which may be difficult to visualize in a straight AP projection. Keeping the lateral camera in a straight lateral (90° LAO) projection usually provides excellent imaging of the right ventricular outflow tract and allows evaluation of the infundibular, valvar, and supravalvar areas. Additionally, right-to-left shunting across the VSD may be seen in this view.

Evaluating the coronary arteries and aorta can often be accomplished with a single injection of contrast material into the ascending aorta. The catheter should be positioned close to the aortic valve to ensure adequate visualization of the coronary arteries. Camera positioning should be tailored to delineate the proximal coronary artery origins and distribution. A variety of camera angles have proven useful. Some have even advocated selective coronary angiography, although this has a risk in small infants and children. We have found that with the AP camera in 30° right anterior oblique (RAO) and the lateral camera in 70° LAO and 20° cranial (long axial oblique) positions, the injection usually delineates the coronary distribution adequately (see Figure 41.2). Should a particular view not demonstrate the coronary anatomy adequately, the operator should be prepared to try alternative views. The ascending aortic injection also provides information about the aortic arch (right- or left-sided), brachiocephalic vessels (distribution and size), and the ductus arteriosus and collateral vessels. Embolization of collateral vessels can be performed if deemed necessary.

An injection of contrast material into the left ventricle provides useful information about VSDs, degree of aortic override, and, if there is any significant left-to-right shunting, the right ventricular outflow tract obstruction. This is often best accomplished with the AP camera in a 30° RAO projection and the lateral camera in a long axial oblique projection.

Postoperative catheterization is usually reserved for patients with residual abnormalities, such as intracardiac shunting, right ventricular outflow tract obstruction, significant pulmonary regurgitation, or branch pulmonary artery stenosis. The goal may be purely diagnostic but is often therapeutic. The refinement of balloon angioplasty and percutaneous stenting techniques have proved invaluable in managing patients with residual obstruction that may be difficult or impossible to repair surgically (Figures 41.11 and 41.13).

Patients with pulmonary atresia and VSD present a difficult challenge for both diagnostic and interventional catheterization. Preoperative catheterization must attempt
Figure 41.13 Balloon occlusion angiogram in the descending aorta. Berman's angiographic catheter has been passed from the right ventricle anterograde into the ascending aorta and positioned in the descending aorta. The balloon has been inflated to prevent runoff into the distal aorta during the injection. Dense opacification of the descending aorta with a large unobstructed collateral to the left lung and a severely stenotic collateral to the right lung can be seen.

Figure 41.14 Selective injection of a major aorticopulmonary collateral vessel. A 4 French right coronary catheter is engaged to the ostium of a single collateral vessel arising from the mid-thoracic aorta, and contrast agent is injected manually. Opacification of a well-developed lower left pulmonary artery is demonstrated. In addition, one can clearly see the seagull appearance of the extremely hypoplastic true or native pulmonary arteries (arrow).

to delineate all sources of pulmonary blood flow and identify the number of bronchopulmonary segments supplied by central pulmonary arteries and by MAPCAs. Ascertaining whether dual blood supply is present is also a goal, in addition to determining the severity of stenoses of central pulmonary arteries and MAPCAs. Various techniques to obtain these data include balloon occlusion aortography at various levels in the descending aorta (Figure 41.13), selective injection of MAPCAs or ductus (Figures 41.14 and 41.15), and pulmonary vein wedge angiography (Figure 41.16).

Postoperative catheterizations may be necessary to assess the patency of shunts or unifocalization procedures that have been performed, the growth of central pulmonary arteries, the distribution of flow to various bronchopulmonary segments, the presence of stenoses, and the presence of unifocal or dual blood supply from central pulmonary arteries and MAPCAs to various bronchopulmonary segments. Balloon dilatation of stenotic arteries and stenting of vessels are a major part of the reconstructive process for these patients. In addition, some patients need coil occlusion of redundant collaterals or MAPCAs to prevent pulmonary overcirculation.

Surgical repair

The report of the Blalock–Taussig (BT) shunt in 1945 opened the door to palliation of patients with tetralogy of Fallot by creating some type of aortopulmonary anastomosis [3] (see Chapter 14). A modification of this approach – anastomosis of the main pulmonary artery to the ascending aorta – is sometimes performed in patients with pulmonary atresia and MAPCAs in an attempt to grow diminutive but confluent pulmonary arteries.

The BT shunt provides excellent palliation, and it was not until 1954 that complete intracardiac repair, with closure of the VSD and relief of the right ventricular outflow obstruction, was demonstrated by Lillehei and colleagues [3]. Although fundamentally the technique has changed little, there have been many modifications. The VSD is now rarely closed via a ventriculotomy, with a transatrial approach now the method of choice. The extent of the ventricular incision has thus been markedly reduced and, when possible, avoided altogether in order to preserve infundibular and global right ventricular function. Similarly, the degree of resection of outflow tract muscle has diminished with experience. Formerly, cardiologists thought that residual obstruction was the root of all postoperative evils, but pulmonary regurgitation is now regarded as a much more frequent culprit. Consequently, transection of septoparietal trabeculations is preferred over removal, and preservation of the pulmonary valve has become more frequent. Indeed, often a small amount of residual obstruction will be tolerated, if a transannular patch can be avoided.

(a)

(b)

(c)
Figure 41.15 Collateral vessels arising from the brachiocephalic vessels. Selective manual injections are performed in the subclavian arteries. (a) A small but well-developed left pulmonary artery is supplied by a collateral from the left subclavian artery. (b) A well-developed right pulmonary artery is supplied by a collateral vessel arising from the right subclavian artery. (c) As the contrast agent passes further into the right pulmonary artery, the hypoplastic true or native pulmonary arteries can be seen with the typical seagull appearance (arrow).

One of the more important postoperative abnormalities is restrictive right ventricular physiology. Although much decreased in frequency since its original description in the mid-1990s [46–49], when present it predictably slows postoperative recovery, and can be associated with a markedly reduced cardiac output. As a result, it has become common to leave a patent foramen ovale to enhance systemic output from right-to-left atrial shunting in the early postoperative period.

The surgical approach to the patient with tetralogy of Fallot and absent pulmonary valve is less clear, particularly in the patient with significant respiratory compromise. Arguments have been made both for initial palliation to control the pulmonary blood flow and regurgitation and for initial complete repair. Most now favor early complete repair for symptomatic infants [3]. In essence, the surgeon closes the VSD, reconstructs the outflow tract, if necessary with a patch, and attempts to remove bronchial compression by plicating the aneurysmal pulmonary artery or even transecting and reimplanting the pulmonary artery in a more suitable position. Some surgeons implant a pulmonary valve.

Patients with tetralogy of Fallot and pulmonary atresia represent a more difficult surgical challenge [3]. Patients with good-sized central pulmonary arteries supplied by a ductus with distribution of normal or near-normal branching patterns to the majority of bronchopulmonary segments, and without significant MAPCAs, can follow a surgical algorithm similar to a standard tetralogy of Fallot patient. Unfortunately, a large number of patients have hypoplastic or absent central pulmonary arteries either with MAPCAs supplying the majority of bronchopulmonary segments alone or with a dual blood supply from MAPCAs and central pulmonary arteries. In these, a major goal of the initial operation has been to enlarge central pulmonary arteries by establishing continuity from the right ventricle to the main
Figure 41.16 Pulmonary vein wedge angiogram. No arterial supply could be identified to the right lung in this child after an initial right unifocalization. A wedge catheter has been positioned in the right upper pulmonary vein. The balloon is inflated to occlude flow. Contrast agent is slowly injected retrograde into the capillary bed, followed rapidly with a saline flush. The right pulmonary artery (arrow) is easily seen and densely filled, indicating that it is patent but not being supplied with anterograde flow.

pulmonary artery or to the confluence of the right and left pulmonary arteries, or by implementing a central shunt to provide growth of these arteries, such that an eventual repair could be performed. When central pulmonary arteries provide blood flow to only a limited number of bronchopulmonary segments, however, unifocalization procedures must be performed so that central pulmonary arteries can be connected to the majority of the bronchopulmonary segments. This may require procedures in which shunts are performed to each lung with separate operations in which MAPCAs are divided from the aorta and connected together, with the shunt then providing all the blood flow to the ipsilateral lung. If possible, these unifocalized vessels are connected to a central right or left pulmonary artery. If no central pulmonary arteries are present, the eventual goal is to connect the unifocalized pulmonary arteries in the right and left hila using a central graft that can then be connected to the right ventricle with a valved or nonvalved conduit or homograft. Although this approach has been reported since the late 1980s, success has been variable, and many patients have not had enough growth of pulmonary arteries to undergo closure of the VSD [50–55].

Hanley and co-workers advocated early repair using extensive mobilization of MAPCAs and central pulmonary arteries with preferred time of operation from 3 to 6 months of age [56]. Small central arteries are enlarged considerably

with homograft material, and in most patients, connection is made to the right ventricle with a valved or nonvalved containing graft. If enough bronchopulmonary segments have been connected and the augmented pulmonary arteries appear to be of reasonable size, the VSD can be closed. These authors described a procedure for help with the decision about closure of the VSD. Immediately after pulmonary artery surgery, the heart–lung pump is used to direct a normal cardiac index through the lungs before the decision is made regarding VSD closure. If the pulmonary arterial pressure has not risen markedly during this procedure, the VSD is closed. With this procedure, the authors were able to achieve complete repair in most infants [57]. Although most units have adopted a similar approach, institutional preferences vary, as do results, and this remains a controversial area, with uncertain long-term results [58]. Furthermore, despite successful unifocalization and reparative procedures, these patients frequently have multiple stenoses in both the surgically created anastomoses and the native MAPCAs and pulmonary arteries. These patients require postoperative catheterization and frequently balloon dilatation or stent placement to achieve satisfactory right ventricular systolic pressure.

Postoperative problems and long-term outlook

Postoperative problems include both hemodynamic abnormalities and arrhythmias, which are listed in Table 41.2.

Residual VSD is uncommon with current surgical techniques. Echocardiography is fairly useful to detect left-to-right ventricular shunting but, in the presence of a surgical patch, estimating the size of the defect and the degree of shunting may be difficult.

Residual right ventricular outflow tract obstruction, valvar stenosis, annular stenosis, and supravalvar main pulmonary arterial obstruction can occur, particularly when transannular patching is avoided. The site and severity of obstruction can usually be determined echocardiographically, and balloon valvoplasty may be useful when there is valvar obstruction. If there is a moderate or severe residual supravalvar, annular, or infundibular stenosis, reoperation is usually required. Pulmonary artery branch stenosis is relatively common postoperatively and usually occurs in the left pulmonary artery at the site of prior ductal insertion, or at the site of a previous shunt. Fortunately, these conditions can now be treated with a high degree of success by using transcatheter balloon arterioplasty with or without the use of stents (see Figure 41.12).

Tricuspid regurgitation is relatively rare early after the repair, but increases with progressive right ventricular dilation and dysfunction. When operation is required for pulmonary valve replacement or correction of residual

Table 41.2 Postoperative problems.

Residual hemodynamic problems
Ventricular septal defect
Right ventricular outflow tract obstruction
Pulmonary valvar and/or annular stenosis

Pulmonary artery branch stenosis
Pulmonary regurgitation
Tricuspid regurgitation
Right ventricular dysfunction
Right ventricular outflow tract aneurysm
Left ventricular dysfunction
Pulmonary hypertension

Arrhythmia and conduction disturbances
Supraventricular tachycardia
Ventricular tachycardia
Complete heart block

outflow obstruction, tricuspid valve annuloplasty can be a useful adjunctive procedure.

Pulmonary regurgitation commonly accompanies tetralogy of Fallot repair because of the frequent need for transannular patching for adequate relief of right ventricular outflow tract obstruction. Pulmonary regurgitation is usually well tolerated when pulmonary arterial and right ventricular pressures are low. If any degree of pulmonary hypertension or pulmonary artery stenosis is present, pulmonary regurgitation is enhanced and right ventricular dilatation is accelerated. In the long term, pulmonary regurgitation is the single most important factor in the pathogenesis of symptomatic decline [1]. The natural history of isolated congenital pulmonary valve regurgitation has been reviewed. The development of cardiovascular symptoms increases with age, reaching 20% after 40 years and 48% after 50 years in patients without associated pulmonary stenosis, pulmonary hypertension, or a right ventriculotomy [59]. If right ventricular dysfunction develops in a high percentage of patients with an otherwise normal heart by age 50 years, postoperative patients with prominent pulmonary regurgitation almost certainly will have similar problems with increasing age.

Arrhythmias can be a significant postoperative problem. There has been a history of late sudden death in as many as 5% of patients on long-term follow-up [60–67]. This incidence appears to be declining with earlier age at operation. Patients who appear to be most at risk for ventricular tachyarrhythmia and sudden death have right ventricular dilatation, right ventricular dysfunction, right ventricular pressure overload, marked or rapidly developing QRS prolongation [68], and an older age at the time of repair. Both supraventricular tachycardia and ventricular tachycardia can occur. Because most patients have right bundle branch postoperatively, they have wide complex tachycardia, and it

may be difficult to differentiate between the two types of tachycardia. The "supraventricular" arrhythmia is usually atrial flutter or fibrillation. "SVT" will show a RBBB pattern but VT after tetralogy repair will nearly always have an LBBB pattern because of the right ventricular origin of the tachycardia.

Patients with documented arrhythmia associated with symptoms should undergo electrophysiologic studies and concurrent hemodynamic evaluation by electrophysiologists experienced in congenital heart disease. Supraventricular tachycardia and ventricular tachycardia may coexist. When either type of tachycardia is documented, radiofrequency ablation may be curative, or patients may be treated with an antitachycardia device. An alternative strategy, particularly if pulmonary valve replacement is contemplated, is for intraoperative mapping of the arrhythmia and cryoablation. This has proven particularly successful for those with ventricular tachycardia, where transcatheter ablation is less effective.

Infective endocarditis is rare after operation [69].

Exercise performance after tetralogy repair is less than normal, and the degree of impairment is usually directly related to the amount of pulmonary regurgitation [70–73]. Right ventricular dysfunction, as assessed by ventricular size and ejection fraction, has often been found in patients with more severe pulmonary insufficiency. Such patients also have a larger transannular patch and right ventriculotomy, factors that also depress ventricular function [74,75]. Pulmonary valve replacement usually decreases right ventricular size, increases ejection fraction, and improves exercise capacity [76–78]. However, right ventricular dysfunction [79] and chronotropic impairment of unknown origin [80] also contribute to diminished exercise tolerance.

The decision as to when to perform pulmonary valve replacement for pulmonary regurgitation is difficult. Patients with progressive right ventricular enlargement, particularly if associated with decreased exercise tolerance documented with exercise testing, clinical arrhythmia, or signs of right ventricular dysfunction should have the valve replaced, preferably when these signs or symptoms occur. Several groups have sought to define a threshold for right ventricular dilatation, above which reverse remodeling may not occur after valve replacement. Although far from resolved, most studies have found that a right ventricular end-diastolic volume of 150–170 ml m^{-2} or more makes recovery less likely, at least in adults [81,82]. There is usually a modest decrease in heart size after operation and often resolution of symptoms and ventricular ectopy. Several reports indicate favorable results with pulmonary valve replacement [76–78], with an earlier operation associated with better results.

Right ventricular aneurysms described after tetralogy repairs are usually not true aneurysms but simply prominent outflow patches that were too large to begin with. These patches are akinetic, can contribute to right ventricular

dysfunction, and should be resected and retailored when reoperation is required.

Transcatheter pulmonary valve replacement

Transcatheter valve replacement was first described by Andersen *et al*. in 1992 [83], but it failed to capture the imaginations of cardiologists or industry, perhaps because of a lack of importance attributed to pulmonary valve dysfunction at that time. However, in 2000, Bonhoeffer [84] described the use of a bovine jugular valve mounted in a stent, to reconstruct the right ventricular outflow tract in patients with stenosis and/or regurgitation. A dilated outflow tract makes transcatheter valve replacement infeasible for most patients, at least for the time being. Nonetheless, the introduction of the technique has been one of the most significant advances in the recent history of cardiology, spawning an explosion of methods for treating acquired and congenital valve diseases. For those with tetralogy of Fallot, this therapy is essentially restricted to those patients with a conduit between the right ventricle and pulmonary artery. Even so, the results have been very encouraging. Relief of stenosis and abolition of regurgitation can be expected in most, and these results seem to be sustained in the majority during the first 5 years after implantation. The technique has evolved during the decade since its original description by Bonhoeffer and colleagues [85], so the longer term outcomes of contemporary series remain to be seen. Furthermore, development of techniques to overcome the anatomic limitations in most of those without a conduit will likely change the face of, and indications for, pulmonary valve replacement in these patients (see also Chapters 10 and 33).

Most postoperative patients lead normal or near-normal lives. Patients who have excellent results with normal to near-normal heart size, and no residual significant hemodynamic lesions, can engage in high-level recreational and sports activities [86].

Long-term outcome after repair of tetralogy of Fallot has been reported to be very good for most patients, with actuarial survival reported as 86% after 32 years compared with an expected rate of 96% [87], 85% after 36 years [88], 84% after 20 years [89], and 84% after 15 years [90]. These survival rates are for some of the earliest patients receiving repair, and survival after successful early repair with more current techniques would be predicted to be even better.

42 Complete Transposition of the Great Arteries

Daniel Sidi, Pascal Vouhé & Phalla Ou

Hôpital Necker – Enfants Malades, Université Paris V, Paris, France

Complete transposition of the great arteries (TGA) is a common and life-threatening cardiac malformation characterized by isolated ventriculo-arterial discordance. Neonatal survival depends on shunts between the two parallel circulations, mainly through the foramen ovale. Ductus arteriosus patency [natural or by prostaglandin E_1 (PGE_1) infusion] can also influence clinical tolerance but to a lesser extent and not always favorably.

About two-thirds of the neonates have no other cardiac abnormalities apart from a patent foramen ovale and a small patent ductus arteriosus. The remainder may have a ventricular septal defect, a large atrial septal defect, a large patent ductus arteriosus, or significant subpulmonic stenosis. The first group and those with only a small ventricular septal defect are often termed simple TGA. The rest are included in the group of complex TGA, which also includes those with pulmonic or tricuspid atresia and various types of double-outlet ventricles (see Chapter 44). Other terms that are used include dextro-TGA (d-TGA), aortopulmonary transposition, and transposition of the great vessels.

Key points

- Every cyanotic neonate without respiratory distress should be considered as possibly having TGA until two-dimensional echocardiography has shown a normal relationship between the great vessels and the ventricles.
- TGA is usually fatal soon after birth, and neonates can be saved by an early balloon atrioseptostomy (the Rashkind procedure).
- Prenatal diagnosis is possible. Deterioration soon after birth can be predicted from the size of the foramen ovale *in utero*, and delivery should be organized at a center where an early

Rashkind procedure can be performed with two-dimensional echocardiographic guidance in the delivery room.
- Atrial repair leaving the ventriculo-arterial discordance but adding atrioventricular discordance (the Mustard or Senning procedure) gives good immediate and midterm results but leads to frequent rhythm disturbances, and right ventricular failure may occur in the long term.
- Anatomic repair (arterial switch) gives excellent long-term results with a low perioperative mortality, but it can be performed only in a neonate while the left ventricle is still able to develop systemic pressures. Long-term follow-up is necessary to be sure that the fate of the great arteries and coronary arteries will allow a normal life.

Embryology and epidemiology

This lesion represents ~5% of congenital heart disease, occurring in ~1/3000 liveborn infants. TGA, especially simple TGA, has a marked male preponderance [1,2]. Extracardiac malformations or chromosome anomalies are uncommon [1,2]; in particular, there is no association with microdeletion of chromosome 22. The etiology is unknown, and the low recurrence rate in siblings and the low transmission rate to offspring [1,2] suggest that genetic effects play little role. Overt maternal diabetes has been associated with TGA [1,3].

The embryology is discussed in Chapter 1.

Pathologic anatomy

In TGA, the aorta rises from the right ventricle above an infundibulum, so that there has not been resorption of the subaortic conus. The pulmonary artery rises from the left

Figure 42.1 Pathology to show discordant ventriculo-arterial connections.

ventricle and is usually in continuity with the mitral valve, indicating complete resorption of the subpulmonic conus (Figure 42.1) (see Chapters 1 and 20). This means that TGA has a discordant ventriculo-arterial connection. The pulmonary artery rather than the aorta is situated in the center of the heart in continuity with both atrioventricular valves (see Chapter 44). The aorta is usually positioned anteriorly and to the right of the pulmonary artery (d-TGA), but can be in front of or beside the pulmonary artery; rarely, it can to the left of or posterior to the pulmonary artery, even though it is connected to the right ventricle.

The atria are normal, and there is almost always a patent foramen ovale, seldom a true secundum atrial septal defect. The ventricles are also normal, but the wedging of the pulmonary artery into the center of the heart produces a small central fibrous body and atrioventricular and membranous interventricular septa that are smaller than normal [4,5]. The ventricular septum, if intact, is relatively straight rather than sigmoid, so that the right and left ventricular outflow tracts are parallel. After 2 months of age, there is often functional subpulmonic obstruction from the ventricular septum bulging into the left ventricular outflow tract where it is apposed to the septal leaflet of the mitral valve [4–10]. A ridge of endocardial thickening may be found where the mitral valve edge contacts the septum. The obstruction usually disappears after an arterial switch repair but persists after an atrial baffle repair.

There may be minor anomalies of the mitral and tricuspid valves, but these are clinically important in <5% of patients with simple TGA [4,5,11].

The conduction system is normal except that the left bundle originates more distally than usual from the bundle of His and as a single cord rather than as a sheaf of fibers [12].

The coronary arterial anatomy is of great importance. The posterior commissure of the aortic valve is usually aligned with the anterior commissure of the pulmonary valve, and the coronary arteries arise from the posterior sinuses (never from the anterior sinus). The origin and distribution of the coronary arteries are important for a surgeon performing an arterial switch, because they have to be moved to the new aortic root. The right coronary artery is nearly always dominant. The left circumflex artery comes frequently (25%) from the right coronary artery (Figure 42.2). The two coronary ostia usually rise laterally from the two posterior sinuses, but they can rise in between the vessels from a single ostium or from two ostia near the posterior commissure; the latter pattern is often associated with an intramural left coronary artery (usually the left anterior descending). Multiple classifications have been used to describe the coronary arterial origin and distribution [11,13–15], the first and still most commonly used being the Yacoub classification [13] shown in Figure 42.2. The sinus node artery usually originates from the proximal right coronary artery and courses upward and to the right, being partly embedded in the upper part of the limbus of the atrial septum [11].

Although there is no structural abnormality of the cardiac chambers in complete TGA, the function and the mass of the right and left ventricles are normal only in the fetal and neonatal periods when both ventricles have similar afterloads. After birth, the right ventricle facing a systemic afterload grows more than the left ventricle because the latter supports the low pressure of the pulmonary circulation. Thus, after a few weeks, the left ventricle becomes unable to sustain a systemic pressure unless it is prepared for it by an artificial increased afterload (pulmonary arterial banding) that leads to preoperative hypertrophy.

In some patients, for unknown reasons, pulmonary vascular disease occurs. This complication is rare at <3 months of age [16–19], but it may develop in 25% of patients aged <1 year and in 15–67% of patients >12 months of age [11,16–19]. These pulmonary vascular changes are mild and do not cause profound pulmonary hypertension, but rarely (~1%) they may do so [17]. When pulmonary hypertension is significant, it does not react to oxygen or nitric oxide, and the small arteries histologically resemble classic pulmonary vascular disease, although sometimes numerous microthrombi are seen.

Hemodynamics and pathophysiology

The fetus

The fetus with TGA appears to have no disability. Because the pattern of streaming of the venous return is normal in these fetuses, the left ventricle receives much of its blood from the umbilical circulation (see Chapter 3), as in normal subjects, but then this blood, with an oxygen tension of about 24 mmHg, is distributed to the lungs and through the ductus arteriosus to the lower body (Figure 42.3). The heart and brain, on the other hand, receive blood with an oxygen tension of about 18 mmHg. There might possibly be greater flows through the lungs (less hypoxemia to cause vasoconstriction) and the heart and brain (autoregulation because of more hypoxemia). Whether these changes cause differences in vascular development of the organs is unknown.

Normal development of the cardiac chambers is expected in a fetus with TGA, because atrial and ductus communications equalize preload and afterload of the ventricles. The respective volumes and outputs of the two ventricles should be the same in a fetus with TGA as in a normal fetus with right ventricular output greater than left ventricular output. On the other hand, the sizes of the great arteries and of the foramen ovale that depend on the flow through them during fetal life are likely to be different (see Figure 42.3). Fetuses with TGA are likely to have a larger ascending and transverse aorta and a larger aortic isthmus because

of the higher right ventricular output, and the ductus arteriosus and the foramen ovale should be smaller because the higher pulmonary blood flow (due to a higher than normal PaO_2 in the pulmonary artery) decreases the amount of blood that passes through these structures during fetal life (see Figure 42.3). These factors may explain the rarity of coarctation of the aorta in simple TGA, and may also explain the devastating postnatal course due to inadequate shunting of blood between the two circulations in the absence of treatment.

There are increased number and size of pancreatic islet cells and an increased weight of the adrenal cortex; both of these findings resemble those found in infants of diabetic mothers.

The neonate

Without communications between systemic and pulmonary circulations, a neonate with TGA cannot survive more than a few minutes after the neonatal "placental–pulmonary switch." Because the two circulations are in parallel, blood oxygenated in the lungs returns exclusively to the lungs, whereas the desaturated systemic blood returns through the aorta to the systemic tissues. Survival is possible only through one or more communications that allow some oxygenated blood to cross from the left side of the heart or the pulmonary artery to the right side of the heart or the aorta and desaturated blood to cross back from the right side of the heart to the left side (Figure 42.4). Of necessity, the same
Figure 42.3 Fetal circulation in a normal subject (a) and one with TGA (b). The percentages shown are proportions of the combined ventricular output coming from each ventricle and being distributed to various regions of the body. The figures in parentheses in the ventricles are the oxygen tensions (mmHg). In (a), the desaturated blood returning from the lungs and body is shown by dark arrows. The better oxygenated blood returning from the umbilical vein is shown by the pale arrow, and it is distributed to the head, coronary arteries, and aortic isthmus, which is the narrowest part of the aortic arch. The lungs and descending aorta receive blood of intermediate saturation. In (b), note that in TGA, the aorta, main pulmonary artery, and aortic isthmus are wider than in the normal subject and that the foramen ovale and the ductus arteriosus are smaller. The distribution of well and poorly saturated blood differs from the normal. CS, coronary sinus; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (Courtesy of Dr David F. Teitel.)

amount of blood must cross in each direction; otherwise, one circulation would empty into the other. It is only this shunted blood that allows some oxygen uptake in the lungs and some oxygen transport to the tissues.

Initially, there may be bidirectional shunts through the ductus arteriosus and across the atrial septum. At birth, the ductus arteriosus is open, and aortic and pulmonary arterial pressures are similar. During systole, left ventricular ejection imparts enough kinetic energy to the blood that some oxygenated blood passes through the ductus arteriosus into the descending aorta. In diastole, aortic blood may enter the pulmonary artery with its lower vascular resistance. Then, with the rise in systemic vascular resistance that follows removal of the placenta and a decrease in pulmonary vascular resistance, pulmonary to aortic shunting ceases. The flap (Vieussens valve) of the foramen ovale (that is intended to close the atrial septum when the pressures become higher in the left compared

with the right atrium) usually crosses a foramen ovale distended by the increased pulmonary blood flow and allows a left-to-right atrial shunt; in addition, the rise in right atrial pressure due to the increased systemic vascular resistance helps to keep the valve of the foramen ovale open. In early ventricular diastole, blood shunts from right to left atrium because of the lower resistance to filling of the left ventricle [20]. In ventricular systole, blood shunts from left to right atrium because the left atrium has higher pressures and is less distensible. Respiration also influences atrial shunting because inspiration increases the caval venous return to the right atrium. These atrial shunts explain why most neonates with TGA do well at birth with an adequate flow through the ductus arteriosus from aorta to pulmonary artery (shunt of desaturated blood destined for the lungs) associated with a quantitatively equivalent left-to-right atrial flow of oxygenated blood destined for the body.
Figure 42.4 Diagram to show where shunts essential for survival (gray circles) after birth take place in simple TGA. It is possible for bidirectional shunting to occur through the ductus arteriosus, but the amounts are small. The least saturated blood is indicated by the darkest arrows, the best saturated blood by the lightest arrows. Intermediate saturations are suggested by intermediate shades of gray. CS, coronary sinus; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

The ductus arteriosus, smaller than normal in TGA, becomes progressively smaller soon after birth. When this happens, the neonate's survival depends on bidirectional shunting at the atrial level. If, however, the foramen ovale is too small or the flap is too large and closes the foramen ovale instead of crossing it, the atrial communication is absent or restrictive. These changes are poorly tolerated because the shunt is inadequate (severe hypoxemia); any shunting that occurs is possible only with a high left atrial pressure (due to increased pulmonary flow) and a resulting high capillary pressure that can cause pulmonary edema.

After the neonatal period, with adequate atrial shunting through a natural or post-Rashkind atrial communication, the hemodynamic status usually improves. There is an increased pulmonary blood flow ($Qp/Qs \approx 2$) and adequate shunting (about half of systemic flow) so that aortic saturation is ~70%, the pulmonary arterial saturation is ~85%, and mixed venous caval blood saturation is ~40%. With a normal decrease in pulmonary vascular resistance, pulmonary arterial pressure is low, and the pathophysiologic process resembles a simple atrial septal defect but with obligatory

cyanosis from blood going directly from the caval veins to the aorta. The major consequence of this fall in pulmonary arterial pressure is that the left ventricle in a neonate or infant behaves like a right ventricle in a normal circulation with an atrial septal defect. The left ventricle increases in size but loses wall thickness and perhaps forever the ability to develop a normal systemic pressure, and probably loses adequate coronary vascular bed growth.

Collateral circulation from the aorta to the pulmonary artery by bronchial arteries and from pulmonary veins to azygos vein can also play a role in the physiologic circulation in TGA. It can ensure some shunting in patients with closed foramen ovale, but the amount is insufficient to compensate for inadequate shunting at atrial and ductus levels. The collateral circulation complicates the evaluation of pulmonary blood flow and vascular resistance by the Fick method during catheterization because it alters the oxygen saturation proximally in the caval veins and distally in the pulmonary artery.

About half of the children with TGA have a greater than normal distribution of blood flow to the right lung, as shown by chest radiography, angiography, or radionuclide lung scans [21]. This effect is thought to be due to the abnormal rightward inclination of the main pulmonary artery towards the right pulmonary artery. This diversion probably does not have major physiologic effects, but it may explain associated hypoplasia of the left pulmonary arterial vessels and the occasional report of unilateral (always left-sided) pulmonary vein hypoplasia or stenosis [22,23].

Natural history

The natural history of untreated simple TGA is bleak; <5% survive more than 2 months [2,11,24]. Some with a large atrial septal defect may survive longer, but only 5–10% of them reach their first birthday. Death is usually from hypoxemia and acidosis, sometimes complicated by pulmonary edema.

Physical examination

These neonates are usually of normal birth weight, although reports of underweight and overweight exist, especially in the complex group [1]. They are initially well but may look dusky rather than overtly cyanotic. At this stage, pulses and breathing patterns are normal, as is activity. The heart is not enlarged and has the expected normal neonatal right ventricular lift. The first heart sound is normal. The second sound is usually single and heard with greatest intensity at the upper left sternal border because of the high position of the anterior aortic valve above the conus. A soft pulmonic closing sound is occasionally heard. No other sounds or clicks

are present. There may be no murmurs or only the soft murmur of a ductus arteriosus or a short midsystolic murmur along the midsternal border.

As hours or days pass, the ductus closes and shunting at ductus and atrial levels becomes inadequate. The neonate becomes deeply cyanotic, and this is usually equal in fingers and toes. Respiration becomes deep but without retractions, and there is usually no tachypnea unless there is acidosis. With the onset of severe acidosis, the baby's activity becomes reduced.

In older children who have not undergone surgical correction, there may be a soft ejection murmur along the upper left sternal border to indicate mild subpulmonic stenosis.

Electrocardiography

This shows merely the expected right ventricular dominance of the newborn term infant. After the first week, however, persistent upright T waves in the right precordial leads suggest abnormal right ventricular hypertrophy, as do decreased r waves in the left precordial leads. Should left forces be prominent (tall R waves in leads V_5 and V_6), some cause for a high left ventricular systolic pressure, such as pulmonary vascular disease or severe subpulmonic stenosis, should be sought.

Chest radiography

The pulmonary vascular markings are increased because pulmonary blood flow is usually increased. The heart is slightly enlarged, and the characteristic oval shape is due to absence of the pulmonary artery segment. As a rule, the thymus, although present, is notably small, so that the narrow mediastinal shadow gives an "egg on its side" or "apple on a string" appearance that is almost pathognomonic. The aortic arch is almost invariably left sided. The chest film may lack these diagnostic features immediately after birth. It is important not to exclude the diagnosis of TGA because of a nonspecific X-ray picture.

Echocardiography

In the fetus

TGA is well tolerated by the fetus, and the diagnosis can be made on two-dimensional echocardiography if the screening is not limited to the four-chamber view (that is normal in TGA) but includes the great vessels (see Chapter 8). It is crucial to check the size of the foramen ovale and the anatomy of the atrial flap to predict early closure of the atrial septum at birth and the need for an early Rashkind procedure.
Figure 42.5 Echocardiogram, subcostal view, from a neonate with simple TGA. The left ventricle (LV) gives rise to the pulmonary artery (MPA), which divides into the left pulmonary artery (L) and ductus arteriosus (D). The right ventricle (RV) gives rise to the aorta (AO) from which the innominate artery (IA) originates. (Courtesy of Dr Norman H. Silverman.)

In the neonate

Two-dimensional echocardiography with Doppler interrogation is the major diagnostic method. It confirms the diagnosis by demonstrating a normal heart architecture but with two great vessels arising in parallel from the ventricles instead of crossing early after their origins (Figure 42.5). The anterior vessel that arises from the right ventricle above an infundibulum is the aorta because it is directed anteriorly and gives off the neck vessels, and the posterior vessel arising from the left ventricle in continuity with the mitral valve is a pulmonary artery because it is directed posteriorly and bifurcates or trifurcates into two branches and the ductus arteriosus. The two outflow tracts are parallel. On a transverse view, the aorta is usually anterior and to the right of the pulmonary artery, and there is usually good alignment between the commissures of the aorta and pulmonary artery with coronary arteries arising always from the posterior sinuses of the anterior vessel (Figure 42.6).

It is especially important to visualize the atrial septum (subxiphoid view) and the ductus view, as these are the sites of shunting in TGA. Although the need for the Rashkind procedure is primarily determined clinically, it should be performed early when the foramen ovale is obstructed by the flap as shown by a high Doppler velocity (>1 m s^{-1}) (unless arterial switch can be performed immediately). Conversely,

(a)   (b)
Figure 42.6 Echocardiograms showing the origin of the coronary arteries in TGA. (a) The left coronary (LCA) and right coronary (RCA) arteries arise from the facing aortic (AO) sinuses. PA, pulmonary artery. (b) Long intramural course of the LCA. RA, right atrium; RVO, right ventricular outflow tract. (Courtesy of Dr Norman H. Silverman.)

if the atrial communication is large and the patient is not doing well, echocardiography helps to find a reason for the symptoms (e.g., high pulmonary vascular resistance, or associated cardiovascular anomalies such as coarctation of the aorta or subpulmonic stenosis), and eventually indicate early surgery to obtain better oxygenation of the neonate and deal with high pulmonary vascular resistances.

It is particularly helpful to look at the atrial shunting. With an exclusive left-to-right atrial shunt, there must be another communication at the ventricular or the arterial level; if it is not at the ductal level, it must be elsewhere (ventricular septal defect or collateral circulation). If there is a bidirectional atrial level shunting, then no other significant communication is present and the ductus arteriosus is closed. If the ductus is widely patent and bidirectional atrial shunting is present, then the pulmonary vascular resistance is high.

Echocardiography helps to assess the hemodynamics by assessing the velocity of flow across the ductus arteriosus and foramen ovale and analyzing septal geometry. (Left ventricular deformation is related to the pressure difference between the ventricles.)

Finally, the coronary artery ostial origins and course should be examined. It is important to note an unfavorable distribution, for example, if one coronary artery passes between the great vessels and especially if it is intramural. However, because coronary artery transfer is always possible by a highly trained cardiac surgeon, it does not seem legitimate to use invasive techniques and deliver irradiation to the neonate to define precisely coronary anatomy.

Cardiac catheterization

Cardiac catheterization is useful only when a Rashkind procedure is indicated. Rarely is it used to look for associated abnormalities such as a trabecular ventricular septal defect, collateral circulation, abnormal coronary arteries, or a small aortic isthmus if a coarctation is suspected (this can also be looked at by MRI or CT scan).

The technique of cardiac catheterization is standard, except that special maneuvers are needed to enter the pulmonary artery from the left ventricle [24,25].

Calculating flows by the Fick method is inexact because it is difficult to have mixed pulmonary arterial saturation samples if the ductus is open and when there is bronchial circulation (common). Pulmonary arterial samples are taken proximal to the entry of the bronchial collaterals that contain desaturated blood, so that a true mixed pulmonary arterial blood sample cannot be obtained. If bronchial collateral blood flow is only 10% of total pulmonary blood flow, there could be a 40% overestimate of pulmonary blood flow [17]. Another complication is that the arteriovenous difference of oxygen saturation across the pulmonary vascular bed is usually small, so that a tiny measurement error is translated into a large error in estimating pulmonary blood flow. Comparison of pulmonary blood flows measured by angiographic and Fick techniques suggests that pulmonary flows as calculated by the Fick method are about twice the true flows [26]. This means that pulmonary blood flow is usually

overestimated, and pulmonary vascular resistance is underestimated. Nevertheless, in simple TGA, pulmonary blood flow is usually almost twice that in normal children, even without a large shunt.

Differential diagnosis

In a cyanotic neonate without respiratory distress, TGA must be the diagnosis until two-dimensional echocardiographic–Doppler examination shows a normal position of the great arteries. The differential diagnosis therefore concerns the distinction between simple and complex TGA in which a ventricular septal defect, an abnormality of the great vessels (pulmonary artery stenosis, coarctation of the aorta), an anomaly of the atrioventricular or semilunar valves, or an abnormality of size or function of the ventricles is present.

Three major diagnostic difficulties exist:

1 A muscular ventricular septal defect, especially at the apex, may be difficult to see on echocardiography. Such a ventricular septal defect should be sought when there is left ventricular hypertension unexplained by a widely patent ductus arteriosus or an exclusive left-to-right atrial shunt with a closed ductus arteriosus (see earlier).

2 An associated coarctation of the aorta when the ductus is open, especially if the right ventricle is smaller than the left ventricle and the pulmonary artery is much larger than the aorta. In this circumstance, it may be useful to stop PGE_1, so that the ductus arteriosus closes, and then evaluate the femoral pulses and the aortic isthmus. Catheterization may be needed to decide whether a coarctation repair should be done with an arterial switch.

3 Anatomic subpulmonic stenosis when an abnormal pulmonary arterial gradient cannot be explained by bulging of the ventricular septum. Particular attention should be paid to the mitral valve insertions on the septum or an abnormal pulmonary artery valve (bicuspid and/or dysplastic pulmonary valve).

Clinical course

Without an adequate atrial communication, death occurs early with metabolic acidosis. With an adequate atrial communication (natural or after a Rashkind procedure), the infant with TGA survives for years with only mild or moderate cyanosis. These patients are exposed to the complications of hypoxemia and polycythemia, mainly brain abscess or infarction (see Chapter 52) and progressive right ventricular failure. Some survive into adulthood, but most have problems by the age of 5 years (an age chosen in the 1960s and early 1970s for the Mustard operation). Progressive subpulmonic stenosis due to the bulge of the septum (displaced by the systemic right ventricle) under

Rashkind procedure
Figure 42.7 Diagram of Rashkind balloon atrial septostomy. (a) The catheter with the balloon deflated is passed from the right atrium (RA) through the foramen ovale into the left atrium (LA). (b) The balloon is inflated. (c) The inflated balloon is jerked back into the right atrium, tearing the atrial septum. RV, right ventricle; LV, left ventricle.

the pulmonary valve causes a systolic ejection murmur and left ventricular hypertrophy [6–10].

Medical management

Medical therapy at birth is based on balloon atrial septostomy (the Rashkind procedure) and maintaining or vasodilating the ductus arteriosus by PGE_1 infusion. These therapies have greatly improved the outcome of neonatal TGA.

When TGA is diagnosed prenatally, delivery should be carried out at a center where a Rashkind procedure can be performed safely and quickly (Figure 42.7; see Chapter 10 for details of the procedure). This can be done under two-dimensional echocardiographic guidance via the umbilical vein (through the ductus venosus) even in the delivery room.

If prenatal diagnosis was not made and severe hypoxemia occurs in the delivery room, PGE_1 should be infused and an emergency transfer organized to the nearest pediatric cardiology center that is able to perform the Rashkind procedure. Meanwhile, it may be useful to put an umbilical catheter into the heart in an attempt to push the flap and allow some atrial mixing before the Rashkind procedure or an emergency arterial switch.

PGE_1 infusion may be useful in the hypoxic neonate before the Rashkind procedure to allow some mixing and avoid

(sometimes, but not always) metabolic acidosis and death. It can also be useful after the Rashkind procedure to improve mixing (decrease hypoxemia) and increase pulmonary arterial and left ventricular pressure in preparation for an anatomic repair.

PGE_1 infusion has its drawbacks, however, because it can lead to apnea (with the need for artificial ventilation) and to pulmonary edema by the increase in pulmonary blood flow and pressure (especially if the foramen ovale is restrictive before or after a Rashkind procedure). This is why PGE_1 infusion should not be used routinely but reserved for neonates who do not tolerate hypoxemia. Rashkind procedure has also its drawbacks, even if it is done carefully with good equipment. A clot or air in the catheter may pass to the brain [27], and if the balloon is not kept in the left atrium it may damage the mitral valve. In addition, if the foramen ovale is small, the Rashkind procedure is only mildly efficient but can leave profound cyanosis. This is why, in a setting where surgery can be performed quickly, the Rashkind procedure is limited to real emergencies or when surgery has to be postponed for several days (infection, enterocolitis, or other).

Neonates with TGA are also at risk for hypoglycemia (they have pancreatic hyperplasia and increased insulin secretion) and necrotizing enterocolitis (the gut is perfused with a higher PaO_2 *in utero* than after birth). Therefore, these patients benefit from parenteral alimentation with high glucose concentrations for the first day of life and for 24h after a Rashkind procedure.

Surgical management

Surgery is the only solution for these patients. Their natural history is catastrophic in the short term unless the atrial septal defect is large, and even then they are exposed to serious neurologic and myocardial complications in the long term because of the chronic cyanosis.

There are two surgical options for treating TGA. The first is the anatomic option of correcting the ventriculo-arterial discordance by an arterial switch of the great vessels above the sinuses of Valsalva (Figure 42.8). Both arterial roots and semilunar valves have similar sizes, shapes, and histologic features, at least at birth. The coronary arteries that arise from the aortic sinuses of Valsalva need to be moved to the new aortic root to perfuse the myocardium at high pressure with fully oxygenated blood. Second is the "physiologic" option or atrial repair consisting of creating atrioventricular discordance (by intra-atrial rerouting) to correct the physiologic consequences of the ventriculo-arterial discordance (Figure 42.9).

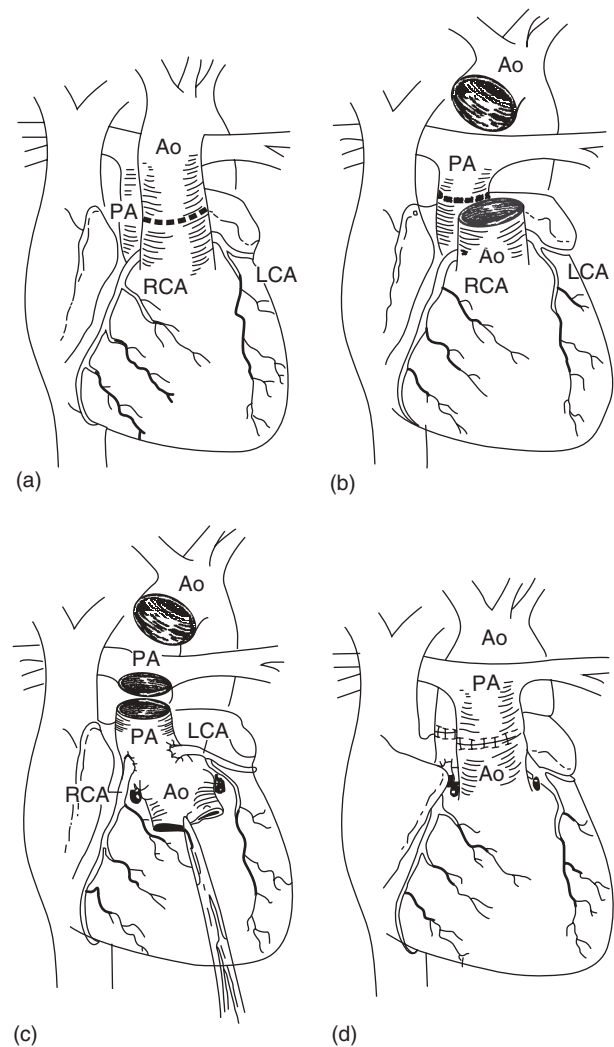
In most pediatric cardiologic centers, anatomic repair is the choice in neonates. It restores the left ventricle to its normal systemic function and avoids extensive atrial surgery that is often responsible for subsequent rhythm disturbances.


Figure 42.8 Diagram of arterial switch operation. (a) The anterior aorta is shown giving off the coronary arteries. The dashed line shows where the ascending aorta is transected. (b) The posterior pulmonary artery. The dashed line shows where the main pulmonary artery is transected. (c) The coronary arteries have been removed from the aorta and implanted into the old pulmonary root, now the neoaortic root. The holes left in the aorta are patched. (d) The distal pulmonary arteries are brought anteriorly after cutting the ligamentum arteriosum or the ductus arteriosus (Lecompte maneuver) and anastomosed to the old aortic root, now the neopulmonary arterial root. The pulmonary artery now receives blood from the right ventricle. The distal aorta has been anastomosed to the neoaortic root behind the pulmonary artery, and it receives blood from the left ventricle. Ao, aorta; LCA, left coronary artery; PA, pulmonary artery; RCA, right coronary artery.

The arterial switch remains challenging (see Figure 42.8), particularly because the transfer of the coronary arteries may sometimes be difficult.

The operation is performed with cardiopulmonary bypass. The ductus arteriosus is ligated and divided at the beginning

(a)

(b)

(c)
Figure 42.9 Diagram of atrial switch operation. (a) The right atrium has been opened. The four pulmonary veins and the tricuspid valve can be seen. (b) A patch made of pericardium (the Mustard procedure) or a displaced atrial septum (the Senning procedure) is shown in the shaded structure. It is placed to direct the drainage from the superior and inferior venae cavae through the mitral valve into the left ventricle, thence into the pulmonary artery (not shown, but posterior to the patch). At the same time, the patch directs the pulmonary venous return through the tricuspid valve into the right ventricle and thence into the aorta (arrow). This diagram does not show the precise anatomy of the patch. (c) The right atrium is closed with a patch to enlarge it and minimize the risk of obstruction to the pulmonary venous drainage.

of cardiopulmonary bypass. The aorta is cross-clamped and the heart is arrested with a cardioplegic solution infused into the aortic root. The aorta and the pulmonary trunk are transected above the semilunar valves. The coronary arteries are excised from the aortic root with a button of aortic wall and relocated on the native pulmonary root. The branch pulmonary arteries are dissected down to the pulmonary hila to gain sufficient length and allow a tension-free translocation of the pulmonary bifurcation anterior to the ascending aorta (Lecompte or "French" maneuver [28]). The native pulmonary root (now the neoaortic root arising from the left ventricle) is anastomosed to the ascending aorta. The defects created by the excision of the coronary arteries are covered with a patch of autologous pericardium. The native aortic root (now the neopulmonary root arising from the right ventricle) is anastomosed to the pulmonary artery.

The most difficult surgical step is the transfer of the coronary arteries with its inherent risk of coronary ischemia. Coronary transfer is usually easy in patients with "normal" coronary arteries (60–65% of neonates). In coronary patterns with arteries coursing either posterior or anterior to the great vessels (posterior and/or anterior loops – 30% of patients), there is an increased risk of kinking or elongation of the abnormal artery, but these potential problems can usually be overcome. In ~5% of neonates, the coronary arteries course between the great arteries; this is very often associated with an intramural course which may be stenotic. Coronary transfer is then always difficult; innovative and aggressive surgical techniques are necessary to avoid coronary ischemia.

The perioperative mortality, in experienced centers [29,30], is <5%; most deaths are due to ischemia from inadequate coronary artery transfer. Beyond the perioperative period, mortality and morbidity are extremely low [31]. Morbidity concerns the fate of three structures:

1 *The new pulmonary artery.* When the coronary arteries are removed from the aortic root, large buttons of aortic tissue are taken so as not to encroach on the coronary ostia. Large pericardial patches are used to fill the holes made by the harvesting of the coronary arteries. Following the Lecompte maneuver, the pulmonary trunk becomes anterior to the aorta and the pulmonary bifurcation may be elongated, leading to PA branch stenosis and asymmetrical PA blood distribution Thus, the previous aortic root (new pulmonary root) is the great artery that has had the most damage during the arterial switch operation [32]. Mild supravalvar pulmonary stenosis is the rule after an arterial switch (with systolic gradients of ~30 mmHg). Some patients, about 10% in our early experience, needed an operation during childhood to treat PA stenosis, but this is now fairly rare even with a 20 year follow-up, and it is unlikely to be a significant long-term problem. In the few patients with stenosis, percutaneous balloon dilatation of the stenotic pulmonary trunk has partially relieved the obstruction, but this procedure is successful in only one-third of patients. Stenting may improve the percutaneous results, but it is essential to check that the dilatation before the stenting does not compress the left coronary artery, which is usually close to the pulmonary trunk. If the artery is compressed, ST

Figure 42.10 Gothic arch. The ascending aorta is pushed posteriorly by the Lecompte maneuver so that is embraced by the pulmonary artery branches. Note the acute angulation of the aortic arch.

changes develop during dilatation. Before reoperation on the pulmonary trunk, we recommend a selective coronary angiogram to ascertain that no coronary arterial branches run in front of the pulmonary artery (commonly there is a right coronary artery in type E distribution). Pulmonary regurgitation is common after the switch operation, but it is usually mild and well tolerated by the right ventricle.

2 *The new aorta*. Dilatation of the new aortic root and minor leak of the new aortic valve is the rule after a neonatal switch operation. In our experience, it has nearly always been mild and well tolerated, and it has never required medical or surgical treatment during a 15 year follow-up. In patients from the late 1970s and early 1980s who had pulmonary artery banding before the arterial switch, aortic regurgitation can be moderate or even severe, and now after 30 years we recommend a Bentall operation in more patients because of LV or aortic root dilatation We have twice had to change the valves and the aortic root in such patients. However, dilatation of the aortic root and aortic regurgitation have a tendency to increase also in patients with neonatal switch, and this may lead in the long term to more aortic regurgitation and sinus of Valsalva dilatation. Reoperation may become necessary and involve, according to the lesions, aortic valve replacement, replacement of the ascending aorta with preservation of the valve (David operation), or combined replacement of the valve and ascending aorta (Bentall operation). The indications for these procedures are similar to those in other diseases, such as Marfan syndrome and bicuspid aortic valve. To date, the need for such reoperations has been extremely low. The

shape of the aorta is different after the Lecompte maneuver because the ascending aorta is pushed posteriorly which leads to a more angulated aortic arch. The so-called "gothic" arch (see Figure 42.10) is associated with enhanced reflection of the systolic pulse wave, dilatation of the ascending aorta, and aortic regurgitation [33]. The pathophysiologic mechanisms of the gothic arch have been well studied in post-coarctectomy patients with abnormal geometries of the aortic arch. Using MRI, we have demonstrated the direct impact of the acute angulated arch on the central aortic fluid and biomechanics. A gothic arch is associated with increased systolic wave reflection that leads to a systolic reflux in the ascending aorta, and also increased central aortic stiffness that contributes to the dilatation of the aortic root [34,35].

3 *The coronary arteries*. The major long-term concern after the arterial switch operation is left ventricular myocardial ischemia. Indeed, left ventricular coronary perfusion may be impaired by acquired lesions of the coronary arterial ostia resulting from surgical transfer, for example, stenosis or atresia by torsion or compression by the pulmonary artery or by fibrous tissue. This is the major cause of operative and early postoperative mortality and morbidity of the arterial switch procedure. Late coronary ostial stenosis or atresia is rare after an arterial switch, but most centers have not looked carefully at the fate of the coronary arteries after the switch. The assumption has been made that if clinical, electrocardiographic, or echocardiographic signs of ischemia did not develop after the operation and before discharge from the hospital, the coronary arteries were normal and would remain normal and grow normally. Coronary arterial damage, however, has been responsible for late deaths [31]. By performing selective coronary arterial angiograms in postoperative patients, we found coronary arterial anomalies in ~5% of patients who apparently had no evidence of postoperative ischemia [36,37]. Most had minor signs of ischemia on electrocardiography and echo-cardiography, but some showed no ischemia at all, even on a myocardial perfusion thallium scan. Selective coronary arterial angiograms disclosed coronary arterial stenosis or complete obstruction, almost always in the left coronary artery (except one in the right coronary artery), usually with adequate collateral circulation from the right coronary arterial bed. Patients in whom reversible ischemia could be demonstrated underwent reoperation. In most patients (even with obstructed arteries), normal coronary perfusion can be restored by surgical patch angioplasty of the stenosed/obstructed coronary artery. The patients who do not have ischemia are left with only one coronary artery; they may in the long term develop coronary arterial disease sooner and more often than will the normal population. Even without coronary artery stenosis, myocardial reserve may be impaired by inadequate position of the ostia for perfect diastolic filling, because of the high implantation of the coronary artery on the upper part of a dilated sinus of Valsalva, or by endothelial

damage from the operation (cannulation and cold blood flushing). In theory, there could be a constitutional inadequacy of the left ventricular coronary circulation because the right coronary artery is nearly always dominant in TGA, and the left circumflex or left anterior descending artery is frequently small. We do not have information on myocardial reserve in these patients, but positron emission tomographic scanning with dipyridamole (Persantine) in a few patients suggests that myocardial reserve may be decreased.

Despite these concerns, however, with a mean follow-up of >14 years, and more than 20 years for 300 patients, almost all these children after an arterial switch live a normal life, including participation in competitive sports.

Our patients are followed up yearly in the outpatient clinic with clinical history and examination, two-dimensional echocardiography–Doppler study, and an electrocardiogram; after 5 years of age, they have formal exercise testing. If ischemia is suspected, a coronary angiogram is indicated. We checked the coronary arteries systematically by a selective coronary angiogram by the age of 6 years, but we now perform a multislice CT scan and perform selective coronary angiogram only if the scan is abnormal. We have shown that 64-slice CT coronary angiography performs as well as invasive angiography for detecting significant coronary lesions (>30% reduction diameter) [38]. It allows direct visualization of the coronary artery lumen, and the course of the vessel in relation to the nearby major cardiovascular structures. CT also provides information about the underlying mechanism of coronary lesions, for example through stretching, compression, and/or kinking caused by the surrounding great arteries (see Figure 42.11). MRI is another modality that may be useful for follow-up imaging after arterial switch operation, particularly because it does not deliver X-radiation [39]. New-generation machines already offer promising results on cooperative children who can hold their breath during image acquisition. Our current policy is to perform a cardiac MRI in cooperative children for a complete and comprehensive anatomic and functional evaluation after the arterial switch. Coronary arteries and the great vessels are assessed on high-resolution 3D imaging with ECG- and respiratory-gated sequences (see Figure 42.12). Central aortic fluid dynamics and biomechanics of the ascending aorta are assessed on velocimetry mapping sequences. Myocardial perfusion and viability are also evaluated using first-pass perfusion and myocardial delayed enhancement, respectively. The long time required for the scan and the potential need for anesthesia are substantial drawbacks in small children. With a normal exercise test result and coronary angiogram, the children are allowed to participate in all sports, including competition.

Beyond the neonatal period

The arterial switch can be performed only in the neonatal period while the left ventricle is still competent to develop systemic pressures. Until recently, on the basis of echocar-

diographic characteristics of the thickness and shape of the left ventricle [40], the upper age limit for the arterial switch was set at 3–4 weeks. The belief was that if the left ventricle was much thinner than the right ventricle, and if the ventricular septum bulged into the lower pressure left ventricle, the left ventricle would be unable to support systemic arterial pressures and flows. However, some centers have observed that the arterial switch can be performed safely up to 8 weeks of age, whatever the shape of the left ventricle and the interventricular septum [41,42]. Beyond that age, only patients with a left ventricle having a high systolic pressure (because of an open ductus or subpulmonic stenosis) are good candidates.

For patients who do not meet these criteria, the arterial switch can be performed safely only if the left ventricle is prepared by an afterload challenge (usually pulmonary artery banding). If this causes severe hypoxemia, the patient may also need an aortopulmonary shunt. This two-stage surgery with a quick (~10 days) left ventricular preparation before the arterial switch has been successful in some centers [43]. It is not an easy procedure, however, and in our experience it has an increased mortality and morbidity. Furthermore, the left ventricular myocardium may have inadequate fiber quality and decreased coronary reserve; there is little evidence for growth of coronary arteries after the newborn period. Therefore, many centers (such as ours in Paris) perform an "atrial repair" rather than an arterial switch. Our current practice is to place a loose pulmonary band to maintain a degree of high pressure in the left ventricle; if the atrial switch is performed in infancy, the banding should become tighter as the child grows with subsequent increase in left ventricular pressure; the hope is to preserve septal geometry and tricuspid valve function and also to prepare the left ventricle for a late arterial switch.

Atrial repair: the Mustard and Senning operations

When the left ventricle has lost its systemic competence or when the surgical team has too high a mortality with the arterial switch, an atrial baffle repair can correct the physiologic abnormalities by rerouting the venous return. This is done by directing systemic venous drainage towards the mitral valve and pulmonary venous drainage toward the tricuspid valve by placing pericardial patches around the caval veins, as in the Mustard operation [44] introduced in 1964, or by moving the atrial septum in the Senning operation [45], described in 1959 but subsequently modified and made easier to perform in 1977 [46].

These operations can be performed at any age and have a low mortality. Most of the patients (80–90%) are doing well with a follow-up of >20 years [47]. There are, however, three major problems or theoretical concerns with this procedure.
1 The atrial channels can become obstructed, leading to caval or pulmonary venous hypertension. These uncommon complications can usually be treated or improved by
Figure 42.11 CT assessment of the coronary arteries and their relationship with the surrounding great arteries. (a) Note the anterior position of the reimplanted left ostium so that the left coronary artery has a course between the pulmonary artery (PA) and the aorta (Ao). There is a tight compression of the left ostium in (b).
Figure 42.12 Cardiac MRI for the follow-up imaging of the reimplanted coronary arteries. The left ostium gives rise to both the left anterior descending artery (LAD) and the right coronary artery (RCA). The circumflex artery (Cx) rises from the right aortic sinus and has a long retro-aortic course.

interventional catheterization with dilatation and stents. They rarely require reoperation. When the stenosis is limited to the superior vena caval channel, there is usually an efficient rerouting of the blood by the azygos or hemiazygos veins towards the inferior vena cava. When the pulmonary venous channel is obstructed, the clinical picture resembles cor triatriatum or mitral stenosis with pulmonary edema and postcapillary hypertension. In some patients, this pulmonary arterial hypertension "prepared" the left ventricle for a late switch procedure.

2 The incidence of atrial dysrhythmias is high, probably because of damage to the sinus node or its artery, or the internodal tracts, during the operation. The dysrhythmias can be severe and difficult to treat, with a risk of sudden death even after pacemaker implantation. Abnormal sinus node dysfunction was reported first in 1972 [48]. Sinus node dysfunction progresses over time [49–51], and 10 years after operation only ~14% of these children remain in normal sinus rhythm [51]. The others have a tendency for bradycardia and junctional rhythm, sometimes with a restored sinus rhythm during exercise. These passive bradycardias are usually benign and rarely symptomatic, but 10–20% need a pacemaker. Dysrhythmias can also be "active" in these patients, with the appearance of ectopic atrial tachycardia, atrial flutter, or even atrial fibrillation [52]. A high proportion of these patients have inducible atrial flutter during electrophysiologic studies postoperatively [53], and many of these later develop spontaneous atrial flutter. On electrocardiographic examination, the atrial flutter is atypical, with rates often from 180–260 beats per minute, frequently with 1:1 atrioventricular conduction. The flutter waves are of low amplitude and may be difficult to see. In fact, any patient after an atrial baffle repair with a resting heart rate above 100 beats per minute should be checked carefully to exclude atrial flutter with 2:1 or 3:1 atrioventricular block. These active tachycardias or arrhythmias are dangerous for the patients and for right ventricular function. They can lead to serious myocardial or neurologic complications and even sudden death [54]. They are difficult to treat because they are associated with a weak or damaged sinus node, and antiarrhythmic drugs may be hazardous because of the risk of severe bradycardia. Therefore, treatment of these atrial tachycardias often requires pacemaker implantation.

3 The long-term function of a right ventricle and a tricuspid valve working at systemic pressure is uncertain [55]. Some of these patients develop heart failure after 10, 20, or 30 years. The example of patients with double discordance (corrected transposition) shows that the long-term failure of a systemic right ventricle is not a certainty (some patients can live to 70 years without heart failure). Most of those with an atrial baffle, however, will probably develop heart failure, perhaps in part owing to inadequate myocardial protection during surgery (especially in the early days of this repair) and in part owing to associated anomalies of rhythm and atrioventricular conduction.

When the right ventricle begins to dilate, the attachments of the tricuspid valve to the septum are pulled laterally, thereby inducing tricuspid regurgitation that increases the ventricular dilatation. A vicious circle is thus established. Furthermore, because the regurgitant blood enters the new pulmonary venous atrium, tricuspid regurgitation causes pulmonary venous hypertension and eventually pulmonary edema.

When right ventricular failure develops after a Senning or Mustard procedure, chronic dysrhythmia may be the mechanism. If right ventricular failure is present without dysrhythmia, nonspecific medical therapy with diuretics, converting enzyme inhibitors, and digoxin (with care for sinus node dysfunction) can be tried, but are seldom successful for long. The only possibility other than cardiac transplantation is conversion of the right ventricle into a subpulmonary ventricle by performing an arterial switch procedure and taking down the atrial baffle to reroute the venous returns to their original ventricles [56]. For this transformation, the left ventricle must be prepared for the arterial switch by an afterload challenge (pulmonary arterial banding).

This procedure of late preparation is different from the two-stage preparation done in the older infant with TGA and a low-pressure left ventricle. After a Mustard or Senning procedure, the heart has a circulation in series without hypoxemia, and the banding will directly affect only the left ventricle, although it may indirectly affect the preload of the right ventricle. The severe hypoxemia attendant on preparing the left ventricle in the infant with TGA is not a problem. The preparation of an older left ventricle cannot be obtained in few days, however, and it needs a long and uncertain process (several years in some patients) before achieving adequate left ventricular mass. Little information is available about the quality of the fibers and the coronary reserve. This situation is identical with the problem of treating a patient with double discordance or congenitally corrected transposition in whom the right ventricle is failing and the tricuspid valve regurgitating. The issues concern fundamental unanswered questions about postnatal ventricular growth and coronary artery angiogenesis.

Experience has shown, however, that pulmonary arterial banding changes the septal geometry in some patients, pushing the septum back towards the right ventricle, and improves both right ventricular and tricuspid valve function by decreasing tricuspid regurgitation. Often two or three banding adjustments may be needed to prepare the left ventricle during several years, while avoiding left ventricular failure. Hence it is crucial to evaluate right ventricular function in the follow-up of these patients and not wait for severe dysfunction and heart failure to develop before "retraining" a left ventricle.

43 Congenitally Corrected Transposition of the Great Arteries

Tim S. Hornung & A. Louise Calder

Auckland City Hospital, Auckland, New Zealand

Congenitally corrected transposition of the great arteries (CCTGA) is a rare cardiac anomaly characterized by combined atrioventricular and ventriculoarterial discordance. Other terms for this anomaly include physiologically corrected transposition of the great arteries, l-transposition, double discordance, and ventricular inversion. Congenitally corrected transposition is used preferentially because systemic venous blood is directed to the pulmonary arteries and pulmonary venous blood is directed to the aorta. This differentiates CCTGA from "complete transposition" (d-TGA) in which there is ventriculoarterial discordance but atrioventricular concordance.

Incidence

CCTGA represents approximately 0.5–1% of all congenital heart disease. In one series of 10 535 patients with congenital heart disease, 101 had corrected transposition [1]. Excluding patients with a univentricular atrioventricular connection reduced the prevalence to 0.57%. In another study of 4390 infants, there were 47 infants with CCTGA [2]. The anomaly is more common in males.

Embryology

CCTGA is due to failure of normal looping of the primitive heart tube. The heart tube has fixed proximal and distal attachments so its rapid growth necessitates looping of the tube. Looping is normally rightwards (D looping), but in CCTGA with situs solitus looping is leftwards (L looping). Therefore, the morphologic right ventricle is displaced leftwards and the morphologic left ventricle rightwards. The ventricles are in a more side-by-side relationship than the usual anteroposterior position. The atrioventricular valves loop with the respective ventricles, so the tricuspid valve connects to the morphologic right ventricle and the mitral valve to the morphologic left ventricle. After the looping process, truncus arteriosus development occurs. The conotruncal ridges divide the truncus into an aorta that connects to the left-sided ventricle and is displaced leftwards, anterior and superior, and a pulmonary artery that connects to the right-sided ventricle and is displaced more posteriorly and rightwards. The outflow tracts and great arteries are essentially parallel rather than crossing as in a normal heart.

Anatomy

There is usually normal connection of the systemic veins to the right atrium and the pulmonary veins to the left atrium. The right atrium connects via the mitral valve to the morphologic left ventricle, which supplies the pulmonary artery. The left atrium connects via the tricuspid valve to the morphologic right ventricle, which supplies the aorta via a subaortic infundibulum or conus. The cardiac connections are therefore:

systemic veins → right atrium → morphologic left ventricle → pulmonary artery

pulmonary veins → left atrium → morphologic right ventricle → aorta

An important anatomic implication is that the morphologic right ventricle supplies the systemic circulation.

The exact anatomic arrangement varies considerably (Table 43.1). The usual arrangement is situs solitus with L-looping of the ventricles and the aorta anterior and leftward of the pulmonary artery {S,L,L}, found in 19/22 of our postmortem subjects [3]. The aorta was anterior and

[a]One unknown in each series.

rightwards {S,L,D} in two subjects with situs solitus, both with criss-cross atrioventricular connections. The remaining subject (5%) had situs inversus with D-looping of the ventricles and aorta anterior and rightwards {I,D,D}.

In patients with situs solitus, the heart is frequently mesocardic but the apex remains leftwards in most: in our series, there was true mesocardia in one and dextrocardia in two others with situs solitus. Either ventricle may be hypoplastic, particularly the left-sided right ventricle. The anomaly may be associated with double-inlet ventricle or AV atresia [4].

Coronary artery anatomy

The coronary arteries are inverted (Figure 43.1). Thus, the morphologic left coronary artery (LCA) arises from the patient's right-sided sinus and the morphologically right coronary artery (RCA) from the left-sided sinus (Figure 43.1a and b). A variety of coronary arterial patterns is seen [4–7] (Figure 43.1). The two main coronary arteries may arise from the same sinus. The RCA may arise from the LCA and pass either anterior to the aorta (Figure 43.1c) or around and behind the pulmonary artery (Figure 43.1d). A variant of Figure 43.1d shown in Figure 43.1e is a separate right ventricular branch from the aorta. Another variation (Figure 43.1f) in a patient with pulmonary atresia and commisural malalignment had both coronary arteries arise from the same sinus. The single coronary artery may arise from either the right or left coronary sinus.

Anderson *et al.* pointed out the vulnerability of the coronary arteries in CCTGA with surgery [8], particularly the anterior descending artery running anterior to the pulmonary artery. Careful preoperative delineation of the coronary anatomy is particularly important before the double-switch operation.

Coronary venous anatomy

Coronary sinus anatomy varies and shows abnormalities in about 25% of patients. It usually drains normally into the right atrium. It may be absent with the coronary veins draining into the ipsilateral atrium, and in other patients some veins drain to one of the atria and others to the coronary sinus [9].

The coronary sinus could be assessed in 20 of our patients and was absent in five (25%). When the coronary sinus is absent, the coronary veins usually drain to the ipsilateral atria. In one of our patients, the coronary veins entered the right atrium via separate entrances. In Uemura *et al.*'s series with atrioventricular discordance (including double-outlet right ventricle) [9], all the left coronary veins drained directly to the right atrium in 20%, some directly to the right atrium and some to coronary sinus in 63%, and completely to coronary sinus in 17%. The right coronary veins all drained to coronary sinus in 87% and partially or totally directly to left atrium in 11%.

Conduction system

The anatomy of the conduction system is abnormal with the atrioventricular node because of the septal malalignment unable to connect to a penetrating atrioventricular conduction bundle. A second atrioventricular node positioned anteriorly gives rise to an elongated atrioventricular bundle [10].

Associated cardiac abnormalities

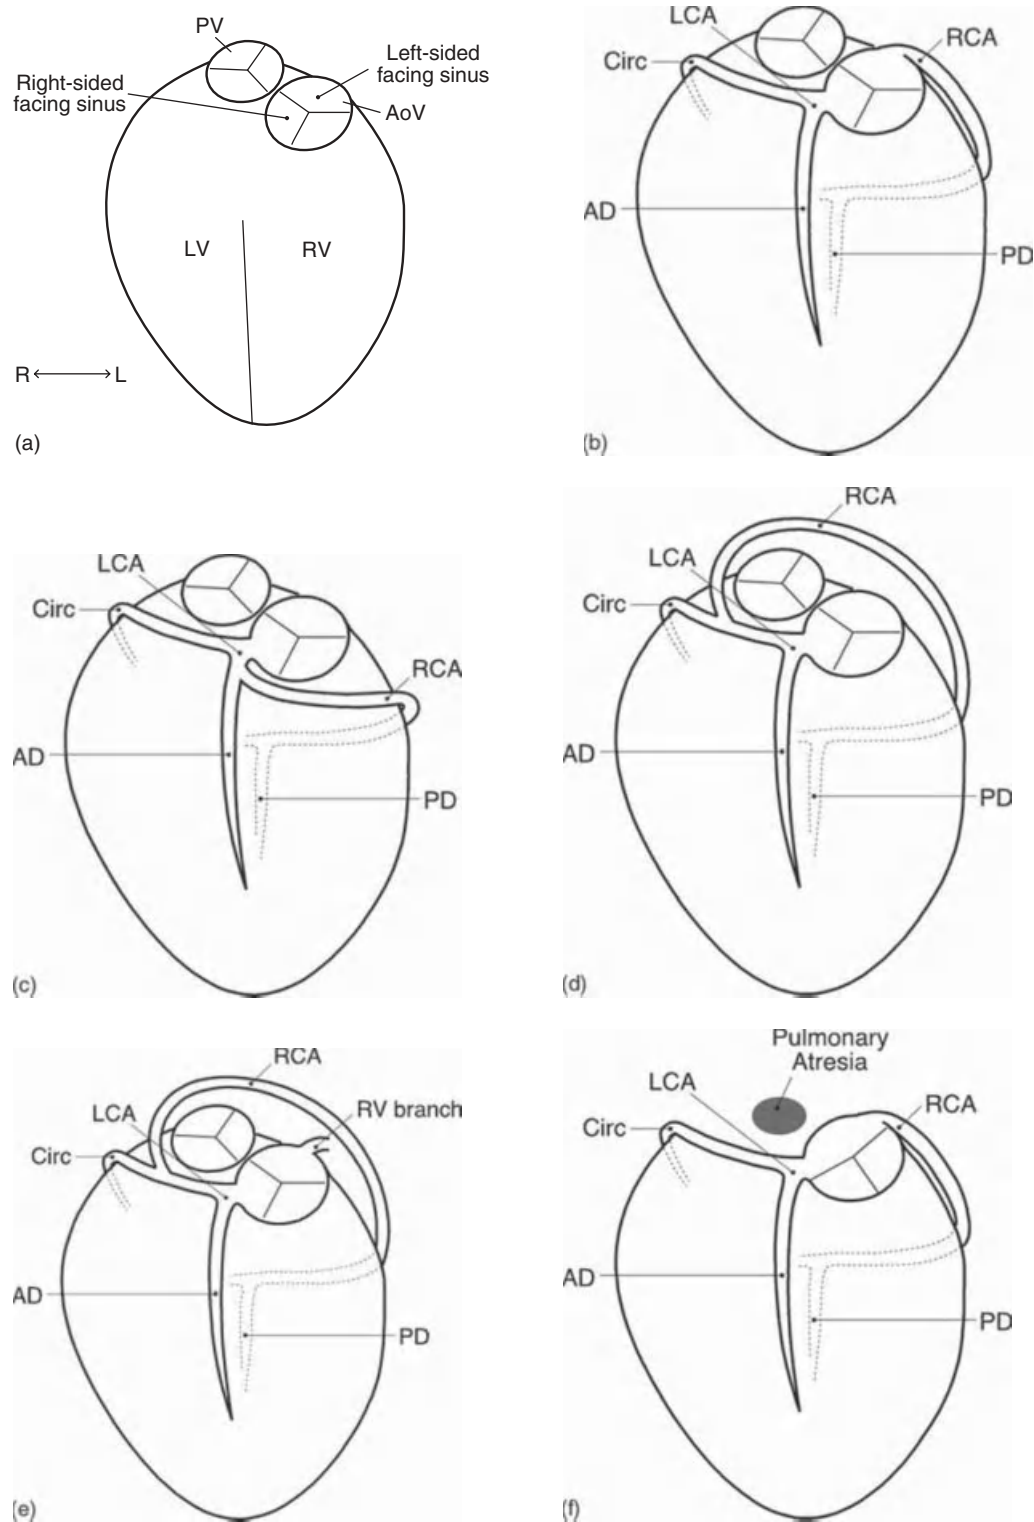
CCTGA without associated intracardiac abnormalities is rare. Coexisting lesions occur in >90% of patients, most frequently ventricular septal defect, left ventricular outflow tract


Figure 43.1 Coronary arterial patterns in CCTGA {S, L, L}. (a) A sketch of the morphological left ventricle (right-sided) and the morphological right ventricle (left-sided) viewed from the front, and the leftward, anterior aortic valve and the rightward, posterior pulmonary valve in a superior plane view. The coronary arteries usually arise from the right- and left-sided facing sinuses. (b) The usual coronary arterial pattern in CCTGA with the morphologic left coronary artery arising from the right-sided facing sinus. The anterior descending and circumflex coronary arteries arise from the left coronary artery. The morphologic right coronary artery arises from the left-sided facing sinus and passes around the atrioventricular groove adjacent to the right ventricle. (c–f) Single sinus origins of coronary arteries. In (c) the right coronary artery arises from the left anterior descending and then crosses anteriorly to the aorta to reach the atrioventricular groove. In (d) the right coronary artery arises from the left circumflex coronary artery and passes posteriorly to the great arteries to reach the atrioventricular groove. (e) is similar to (d) but with an additional branch to right ventricle arising from the left-sided coronary sinus. In (f), because of commissural malalignment, the coronary arteries do arise form the same sinus but on opposite sides. AD, anterior descending; AoV, aortic valve; Circ, circumflex; L, left; LCA, left coronary artery; LV, left ventricle; PV, pulmonary valve; PD, posterior descending. R, right; RCA, right coronary artery; RV, right ventricle.

[a]Six patients had both valvar and subvalvar stenosis.

obstruction, tricuspid valve abnormalities, and conduction abnormalities. All may occur in the same patient. Data from three postmortem series [7,11] with data from 93 patients are given in Table 43.2.

Ventricular septal defect

From the three combined series, a ventricular septal defect (VSD) was present in 84% of autopsies (Table 43.2); most clinical series have a similar high incidence. The defect is commonly a large perimembranous outflow (subpulmonary) defect and is thought to result from malalignment between the atrial and the ventricular septum. Other types of VSD have been described, including doubly committed subarterial (conal) (Figure 43.2a and b), muscular, and atrioventricular canal type Perimembranous defects may be partially obstructed by aneurysmal membranous septum tissue or overriding or straddling tricuspid valve tissue.

Left ventricular outflow obstruction

Left ventricular (pulmonary) outflow tract obstruction is also common, and in the three series was found in 53%, including 16% with pulmonary atresia (Table 43.2). The severity of the obstruction varies from mild stenosis to atresia. Obstruction occurs at the valvar or subvalvar level.

Subpulmonary stenosis may be from a fibromuscular membrane or tunnel-like hypoplasia. It may be related to an aneurysm of the membranous ventricular septum prolapsing into the left ventricular outflow tract because of the systemic pressure in the morphologic right ventricle (Figure 43.3) or from accessory mitral or tricuspid valve tissue or systolic anterior motion of the mitral valve.

Tricuspid valve abnormalities

The tricuspid valve is abnormal in most patients at autopsy, but not necessarily clinically relevant. The abnormality often involves dysplastic valve leaflets and/or Ebstein's anomaly (Figure 43.2c). The severity varies widely, with the worst being severe Ebstein's anomaly. In the three combined series, the tricuspid valve was abnormal in 87%, with Ebstein's anomaly in 50% (Table 43.2).

Mitral valve abnormalities

Mitral valve abnormalities are less frequent than those of the tricuspid valve (Table 43.2). Gerlis *et al.* reported mild abnormalities in the number of leaflets in 21% and of the tension apparatus in 21% in their autopsy series of 29 hearts [12]. Less common abnormalities present in 13% included dysplasia, common atrioventricular orifice, stenosis, and cleft valve.

(a)

(b)

(c)
Figure 43.2 Ventricular septal defects in CCTGA. (a) and (b) from a 48-year-old man with a doubly committed (conal) type of VSD. (a) View from the left ventricle shows the VSD adjacent to both pulmonary and aortic valves. (b) A view of the VSD from the right ventricle with a deficient conal septum. (c) View from left atrium to right ventricle from a 10-year-old with a dysplastic (*) and mildly downwardly displaced (DD) left-sided tricuspid valve. AoV, aortic valve; LA, left atrium; MV, mitral valve; PV, pulmonary valve; RV, right ventricle; TV, tricuspid valve; VSD, ventricular septal defect.

Aortic valve abnormalities

Aortic valve abnormalities are uncommon (Table 43.2). Unusual extensions of the aortic valve sinuses inferiorly have been reported by McKay *et al.* [6]. The wall of the sinus in the enlarged areas was irregular with a lattice-like appearance.

Pathophysiology

In the patient with CCTGA without associated cardiac abnormalities, the prognosis is determined by progressive systolic dysfunction of the systemic right ventricle. Although there are macroscopic and microscopic structural differences between the morphologically left ventricle and right ventricle, the reasons for developing right ventricular dysfunction remain unknown. At a microvascular level, the coronary supply to the right ventricle differs from that of the left ventricle. Sestamibi myocardial perfusion scanning suggests that impaired myocardial perfusion and right ventricular myocardial fibrosis are frequent in this condition and associated with regional hypokinesis [13]. Recent attempts to confirm this finding using magnetic resonance delayed enhancement imaging have produced conflicting results [14,15]. Positron emission tomographic data have demonstrated that although resting myocardial blood flow to the systemic right ventricle does not differ from the systemic left ventricle in normal subjects, coronary flow reserve to the systemic right ventricle is substantially reduced (2.5 compared with 4.0) in the CCTGA group [16]. Thus, chronic low-grade coronary insufficiency may contribute to the progressive right ventricular dysfunction.

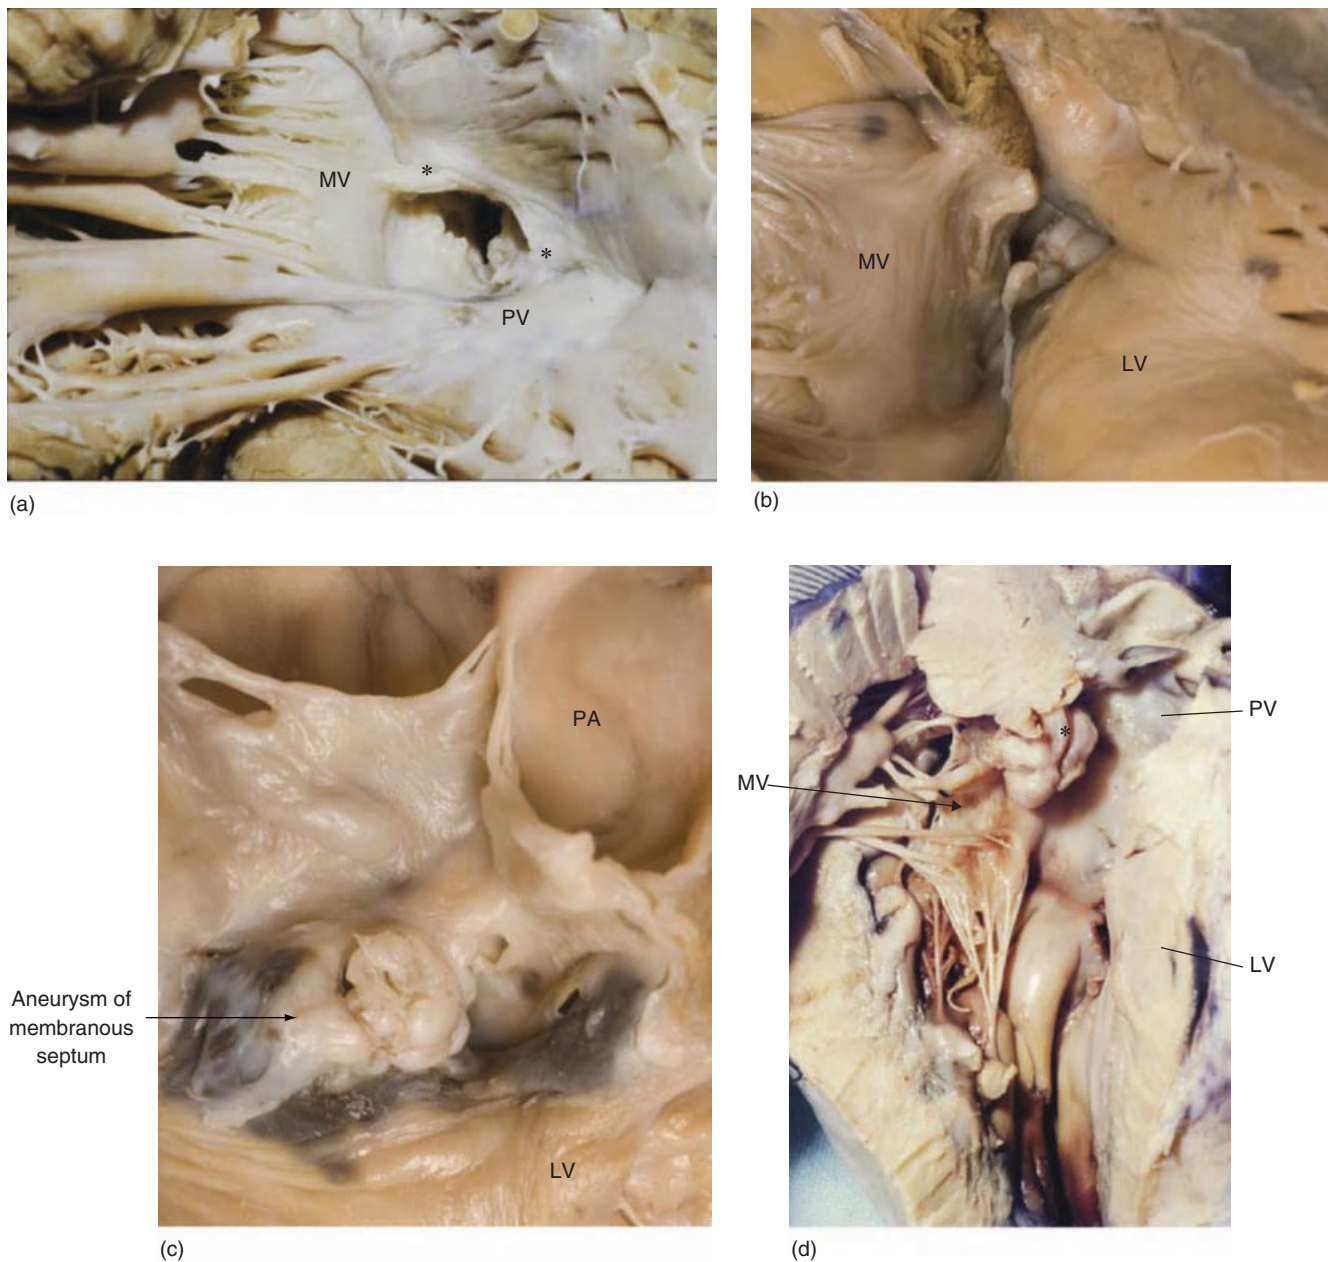
Tricuspid valve regurgitation frequently accompanies right ventricular dysfunction. The effect of tricuspid valve abnormalities may be greater in CCTGA because the right ventricle


Figure 43.3 Left ventricular outflow tract obstruction in CCTGA. Views of left ventricular outflow obstruction produced by a postoperative remnant of a fibromuscular membrane between asterisks in (a), poor expansion and fibrous nodules in (b), aneurysm of the membranous septum bulging into the outflow in (c), and by accessory tissue (asterisk) attached to the mitral valve (MV) in (d). LV, left ventricle; MV, mitral valve; PA, pulmonary artery; PV, pulmonary valve.

is developing systemic pressure, therefore increasing the back-pressure on the tricuspid valve. The altered ventricular pressure relationship shifts the ventricular septum towards the left ventricle. This alters the geometry of the tricuspid annulus, which becomes more rounded than usual, and increases the likelihood that the tricuspid valve will become regurgitant. As the right ventricle fails and becomes more dilated, the associated tricuspid regurgitation worsens, adding to the right ventricular volume load.

Natural history

In a series of antenatal diagnoses from Guy's Hospital, when the pregnancy was continued, 19 of 23 babies survived to the end of pregnancy [17]. Postnatally the natural history of patients with CCTGA is largely dictated by right ventricular function and by the nature of associated lesions [18]. Patients with isolated CCTGA who have been diagnosed incidentally in

the fifth to seventh decades of life have been reported [19,20]. Although the right ventricle may supply the systemic circulation for decades, this appears to be the exception. Most patients develop progressive right ventricular dysfunction, sometimes as early as the first decade of life. A multinstitutional study of 182 adults with CCTGA showed that important systemic right ventricular dysfunction and congestive cardiac failure symptoms are common by the third decade of life and increase in frequency with advancing age, both in patients with and without associated lesions [21]. In this study, 25% of patients without associated lesions had clinical heart failure by age 45 years, compared with 67% of those with associated lesions. The study showed moderate or severe right ventricular dysfunction in 32% of patients without associated lesions and 56% of those with associated lesions. A single center review of 131 patients with CCTGA showed a survival rate of 75% at age 20 years, with a median age at death of 13 years [22].

Functional outcomes

In the muticenter study mentioned above [21], approximately 60% of patients with associated lesions were in Warnes–Sommerville functional class one, with most of the remainder being in class two. In patients without associated lesions, ~70% were in class one. Nevertheless, when measured objectively, most patients with CCTGA have impaired functional capacity. In a group of 41 adult patients [23], there was a markedly reduced maximal oxygen uptake of 22 ml kg^{-1} min^{-1} in the 19–29 years age group and 21 ml kg^{-1} min^{-1} in the 30–39 years age group (both were approximately half that of normal controls). In the 40–55 years age group, this dropped to 11 ml kg^{-1} min^{-1}, less than one-third of that of the healthy controls. Important causative factors include impaired ventricular function, limited chronotropic response to exercise, and abnormal lung function, particularly following cardiac surgery.

Electrophysiologic issues

Because of the abnormal anatomy of the atrioventricular node and the atrioventricular conduction bundle, patients with CCTGA have a 2% annual risk of developing complete heart block [24]. Careful follow-up with regular electrocardiograms and ambulatory electrocardiographic (Holter) monitoring should be performed to monitor cardiac conduction.

These patients have a high incidence of tachyarrhythmias [20,21,25], typically re-entry tachycardia due to either accessory atrioventricular pathways or a re-entry circuit between the two atrioventricular nodes [25]. In adult patients, the risk of atrial fibrillation increases and is related to ventricular dysfunction, atrioventricular valve regurgitation, and atrial dilatation.

Pregnancy

In a retrospective review of 60 pregnancies in 22 women with CCTGA over a 17 year period [26], 49 pregnancies resulted in live births. One woman had 12 pregnancies, of which 10 were successful; she had various complications, including congestive heart failure, endocarditis, and myocardial infarction. Only one of the 22 patients developed cardiac complications, congestive heart failure related to tricuspid valve regurgitation necessitating tricuspid valve replacement at 2 months postpartum. In another experience of 45 pregnancies in 19 patients, five had cardiac complications, including heart failure, worsening cyanosis, and cerebrovascular accident [27].

Although pregnancy may be well tolerated, detailed pre-pregnancy assessment should be performed. Women with functional class three or four, more than mild ventricular dysfunction, or significant tricuspid regurgitation should be counseled against pregnancy. Some data suggest that systemic right ventricular function may deteriorate, potentially irreversibly, during pregnancy. This concern should be discussed with patients [28]. During pre-pregnancy counseling, the uncertain maternal longevity in patients with CCTGA should be discussed.

Outpatient follow-up

Because of the concerns regarding the longer term outlook for patients with this diagnosis, all patients with CCTGA should be followed by a pediatric cardiologist or adult cardiologist with specific expertise in congenital heart disease. A follow-up interval of at least every 1–2 years is necessary. Because of the risk of progressive heart block, electrocardiography should be performed at each visit, with consideration of 24 h ambulatory electrocardiographic monitoring. Regular assessment of ventricular function is important. As cardiac magnetic resonance imaging (MRI) becomes more widely available, this should be performed at least every 3 years in patients without permanent pacemakers.

Clinical features

Clinical history

If not diagnosed antenatally, young children with CCTGA without associated lesions are likely to be asymptomatic. With an associated lesion, a murmur and/or symptoms of congestive cardiac failure are likely to be present. Older children and adults present with symptoms related to systemic right ventricular dysfunction. Cardiac conduction defects cause symptoms related to bradycardia. The diagnosis of isolated CCTGA is sometimes made in a previously asymptomatic adult patient in their sixth or seventh decade during investigation of a coronary event [19,20].

Physical examination

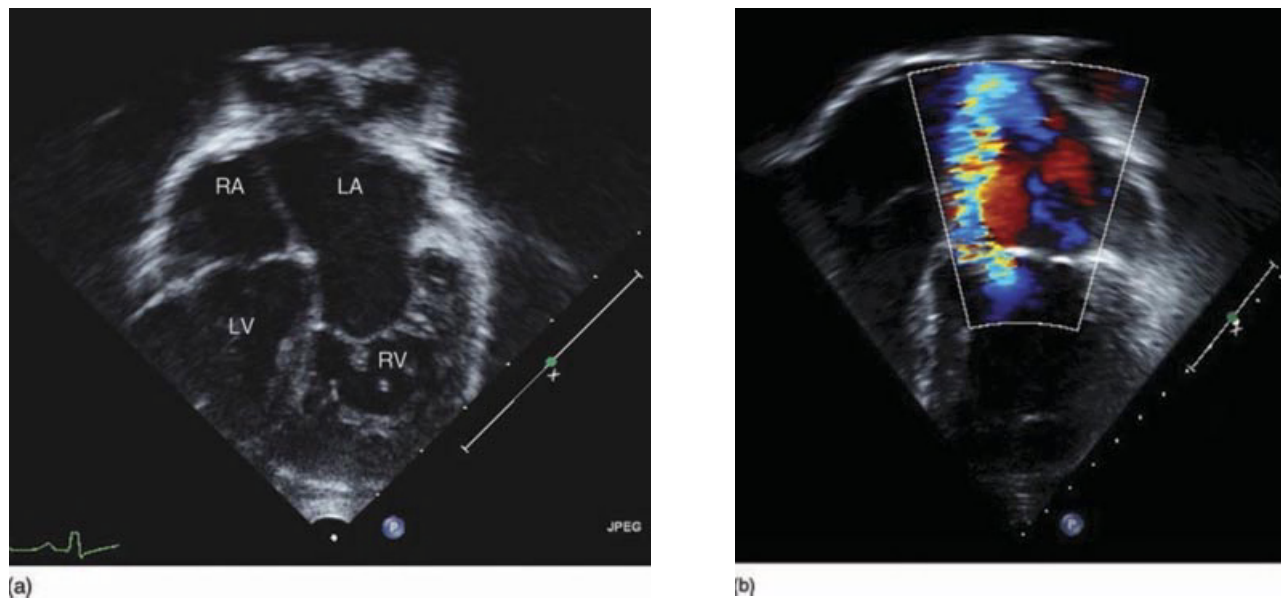
The pulse may be slow due to complete heart block. Palpation of the cardiac apex may reveal relative mesocardia or dextrocardia. A very loud single second heart sound due to the anterior positioning of the aorta is heard. With an associated lesion, a murmur is present. This may be a pan-systolic


Figure 43.4 Echocardiographic images of CCTGA. (a) Apical four chamber view showing atrioventricular discordance with apical displacement of the tricuspid valve (Ebstein's anomaly). (b) Equivalent apical four chamber view with color Doppler showing regurgitation through the tricuspid valve. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

murmur of a VSD or of tricuspid regurgitation, or may be an ejection systolic murmur of left ventricular outflow tract obstruction. With a large left-to-right ventricular level shunt, the infant shows signs of congestive cardiac failure with tachypnea, dyspnea, and hepatomegaly. Likewise, an older child or adult may develop signs of heart failure secondary to progressive systolic dysfunction of the systemic right ventricle.

Electrocardiographic features

The electrocardiogram is characteristic, at least in patients with situs solitus, with left-axis deviation and Q waves in the right but not the left precordial leads. Varying degrees of atrioventricular block may also be present and the combination of these two features strongly suggests the diagnosis of CCTGA.

Chest X-ray

There is a variable degree of mesocardia in some patients with CCTGA, and a minority have dextrocardia. The upper left heart border is straightened, representing the leftward position of the ascending aorta. The right pulmonary artery is often prominent because of the more medial position of the pulmonary trunk. Depending on associated lesions, there may be cardiomegaly, for example with a large VSD or significant tricuspid regurgitation.

Echocardiography

With increasing frequency, the diagnosis is made at antenatal echocardiography. Sharland *et al.* published a series of 34 antenatal diagnoses over a 10 year period [17]. In the fetal four-chamber echocardiographic view, the normal apical offsetting of the tricuspid valve is reversed, thus alerting the sonographer to the fact that the right atrium connects to a ventricle of left ventricular morphology. In a large VSD with inlet extension, especially with straddling or overriding of the tricuspid valve, the normal offsetting is not present.

Postnatally, echocardiography is the mainstay of diagnosis (Figure 43.4) A detailed sequential approach to the cardiac anatomy, starting with the visceral atrial situs and working through to the great arteries, must be used. The subcostal coronal view is very informative, allowing identification of venous, atrioventricular, and ventriculoarterial connections by sweeping through from posterior to anterior. In patients with CCTGA and situs solitus, the systemic veins connect to the right-sided atrium, which then connects via a mitral valve to a right-sided morphologically left ventricle. The mitral valve and left ventricle can be identified by the fine apical trabeculations, the smooth upper half of the ventricular septum, the basal offsetting of the septal hinge point of the atrioventricular valve, and the absence of septal insertions of the atrioventricular valve. The morphologic left ventricle connects to a bifurcating vessel (pulmonary artery), and there is mitral–pulmonary continuity.

On the left side, the pulmonary veins connect normally to the left atrium, but the left atrium connects via a tricuspid valve to the left-sided morphologic right ventricle. The tricuspid valve and right ventricle have characteristic features of heavy trabeculation of the ventricle apex, apical offsetting of the septal hinge point of the atrioventricular valve and septal insertions of the atrioventricular valve. The right ventricle connects to an arching vessel (aorta), which gives

rise to the coronary arteries. The aorta arises from a muscular infundibulum or conus. Therefore, there is tricuspid–aortic discontinuity.

In the parasternal short-axis view, the ventricles are essentially side-by-side and the septum is in an anteroposterior plane. The aortic and pulmonary valves are both seen en face in the short-axis view, due to the parallel arrangement of the great arterial origins. In most patients, the aorta is anterior and leftwards and the pulmonary artery posterior and rightwards. The coronary arterial anatomy is important and can usually be delineated by careful echocardiographic imaging, particularly using the parasternal short-axis view. The parasternal long-axis view is oriented more vertically than usual and, because of the anteroposterior orientation of the ventricular septum and side-by-side relationship of the ventricles, images may be obtained of only a single ventricle and outflow (either right ventricle and aorta, or left ventricle and pulmonary artery), which would not be possible when imaging a normal heart.

Associated lesions should be defined and the function of the systemic right ventricle and tricuspid valve assessed.

Cardiac catheterization and angiography

Prior to echocardiography, when cardiac catheterization was the major diagnostic method, the course of the catheters helped to reveal the abnormal relationships of the great arteries to the ventricles. Ventriculography demonstrated the ventricular "inversion" and the more vertical orientation of the ventricular septum. Occasionally, aortography may be necessary to delineate coronary anatomy, for example when the patient is being considered for a double-switch procedure, although cardiac computed tomography (CT) or MRI may provide this information noninvasively. Hemodynamic catheterization is usually necessary prior to considering the double-switch procedure, and to assess left ventricular retraining and adequacy of left ventricular pressure loading.

Other imaging modalities

Magnetic resonance imaging

Cardiac MRI has an increasing role in the quantitative assessment of systemic right ventricular function (Figure 43.5). Even MRI assessment of right ventricular function is challenging because of the complex shape of the right ventricle and the multiple coarse apical trabeculations and hypertrophy associated with systemic pressure functioning [29]. We use cardiac MRI as our primary method of tracking right ventricular size and function in patients without pacemakers, usually performing MRI approximately every 2–3 years in clinically stable patients.

Radionuclide ventriculography

In patients with a permanent pacemaker, MRI is not possible and echocardiography remains the primary imaging modality. In such patients, radionuclide ventriculography can assess the right ventricular function. This technique holds theoretical appeal for assessing the morphologic right ventricle because it is a blood pool technique which potentially solves the problems related to its shape and trabeculations. Radionuclide ventriculography, however, requires careful positioning and analysis, and should be performed by cardiologists trained in nuclear medicine or radiologists with expertise in the analysis of congenitally abnormal hearts. Radionuclear ventriculography of the systemic right ventricle correlates well with MRI in the related Mustard and Senning groups [30].

Medical management

Drug therapy

Data regarding the drug management of ventricular dysfunction of a systemic right ventricle are limited. In patients with symptomatic heart failure or moderate systemic right ventricular dysfunction, conventional left ventricular protection strategies are usually used. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers have little or no benefit in postoperative Mustard and Senning patients, but the studies are small [31]. Beta-blocker use has not been studied in the CCTGA population, but there is some suggestion of benefit in Mustard and Senning patients [32].

Resynchronization therapy

Many CCTGA patients eventually require permanent pacing for complete heart block, with the ventricular lead being placed in the morphologic left ventricle. This may negatively affect the systemic right ventricle because of the resulting interventricular dyssynchrony. Resynchronization approaches to the systemic right ventricle have been used in patients with severe ventricular dysfunction, a coronary sinus lead being used to pace the right ventricle [33]. This approach has produced symptomatic improvement in some patients with class three to four symptoms.

Anatomic variations of the coronary sinus, mentioned above, have implications for placement of a coronary sinus lead to pace the right ventricle and would potentially make this approach impossible, necessitating a more invasive epicardial approach.

Surgical management

Conventional repair

Until recently, patients underwent repair of their associated lesions, for example VSD repair and/or insertion of a left ventricle to pulmonary artery conduit for pulmonary valve
Figure 43.5 Magnetic resonance images of CCTGA. (a) Four-chamber image demonstrating atrioventricular discordance and mesocardia. The left atrium connects to a ventricle with heavy apical trabeculations and an apically displaced atrioventricular valve. (b) Short-axis image showing a hypertrophied, heavily trabeculated right ventricle on the right of the image and a thin-walled left ventricle on the left of the image. The septal position reflects the high-pressure right ventricle. (c) Long-axis view demonstrating the left atrium connecting to the right ventricle which supplies the aorta. (d) Image demonstrating the parallel course of the great arteries.

atresia or stenosis. After this repair, the right ventricle remained the systemic ventricle and the right ventricular dysfunction could be exacerbated by the negative myocardial effect of bypass surgery. Long-term results of this type of repair are disappointing: one group reported 52 patients with 15% operative mortality and a 10 year survival of 55% for patients with VSD and left ventricular outflow obstruction and 71%

for patients with VSD alone [34]. Another group reported 123 patients with a 10 year survival of 70% for VSD ± pulmonary stenosis or atresia [35]. Freedom from right ventricular dysfunction was ~40% at 15 years, with factors predicting right ventricular dysfunction being Ebstein's anomaly, tricuspid valve replacement, and postoperative complete heart block. Another group reported 127 patients (including nine

double-switch procedures) [36]. Operative mortality was 6%, 20 year survival was 48%, and the reoperation rate was 56%. Survival did not differ according to type of lesion.

Surgical management of systemic tricuspid valve regurgitation

Progressive tricuspid regurgitation is common and often associated with increasing right ventricular dysfunction. At the Mayo Clinic, 40 patients underwent tricuspid valve surgery, with valve replacement in 39 [37]. Preoperatively 68% were NYHA class three or four. Early mortality was 10%. With a median follow-up of 4.7 years (maximum 26 years), there were eight late deaths from congestive cardiac failure related to systemic right ventricular dysfunction. The 5 year survival was 78% and 10 year survival 68%. The surgery and preoperative right ventricular ejection fraction were correlated with survival. With right ventricular ejection fraction <44% the survival was 49% at 5 years and 20% at 10 years, whereas with right ventricular ejection fraction ≥44% the survival was 100%. The authors recommended that surgery for significant tricuspid regurgitation should be considered at the earliest sign of progressive right ventricular dysfunction. The Leiden group recently reported tricuspid valve surgery in 16 patients with a systemic right ventricle (including patients with d-TGA after the Mustard and Senning operations) [38]. Eight patients underwent repair and eight replacement. There was a trend towards decreased survival after valve repair compared with replacement and, after initial improvement in those undergoing repair, the regurgitation increased over the first postoperative year. This supports the impression that an approach of primary tricuspid valve replacement should be taken. Finally, pulmonary artery banding has been proposed as a definitive procedure to reset the position of the ventricular septum and improve tricuspid regurgitation in a systemic right ventricle [39].

Anatomic repair

Recent surgical approaches have focused on "anatomic" repair which returns the left ventricle to the systemic circulation and may improve long-term prognosis. These are major and technically challenging surgical procedures. Patients without left ventricular outflow obstruction and a pulmonary valve suitable to function as a neo-aortic valve may be operated using the double-switch procedure: this combines (1) the Senning atrial baffle procedure which redirects blood flow at atrial level and (2) the arterial switch procedure where the great arteries are transected and switched. Successful outcome depends on the left ventricle being adequately prepared to function at systemic arterial pressure. With a large VSD, the left ventricle has functioned at systemic pressure, but in the absence of associated lesions it has been functioning at normal pulmonary artery pressure. The low-pressure left ventricle can be "retrained" in younger children by pulmonary artery banding to increase left ventricular systolic pressure, although this approach has had mixed success. Patients with coexisting

VSD and left ventricular outflow obstruction can be approached using the Rastelli–Senning procedure. The Senning operation is combined with a Rastelli procedure which channels the left ventricular outflow across the VSD to the aorta and then places a right ventricle to pulmonary artery valved conduit.

Several series of double-switch and Rastelli–Senning procedures have reported a surgical mortality generally ranging from 0 to 10%. At the Cleveland Clinic, 46 patients underwent anatomic repair, with median age at surgery 28 months, the oldest patient being 16 years of age [40]. There were no hospital deaths and one late cardiac death during a median follow-up of 24 months. The Tokyo group published a series of 84 anatomic repairs with a 15 year survival of 75% for the double-switch and 80% for the Rastelli–Senning/Mustard procedure [41]. In another series of 54 patients, 7 year survival was 85% for the double-switch and 95% for the Rastelli–Senning procedure [42].

Left ventricular dysfunction is common after the double-switch procedure, being more frequent in those who required retraining [43]. The requirement for permanent pacing was a predictor for left ventricular dysfunction in one study of 44 patients [44].

Anatomic repair: patient selection

Most groups consider anatomic repair in patients requiring repair of associated defects when the left ventricle has been functioning at high systolic pressure. In patients without an associated lesion, subsystemic left ventricular pressure, and either right ventricular dysfunction or significant tricuspid regurgitation, retraining the left ventricle with pulmonary artery banding should be considered. Most centers would not recommend a double-switch procedure for such patients who have normal right ventricular and tricuspid valve function.

During childhood, the left ventricle has been successfully retrained using progressive pulmonary artery banding to increase left ventricular pressure load, promoting hypertrophy. Cardiac catheterization, echocardiography, and MRI can assess left ventricular pressure and wall thickness, mass, and function. In childhood a left ventricular systolic pressure at least 70–80% of systemic pressure and in adolescence a left ventricular systolic pressure closer to 100% of systemic pressure have been recommended to restore the left ventricle to the systemic circulation [40]. Others recommend a left ventricular mass: left ventricular volume ratio of >1.5 [45] or a normal left ventricular wall thickness and mass, using established echocardiographic or MRI values. During the banding process, the left ventricle must be monitored carefully. Development of left ventricular dysfunction is regarded as failure of left ventricular retraining. Age is one of the best predictors of failure of retraining, with most successfully retrained patients being <10 years of age. In a series of 23 patients considered candidates for a Senning plus arterial switch protocol [46], pulmonary artery banding was performed in 15 patients, in 11 for the sole purpose of

left ventricular retraining. The two oldest, aged 12 and 14 years, developed left ventricular failure necessitating band removal. Another banding patient following a double-switch procedure at age 7 years required heart transplantation for severe left ventricular failure with diastolic dysfunction.

The early results with the double-switch procedure have been promising, but long-term follow-up is uncertain.

44 Transposition and Malposition of the Great Arteries with Ventricular Septal Defects

Daniel Sidi, Pascal Vouhé & Phalla Ou

Hôpital Necker – Enfants Malades, Université Paris V, Paris, France

Introduction: A new approach based on surgery

Conventionally, pediatric cardiology books have different chapters covering transposition of the great arteries with ventricular septal defects (VSDs) and double-outlet ventricles (especially double-outlet right ventricle). This is because the usual approach in pediatric cardiology is to classify malformations into subgroups according to their anatomy and hemodynamics and then apply the surgical technique appropriate for each subgroup. This approach, however, does not work well for this group of malformations because of their extreme anatomic polymorphism and because of the difficulty in defining surgically helpful subgroups based on classical definitions. In addition, there are controversies about the definitions of some malformations, for example, double-outlet right ventricle, that are based by some authors on embryology (the double infundibulum, regardless of the malposition of the vessels or the location of the VSDs), by others on anatomy (focusing on the malalignment between the vessels and the presumed septum), and by yet others on hemodynamic and surgical features depending on the position of the VSD relative to the great arteries.

Our group therefore decided to put these malformations together under the global appellation of either "malposition of the great arteries" or "abnormal ventriculoarterial connection with ventricular septal defect" and to base our approach in a nonconventional way on the different surgical options rather than on the different anatomic subgroups. We first describe the different surgical techniques and their anatomic and hemodynamic requirements, then look at the malformations to determine the best match between the repair and the malformation. We believe that each of these malformations deserves a "tailor-made" operation and not an operation "off the peg."

Key points

1 This group of lesions includes a large variety of malformations with different embryologic origins and different pathologic definitions but a common surgical approach.

2 The clinical presentation and surgical indications are based on the presence or absence of pulmonic stenosis and the position of the great arteries with respect to the VSD and the annuli of the atrioventricular valves.

3 Surgery is based on anatomic correction by constructing a tunnel between the left ventricle and the aorta (or the switched pulmonary artery) and reconstructing a right ventricle–pulmonary artery communication (or a communication to the switched aorta), if possible without prosthetic material. Despite the apparent complexity, with pertinent indications and when the VSD is perimembranous (below the infundibula of the great arteries) without added malformations of ventricular sizes or atrioventricular valves, the surgical results and the prognosis are good.

Epidemiology

These lesions represent ~5% of congenital malformations and ~20% of conotruncal malformations. Unlike tetralogy of Fallot, pulmonary atresia with VSD, and truncus arteriosus, these malformations are rarely (except in heterotaxia syndromes) associated with extracardiac malformations or chromosome abnormalities and have a low recurrence rate.

Embryology, pathology, and definitions

Cardiac malformations involving the ventriculoarterial connection are linked to the fate of the subarterial conus (infundibulum) during the later part of cardiac embryogenesis (see Chapter 1). Because conotruncal resorption participates not only in the spatial relationship between the aorta, the pulmonary artery, and the atrioventricular valves but also in the closure of the ventricular septum in the perimembranous and infundibular portion, the association of the three anomalies is frequent. The association results in an extreme polymorphism of malformations, however, because the three anomalies will not always combine in a consistent pattern. The VSD is usually in the perimembranous part of the septum just beneath the infundibulum of the great arteries (often persisting below both great arteries) and is often the consequence of malalignment between the infundibular septum and the rest of the ventricular septum (trabecular septum) [1–6]. This malalignment eventually produces sub-pulmonic stenosis when the infundibular septum is deviated towards the pulmonary artery (as in tetralogy of Fallot) [1,4,6] or subaortic stenosis when the infundibular septum is deviated towards the aorta (as in coarctation of the aorta or an interrupted aortic arch) [7]. As a result of the obstruction, the fetal growth of the corresponding great artery is impaired, producing a small aorta or pulmonary trunk (but with normal intrapulmonary branches).

The other major intracardiac consequence of a persistent conus is that it maintains the arterial orifice at a distance from the atrioventricular annulus and, depending on the length of the infundibulum, the great vessels arise near to or far from the atrioventricular valve annulus (Figure 44.1). In addition,

if there is an asymmetric infundibulum, the distances from the artery to the mitral valve and the tricuspid valve will differ.

To understand the wide spectrum of these malformations and why there are difficulties and debates about defining and classifying some of them (namely, the wide spectrum of the malformation called double-outlet right ventricle), it is necessary to describe the normal relationships between the great arteries and the ventricles and to realize that there is a large difference between concordance and alignment. The normal heart is characterized by an aorta that with the resorption of its infundibulum moves posteriorly into the center of the heart, in continuity with the annuli of the atrioventricular valves and the ventricular septum, whereas the pulmonary artery stays well above its persisting infundibulum in discontinuity with the atrioventricular valves (Figures 44.2 and 44.3). In addition, there is torsion
Figure 44.2 Diagram of normal heart to show aortic annulus in center of heart, closely associated with the annuli of the other three valves. (a) Right ventricular (RV) view. (b) Left ventricular (LV) view. o, aortic valve annulus; MV, mitral valve annulus; PA, pulmonic valve annulus; TV, tricuspid valve annulus.
Figure 44.1 Diagram to show different relationships of the annulus of a great artery (A, shown by the upper circle with the triradius in it) to the mitral valve annulus (M) and the tricuspid valve annulus (T). (a) Close relationship. (b) The great artery annulus is further away, but its distances to both atrioventricular annuli are equal. (c) Not only is the great artery annulus far away, but also its distances from the mitral and tricuspid valve annuli are unequal.
Figure 44.3 Diagram of normal heart to show continuity between the aortic valve annulus (Ao) and the annuli of the tricuspid valve (TV) and the mitral valve (MV). It also shows the discontinuity between the pulmonic valve annulus (PA) and the annuli of the tricuspid and mitral valves. Note that the pulmonary artery is anterior. (a) Cross-sectional view; (b) LA, left atrium; longitudinal section; LV, left ventricle; RA, right atrium; RV, right ventricle.

between the upper part of the heart (the origin of the great arteries) and its apical part (determined by the axis of the trabecular septum). This torsion explains why, in a normal heart, the aorta rises from the left ventricle but because of the twist appears to arise in line with the right ventricular outlet and the pulmonary artery from the right ventricle but above the left ventricle (Figure 44.4). Therefore, concordance does not match alignment even in the normal heart. When the septum is intact, however, concordance is evident, nobody pays attention to the "physiologic anatomic malalignment," and there is no controversy about the connections of a normal heart or the ventriculoarterial discordance of a complete transposition of the great arteries. When there is a large subarterial VSD, the question of connection and alignment is much more difficult to answer because the origin of the great artery depends on the supposed situation of the upper part of the ventricular septum (Figure 44.5).
This is precisely the problem with double-outlet right ventricle, a congenital anomaly in which both great arteries arise wholly or principally from the right ventricle. This definition is clear only in theory. In reality, this definition leads to controversies when there is a large VSD beneath the infundibula of the great arteries.

Most pathologists insist on the alignment of the great arteries in relation to the ventricle; if more than half of the artery is over one ventricle, it is considered to arise from this ventricle, regardless of atrioventricular discontinuity (or subarterial conus) [4,8–10]. Because septal alignment is not physiologic, even in the normal heart, we believe that this definition is misleading, particularly when the two great arteries are above a VSD. Indeed, the origin of the vessel depends entirely on the way in which the VSD is closed at the upper edge of the septum, and this is not constant (see Figure 44.5). If the upper part of the septum is the conus between the aorta and the pulmonary artery, each artery arises from a different ventricle and there is no double-outlet right ventricle (Figure 44.5b). If the upper part of the septum is at the lateral edge of the conus, the two arteries arise from the right ventricle if the septum is at the left edge of the conus (double-outlet right ventricle) (Figure 44.5c). On the other hand, if the septum is at the right edge of the conus, the heart ends up with a double-outlet left ventricle (Figure 44.5a) [11]. In addition, what matters for the patient is not which part of the persisting infundibulum is really the upper septum, but what difficulty the surgeon has in closing the VSD in a correct position and allowing normal ventriculoarterial concordance or discordance without obstruction.

Figure 44.4 Diagram to show the normal spiral relationship of the aorta (Ao) and pulmonary artery (PA) to the right ventricle (RV).
Figure 44.5 Diagram to show how the position of the infundibular septum determines whether there is a double-outlet left ventricle (a), a normal connection (b), or a double-outlet right ventricle (c). Ao, aorta; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.
Figure 44.6 Diagram to show how the simple classification of Lev *et al*. [9] (a) becomes less useful once variations in the position of the infundibular septum occur (b).

Other pathologists require for the definition of double-outlet right ventricle a double infundibulum, regardless of the septal alignment [6]. This may have interesting embryologic or etiologic implications (in the chicken, various kinds of double-outlet right ventricle are created by stopping the embryologic process prematurely), but surgically speaking, it is not helpful or can even be misleading because the malformation is not completely identified by the conus abnormality alone. Some double-outlet right ventricles are nearly like a simple VSD despite a long subaortic infundibulum. Others with subpulmonary stenosis resemble a tetralogy of Fallot or a transposition of the great arteries with VSD with or without pulmonary stenosis. Some even resemble a more complex malformation such as a single ventricle if atrioventricular valve abnormalities, significant differences in ventricular cavity sizes, or even multiple VSDs are present.

This dilemma cannot be solved by the recommendation of Lev *et al*. [9] to identify double-outlet right ventricle by the position of the VSD relative to the great arteries: subaortic, subpulmonary, doubly committed, or noncommitted. The problem with this classification is that it is impossible to define clearly the extreme polymorphism of these malformations by this method alone because the polymorphism is determined by three independent variables (Figure 44.6). More important, there is no strict correlation between the commitment of the VSD to one or the other artery and the surgical options. Repair in many patients with double-outlet right ventricle and a subpulmonary VSD can be achieved by intraventricular rerouting, as for a subaortic

VSD, without an arterial switch or displacement of the pulmonary artery. Conversely, some subaortic VSDs may require other types of repair than just an intraventricular patch or a tunnel between the left ventricle and the aorta.

Double-outlet left ventricle is less controversial because this rare malformation is characterized almost always by complete resorption of the two infundibula, which brings the two great arteries into continuity with the atrioventricular valves above a large perimembranous VSD [11]. Pulmonic stenosis is usually present, there being a small annulus with a stenosed valve. The relation between the vessels and the atrioventricular valves and the presence or absence of pulmonic stenosis determine the best surgical strategy by the same rules as for any "malposition with a VSD."

Malposition of the great arteries can occur also in complex malformations such as atrioventricular canal or a large inlet VSD, particularly in heterotaxia syndromes.

The problem with any anatomic definition of these malpositions with VSD is that the malformation cannot be fully characterized by identifying the relationship between the great arteries alone, or the relation of the arteries with the atrioventricular valves alone, or the location of the VSD alone, because the three anomalies play independent roles. It is necessary to consider each of the three anatomic components, because they determine an infinite variety of anatomic malformations with different hemodynamics and surgical strategies. To summarize, under the conditions discussed in this chapter, if neither the clinician nor the surgeon is able to classify the individual patient into a single clear category, the

patients may receive a standardized but nonoptimal operation based on an incomplete anatomic description. Furthermore, the medical community cannot evaluate the results because it is difficult to know from the literature which anatomic lesion was operated on with each particular technique.

We think that the only way to achieve appropriate surgical decisions is not to classify subgroups of patients anatomically but to consider each patient with malposition and VSD as unique [12]. Then we need to determine whether the cardiac anatomy and hemodynamics fit with one of the possible anatomic repairs. If more than one surgical option exists for any given patient, one should choose the best and least risky procedure. It is therefore necessary for the pediatric cardiologist to know in detail the surgical requirements for the different operations. *Then the cardiologist checks by constructing mentally and on the echocardiography screen what the outflows of the two ventricles will be after repair*.

Surgical options and preoperative screening

Anatomic repair

We call anatomic repair a surgical procedure that allows the left ventricle to be connected to the aorta and the right ventricle to be connected to the pulmonary artery as directly as possible, preferably without a prosthetic conduit.

Before the different surgical options are described, it is necessary to remember certain important facts:

1 The infundibular septum can be removed with no risk of atrioventricular block if the VSD is perimembranous [8,13,14], even when there are tricuspid insertions on the septum.

2 The great arteries can be switched if there is no organic subpulmonic stenosis and if the pulmonary valve is normal, regardless of the coronary artery distribution (see Chapter 42).

3 The pulmonary artery can be connected to the right ventricle without a prosthetic conduit if the pulmonary artery branches are not fixed because of previous surgery (aortopulmonary shunts) [11,15–18]. This maneuver, however, sacrifices the pulmonary valve and therefore can be applied only if the pulmonary vascular resistance is low, pulmonary arteries are of adequate size without stenoses, and postcapillary hypertension (due to left ventricular or mitral valve dysfunction) is absent.

On the basis of these considerations, there are three fundamental types of anatomic repair (two ventricles and no tube).

Intraventricular repair

Intraventricular repair (IVR) consists of creating an intraventricular patch to direct the left ventricular blood towards the aortic orifice (Figure 44.7). The operation resembles simple closure of an isolated VSD, but if the aorta is far removed from the mitral valve, the operation requires a long intracardiac tunnel that passes posterior to the right ventricular outflow tract. The fundamental consideration is that the right ventricular outflow tract should not be obstructed by the tunnel, and this depends mainly on the position of the pulmonary artery in relation to the tricuspid valve. If the distance between the tricuspid valve and the pulmonary artery is long enough (equal to or greater than the distance to the aortic annulus), the left ventricular to aortic tunnel will not obstruct the right ventricular outflow tract regardless of the length of the tunnel (Figure 44.7a). If the distance from the pulmonary artery to the tricuspid valve is less than to the aortic annulus, either the pulmonary artery must be moved (Figure 44.7b) (see the later section on REV) or the tunnel must be constructed from the left ventricle to the pulmonary artery in association with a switch of the great arteries (Figure 44.7c) (see the next section on arterial switch).
Figure 44.7 Diagram to show factors affecting the type of surgery for double-outlet right ventricle. (a) A long tunnel connects the left ventricle to the aorta without obstructing the outflow to the pulmonary artery. (b) If the tricuspid valve annulus is closer to the pulmonary artery than to the aortic annulus, the pulmonary artery can be removed and inserted into the anterior wall of the right ventricle in the REV operation. (c) Alternatively, the great arteries can be switched, and a tunnel connects the left ventricle to the pulmonary artery. Ao, aorta; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

To avoid left ventricular to aortic obstruction and to make this tunnel as short as possible (to avoid diminishing the size of the right ventricular cavity), the infundibular septum should be removed whenever it is in the way, that is, posterior to the aorta. If the VSD is perimembranous, there is no theoretical risk of atrioventricular block. If the tricuspid valve is inserted on the infundibular septum, the septum is not resected but mobilized posteriorly and reinserted on the patch. The only contraindication to this operation is insertion of the mitral valve on the infundibular septum.

Arterial switch with ventricular septal closure (IVR + Switch)

This operation consists in creating an intraventricular patch to direct the left ventricular blood towards the pulmonary artery, which will become an aorta after the arterial switch (Figure 44.7c). This is possible when the pulmonic valve is normal and there is no subpulmonic organic obstruction due to musculofibrous pulmonary valve tissue or mitral valve insertion in the subpulmonic region. As in IVR, the patch should not obstruct the future right ventricular outflow tract. In this respect, the same rules as for IVR are applied and the infundibular septum should be resected if it is anterior to the pulmonary artery (future aorta).

Intraventricular repair with reposition of the pulmonary artery on the right ventricle (Rastelli and REV)

Both operations have the same principles: creating an intraventricular tunnel to direct the left ventricular blood flow towards the aortic orifice and creating a new connection between the right ventricle and the pulmonary artery.

In the classical Rastelli operation [19], the left ventricle to aorta connection is achieved without resecting the conal septum and the right ventricle to pulmonary artery pathway is created using an extracardiac valved conduit. This procedure has major drawbacks: risk of subaortic stenosis, severe amputation of the right ventricular cavity, need for multiple reoperations for conduit obstruction, and high risk of endocarditis.

To obviate most of these problems, Lecompte and coworkers developed an operation called REV (réparation à l'étage ventriculaire) [17]. Compared with the Rastelli procedure, the REV operation presents two major modifications (Figure 44.7b). (1) The infundibular septum is always resected extensively (even if the VSD is large). This creates a short and straight intracardiac tunnel and reduces the risk of subaortic stenosis, reduces the amputation of the right ventricular cavity, and thus preserves right ventricular function, and finally improves left ventricular function by avoiding a large septal patch which may act as a diverticulum or even an aneurysm. (2) The pulmonary artery is translocated anterior to the aorta and reimplanted directly on the right ventricle; this reduces the need for multiple reoperations

(although the risk of developing RVOT obstruction is not completely avoided).

For all these reasons, in patients who need intraventricular repair with repositioning of the pulmonary artery, the REV operation is the procedure of choice, unless there are anatomic reasons (hypoplastic pulmonary arteries, elevated pulmonary arterial pressure) which demand a competent pulmonary valve.

Bex–Nikaidoh operation

The Bex–Nikaidoh procedure can be used when it is not possible to connect the left ventricle with one of the great arteries through the VSD [20,21]. This usually occurs when the VSD is not beneath the arteries (inlet or trabecular VSD), and may sometimes happen when there are abnormal insertions of the mitral valve on the infundibular septum.

The principle is to excise the aortic root with the subaortic conus from the right ventricle (as for the Ross operation) and to reimplant the aortic root on the left ventricular outflow tract (eventually after enlarging the conal septum, as for the Konno–Ross operation); this, of course, needs the concomitant transfer of the coronary arteries. The right ventricular outflow tract can be reconstructed using various techniques: with the native pulmonary valve when it is abnormal, using an extracardiac valved conduit, or by direct reimplantation (as for the REV procedure).

Nonanatomic repair

We consider a repair to be nonanatomic when the operation results in the right ventricle being located beneath the aorta or when each ventricle does not receive the correct venous return. We also need to differentiate between the one-ventricle repair (total cavopulmonary circulation equivalent to the repair of a single ventricle) and the "1½-ventricle repair," in which only part of the caval venous return (usually from the inferior vena cava) enters the right ventricle while the other part (usually from the superior vena cava) goes directly to the lungs (partial cavopulmonary anastomosis) [22,23].

A biventricular but nonanatomic repair can be achieved by leaving the right ventricle beneath the aorta in very special anatomy where the left ventricle or mitral valve is abnormal. The VSD is closed, allowing the creation of a nonstenotic right ventricle to aorta tunnel, and the left ventricle to pulmonary artery connection can be achieved with or without a tube depending on the anatomy. Sometimes it is necessary to add an atrial switch by a Mustard or Senning procedure in order to bring the oxygenated blood from the pulmonary veins to the subaortic right ventricle, as in double switch for corrected transposition when a Mustard or Senning procedure is necessary to bring oxygenated blood to the left ventricle.

If the ventricle is small, one can achieve the so-called "1½ ventricle repair" by adding to the repair a partial cavopulmonary circulation (usually performed as a palliative procedure first).

This type of surgery can leave the right ventricle beneath the aorta if it is the left ventricle or mitral valve that is not well developed or be more anatomic if the left ventricle can be put beneath the aorta when the right ventricle is too small.

Finally, sometimes the "best or the least worst" option is to abandon the idea of an intraventricular repair and plan for a single-ventricle strategy with a total cavopulmonary circulation. This option is often due to reduced left ventricle cavity size, straddling of the mitral valve, or multiple VSDs with more holes than septum.

Preoperative anatomic evaluation

Each patient must be regarded as unique, and all anatomic and hemodynamic aspects important to the operation must be investigated. The pediatric cardiologist must, like an architect, construct the tunnel mentally and use echocardiography to assess whether there is potential outflow tract obstruction after the anatomic repair (left ventricle to future aorta and right ventricle to future pulmonary artery). It is useful to perform the two-dimensional echocardiogram with the surgeon present to clarify particular anatomic details. Three-dimensional echocardiography and MRI will be particularly helpful in the future in this group of malformations [24]. The examination must evaluate the feasibility of an anatomic repair and, if it is possible, the feasibility of IVR. The echocardiographer must look carefully at the position of the VSD and search for multiple VSDs, especially at the apex; the relative position of the great arteries and above all their relation to the atrioventricular valves; the function and the insertions of the atrioventricular valves; and the size of the ventricles. MRI is very useful with relative hypoplasia of the RV in order to decide on the possibility of a two-ventricle repair, the help of a partial cavopulmonary circulation, or the need to accept a single-ventricle strategy. Quantitative assessment of ventricular volumes and function can be determined accurately based on the combination of a 3D data set and a high spatial and temporal resolution of the cardiac cavities regardless of their morphologies and without geometric assumptions. Independence from geometric assumption is especially important in this setting as the right ventricle may have an unusual shape. MRI is also a useful adjunct to echocardiography for a comprehensive assessment of the relationships of the great arteries with respect to each other, and also the relative positions of the great vessels with respect to the VSD and the atrioventricular valves.

Feasibility of an anatomic repair

Anatomic repair requires adequacy of both ventricles to assume their future workload. Therefore, both ventricles must be of adequate size and function; there is usually concern about the size of the left ventricle in malpositions with pulmonic stenosis (and reduced pulmonary venous return) and with the size of the right ventricle in malposition with coarctation of the aorta. Abnormal ventricular size or func-tion, however, also occurs with a restrictive VSD [25,26] or an inlet VSD with an overriding atrioventricular valve. We believe that the best index of ventricular size is the size of the atrioventricular valve annulus (in the absence of an overriding or straddling valve). An atrioventricular annulus size >2 SD below normal is a contraindication to anatomic repair. Assessment of ventricular function is based on ventricular contractility, knowing that the ventricle should be hyperkinetic if the afterload is low (increased pulmonary blood flow or atrioventricular valve regurgitation) or have adaptive hypertrophy secondary to valvar or subvalvar aortic obstruction or secondary to a restrictive VSD that functions like a subaortic stenosis if both great arteries originate from the right ventricle [25,26].

Both atrioventricular valves should be inspected carefully, not only for size and function but also for the subvalvar apparatus (chordae and papillary muscles), particularly any abnormal insertion on the subarterial infundibula. Tricuspid valve chordal attachments on the infundibular septum or even straddling it are not a contraindication because the valve can be repaired adequately and suffice for a low-pressure subpulmonic ventricle. Conversely, abnormal attachments of the mitral valve are usually a contraindication unless the valve is competent and the surgeon can avoid touching it during surgery without creating obstruction.

Multiple trabecular VSDs (Swiss cheese) or an inlet VSD may lead to serious complications.

A restrictive VSD can be a problem not only if it affects normal growth and function of the left ventricle (see earlier), but also if the VSD is not perimembranous. If it is not, any enlargement of the defect is dangerous for the conduction system (although anterior extension of the VSD is theoretically safe).

Finally, the afterload of both ventricles must be acceptable. We should pay particular attention to pulmonary arterial stenosis, especially after an aortopulmonary anastomosis, and to pulmonary hypertension. With pulmonic stenosis, the criteria are similar to those applied to tetralogy of Fallot. With pulmonary hypertension, assessing pulmonary vascular resistance is necessary, just as for a simple VSD with the added questions of operability and necessity for a patent pulmonary valve in the long term. It is these afterload factors that may justify cardiac catheterization.

Feasibility of an intraventricular repair

For this repair, the crucial point is to determine whether it is possible to construct a left ventricular to aortic tunnel between the tricuspid and pulmonic orifices. This is possible if the tricuspid to pulmonic distance is equal to or longer than the diameter of the aortic annulus. This is best seen on a subxiphoid right anterior view (Figure 44.8). If the pulmonary artery is above a well-developed infundibulum with a tricuspid to pulmonic distance greater than the aortic annulus, an IVR is possible regardless of the size of the aortic infundibulum. On the left anterior subxiphoid view (Figure 44.9),

Figure 44.8 Two-dimensional echocardiogram in subxiphoid view (oblique left anterior). This echocardiogram shows where a tunnel from the left ventricle (LV) to the aorta (Ao) would have to be for an intraventricular repair. PA, pulmonary artery; RV, right ventricle.

we can best see the infundibular septum that may need to be resected to construct a nonobstructed tunnel if the aorta is anterior (and the infundibular septum is posterior to the aorta) because it stands in the way from the posterior left ventricle to the anterior aorta. Conversely, when the aorta is posterior to the pulmonary artery, the infundibular septum is anterior to both the aorta and the left ventricular to aortic tunnel and may even constitute part of its wall.

If, however, the tricuspid to pulmonic distance is short (less than aortic annulus size), a simple IVR is not feasible. The choice is then between a tunnel from the left ventricle to the pulmonary artery in association with an arterial switch or a Bex–Nikaidoh operation and a tunnel from the left ventricle to the aorta with occlusion of the pulmonic orifice and direct right ventricle–pulmonary artery continuity (REV) or a right ventricle–pulmonary artery conduit (Rastelli).

Surgical classification

1 *Malposition that can be treated by IVR:* IVR is possible when the pulmonary artery annulus is far from the tricuspid valve annulus (see Figure 44.7a), regardless of the position of the aorta, as that determines only the length of the tunnel. If there is pulmonic or subpulmonic stenosis, the operation is
(a)
(b)

Figure 44.9 Two-dimensional echocardiograms in subxiphoid view (right anterior) of the same patient as in Figure 44.8. Because the distances from the tricuspid annulus to the aortic and pulmonary artery annuli cannot be seen in the same plane, two different views are needed. (a) The crosses show the distance between the tricuspid valve (TV) annulus and the annulus of the aorta (Ao). In this patient, the distance is 6.2 mm. (b) The crosses show the distance between the tricuspid valve annulus and the annulus of the pulmonary artery (PA). In this patient, the distance is 10.1 mm. Because the size of the subpulmonic conus is too short for an IVR, the appropriate correction would be a REV operation (see text). RA, right atrium.

similar to that for a tetralogy of Fallot with the same concerns about the coronary artery distribution (see Chapter 41).

2 *Malposition that can be treated by a tunnel from the left ventricle to the pulmonary artery in association with an arterial switch:* This operation is possible when there is no pulmonic or subpulmonic stenosis and when the aortic annulus is far from the tricuspid valve annulus. This distance allows a nonobstructive right ventricular outflow tract connection to the pulmonary artery (previous aorta) anterior to the left ventricular to aortic (previous pulmonary artery) tunnel (Figure 44.7c).

3 *Malposition that can be treated by a left ventricular to aortic tunnel in association with the displacement of the pulmonary artery (REV):* This operation can be done if there is a pulmonic stenosis (valvar or subvalvar) that contraindicates an arterial switch and when the pulmonary artery annulus is near the tricuspid annulus, which would lead to pulmonary artery obstruction by a left ventricular to aortic tunnel (Figure 44.7b). The pulmonary annulus and valves are sacrificed, and the junction between the right ventricle and the pulmonary artery is made either by a conduit (Rastelli operation) or better by the translocation of the pulmonary artery anteriorly on to the right ventricle (REV).

4 *Complex malpositions that cannot lead to a "simple" biventricular repair:* Biventricular repair usually cannot be performed when the VSD (inlet or trabecular) is not committed to a great artery because placing a tunnel from the left ventricle to one of the great arteries is difficult when both arise from the right ventricle. It can also be difficult to repair these malformations when there are anomalies of the ventricles or the atrioventricular valves or when the conal septum cannot be removed because of mitral attachments.

These complex malpositions need careful discussion before a decision is made between a palliative operation and corrective surgery with a high risk of atrioventricular block, atrioventricular valve replacement, or ventricular damage. Many of these complex situations can probably be solved using the Bex–Nikaidoh principle.

One interesting option in some patients is a 1½ ventricle repair (see earlier) when the right ventricle is too small initially or when it becomes too small after the left ventricular to aortic tunnel has been placed.

For clinical assessment, natural history, and pathophysiology, it is necessary to distinguish patients with and without pulmonary artery stenosis.

Malposition with ventricular septal defect without right ventricular outflow tract obstruction

Pathophysiology

The absence of right ventricular outflow tract obstruction leads (as in simple VSD) to pulmonary artery hypertension with increased pulmonary blood flow and a long-term risk of developing pulmonary vascular obstructive disease.

As in VSD, because the pulmonary vascular resistance decreases slowly after birth, pulmonary blood flow is not excessive in the neonatal period and heart failure does not occur unless there is aortic obstruction, usually associated with coarctation of the aorta [27].

Because of the malposition, some hypoxemia is present, depending on the relative position of the great arteries with respect to the ventricles and on the streaming patterns. Hypoxemia is never severe because of the increased pulmonary blood flow and adequate shunting through the VSD (right ventricle to pulmonary artery in systole and left to right ventricle in diastole).

Clinical findings, diagnosis, and management

In the fetus, malposition of the great arteries with a VSD is well tolerated. Diagnosis can be made on two-dimensional echocardiography if the screening includes exploration of the outlet septum and vessels and is not limited to the four-chamber view that can be normal.

In the neonate, there is usually mild cyanosis without respiratory distress and a systolic murmur (not constant) in an otherwise apparently healthy infant. If there is early heart failure, arterial pulses are usually diminished in the legs because of an associated coarctation of the aorta. After a few weeks, because of the increased pulmonary flow and left ventricular volume overload, congestive heart failure develops, manifested by dyspnea, liver enlargement, nutritional difficulties, and failure to gain weight. The clinical picture is that of a large VSD with mild cyanosis.

Chest radiography

The chest film shows cardiomegaly and increased lung vascularity. The thymus is present, and there is usually a left aortic arch.

Electrocardiography

The electrocardiogram shows right ventricular hypertrophy, sometimes with right axis deviation, depending on the location of the VSD and the course of the conduction pathways.

Echocardiography

Echocardiography confirms the diagnosis, demonstrating the VSD and the abnormal position of the great arteries. These have to be assessed independently. There is no correlation between the relative positions of the great arteries and the position of the VSD [17].

It evaluates pulmonary vascular resistance (if the patient is >3 months old) by evaluating left ventricular dimensions, looking at left ventricular dilatation as a sign of increased pulmonary blood flow and low pulmonary vascular resistance. It may be possible to estimate pulmonary artery

diastolic pressure from the velocity of a pulmonary artery regurgitant jet.

It indicates the likely type of surgery. It is crucial to analyze precisely the relationship of the aortic and pulmonary artery annuli to the atrioventricular valve annuli and also the size and position of the VSD. The two-dimensional echocardiographic subxiphoid view allows visualization of a tunnel between the left ventricle and one of the great arteries to see what it will look like (Figures 44.8 and 44.9). The examination also identifies any valvar attachment to the conal septum that would be removed at surgery.

Cardiac catheterization

Catheterization is usually not needed to define anatomic details except if there is a doubt on two-dimensional echocardiography about pulmonary artery branches or an associated trabecular VSD. Cardiac catheterization is useful for evaluating pulmonary vascular resistance in older children. In particular, it is the only way to assess the streaming patterns and to determine pulmonary artery oxygen saturation and therefore the arteriovenous difference in oxygen content that allows calculation of pulmonary vascular resistance. In the neonate, a streaming pattern with higher saturation in the pulmonary artery than in the aorta is a good indication for a Rashkind procedure that will probably improve aorta saturation without increasing pulmonary artery blood flow.

Natural history

Pulmonary vascular disease can develop as early as 3 months of age and be manifested by increased cyanosis and decreased congestive heart failure.

In some patients, the VSD becomes smaller and obstructs the left ventricular outflow if both vessels originate from the right ventricle, especially if there is no atrial septal defect. If there is a large atrial septal defect, there will be a rerouting of the blood and a progressive exclusion of the left ventricle from the circulation, so that the left ventricle will not grow properly.

Treatment and results

Medical treatment is nonspecific and intended to improve the circulation and stabilize the infant so that an operation can be performed soon. As in all patients with a VSD and heart failure, improvement can usually be obtained by diuretics, blood transfusion in anemic patients (to improve arterial oxygen content and decrease lung flow by increasing pulmonary vascular resistance through increased viscosity), vasodilators, and digoxin. If a neonate has cardiac failure, usually in association with coarctation of the aorta, prostaglandin E_1 (PGE_1) infusion, artificial ventilation, and inotropic support with dobutamine are helpful. If there is inadequate mixing or a high left atrial pressure, with increased flow and a functional gradient across the mitral valve, a Rashkind

atrioseptostomy is indicated to improve the clinical status (heart failure and cyanosis) before surgery.

Surgery is mandatory before 3 months of age to protect the lungs from developing pulmonary vascular disease.

Pulmonary artery banding may be indicated to protect the small pulmonary arteries, either if there is no straightforward anatomic repair or to wait until the infant is larger and healthier before undergoing an operation that may be difficult (e.g., if the tunnel will be long, if the tricuspid valve is attached to the infundibular septum, or if the right ventricle will be small after surgery). The banding is done by thoracotomy or sternotomy, improves congestive heart failure, but increases hypoxemia and may hinder an eventual arterial switch by dilating the pulmonary sinuses of Valsalva and altering the future aortic leaflets.

Corrective surgery with anatomic repair is usually possible (see the surgical classification earlier) either by a tunnel from the left ventricle to the aorta (IVR) if the pulmonary annulus is far enough from the tricuspid valve annulus or by a tunnel from the left ventricle to the pulmonary artery in association with an arterial switch if the aortic annulus is far from the tricuspid valve annulus.

With coarctation of the aorta, most surgical teams perform corrective surgery at once in the neonatal period rather than go through a coarctation repair and pulmonary artery banding as a first-stage procedure.

Hospital mortality for correction is ~10%, with excellent results. The patient needs an annual evaluation with two-dimensional echo Doppler examination to assess the left and right ventricular outflow tracts and the growth of the two great arteries. If an arterial switch has been performed, a coronary artery angiogram should be considered. Obstruction of the left ventricular–aortic junction is rare when the surgery has involved adequate removal of the conal septum. Usually, the heart grows in harmony, close to normal anatomy.

The long-term follow-up and results of IVR are similar to those for isolated VSD, because left ventricular-aortic obstructions are rare (none in the Lecompte series). When an arterial switch is added, complications of the switch procedure may be encountered (see Chapter 42) with common, but rarely severe, supravalvar pulmonic stenosis, common aortic dilatation with minimal (color Doppler) aortic regurgitation, and a few ischemic complications or potential complications due to the association of the coronary artery transfer with coronary ostial stenosis. When coarctation of the aorta is present, the follow-up should include the search for residual aortic obstruction and systemic hypertension at rest or during exercise. A scan or magnetic resonance imaging of the aorta may be useful to check the aortic isthmic anatomy after the aortoplasty.

When anatomic repair is not possible, the situation is similar to a single ventricle with pulmonary hypertension. It is imperative to protect the pulmonary arteries by

banding with the intention of later creating a cavopulmonary circulation.

Malposition with ventricular septal defect and pulmonic stenosis

Pathophysiology

The pathophysiologic features of this combination are similar to those in tetralogy of Fallot with more hypoxemia for the same degree of pulmonic stenosis because some of the oxygenated blood may return to the lungs as a result of streaming. There are usually no hypoxic spells because the subpulmonic stenosis is less muscular (especially if the vessels are transposed). The pulmonary artery branches are usually of normal size without proximal or distal stenosis.

If there is a higher saturation in the pulmonary artery than in the aorta, hypoxemia can be treated by creating an atrial septal defect by a Rashkind procedure (see Chapters 10 and 42).

Clinical findings, diagnosis, and management

In the fetus, malposition of the great arteries with VSD and pulmonic stenosis is well tolerated. The diagnosis can be made on two-dimensional echocardiography if the outlet septum and vessels are examined and the screening is not limited to the four-chamber view that can be normal.

In the neonate, cyanosis is present and is associated with a rough systolic ejection murmur in an otherwise apparently healthy infant. With severe pulmonic stenosis or even pulmonary atresia, cyanosis can be severe in the neonate, who may need early intervention with PGE_1 to maintain patency of the ductus arteriosus, followed by an early operation (usually a palliative shunt, but also a balloon dilatation). Cyanosis increases rapidly because of the increased oxygen consumption and decrease in pulmonary flow.

Chest radiography

The chest film shows normal cardiac size and variable lung vascularity. A thymus is present, and the aortic arch is usually left sided.

Electrocardiography

The electrocardiogram shows nonspecific right ventricular hypertrophy.

Echocardiography

It confirms the diagnosis, demonstrating the VSD, the abnormal position of the vessels, and the pulmonic stenosis.

It evaluates the degree and the type of the pulmonic stenosis, which is usually subvalvar and valvar and only rarely has anomalies of the pulmonary artery branches.

It helps establish the type of surgery. As explained before, it is crucial to analyze precisely the relationship of the aortic and pulmonary annuli with the atrioventricular valve annuli and also the size and position of the VSD. The two-dimensional echocardiographic subxiphoid view allows the physician to visualize the tunnel between the left ventricle and the aorta. The examination can also identify any valvar attachment to the conal septum that might need to be removed at surgery.

Cardiac catheterization

Catheterization is usually unnecessary unless a Rashkind procedure is indicated, except to assess pulmonary artery branches after a previous shunt or if there is a doubt on two-dimensional echocardiography, MRI, or CT scan about the pulmonary artery branches, associated trabecular VSD, or coronary artery disposition if there is to be a Fallot-type repair. Pressures in the pulmonary arteries (taken directly or through an occluded pulmonary vein) may also be useful in deciding about incorporating a valve in the right ventricle–pulmonary junction.

Natural history

Cyanosis increases, polycythemia occurs, and there will be increased collateral circulation from the aorta to the pulmonary arteries.

Treatment and results

If a neonate has severe hypoxemia, usually in association with pulmonic atresia or severe stenosis, PGE_1 infusion maintains ductal flow. A Rashkind procedure is often useful to improve the mixing of the blood.

Balloon dilatation may be useful if there is a valvar component to the pulmonic stenosis to avoid or delay an aortopulmonary anastomosis or defer corrective surgery. Balloon dilatation is especially effective when oxygen saturation is lower in the pulmonary artery than in the aorta (as in tetralogy of Fallot). This finding is common when the aorta is near the left ventricle, but it may occur even when the great arteries are transposed because of the streaming patterns due to the location (especially the angulation) of the infundibulum with respect to the outflow tracts of the ventricles.

Surgery

Aortopulmonary anastomosis can be performed to delay corrective surgery until the infant is larger and healthier. The anastomosis is usually carried out through a median sternotomy and although it improves hypoxemia, it may hinder later corrective surgery by distorting and fixing a pulmonary artery branch that will be difficult to mobilize for the REV.

Corrective surgery is usually possible by a tunnel from the left ventricle to the aorta, either by an IVR associated with removal of a right ventricular tract obstruction, as in a tetralogy of Fallot repair, or by mobilizing the pulmonary artery in an REV or Rastelli repair when the distance from the pulmonary

artery annulus to the tricuspid valve annulus is less than that to the aortic annulus. When the pulmonary artery is near the tricuspid valve annulus, the pulmonary artery is closed above the valve, and the distal pulmonary artery is mobilized and translocated on the right ventricle in an REV operation or connected to the right ventricle by a prosthetic tube in a Rastelli operation.

Most surgical teams try to wait for at least 6 months or for a patient's body weight to reach 6 kg before performing an REV operation, especially to avoid the risk of subaortic stenosis by inadequate resection of the conal septum, and to wait for several years for a Rastelli repair. They start with a Rashkind procedure and an aortopulmonary anastomosis or a balloon dilatation.

Mortality is ~10%, with excellent results. Annual follow-up is needed as in tetralogy of Fallot for IVR or REV and as in truncus arteriosus for a Rastelli procedure.

When indicated, a Bex–Nikaidoh procedure can be performed early in life. The late results are unknown, particularly the fate of the reconstructed right ventricular outflow tract. Nevertheless, over an average follow-up of 11 years, the results of this procedure were far better than those of the Rastelli procedure, albeit with some reoperations for right ventricular outflow tract obstruction [28].

45 Common Arterial Trunk (Truncus Arteriosus)

Albert P. Rocchini & Bryan H. Goldstein
University of Michigan Health System, Ann Arbor, MI, USA

Introduction, incidence, and genetics

Common arterial trunk, also called truncus arteriosus, is an anomaly in which the systemic, pulmonary, and coronary circulations each arise from a single vessel and valve at the base of the heart. First described by Wilson in 1798 [1], it was re-reported by Buchanan in 1864 [2]. It is uncommon, occurring in 0.086/1000 live births [3]. The most common genetic syndrome associated with truncus arteriosus is chromosome 22q11 deletion (DiGeorge syndrome). In a large prospective cohort of patients with conotruncal defects, the 22q11 deletion was found in 34.5% of patients with truncus [4].

Embryology

Van Mierop *et al.* [1] and Bartelings and Gittenberger-de Groot [5] described conal and aortopulmonary septation in great detail. Truncal swellings, similar to the endocardial cushions, develop and divide the truncal lumen into an aortic and pulmonary trunk. The left ventricular origin of the aorta and the right ventricular origin of the pulmonary artery result from fusion of the proximal portion of the truncal septum (derived from the truncal swellings) with the developing conal septum (derived from the conal swellings). Valve swellings develop from truncal tissue at the point of fusion between the truncal and conal septa. Excavation of these swellings leads to formation of the aortic and pulmonary valves. In the embryo of ~5–6 mm, the right and left primitive pulmonary arteries (from the sixth pair of aortic branchial arteries) are symmetrical structures with respect to the truncus arteriosus. However, this symmetrical arrangement is quickly lost, because the primitive right and left pulmonary arteries rotate clockwise, resulting in a relative shift of the primitive right and left pulmonary arteries towards the left. The primitive right pulmonary artery approaches the left and the neighboring parts of the walls fuse and then later the fused part is reabsorbed. Thus a short, undivided stem is formed and the primitive right pulmonary artery appears to originate from the left. The right dorsal aorta distal to the right subclavian artery and the distal part of the primitive right pulmonary artery disappear, and the left dorsal aorta and distal part of the primitive left pulmonary artery persist as the descending aorta and the ductus arteriosus. The result is that the embryonic pulmonary artery originates from the left side of the truncus and the paired fourth aortic arches shift rightwards. The roof of the aortic sac (a structure that lies distal to the conotruncus and gives rise to six bilaterally symmetric aortic arch arteries) invaginates to form an aortopulmonary septum that eventually fuses with the distal extent of the truncal septum. This results in the right and left pulmonary arteries originating from the pulmonary trunk and the aortic arches arising from the ascending aorta. The spiral course of the truncoaortic partition produces the normal intertwinement of the great arteries.

If the conotruncal or truncoaortic septation does not occur normally, various types of conal truncal anomalies may result [1]. If the conotruncal septum fails to develop, the pulmonary trunk has a left-sided origin from the undivided truncus arteriosus. In addition, either deficiency or absence of the conal septum produces a large ventricular septal defect. Because the valve swellings develop from truncal tissue at the point of fusion between the truncal and conal septa, failure of fusion results in deformities of the single truncal valve. If remnants of distal truncoaortic septation develop, the pulmonary arteries may arise together from a

short pulmonary trunk; otherwise, they arise separately from the truncal root.

Migration of neural crest tissue into both the developing cardiac tube and the developing truncal swellings plays a critical role in conal and aortopulmonary septation [6–9]. Preventing migration of neural crest tissue by administering teratogenic agents has been shown to produce conotruncal defects [10]. Finally, Thomas *et al.* demonstrated that mouse embryos lacking Rac1 (a small GTP-binding protein) in neural crest cells develop abnormal craniofacial development and a persistent truncus arteriosus [11]. Their data suggest that although Rac1 is not required for normal neural crest migration, during craniofacial and cardiac development Rac1 plays a critical cell-autonomous role in post-migratory neural crest cells by regulating the integrity of the craniofacial and pharyngeal mesenchyme.

Pathologic anatomy, anatomic classification, and major associated anomalies

Pathologic anatomy

The basic feature of truncus arteriosus is that one large trunk leaves the base of the heart and gives rise to the coronary arteries, aorta, and pulmonary arteries. The single semilunar valve is tricuspid in 69%, quadricuspid in 22%, bicuspid in 9%, and rarely either unicommissural or pentacuspid [12–15]. The truncal valve is always in fibrous continuity with the mitral valve, and when the septal band is not well developed it is also in fibrous continuity with the tricuspid valve. The truncal valve overrides the ventricular septum and faces downwards and slightly forwards. The valve is frequently thickened and also may have nodular dysplastic cusps, prolapse of unsupported cusps, and inequality of cusp size [12]. These abnormalities frequently result in some truncal regurgitation and rarely truncal stenosis.

A ventricular septal defect results from either absence or pronounced hypoplasia of the infundibular septum, and is almost always present and generally large. Very rarely the ventricular septal defect is small and restrictive or even absent [16].

Variations in coronary artery distribution and origin have important surgical implications. Usually there are two coronary arteries, the left arising above a left posterior cusp and the right arising above a right anterior cusp. Van Praagh and Van Praagh studied 57 specimens with truncus arteriosus [13]. In 29 they found abnormalities of the coronary ostia. Of these, one coronary artery arose totally or partially above the noncoronary sinus in 20, with 12 of these being the right coronary. However, in 49%, the coronary ostia are abnormal, the most frequent variant being either right (19%) or left (5%) coronary arteries arising from noncoronary cusps. Other coronary anomalies included the left anterior descending artery being small and displaced leftwards with a large conal branch

from the right, the posterior descending coronary artery arising from the left circumflex (27%), a single coronary artery, and two coronary ostia arising from the same truncal sinus. A high coronary ostial origin (above the sinotubular junction) is common in truncus. However, when the origin is at or slightly above a valve commissure, the ostium involved (frequently the left) may be functionally stenotic. Rarely, the left coronary artery originates from the pulmonary artery [17–19].

Anatomic classification

The variations in pulmonary artery anatomy, in large part, are the basis for the anatomic classification of truncus arteriosus. In 1949, Collett and Edwards proposed the first anatomic classification [14] They described five types:

Type I: A single pulmonary trunk and an ascending aorta arising from the common trunk.

Type II: The left and right pulmonary arteries arising closely together from the posterior or dorsal wall of the truncus.

Type III: Right, left, or both pulmonary arteries arising independently from either side of the truncus.

Type IV: No pulmonary arteries and apparent absence of the sixth arterial arch, the lung being supplied by way of bronchial arteries.

Type V: Aortopulmonary fenestration (AP window).

Currently, most cardiologists take issue with including Types IV and V as variants of truncus. Type IV is really pulmonary atresia with a ventricular septal defect and Type V is an aortopulmonary window.

Van Praagh and Van Praagh proposed a modified Collett and Edwards classification [13]. The Van Praagh classification originally was divided into Type A, those with a ventricular septal defect, and Type B, those without (only 2/57 specimens had no ventricular septal defect). In fact, Type B is probably not truncus, since both of these patients had two semilunar valves and therefore resemble a variety of aortopulmonary window. The Van Praagh Type A is subdivided into:

A1: Same as Collett and Edwards Type I.

A2: Same as Collett and Edwards Type II and III.

A3: Absence of one of the pulmonary artery branches, the respective lung being supplied by collaterals (incidence of 16%).

A4: Truncus with an interrupted aortic arch or severe coarctation and with a large persistent ductus arteriosus (incidence of 11–19%). The interruption of the aorta is almost always between the left carotid and left subclavian (Type B interruption). This lesion has a high incidence of DiGeorge syndrome [20].

The pulmonary arteries usually arise from the left posterolateral aspect of the truncus arteriosus. Frequently, the lesion

appears to be Type 1 when viewed from the front but Type 2 from the posterior aspect. The Van Praagh A3 probably represent patients in which one of the pulmonary arteries is either isolated or severely stenotic at its origin and initially supplied by a patent ductus; when the ductus closes, the pulmonary artery disappears. In a truncus, the absent pulmonary artery is most frequently on the side of the arch, whereas in tetralogy of Fallot, the absent pulmonary artery is frequently on the side opposite to the arch.

Associated anomalies

A right aortic arch with mirror-image brachiocephalic branching is associated more commonly with truncus arteriosus (~36%) than any other congenital cardiac malformation except pulmonary atresia with ventricular septal defect [13,15]. Patent ductus arteriosus is absent in approximately half the patients with truncus arteriosus, but when present remains patent postnatally in nearly two-thirds of patients [13]. A secundum atrial septal defect occurs in 9–20%, an aberrant subclavian artery in 4–10%, and a persistent left superior vena cava draining to the coronary sinus in 4–9%. Other rare associated anomalies include partial anomalous pulmonary venous connections, tricuspid atresia, mitral atresia, ventricular inversion, and asplenia complex [21–24]. Extracardiac anomalies occur in up to 30% of patients, and include skeletal deformities, hydroureter, bowel malrotation, and diaphragmatic hernia.

Pathophysiology

Physiologically, truncus arteriosus is an admixture type of cyanotic heart disease. The ventricular septal defect and single outlet result in nearly total mixing of blood from both ventricles. Sometimes the location of the pulmonary artery may permit preferential flow from the right ventricle into the pulmonary arteries and can result in a difference in oxygen saturation between pulmonary arteries and aorta of up to 10%. The clinical picture of individuals with truncus arteriosus is largely determined by the amount of pulmonary blood flow, which in turn depends on the pulmonary vascular resistance and/or narrowing of the pulmonary arteries. In most infants with truncus arteriosus, there is high pulmonary flow with low pulmonary resistance. This causes severe congestive heart failure and mild cyanosis (an oxygen saturation of 85%). Coexisting insufficiency of the truncal valve further aggravates the congestive failure. For those children who initially survive the initial high pulmonary blood flow without protection of the pulmonary vasculature, pulmonary vascular disease rapidly develops. As the pulmonary vascular resistance increases, pulmonary flow decreases and congestive heart failure gradually disappears, but cyanosis increases and the child ultimately develops Eisenmenger syndrome. Rarely, children are born with some pulmonary artery stenosis, but the stenosis is frequently segmental and only portions of the pulmonary

vascular bed are protected while the other unprotected regions develop aggressive vascular disease.

Natural history

Most infants with truncus present within the first few weeks of life with severe congestive heart failure. Because the pulmonary arteries are exposed to increased flow and pressure in both systole and diastole, congestive failure develops much earlier than in infants with just a ventricular level shunt. In the series of Calder et al., the median age of death was 5.5 weeks and 85% of untreated individuals died before 1 year of age [25]. Other contributors to early death include severe truncal regurgitation or stenosis and coronary artery abnormalities. In infants who survive the first year of life, congestive heart failure gradually improves as pulmonary vascular disease develops and they show better growth and exercise tolerance. By the end of the first decade, however, most of these children develop increasing cyanosis and the improved exercise tolerance begins to deteriorate. Survival into the third decade is extremely uncommon. Death results from hemoptysis, intrapulmonary thrombotic events, heart failure, and/or tachyarrhythmia.

Clinical features

Physical examination

The first heart sound is usually normal and the second sound is loud. In approximately half of the patients, the second sound may be narrowly split. Victorica et al. documented splitting of the second heart sound on phonocardiogram and speculated that the splitting was due either to the cusps not closing synchronously or to a duplicated sound set up by vibrations in the aorta [26]. A constant systolic ejection click is almost always heard. Most patients have a grade 2–3/6 systolic ejection murmur, although occasionally no murmur is heard. A mid-diastolic flow rumble is frequently heard at the apex. An early high-frequency diastolic decrescendo murmur, probably from truncal regurgitation, was heard in 36% of the patients reported by Calder et al. [25]. Rarely, a continuous murmur can be present.

Electrocardiogram

The electrocardiogram is not diagnostic and usually demonstrates right-axis deviation and biventricular hypertrophy (documented by large RS complexes in the mid-precordium).

Chest X-Ray

There is no typical X-ray for truncus arteriosus. In most instances, both the heart size and pulmonary vascularity are increased. In ~36% of patients, a right aortic arch is present;
Figure 45.1 Two-dimensional echocardiographic image in the parasternal long-axis view demonstrates a large conoventricular septal defect in a neonate with truncus arteriosus. The differential diagnosis of this defect includes tetralogy of Fallot and pulmonary atresia with ventricular septal defect.

the combination of a right arch, cardiomegaly, and pulmonary plethora should make one suspect the diagnosis of truncus arteriosus.

Echocardiography

The diagnosis of truncus arteriosus may be made *in utero* with fetal echocardiography. A recent review of the fetal echocardiography database at the University of Michigan yielded 24 patients with prenatally diagnosed truncus arteriosus over 11 years. There were two *in utero* deaths (one spontaneous and one elective termination) and one fetus remains *in utero*. Of the 21 live births, 16 patients (76%) were correctly diagnosed with truncus arteriosus, and five patients (24%) were misdiagnosed (pulmonary atresia with intact ventricular septum and aortic atresia with ventricular septal defect accounted for the correct postnatal diagnoses). Despite vast improvements in ultrasound technology and referral rates to regional perinatal assessment centers, >50% of patients with truncus arteriosus do not receive a prenatal diagnosis [27].

Postnatally, transthoracic echocardiography is currently the standard diagnostic modality of choice. The differential diagnosis includes other conoventricular malformations, including tetralogy of Fallot and pulmonary atresia with ventricular septal defect (Figure 45.1), and also aortopulmonary window and anomalous origin of one pulmonary artery from the ascending aorta ("hemitruncus"). The subcostal coronal view demonstrates the overriding truncal root, posterolateral arising pulmonary artery, and large conoventricular septal defect (Figure 45.2). Truncal valve morphology may be assessed from both the subcostal sagittal and parasternal short-axis views. Truncal valve stenosis and regurgitation may be assessed quantitatively from the apical, suprasternal and parasternal views. A complete study

must evaluate the aortic arch for interruption, determine arch sidedness, examine the ventricular septum for additional defects, define coronary artery anatomy (including origin, branching and course), and visualize the branch pulmonary arteries. Imaging the pulmonary arteries from the subcostal coronal, parasternal short-axis, and suprasternal coronal views allows the determination of the anatomic type of common arterial trunk. Echocardiography may successfully distinguish patients with truncus arteriosus and normal aortic arch from those with interrupted aortic arch, and those with ascending aortic origin of one pulmonary artery ("hemitruncus").

Cardiac catheterization and angiography

Preoperative cardiac catheterization is now rarely undertaken in the neonate with truncus arteriosus. Catheterization may be indicated for angiography when precise anatomic detail, for example, exact pulmonary artery anatomy, is in question after echocardiography (Figure 45.3). With late diagnosis of truncus arteriosus (even if the child is only a couple of weeks old), catheterization may be performed to measure pulmonary vascular resistance and evaluate pulmonary vascular obstructive disease, which may develop fairly rapidly in this lesion [28]. Inhaled oxygen and nitric oxide may be used to measure pulmonary vasoreactivity and determine the appropriateness of surgical correction.

Because of streaming and the small arteriovenous difference in oxygen content across the pulmonary vascular bed, calculated pulmonary blood flow and vascular resistance can be greatly in error. At times, the clinical status (congestive heart failure and failure to thrive versus apparently normal wellbeing and growth) is a better indicator of the presence or absence of pulmonary vascular disease than the data derived from catheterization.

Other imaging modalities

Cardiac magnetic resonance imaging (cMRI) may be utilized in lieu of invasive catheterization when echocardiography fails to provide complete anatomic detail of the lesion. Further evaluation of the pulmonary arteries and delineation of the aortic arch in a complex interruption are the two most common (although still rare) indications for use of cMRI preoperatively (Figure 45.4).

Management

Medical

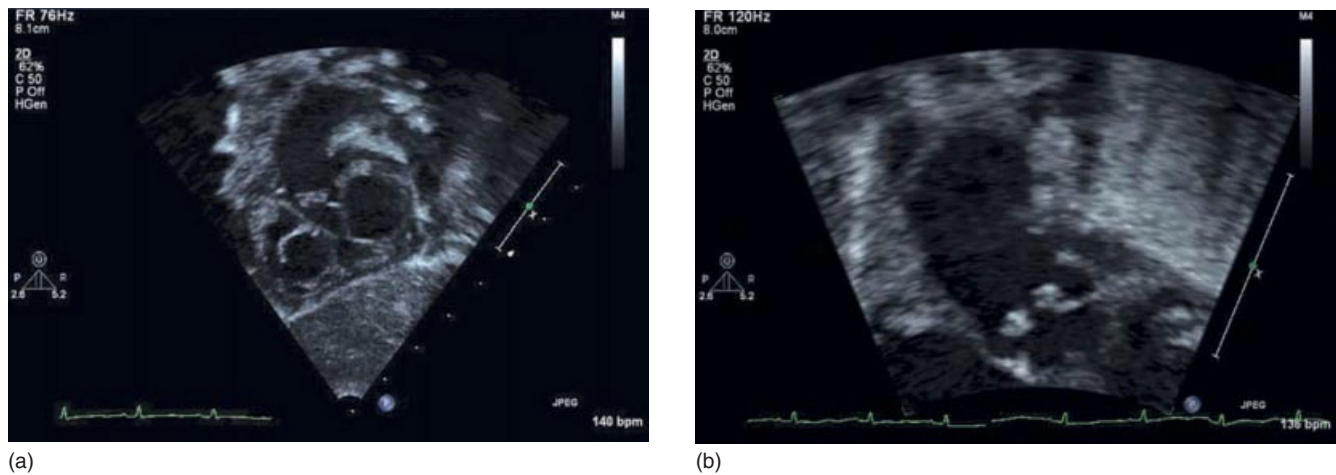
In patients with a fetal or early neonatal diagnosis, surgical repair is generally undertaken within days, after a brief period of intensive care medical management, consisting of general stabilization and treatment of pulmonary overcirculation. Patients with associated arch interruption require continuous prostaglandin infusion to maintain ductal patency.


Figure 45.2 Two-dimensional echocardiographic images in the subcostal coronal view of a neonate with truncus arteriosus. These panels demonstrate a large conoventricular septal defect, common arterial trunk and posterior origin of the pulmonary artery (a) with a thickened, dysplastic truncal valve (b).
Figure 45.3 Angiocardiographic images in left anterior oblique (a) and anteroposterior (b) views in a neonate with truncus arteriosus and discontinuous pulmonary arteries. Panel (a) depicts the right pulmonary artery arising from the common trunk and (b) depicts the left pulmonary artery arising from the patent ductus arteriosus.

Infants diagnosed later than a few months of life may require catheterization for pulmonary vasoreactivity testing prior to surgical repair, if there is concern for early irreversible pulmonary vascular obstructive disease.

Surgical

Because most neonates develop heart failure, early development of pulmonary vascular obstructive disease is common [28], and surgical techniques and outcomes have improved markedly [29–32], complete repair of truncus arteriosus in the neonatal or early infant period is the standard of care. The modern approach of complete repair of truncus arteriosus in the neonatal or early infant period was pioneered in the 1970s by Ebert and co-workers [29]. A staged approach consisting of neonatal palliative pulmonary artery banding, followed by later complete repair, is no longer considered a primary strategy, given its tendency to cause severe anatomic abnormalities of the pulmonary arteries (ranging from stenosis to atresia) [33–36] and the residual risk of pulmonary vascular obstructive disease [36].

(a)   (b)
Figure 45.4 Steady-state free precession sequence cardiac magnetic resonance imaging in a 3-year-old child with unrepaired truncus arteriosus. The sagittal-oblique (a) and axial (b) planes demonstrate the large conoventricular septal defect, overriding truncal valve and posterior origin of the pulmonary arteries.
Figure 45.5 Overall survival after repair of truncus arteriosus at University of Michigan from 1985 to 2007. Numbers in parentheses on the x-axis are the number at risk.

Complete operative repair in the patient without associated lesions consists of ventricular septal defect closure, right ventricular outflow tract reconstruction (to the detached pulmonary arteries) using a valved conduit (typically valved, although some centers utilize a valveless conduit), and repair of the aortic wall deficiency (where the pulmonary arteries once arose). Aortic arch reconstruction (direct end-to-end anastomosis or patch augmentation) is performed for an interrupted aortic arch. Truncal valve repair or replacement at the time of initial repair is considered only in patients with severe truncal valve regurgitation. If necessary, valve repair is preferred as neonatal valve replacement options are severely limited.

Since the initial reports of early primary neonatal repair in the early 1990s by Bove *et al.* [30] and Hanley *et al.* [37], many centers have reported early and mid- to long-term results after neonatal/infant truncus repair [29,31,32,38–40]. Perioperative mortality ranges from 4 to 12.5% with 1-year survival of 84–92%. Commonly identified risk factors for early mortality include weight ≤2.5 kg, need for truncal valve repair or replacement at initial surgery, and, in some series, an interrupted aortic arch [29,41].

We recently completed a thorough review of operated truncus arteriosus patients at the University of Michigan from 1985 to 2007. A total of 113 neonates with truncus arteriosus underwent primary complete repair at a mean age of 19 days and a weight of 3.01 kg. Hospital survival was 87.6%, with no difference in hospital survival between patients with or without interrupted aortic arch. Neither weight nor age at time of repair was a risk factor for mortality. Major postoperative complications, including stroke, cardiac arrest, and need for tracheostomy or extracorporeal membrane oxygenator support, occurred in 21.2% of patients. Survival was 84.4% at 1 year and 77.6% at 5 years (Figure 45.5).

Long-term history of treated and untreated adults

Although survival into adulthood with unrepaired truncus arteriosus has been reported, early death is the norm. Approximately 70% of infants with unrepaired truncus arteriosus die in the first year of life, typically from heart failure [42]. For those surviving beyond the first few years of life, death usually occurs in late childhood or adolescence due to complications of pulmonary vascular obstructive disease, endocarditis, or, less commonly, heart failure. After age 3–4 years, repair is generally not undertaken because of severe, irreversible, pulmonary vascular obstructive disease.

Long-term management of repaired patients revolves, in large part, around the function of the truncal valve. Although mild truncal valve stenosis or regurgitation is generally well tolerated for years, more significant valvar disease (almost always regurgitation) may require intervention. A variety of valve repair techniques have been used [29,32,43]. In the University of Michigan experience, freedom from truncal valve intervention was 89% at 5 years and 84.6% at 10 years (Figure 45.6).
Figure 45.6 Freedom from truncal valve intervention after repair of truncus arteriosus at University of Michigan from 1985 to 2007. Numbers in parentheses on the *x*-axis are the number at risk.

The right ventricle to pulmonary artery conduit will become obstructed and require replacement in all patients. Percutaneous conduit balloon angioplasty and stent placement may delay conduit replacement [44,45]. Nevertheless, most patients will require at least one conduit replacement by the early teen years, if not much earlier. The more recent availability of a transcatheter pulmonary valve may further delay surgical conduit replacement by relieving obstruction and restoring functional pulmonary valve competence [46]. Although patients could once expect to undergo three or four or more operative conduit revisions in a lifetime, the availability of a transcatheter pulmonary valve may substantially reduce this surgical burden.

A single pulmonary artery has also been associated with an increased incidence of late death after repair of truncus arteriosus. In 1985, the Mayo Clinic reported their experience with 19 patients with a truncus arteriosus and a single pulmonary artery [47] who had corrective operations performed from 1969 to 1983. Compared with the 148 patients with truncus and two pulmonary arteries, patients with a single pulmonary artery had a similar operative mortality but a significantly high late mortality. In our series of 113 neonates repaired between 1985 and 2007, there was no patient with a single pulmonary artery.

Additional anatomic sequelae include pulmonary artery stenoses (typically proximal), recurrent aortic arch obstruction (in those who have undergone aortic arch reconstruction), and, less frequently, supravalvar aortic stenosis at the site of initial pulmonary artery connection. Many of these residual lesions can be managed successfully in the catheterization laboratory.

46 Pulmonary Arteriovenous Malformations

Shivu Kaushik & James Gossage

Medical College of Georgia, Augusta, GA, USA

Introduction

Pulmonary arteriovenous malformations (PAVM) are abnormal communications between pulmonary arteries and veins. Although these lesions are uncommon, they are important in the differential diagnosis of common problems such as dyspnea, hemoptysis, hypoxemia, and pulmonary nodules. Churton, in 1897, reported the first description of PAVM [1]. Several terms have been used in the older literature to describe PAVM, including "pulmonary arteriovenous fistulas." We will use the term PAVM, currently the preferred scientific term. Specific literature with regard to PAVM in the pediatric population is sparse and there is considerable overlap with the adult population.

Incidence and genetics

PAVM are uncommon; the exact incidence in the pediatric population is unknown. Three reports, representing the collected Mayo Clinic experience, documented 194 patients of all ages with PAVM over 45 years, yielding an annual incidence of 4.3 patients per year at a large medical center [2–4]. PAVM are uncommonly identified in infancy and childhood, and gradually increase in incidence through the fifth and sixth decades of life. PAVM in the neonatal period are also extremely rare, with only 12 reports in the literature between 1975 and 2000 [5]. Giordano *et al.* [6] studied the incidence of PAVM in 19 children with genetically confirmed hereditary hemorrhagic telangiectasia (HHT). PAVM were detected in 10/19 patients using contrast echocardiography and computed tomography (CT) for an incidence of 53%. The authors noted that the incidence of PAVM in their pediatric population was similar to that in their adult population with HHT.

Much of the study regarding the genetics of PAVM has been done in the context of HHT. HHT is an autosomal dominant inherited disease, with variable inter- and intrafamilial expressivity and age-dependent penetrance [7]. Over 90% of affected subjects manifest signs or symptoms by the age of 40 years. Mutations in at least five genes can cause HHT. HHT1 is due to a mutation in the endoglin gene [8] whereas HHT2 is due to a mutation in the ACVRL1 gene [9]. PAVM are most common in patients with HHT1. In a large study in The Netherlands, PAVM large enough to warrant treatment were found in 32% of patients with HHT1 versus only 3% of patients with HHT2 [10]. Genetic testing of children in families with known HHT may assist in early screening for PAVM, even in those who are asymptomatic [11].

Etiology

There are no universally acceptable criteria for the classification of PAVM. Broadly, PAVM may be divided into congenital and acquired. HHT is the most common congenital etiology of PAVM, with at least 80% of congenital PAVM occurring in the context of HHT [12]. In our own experience, >95% of children with congenital PAVM ultimately have HHT. Although the PAVM in HHT are inherited, they are not always present at birth and, similarly to other clinical manifestations of HHT, the prevalence of PAVM is believed to increase with age.

An extremely rare congenital cause of PAVM is the Abernethy malformation, which arises from defects in vitelline vein formation [13]. In the Abernethy malformation, there is a shunt of venous blood from the intestines and spleen to the inferior vena cava without passing through the liver. It is postulated that there is no first pass metabolism of some unknown pulmonary vasodilator – resulting in a type

of hepatopulmonary syndrome (HPS). The Abernethy malformation syndrome is characterized clinically by radiographic findings of chronic liver disease combined with dilatation of subpleural pulmonary vessels resembling spider nevi, predominantly in the lower lobes of the lung [14,15].

Among the acquired causes of PAVM, one of the most commonly described is the HPS in children with juvenile cirrhosis and chronic liver disease. The prevalence of HPS in children with liver disease is 2–8% [16,17]. The hypoxemia that accompanies this syndrome is due to failure of the blood in the center of the dilated capillaries (15–100μm) to oxygenate completely due to an increased distance from alveolar gas. As in adults, there is no correlation between the severity of hepatic dysfunction and the severity of hepatopulmonary syndrome.

Another common cause of acquired PAVM in children follows surgery for congenital heart disease. PAVM are a well-established complication following the classic Glenn shunt [18], bidirectional cavopulmonary anastomosis (BCPA) [19], and total cavopulmonary shunt (TCPS) [20]. Post-surgical macroscopic PAVM occur most commonly in the right lower lobe and are due to focal exclusion of normal hepatic venous blood from the pulmonary arterial circulation [19,21,22]. Kim *et al.* [20] prospectively studied the prevalence of PAVM in 27 patients after bidirectional cavopulmonary shunt (BCPS) and in 10 patients after total cavopulmonary shunt (TCPS). PAVM was diagnosed if testing showed a shunt fraction >11% by lung perfusion scan, a positive contrast echocardiogram, or a positive pulmonary angiogram. They were further classified to have clinical or subclinical PAVM by the presence or absence of progressive oxygen desaturation by pulse oximetry plus aortic saturation of <80% at heart catheterization. All 10 patients with TCPS had PAVM, of which 50% were clinical. Interestingly, 70% of patients with BCPS had PAVM and all were subclinical. There was a combined mortality of 11% and a combined significant morbidity of 27% after 7 years of follow-up in untreated patients following these procedures [23].

Other rare acquired causes of PAVM more commonly described in adults include trauma, mitral stenosis, actinomycosis, Fanconi's syndrome, metastatic thyroid carcinoma, and schistosomiasis [24].

Embryology

Embryologic development of the vascular system occurs from the fifth to tenth week of intrauterine life, when a continuous differentiation of the vascular bed occurs, resulting in separate arterial and venous channels that are interconnected by capillaries. When a mistake or halt occurs in this process of vascular differentiation, malformations may appear at different sites, including the lungs, and with variable morphology depending on the stage of differentiation [25].

Anatomy and pathogenesis

PAVM are pathologically similar to AVM that occur elsewhere in the body. Two basic elements make up these malformations. The first element is thin-walled vascular channels, lined with a layer of endothelium [26]. The second element is the connective tissue stroma, which is usually scant with little or no connection to the surrounding lung tissue [26]. Occasionally the wall is thickened with fibrous tissue and elastic fibers. The malformation may have one of three typical appearances: (1) a large single sac, (2) a plexiform mass of dilated vascular channels, or (3) a dilated and often tortuous direct communication between an artery and a vein. Uncommonly there may be mural thrombi or mural calcifications associated with the PAVM [26].

Anatomically, PAVM are classified as diffuse or focal, and focal PAVM are further classified as simple or complex. About 80–90% of focal PAVM are simple in both adults and children, with all feeding arteries arising from a single subsegmental artery [27,28]. PAVM perfused by more than one subsegmental artery are defined as complex. Smaller (microvascular) telangiectasias are most commonly complex [29]. Although diffuse PAVM are uncommon in adults, they are seen in 29% of children presenting for treatment with transcatheter embolotherapy (TCE) [28]. About 95% of PAVM are supplied by pulmonary arteries and are usually drained by pulmonary veins, but may occasionally be fed by systemic arteries and/or drain directly into the left atrium or inferior vena cava. Macroscopically, the lesions may appear as a single sac, a plexiform mass of dilated vascular channels, or a dilated and direct anastomosis between artery and vein [29].

The pathogenesis of PAVM remains unknown. Proposed mechanisms include (a) a defect in terminal arterial loops which allows dilation of thin-walled capillary sacs; (b) incomplete resorption of the vascular septae that separate the arterial and venous plexuses during fetal development; (c) development of multiple small PAVM because of failure of capillary development during fetal development, followed by progressive dilation of favored limbs of smaller plexuses and formation of multiloculated sacs (ultimately, rupture of intervening vascular walls may result in formation of a single saccular PAVM); and (d) development of many small PAVM consisting of a single artery to vein connection without an intervening plexus [24].

The role of cytokines and various vascular growth factors in the development of PAVM is under intense investigation. Previous studies had shown serum vascular endothelial growth factor (VEGF) levels to be higher in adults with HHT than healthy controls. Giordano *et al.* [30] studied the correlation between growth factor levels and PAVM in 13 children with genetically proven HHT and age-matched controls. Although they found no difference in VEGF between children with HHT and controls, VEGF was significantly

higher in HHT children with PAVM than in those without PAVM. No difference was seen in transforming growth factor-β_1 levels. The authors suggested that the low levels of VEGF in children without PAVM may protect against PAVM, whereas the high levels in adults might be compensatory for the bleeding that occurs more commonly in adults.

Clinical features

Symptoms

Unlike the adult population, the specific clinical manifestations of PAVM in children have not been well studied. This is partly because symptoms of PAVM often develop between the fourth and sixth decades [24]. The later presentation of symptoms may be because PAVM generally tend to increase in size and rarely regress spontaneously. Features of PAVM that have been correlated with severity of symptoms in some studies have included HHT, the number of PAVM, size of the PAVM, and the magnitude of the shunt fraction [3,4,31,32]. Usually, a single PAVM <2 cm in diameter does not cause symptoms [4,33]. Patients with diffuse microvascular PAVM are always symptomatic [4,28].

Faughnan et al. [28] reported the first large series of children with PAVM and described their clinical presentation. From a database of 617 consecutive patients with PAVM treated by TCE at three HHT centers, they found 42 who were <18 years old. Some 86% of children were diagnosed to have HHT, 57% reported dyspnea on exertion or exercise intolerance, 7% reported previous hemoptysis (minor), and none had previous spontaneous hemothorax.

Epistaxis is the most common symptom of pediatric PAVM patients with HHT and has been reported in children as young as 4 years of age [34]. Bleeding from telangiectasias on the skin and gastrointestinal tract also occurs in HHT [24], but is uncommon in children. Other complaints described in the literature include chest pain, cough, platypnea (improvement in breathing with reclining), migraine headaches, tinnitus, dizziness, dysarthria, syncope, vertigo, and diplopia. Many of these symptoms are vague and may be related to hypoxemia, polycythemia, or cerebrovascular complications such as stroke [24]. The exact incidence of these symptoms as presenting complaints in children with PAVM is unknown.

Neurologic complications of PAVM (transient ischemic attack, MRI-detected stroke, and cerebral abscesses) occurred in 19% of children reported by Faughnan et al. [28]. Seven of the eight patients (88%) with previous neurologic complications were cyanotic [28].

Physical signs

Superficial telangiectasias attributable to underlying HHT are the most common – and frequently the only – physical finding in patients with PAVM. These lesions are macular but occasionally papular, round, 1–3 mm in diameter, ruby colored,
Figure 46.1 Multiple HHT-type telangiectasias on the fingers of an adult with HHT.

well demarcated from surrounding skin with few dendritic projections, and blanch easily with pressure (Figure 46.1). They are most commonly on the fingers, lips, nose, tongue, cheeks, and ears [7,24]. Although telangiectasias have been described in children as young as 1 year [35], their occurrence increases progressively with age. One study found a mean of nine telangiectasias in patients <20 years old, versus a mean of 56 in patients 20–40 years old [36]. In the study by Faughnan et al., cyanosis was seen in 60% and clubbing in 45% of patients requiring TCE [28]. Occasionally, a murmur or bruit may be heard over the site of the PAVM [24].

Chest X-ray

The classic roentgenographic appearance of a PAVM is that of a round or oval mass of uniform density, frequently lobulated but sharply defined, more commonly in the lower lobes, and ranging from 1 to 5 cm in diameter (Figure 46.2) [24]. Individual PAVM may show feeding vessels, with the artery radiating from the hilum and the vein deviating toward the left atrium (Figure 46.2) [3,4]. Cottin et al. [37] in a retrospective study found the sensitivity of chest radiography to be 70% for detecting treatable (amenable to embolization) PAVM in HHT patients. In some patients with complex malformations involving large segments of the lung, the only visible abnormality may be an increase in vascular markings or a hazy increase in opacity over the affected area [38]. Some individuals may show only evidence of a previous thoracotomy for PAVM excision [38].

Diagnosis

Shunt fraction

The fraction of cardiac output that shunts from right to left (shunt fraction, normal <5%) is elevated in 88–100% of selected patients with PAVM [24]. However, all studies thus

Figure 46.2 Screening chest radiograph in a 14-year-old girl with HHT complicated by recurrent epistaxis but no pulmonary complaints. A classic 2 cm PAVM sac is clearly seen in the left lower lung zone along with a feeding artery and draining vein (white arrows). Left-sided pulmonary angiography confirmed this PAVM along with six other smaller PAVMs which are not well seen on this radiograph.

Figure 46.3 Chest CT scan in an adult with HHT complicated by severe hypoxemia and strokes. A bilobed PAVM sac with a prominent associated vessel (long white arrow) is seen in the lateral right lower lobe. A second PAVM sac is seen in the posterior left lower lobe (short white arrow); a feeding artery and vein are visible in other cuts. A possible small PAVM is seen in the anterior left upper lobe (black arrow), but it is too small to characterize fully.

far have reported mainly adults and none have reported children exclusively. Shunt fraction is most accurately assessed by the oxygen method which involves measuring PaO_2 and SaO_2 after breathing 100% oxygen for 15–20 min [24]. A shunt fraction >5% by this method is considered abnormal and warrants consideration of PAVM in appropriate patients. However, this test is usually not performed in children as it requires arterial puncture. Other pitfalls such as technique (air leaks) and duration of oxygen breathing can affect the results [24], making this test ill-suited in children.

Contrast echocardiography

Transthoracic contrast echocardiography (TTCE) utilizes microscopic gas bubbles to visualize the right-to-left shunting characteristic of PAVM. The technique is performed by injecting 4–10 ml of saline that has been agitated with 0.1–1 ml of air into a peripheral vein while simultaneously imaging the atria with two-dimensional echocardiography. Intracardiac shunting is suggested when bubbles appear in the left atrium following a delay of less than or equal to two cardiac cycles after their appearance in the right atrium, whereas intrapulmonary shunting is suggested by a delay of three or more cycles [39–41]. Contrast enhancement may also localize to a draining pulmonary vein in a patient with PAVM [42]. There are no specific criteria about interpreting contrast echocardiography results in children, and studies in children [6] have utilized the standard criteria in adults. Transesophageal contrast echocardiography is more sensitive than transthoracic echocardiography for detecting

intrapulmonary shunt but is more invasive and typically unnecessary in asymptomatic patients [43].

In the largest study to date, van Gent *et al.* examined the prevalence of PAVM by TTCE and CT in 189 patients with genetically characterized HHT and 63 unaffected relatives [10]. TTCE was positive for intrapulmonary shunting in 85% of HHT1 and in 35% of HHT2 subjects. However, only 32% of HHT1 and 3% of HHT2 had treatable PAVM by CT examination. The negative predictive value for TTCE was 100%, making it an ideal screening tool for detecting PAVM. Although this study was performed mainly in adults, in our experience it is equally applicable to children.

One pitfall of contrast echocardiography is that it is positive in some patients with no visible PAVM on chest CT [37]. It also remains positive after TCE of PAVM in up to 90% of patients, even when no residual PAVM are seen on pulmonary angiography [44]. Such positive TTCE tests without visible PAVM are believed to represent microscopic PAVM causing genuine right-to-left shunting (with as yet unknown clinical significance), although a false-positive result cannot be excluded.

Computed tomography

A noncontrasted helical multidetector computed tomography (CT) scan of the chest with 1–2.5 mm reconstructions is now the method of choice for determining whether a PAVM is amenable to TCE. Using this technology, a PAVM typically shows one or more enlarged arteries feeding a serpiginous or lobulated mass, and one or more draining veins (Figure 46.3) [45]. Although contrast enhancement may be seen with central or larger PAVM, the characteristic

appearance on a thin-cut CT makes contrast unnecessary for most patients. Other vascular malformations, such as pulmonary varices, may be mistaken for PAVM, although the diagnosis may be corrected by checking for both afferent and efferent vessels of the putative PAVM [46,47]. In addition, nonspecific micro-nodules of uncertain significance are seen more commonly in children with HHT than in children without HHT [48]. The rare association of pulmonary hypertension with HHT may also be suspected by enlarged central pulmonary arteries and abnormalities in parenchymal attenuation [49].

Magnetic resonance imaging

Magnetic resonance imaging (MRI) of PAVM has not been studied as much as chest CT. With improving technology, however, there may be a role for its use in imaging of PAVM. Schneider *et al.* [50] screened 203 consecutive subjects (6–83 years old) with known HHT or their first-degree relatives using contrast-enhanced magnetic resonance angiography (CE-MRA). CE-MRA detected 124 PAVM in 56 patients. Direct comparison in 40 evaluable patients who subsequently underwent pulmonary angiography showed that only 79% of PAVM seen on CE-MRA were detected on pulmonary angiography. The authors concluded that CE-MRA is a sensitive screening tool for PAVM and potentially superior to pulmonary angiography.

The advantages of MRI lie in the true noninvasiveness of the examination, and also the ability to delineate PAVM angioarchitecture without ionizing radiation. The main limitations include expense, limited availability, breath-holding time exceeding 20s, respiratory motion artifact, need for sedation in children, and the need for highly specialized techniques for accurate interpretation.

Cardiac catheterization/pulmonary angiography

Pulmonary angiography has been the gold standard to determine the position and structure of abnormal vascular lesions in the lungs prior to treatment. Angiography is sensitive for detecting PAVM that are amenable to TCE, and when supplemented with hyperselective angiograms can accurately define the angioarchitecture of individual lesions [24]. Unfortunately, pulmonary angiography is cost, time, and radiation intensive, and therefore is impractical as a screening tool for patients with HHT. Radiation exposure is especially problematic in children. Minor and major complication rates ranging from 0.17 to 7% have been reported [51,52]. Therefore, pulmonary angiography is generally reserved for patients who have been determined by other screening techniques such as CT or CE-MRA to have PAVM large enough for TCE.

Diagnostic approach

The consensus guidelines for HHT recommend screening all adults with possible HHT for PAVM with TTCE, but do not specifically address the optimal method to screen children [11].

There is general agreement that children with HHT with cyanosis, clubbing, dyspnea, or possible neurologic complications of PAVM should undergo TTCE screening. In addition, our own approach involves supine and seated pulse oximetry in children <10 years old followed by TTCE in those with a resting saturation of <97% or in those who require an IV at the time of screening for other aspects of HHT (e.g., brain MRI). Children ≥10 years also receive TTCE. Children with a grade 2 or 3 shunt [41] or neurologic complications are referred for noncontrasted CT.

Management

Medical

In general, all PAVM with a feeding artery diameter of ≥2–3 mm should be treated [11]. The treatment of choice for PAVM in adults is transcatheter embolotherapy (TCE) because it avoids major surgery, prolonged periods of general anesthesia, and loss of pulmonary parenchyma. Data in children are, however, limited. Faughnan *et al.* retrospectively studied the outcome of TCE in 42 patients with a mean age of 12 years (range 4–18 years) [28]. TCE was performed for 172 focal PAVM and 35 diffuse regions (regional TCE) using standard embolic material: stainless-steel coils, platinum coils, detachable balloons, or a combination of these. The technical aspects of TCE were similar to those described in adults, except that general anesthesia or heavy sedation was frequently required in children. After TCE in patients with focal PAVM, oxygenation improved significantly. Acute complications included pleurisy after 24% of TCE sessions and deployment complications in <3% of sessions. Other rare complications included transient intraprocedural angina, perioral pain, intraprocedural leg pain, and transient brachial plexus injury caused by prolonged decubitus position. During long-term follow-up over a mean of 7 years, they found that 15% of PAVM reperfused in 45% of children, similar to the 10–15% reperfusion rate in adults [53]. The authors concluded that TCE has similar efficacy and safety in children and adults, and should be considered the treatment of choice in children. Although there are minimal data on the use of TCE to treat PAVM in the rare pediatric patient without HHT, there is no reason to expect that the results would be any different. In general, children should be referred to an HHT center of excellence for treatment of PAVM.

Surgery

With excellent safety and efficacy of TCE in children, there is little role for surgery in the management of PAVM in this age group [11]. This is because children may develop more PAVM or enlargement of small PAVM later in life, requiring repeat therapy. Rarely, surgery may be considered for complex PAVM not amenable to TCE, in patients with life-threatening

hemoptysis in hospitals without TCE expertise, or in patients with untreatable allergy to contrast material. Surgery may involve ligation or excision of the PAVM and carries the same risks of any similar thoracic surgical procedure. Successful video-assisted thoracoscopic resection of PAVM has been described in adults [54]. Lung transplantation has also been performed in patients with diffuse and bilateral PAVM not amenable to TCE [55,56].

Complications and long-term follow-up

The main aim of treating PAVM is to prevent serious complications. Neurologic complications are the most common and include strokes, transient ischemic attacks, cerebral abscess, migraine, and seizures. Less common but potentially life-threatening complications include hemothorax and hemoptysis. As mentioned previously, neurologic complications are less frequent in children than adults. However, serious complications are more common in cyanotic than acyanotic children [28].

Long-term follow-up is recommended following TCE. Although only 15% of PAVM develop reperfusion during follow-up, this occurs in almost half of children [28]. In the study by Faughnan *et al.* [28], follow-up was performed annually or biannually with helical CT of the chest. Our own practice is to follow the HHT consensus recommendations to repeat a noncontrasted CT scan at 6–12 months after TCE and then every 3 years thereafter [11], and also to follow the development of worsening hypoxemia or dyspnea. A significant increase in the size of PAVM warrants closer follow-up or repeat pulmonary angiography to detect continued or recurrent perfusion of the PAVM.

Finally, we recommend that patients with PAVM – even if only detectable on TTCE – be given antibiotic prophylaxis before dental and potentially bacteremic surgical procedures to the reduce risk of brain abscess [11]. Scuba diving should be avoided owing to the theoretically increased risk of air embolism, but snorkeling and flying are safe. When placing intravenous lines, care should be taken to avoid air embolism. Also, patients and their families should be educated about their diagnosis of PAVM and its clinical implications and complications.

47 Vascular Rings

Kevin K. Whitehead & Paul M. Weinberg

The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Introduction

Vascular rings are generally defined as complete encirclement of the trachea and esophagus by segments or atretic remnants of vascular tissue [1,2]. Although individually there are a confusing array of anatomic configurations, the etiology of all vascular rings can be thought of as occurring from two causes: incomplete regression of the distal fourth arch and dorsal aorta bilaterally or a ductus arteriosus contralateral to the side of the aortic arch, arising from the descending aorta or aberrant (retroesophageal) subclavian artery.

Incidence and genetics

The incidence of vascular rings in most surgical series represents ~1% of operations for congenital defects. Most vascular rings are secondary to either double aortic arch or right arch with aberrant left subclavian artery and diverticulum of Kommerell, which together account for ~90% of all vascular rings.

The genetics of vascular rings are ill-defined. Although they are occasionally associated with syndromes, most patients have no identified genetic abnormalities. The most commonly associated syndrome is 22q11 microdeletion [3]. There is also an increased incidence of vascular rings in patients with congenital heart disease, especially those with conotruncal abnormalities, such as tetralogy of Fallot, transposition of the great arteries, and truncus arteriosus.

Embryology

The embryology of the aortic arch is well described, with six bilateral primitive arches appearing and involuting sequentially, eventually forming the definitive arch, proximal head and neck vessels, and ductus arteriosus. Vascular rings are caused by changes in the regression of the various segments of the arch such that the trachea and esophagus are encircled by vascular tissue. (Figure 47.1) Normally, the dorsal aorta on one side (generally the right) regresses, leaving a single arch. If neither regresses or one only partially regresses, then a double aortic arch is formed. Similarly, an aberrant subclavian artery results from regression of the fourth aortic arch instead of the dorsal aorta. A diverticulum results when there is a ductus arising from the dorsal aorta on the side of the aberrant subclavian artery, such that all ductal flow must run through this region and dilate this dorsal aortic segment.

Pathologic anatomy and major associated anomalies

When addressing vascular rings, it is useful to classify them by the three fundamental mechanisms by which a vascular ring is formed: (1) double aortic arch with or without atresia of one arch, (2) duct from an aberrant subclavian artery on the opposite side of the arch, and (3) duct directly from the descending aorta on the side opposite the aortic arch.

Double aortic arch

The double aortic arch is the most common form of a vascular ring, accounting for about half of all surgical procedures in vascular rings. Usually both aortic arches are patent. The most common pattern is a right-dominant double arch, the right aortic arch being larger than the left arch (Figure 47.2). Less common is the dominant left arch, followed by both arches being relatively equal in size. Often one of the apparently equal arches narrows posteriorly near the connection with the descending aorta and may be better visualized by 3D modalities.
Figure 47.1 Hypothetical double aortic arch. During development, interruptions may occur at various sites (1 to 4), which give rise to different anatomic patterns of arch anatomy. If interruption occurs at site 1, a normal left aortic arch forms (c). If interruption occurs at site 4, a right aortic arch with mirror-image branching is formed (d). Interruptions at sites 2 and 3 form a left aortic arch with aberrant right subclavian artery (a) or a right aortic arch with aberrant left subclavian artery (b), respectively. If neither arch is interrupted, a double aortic arch with either right descending aorta (e) or left descending aorta (g) results. Two interruptions may occur in the hypothetical double aortic arch, giving rise to interruption of the aortic arch. One example is shown (f) in which the double arches were interrupted at sites 1 and 3, giving rise to interruption of the aorta distal to the left carotid artery. Ao, aorta; LCC, left common carotid artery; LPA, left pulmonary artery; LSC, left subclavian artery; PT, pulmonary trunk; RCC, right common carotid artery; RPA, right pulmonary artery; RSC, right subclavian artery.
Figure 47.2 (a) Off-axis axial gradient echo image of a double aortic arch with a severely hypoplastic left arch (LAoA). (b) Volume rendered 3D reconstruction of the gadolinium magnetic resonance angiograph from the same patient, demonstrating the vascular ring. Note that the narrowest part of the arch is between the left carotid and the left subclavian arteries, but it can often occur distal to the left subclavian artery. This is difficult to discern with 2D imaging, but is fairly clear on the 3D volumetric rendering. This information is important in surgical planning. (c) 3D rendering of patient with double aortic arch and nearly equal arches. In these patients, flow measurements using magnetic resonance phase contrast velocity mapping can be useful in determining the dominant arch. RAoA, right aortic arch. Double-headed orientation arrows: A, anterior; L, left; P, posterior; R, right.
Figure 47.3 (a) Double aortic arch with atresia of the left arch (LAoA) distal to the left subclavian artery. Note that the distal left arch points towards the proximal left arch and note the dimple on the posterior aspect of the left subclavian artery. (b) Similar configuration of a right aortic arch (RAoA) and mirror image branching with a left ductus from the descending aorta. However, note the different configuration of the duct dimple (DD) and lack of significant posterior course of the left subclavian artery. Double-headed orientation arrows: as in Figure 47.2 plus I, inferior and S, superior.
Figure 47.4 (a) Superior view of right aortic arch with an aberrant left subclavian artery (ALSCA) and diverticulum of Kommerell (Div). (b) Similar appearance of a cervical right aortic arch with a left descending aorta and ALSCA. Note that the subclavian artery does not pass behind the trachea. Instead, the aortic arch (Arch) itself crosses the midline and forms the posterior portion of the vascular ring. Double-headed orientation arrows: as in Figure 47.2.

Less commonly, a double aortic arch may be associated with atresia of the left arch. The atresia can be distal to the subclavian artery (Figure 47.3a, Video 47.1) or between the carotid and subclavian arteries. The former can appear similar to a contralateral ductus from the descending aorta (Figure 47.3b) and the latter can be difficult to distinguish from an aberrant subclavian artery with a diverticulum of Kommerell (Figure 47.4a). Clues that can distinguish an atretic arch from a ligamentum arteriosum include the posterior dimple on the subclavian or carotid artery, the extent of posterior course of the proximal head and neck vessels, and the orientation of the distal diverticulum or dimple.

Retroesophageal subclavian artery with diverticulum of Kommerell

The second most common type of vascular ring consists of a right aortic arch with an aberrant left subclavian artery with a diverticulum of Kommerell (Figures 47.4a and 47.5a). The diverticulum represents the pathway of fetal ductal flow across the proximal subclavian artery and implies a ligamentum arteriosum on the opposite side of the arch, completing the vascular ring. It is important to understand that the diverticulum extends behind the trachea and the caliber change will be on the side of the aberrant subclavian artery and opposite the arch. A subclavian artery without a duct has some tapering at its base but it is more gradual and does not extend to the level of the trachea (Figure 47.5c).

Although much less common, it is possible to have a diverticulum associated with a left arch and aberrant right subclavian artery (Figure 47.5b). In fact, the original diverticulum described by Kommerell was in the setting of a left aortic arch and aberrant right subclavian artery. Hence patients diagnosed with an aberrant right subclavian artery by echocardiography and with high clinical suspicion of a vascular ring clinically should generally undergo a magnetic resonance imaging (MRI) scan to rule out a vascular ring.
Figure 47.5 (a) Coronal dark blood view of right aortic arch with an aberrant left subclavian artery (ALSCA) and diverticulum of Kommerell (Div). (b) Off-axis coronal of rare left arch with aberrant right subclavian artery (ARSCA) and Div. (c) For comparison, right arch with ALSCA and no Div, which is not a vascular ring. (d) Bright blood image demonstrating an ARSCA without a Div. Note the gradual taper typical of an aberrant subclavian artery. Double-headed orientation arrows: as in Figure 47.3 plus RA, right anterior and LP, left posterior.

Duct from descending aorta, contralateral to side of aortic arch

A less common vascular ring comes involves a duct arising directly from the descending aorta on the opposite side of the aortic arch. This can be with either a thoracic descending aorta on the same or opposite side of the aortic arch. The most common in this category is a right aortic arch with a left thoracic descending aorta, also known as circumflex aortic arch, usually associated with a cervical arch (Figure 47.4b). Note that whereas nearly all descending aortas of right arches eventually cross over to the left by the level of the diaphragm, this circumflex arch refers to the fairly abrupt high crossing of the thoracic aorta superior to the level of the carina. A circumflex arch implies a left ductus or ligamentum or an atretic left arch. Similarly, a left aortic arch with a right descending aorta, again often with a cervical aortic arch, implies a right ductus or ligamentum creating a vascular ring. Note that although these forms of a vascular ring often also occur in the setting of an aberrant subclavian artery (Figure 47.4b), in this anomaly the aberrant subclavian artery is incidental and does not directly contribute to the ring. The subclavian artery does not cross the trachea or esophagus and therefore cannot contribute to symptoms. The posterior limb of the vascular ring is actually the crossing aortic arch.

Another form of vascular ring in this category is a right aortic arch with mirror image branching and a left ligamentum from the right-sided descending aorta (Figure 47.3b, Video 47.2). In this anomaly, the ligamentum actually forms the posterior limb of the vascular ring. As such, no diverticulum or posterior limb can be visualized. The only evidence will be a leftward-directed dimple on the descending aorta that represents the residual aortic ductal ampulla. A theoretical analog with a left aortic arch has not been described. Therefore, a left aortic arch with a left descending aorta is the only arch anatomy that can always be assumed to rule out a vascular ring.

Other arch anomalies

As discussed, a retroesophageal subclavian artery without a diverticulum is not a vascular ring and generally does not cause symptoms. However, some patients report varying degrees of dysphagia with only an aberrant subclavian artery and no other structural abnormalities. Furthermore, these patients have apparent relief from symptoms when the aberrant subclavian artery is either ligated or reimplanted. This finding is generally referred to as dysphagia lusoria. It most commonly occurs in adults in their fourth or fifth decade of life and is thought to be related to dilatation, calcification, and hardening of the subclavian artery. However, it has been reported in teenagers, and less commonly in infants and children. Esophageal manometry has been reported as helpful in confirming compression as the cause of symptoms in these patients [4].

Occasionally there can be significant vascular compression of the trachea in the absence of a vascular ring. However, these rarely reach clinical significance. These anomalies include compression between the ascending and descending aorta when they are in the same anterior–posterior plane, and compression by the innominate artery, often with

tracheomalacia. Innominate artery compression that needs relief can occur with extreme opisthotonus.

Another arch anomaly of note is that of a retroesophageal innominate artery because it is one of the rare instances when the branching pattern fails to identify arch sidedness. The first branch is on the same side as the aortic arch and can therefore make the identification of arch sidedness by the branching pattern (as done routinely in echocardiography) misleading. In a right aortic arch with an aberrant innominate artery, the first arch branch will be the right carotid artery (Video 47.3).

Natural history

The age and type of presentation are presumably in part secondary to the "tightness" of the ring. About 75% with a double aortic arch, 55% with a right aortic arch and aberrant left subclavian artery, and 95% with compression by an aberrant innominate artery [5] present in infancy with respiratory symptoms, including stridor, persistent cough, and frequent respiratory illnesses. Others can present in later childhood or even as teenagers and young adults with a history of respiratory symptoms that can mimic asthma or exercise-induced asthma. Some subjects remain asymptomatic throughout childhood and are occasionally diagnosed incidentally later in life. Because surgery is usually recommended for symptomatic vascular rings, the natural history of untreated symptomatic vascular rings has not been well studied.

The later the presentation, the more likely are gastrointestinal symptoms to be the prevailing symptoms. Vascular rings can present with significant dysphagia, occasionally with weight loss or failure to thrive. Choking or gagging on solid foods can result from interference with esophageal motility caused by vascular compression.

In adults, an aneurysmal origin of an aberrant subclavian artery can dissect or rupture.

Clinical features

History
The clinical history should be focused on the nature, severity, and timing of respiratory and gastrointestinal symptoms. Recurrent stridor and coughing in infants and children without concurrent infection are highly suspicious for a vascular ring. A history of refractory asthma, often with minimal or incomplete relief by bronchodilators and steroids, should raise the suspicion of a vascular ring. Older children may complain of wheezing or coughing with exercise or activity; they may carry the diagnosis of exercise-induced asthma. Dysphagia is a common presenting complaint in older patients. This is usually with solid foods, such as a piece of steak, that are not masticated completely. Occasionally, dysphagia can present in infants as choking or gagging on foods after solids are introduced into the diet, occasionally progressing to feeding refusal and failure to thrive.

Physical examination
The physical examination is often unremarkable. Stridor or wheezing may occur, but their absence does not rule out a vascular ring.

Electrocardiographic features
There are no characteristic findings in patients with vascular rings, because most have normal cardiac position and segmentation with structurally normal hearts. Any abnormalities are secondary to other associated structural heart disease.

Chest X-ray
A routine chest film may reveal a right-sided aortic knob or suggest a double aortic arch, but cannot definitively diagnose or exclude a vascular ring. Therefore, it should play little role in the routine workup of a suspected vascular ring. It may be useful in excluding other causes of respiratory symptoms.

Echocardiography
Because the air-filled trachea is often difficult to visualize on ultrasound, arch imaging tends to rely on defining the branching pattern of the aortic arch. A double aortic arch can be diagnosed by suprasternal sagittal imaging, defining two separate arches in different sagittal planes. A right aortic arch can be diagnosed if the first branch off the aortic arch goes to the left. If the first vessel does not branch, then an aberrant subclavian artery is suspected. However, it is often difficult to image directly posterior structures such as the subclavian artery, and defining the subclavian artery to determine whether there is a diverticulum is especially challenging. Furthermore, there are exceptions to these branching rules, including the rare aberrant innominate artery, in which the first branch off the arch is on the same side as the arch.

The reported degree of success in correctly identifying vascular rings by transthoracic echocardiography has ranged from one in six [6] to 100%.

Cardiac catheterization
Aortic angiography can certainly delineate aortic arch anatomy, and in the past has been the gold standard for the diagnosis of vascular rings. However, with better noninvasive tomographic and volumetric imaging methods now available, invasive angiography should no longer play a role in the routine diagnosis of vascular rings.

Other imaging modalities

Magnetic resonance imaging (MRI)

Because of their noninvasive nature and better ability to visualize 3D structures, tomographic and volumetric imaging methods are now the preferred technique in diagnosing vascular rings. Because it does not use ionizing radiation and has the ability to diagnose definitively all forms of vascular rings reliably, MRI is the preferred imaging modality for diagnosis.

Axial, bright blood images gated to end-diastole can be used effectively to visualize the branching pattern of the aorta. A second coronal stack, preferably turned slightly off-axis by multi-planar reformatting of the initial axial stack to align with the vessel of interest, is useful for identifying the caliber change of a diverticulum. If a vascular ring is identified, dark blood imaging aligned with the trachea can be performed to identify tracheal narrowing.

Volumetric imaging such as gadolinium angiography (or whole heart bright blood techniques if gadolinium is contraindicated) can allow the visualization of features difficult to see by planar imaging. These include identifying an aortic dimple where a ligamentum or atretic arch inserts, better visualization of a diverticulum, and visualizing the posterior portion of the two limbs of a double arch to determine which arch is smaller. The first two are important in diagnosis and the last is crucial information for the surgeon in planning which side to perform the thoracotomy. For this reason, high-resolution 3D magnetic resonance angiography should be performed routinely in the evaluation of a vascular ring. The only time when a vascular ring can be ruled out definitively by static axial imaging alone is a left aortic arch with normal branching and a left descending aorta.

Phase contrast velocity mapping can play a role in a double aortic arch with both arches nearly equal in size. Flow quantification in both arches distal to the origins of the subclavian arteries permits the determination of which arch carries the lesser flow.

Computed tomography (CT)

Chest CT can provide much of the same information as MRI, with the potential for decreased scan times and increased resolution. However, this comes at the cost of significant doses of ionizing radiation in a particularly vulnerable population.

Management

Medical

There is little role for medical management in vascular rings. Because airway symptoms are caused by a fixed obstruction, medications are ineffective. Older, asymptomatic individuals may be followed expectantly without intervention.

Surgical

Most recommend that all symptomatic young children diagnosed with vascular rings undergo surgical repair. Infants and toddlers have a very high likelihood of becoming progressively symptomatic, so even relatively minor symptoms should be considered for repair. Older children and adults with symptoms should also be referred electively for repair. However, incidental findings in older patients may be managed expectantly, with the understanding that future symptoms cannot be ruled out.

Surgical repair generally involves a thoracotomy on the side of the vascular structure that needs to be divided, either the opposite side of the arch or in a double arch, the side of the smaller or atretic arch. In the double aortic arch, the smaller arch is ligated and divided, generally at the narrowest segment, which is either between the carotid and subclavian arteries or distal to the subclavian artery. In a diverticulum, the ligamentum is simply ligated and divided [1]. Compression from an innominate artery can be treated by arteriopexy or transection and reimplantation.

Recovery is generally rapid and the primary postoperative issue is pain management. Some infants, however, require prolonged intubation for tracheal narrowing, and occasionally need reconstructive tracheal surgery. Transient pleural effusions are not uncommon. Rarely, recurrent chylous pleural effusions secondary to thoracic duct injury may require longer chest tube placement. The risk of recurrent laryngeal nerve injury should be minimal in the hands of an experienced surgeon.

In younger patients, division of the ring is almost always sufficient and relief of symptoms is rapid. Surgeons report dramatic relief of the vascular compression in the operating room. However, in older patients, long-standing compression and reduced tissue elasticity may make relief less dramatic. Some have advocated resecting the compressing diverticulum in this population [7] by reimplanting or ligating and sacrificing the subclavian artery. The ligation is generally well tolerated, but can put the patient at risk for a subclavian artery steal.

Long-term history

Children undergoing vascular ring division generally have long-term relief of symptoms. One series reported freedom from stridor in 19/20 in follow-up for 18 months [8] and another reported freedom from all symptoms in 47/48 patients with follow-up from 6 months to 14 years [9]. However, the latter study noted abnormal pulmonary function testing in 9/17 patients who consented to pulmonary function testing [8]. Others have reported that up to 40% of patients have long-term stridor, particularly those with younger age at repair [10].

48 Coronary Arterial Abnormalities and Diseases

Julien I. E. Hoffman

University of California San Francisco, San Francisco, CA, USA

Classification

Anomalies of coronary arteries are classified as anomalies of origin from the aorta, of intrinsic anatomy and distribution, and of termination [1].

Incidence

Isolated coronary vascular anomalies (excluding innocuous variants) occurred in 0.3–1.3% of autopsies at all ages [2], 0.13–0.19% of pediatric autopsies [3], 0.3–1.5% of angiograms performed in adults [4–7], and 1.14% in echocardiograms of children [8]. In congenital heart disease, various coronary vascular anomalies that may be important only during surgery are common, and are described in their respective chapters.

Embryology

The primitive myocardium has sinusoids that develop into intramural vessels. These join a network of subepicardial vessels, which in turn join endothelial buds that emerge from the sinuses of Valsalva of both the aorta and main pulmonary artery [9]. The regulation of this organization is beginning to be explored [10].

Normal anatomy and variants

The right coronary artery (RCA) and left main coronary artery (LMCA) arise from the right and left sinuses of Valsalva (RSV, LSV), respectively, but sometimes are at or just above the supravalvar ridge. Their ostia are round or elliptical, and the arterial stems emerge approximately radially from the aorta [11]. The LMCA divides into the left anterior descending (LAD) and circumflex (LCx) branches, and the RCA gives off the conus branch and continues as the posterior descending artery to supply part of the posterior left ventricular wall (Figure 48.1a). About 35–50% of people have a separate conus branch coming from the RSV [7,12] (Figure 48.1b). About 1% of people have separate origins of the LCx and LAD arteries from the LSV [5–7,12–14] (Figure 48.1c). About 1% of coronary angiograms show a dual LAD, with a short proximal portion coming from the LCA and a longer portion arising from the RCA or RSV and taking a variable course to supply the distal part of the ventricles [15,16]. In 2% of angiograms, the origin of the LCx is acutely angulated where it arises from the LMCA [17]. None of these variants is clinically important unless it affects selective coronary artery catheterization, percutaneous transluminal coronary angioplasty (PTCA) or surgery.

There are excellent articles illustrating the anatomy of normal and abnormal coronary arteries as shown by magnetic resonance imaging (MRI) [18] and multidetector computed tomography (CT) [19].

Disorders of origin

Ectopic aortic origin of one or more coronary arteries

Origin of a coronary artery from the appropriate sinus of Valsalva with an abnormal orifice or intramural course

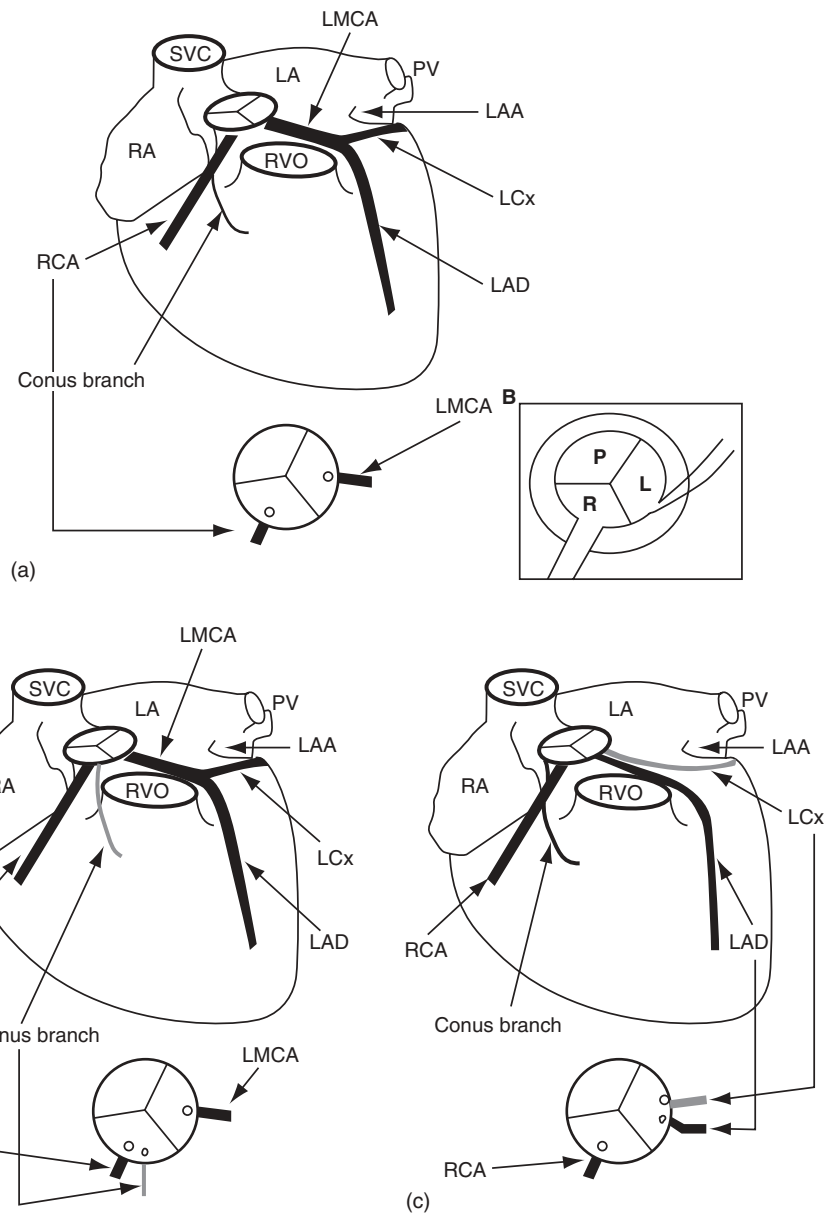
In some patients who died suddenly, and a few at operation, a coronary artery, usually the right, had a long intramural aortic course and emerged tangentially, making an angle of <45° to the aortic wall (Figure 48.1, inset). The ostium of the


Figure 48.1 Normal and innocuous variations. (a) Normal main right and left coronary arteries, seen in an exploded frontal view (above) and diagrammatically from above (below). The inset shows a normal radially directed right coronary artery but an abnormal narrow, intramural LMCA emerging at an acute angle from the aortas. (b) Separate origin of conus branch of right coronary artery. (c) Separate origins of left circumflex and left anterior descending coronary arteries. The abnormal anatomy is shown in gray shading. L, left coronary sinus; LA, left atrium; LAA, left atrial appendage; LAD, left anterior descending coronary artery; LCx, left circumflex coronary artery; LMCA, left main coronary artery; P, posterior or non-coronary sinus; PV, pulmonary veins; R, right coronary sinus; RA, right atrium; RCA, right coronary artery; RVO, right ventricular outflow tract; SVC, superior vena cava.

artery was slit-like and partly covered by a valve-like ridge [11,20].Most of these patients were adults.

Abnormal origin of one coronary artery or a branch from the wrong sinus of Valsalva

Left main coronary artery from right sinus of Valsalva
This constitutes 1–12% of major coronary artery anomalies [4,5,14,21,22]. Four patterns are found [8,23,24]. In ~60%, the LMCA passes obliquely through the aortic wall and then between the aorta and the main pulmonary artery before bifurcating (interarterial course, Figures 48.2a and 48.3a). Its aortic origin may be slit-like and covered by a flap.

The intramural portion is elliptical with a diameter smaller than that of the extramural portion of the artery [25].The posterior or retro-aortic type occurs in 18%; a long LMCA passes behind the aorta and pulmonary artery before bifurcating (Figures 48.2b and 48.3b). In ~16% of these anomalous arteries [26], the LMCA passes intramyocardially through the ventricular septum along the floor of the right ventricular outflow tract (the septal type), and then reaches the surface before bifurcating (Figures 48.2c and 48.3c). The anterior type occurs in 8%; the LMCA runs on the anterior surface of the right ventricle almost like a normal conus branch, and bifurcates at about the mid septum (Figures 48.2d and 48.3d).

Right coronary artery from left sinus of Valsalva

This accounts for ~33% of all major coronary arterial anomalies [26]. The orifices of the RCA and LMCA are adjacent, and in 97% of patients the RCA passes between the aorta and the right ventricular outflow tract to reach the atrioventricular groove, after which it is distributed normally (Figures 48.4 and 48.5). The orifice can be slit-like and the proximal portion of the artery may be angulated [27–30].

Origin of left anterior descending, left circumflex, or both arteries from the right sinus of Valsalva or right coronary artery

An LCx coming from the RCA or RSV is common [26]. The LCx runs behind the aorta to the atrioventricular sulcus behind the atrioventricular valve rings (Figure 48.6a).

The LAD can originate in the RSV or the RCA. This anomaly is rare without congenital heart disease but is common in tetralogy of Fallot. The artery usually passes in front of the right ventricular outflow tract or through the interventricular septum. (Figure 48.6b).

Occasionally, both the LCx and the LAD arise by separate orifices from the RSV. These arteries take posterior and anterior courses, respectively, as described above.

Single coronary artery

These comprise 5–20% of major coronary arterial anomalies [26].

The best known of many classifications are those by Lipton *et al.* [31] and a variant by Shirani and Roberts [32]. There is a single ostium in the RSV or LSV; these are equally frequent. In type I, the single coronary artery (SCA) from the left ostium forms an LMCA that divides into LAD and LCx arteries, the latter continuing past the crux to form the RCA (type L1 of Lipton *et al.*, IB of Shirani and Roberts) (Figure 48.7a) or the SCA from the right ostium forms an RCA that is normally distributed, but the right posterior circumflex artery continues beyond the crux of the heart to

form the LCx and LAD arteries (type R1 of Lipton *et al.*, IIA of Shirani and Roberts) (Figure 48.8a). Alternatively, the single artery branches early into typical right and left coronary arteries; each of these type II patterns is further subdivided according to whether the transverse branch passes anterior to the pulmonary artery (R2a and L2a, or IB1 and IIB1) (Figures 48.7b and 48.8b), between the great arteries (R2b and L2b, or IB2 and IIB2) (Figures 48.7c and 48.8c), posterior to the aorta (R2p and L2p, or IB4 and IIB4) (Figures 48.7d and 48.8d), or through the septum (IB3 and IIB3). Both classifications introduce added groups (three for Lipton *et al.*, groups IIC and IID for Shirani and Roberts) in which the branching patterns are uncommon. Type II variants are more common than type I variants. Type I variants are seen more often in single left coronary arteries, whereas type II variants occur slightly more often with single right coronary arteries.

Miscellaneous anomalies

Many uncommon variations of coronary arterial origins have been reported [26].

Associated anomalies

Most coronary anomalies are isolated but may be associated with other forms of congenital heart disease, particularly conotruncal abnormalities.

Pathology and pathophysiology

Some patients with a coronary arterial anomaly have a subendocardial scar from episodes of ischemia, or even a myocardial infarct. The suddenness of death, however, usually prevents infarction. Some patients had physiological hypertrophy of the left ventricle. Severe atherosclerosis may occur in a segment of the abnormal coronary artery, even in children, and is particularity frequent in the anomalous LCx

[4,21,33,34]. Occasionally, the initial few millimeters of artery run in the aortic wall or may be narrowed, or the whole anomalous artery is hypoplastic. Finally, the anomalous artery may arise tangentially from the aorta, and its ostium may be slit-like and partly covered by a valve-like flap.

Mechanisms of death

Sudden death is common, especially during exercise, almost certainly from myocardial ischemia that produces ventricular fibrillation or electromechanical dissociation. During strenuous exercise, blood flow and pressure increase and the left ventricular myocardium has an enormous demand for oxygen. The aortic root distends in systole, and any intramural anomalous artery may be compressed, or an artery running adjacent to the wall may be stretched or compressed. The ostial flap may occlude the inflow into the artery when maximal flow is needed, especially when blood pressure decreases rapidly post-exercise but skeletal muscle arterioles are still dilated [35,36]. Ischemia may cause acute ventricular dilatation with stimulation of cardiac sensory nerve endings that causes vasodepressor syncope. Why some patients have apparently identical anomalies but survive without ischemia until old age is unknown; there may be progressive obstruction to the orifice and first part of the artery with aging.

Natural history

Whereas ischemic pain usually leads to tests that reveal the diagnosis, the major concern with these anomalies is sudden death, a risk that varies with the precise anomaly.

The most dangerous anomaly is the LMCA arising from the RSV. Sudden death is rare <10 or >20 years of age, and is predominantly in those with intra-arterial passage (Table 48.1).

There were 228 patients with LCA from the RSV, of whom 175 had an interarterial course. Of these 175, 132 (75%) either died or had symptoms of ischemia, whereas the figure was 24/53 for all other courses combined. There were 109 deaths; 83(76%) were from the anomaly and the other 26 from other causes. Among the 83 deaths from the anomaly, 78/83 (94%) were from an interarterial course.

A similar literature search of patients with an interarterial course by Moustafa et al. [37] (almost certainly with overlap of patients) showed sudden death in 96/130 (74%) of these patients.

The issue is less clear for an RCA from the LSV. Once considered benign, there are now many reports of myocardial ischemia, infarction, deaths, and near deaths with this lesion [38]. Most deaths occur in teenagers or young adults, but seven neonates and infants died with this anomaly. There were 45 deaths in 83 patients (54%) due to the anomaly. Compared with anomalous LMCA, more deaths at <10 years of age occurred with anomalous RCA [26].

Table 48.1 Details of outcome with LCA from RSV.

Course	Due to anomaly		Not due to anomaly		Total
	Death	Symptoms	Death	Symptoms	
Interarterial	78	54	15	28	175
Other	5	19	11	18	53
Total	83	73	26	46	228

Based on data from the literature reported by Hoffman *The Natural and Unnatural History of Congenital Heart Disease.* Oxford: Wiley-Blackwell. 2009:384–400.
LCA, left coronary artery; RSV, right sinus of Valsalva.

Anomalous origin of the LCx is usually benign, except for a tendency for premature atherosclerosis [21], and it can be compressed if both aortic and mitral prosthetic fixation rings are implanted [39].

An anomalous LAD can cause ischemic symptoms, but rarely sudden death, in the absence of coronary atherosclerosis.

A single coronary artery usually produces no symptoms without severe atheroma (which is more serious with only one main artery supplying the whole heart), but a few premature deaths or infarctions have been reported [40,41].

Clinical features

Anomalous coronary arteries may be found during angiography for congenital heart disease or myocardial ischemia. As lesions causing primary problems, they are most often found in autopsies performed for sudden death. They may be detected by imaging studies of children and young adults presenting with syncope (especially with exercise), chest pain, arrhythmia, or other evidence of myocardial ischemia, including myocardial infarction. These symptoms usually come on during or just after strenuous exercise, and most victims have been athletes. There are no specific clinical findings.

Diagnosis and diagnostic studies

Any episode of syncope or severe chest pain during or after exercise requires intensive cardiac investigations, beginning with a standard clinical examination and an electrocardiogram to look for ventricular hypertrophy, arrhythmias, or prior infarction. A near maximum exercise test to evaluate blood pressure response and the electrocardiogram can be useful but has some risk; injecting a radioisotope at peak exercise might reveal ischemia. A normal exercise test, however, does not exclude a serious coronary artery anomaly, and exertional syncope or prolonged chest pain in a child or young adult warrants careful imaging studies.

Imaging studies

Echocardiography

An echocardiogram with Doppler interrogation should always be done to exclude intracardiac anomalies and hypertrophic cardiomyopathy. Arteries arising tangentially from the sinuses of Valsalva are readily detectable. Technically satisfactory transthoracic echocardiography has, however, sometimes failed to detect an anomalous coronary artery. In larger children and adults, transesophageal echocardiography has been more useful [42].

Aortic and coronary angiography

Failure to recognize an anomalous coronary arterial origin or branching pattern can lead to misdiagnosis of branch occlusion when selective coronary arteriography is done or a sinus of Valsalva shows no coronary ostium during an angiogram. In addition, an anomalous artery can be injured during an operation performed near the aortic and pulmonary arterial roots, particularly if the anomalous artery was buried in muscle or concealed in scar tissue.

Good descriptions of the cineangiographic features have been published for the various types of course taken by an LMCA arising from the right aortic sinus [43], other anomalies [44], and single coronary arteries [31].

Other imaging studies

Ultrafast CT or MRI has been used successfully [18,19,45,46]. MRI has excellent sensitivity and specificity for detecting these anomalies [47,48]. The sensitivity and specificity of axial CT have not been evaluated.

Treatment

Treatment is advisable for a known sinister anomaly with symptoms indicating myocardial ischemia, and is advisable for symptoms even without ischemia [49,50]. With a more benign anomaly, or no symptoms, provocative testing with exercise, pacing, dobutamine, or ergonovine might determine if the patient is at risk.

Coronary arterial bypass graft is inadvisable in younger patients because of doubts about graft longevity and the risk of competitive flow. No long-term follow-up has been described. The alternative is to remove tissue flaps that are covering the orifice, and revise the intramural aortic course of the artery. If the intramural artery runs distal to the commissure, unroofing the artery along its length creates a long orifice without obstruction [37,51,52]. If, however, the intramural artery is below the commissure, unroofing requires detaching and then replacing the commissure, risking aortic regurgitation. The surgeon may then unroof the distal part of the intramural anomalous artery up to the commissure and suture the edges to the aorta, creating a neo-orifice, and then obliterate the proximal part of the artery [52]. Both procedures eliminate stenosis at the orifice and the acute angulation of the first part of the artery. With

no intramural course, the surgeon reimplants the coronary artery into the correct sinus.

With these procedures, the portion of the LMCA between the aorta and pulmonary artery is not rerouted, suggesting that intra-arterial compression is not a major factor in producing ischemia. Occasionally there is a single coronary artery ostium that does not permit any of the above procedures to be done. In these patients, the pulmonary artery has been transected and translocated in such a way as to open up the space between the aorta and the pulmonary artery [52]. Perhaps opening the space reduces the angulation that may contribute to ischemia.

Because the obstruction may be from a narrowed intramural passage as well as acute angulation as the artery leaves the aorta, stenting of the initial portion of the artery may relieve the obstruction [25]. This is unproven.

After surgery, there has usually been relief of symptoms, and few late postoperative deaths are reported [49,53]. Exercise tolerance and quality of life are excellent [54].

In older patients with atherosclerotic occlusion of the anomalous artery, PTCA or stenting has been used. Relieving a stenosis in an anomalous artery, however, does not mean that angulation or narrowing at its origin may not cause problems later.

Absence or atresia of both main coronary arteries

Complete absence of both main coronary arteries is rare, occurring most often in pulmonary or aortic atresia with a small hypertrophied ventricle, suprasystemic pressures, and sinusoids supplying distal coronary arteries.

Atresia or stenosis of the coronary arterial origin

Pathological anatomy

Stenosis or atresia of the ostium or first few millimeters of the LMCA has been reported in ~60 patients. The LMCA is connected by a fibrous cord to a dimple in the LSV, but its distal branches are normal and supplied by multiple collaterals from the RCA [55,56]. Atresia of the RCA is rare [57,58]. Atresia may be associated with supravalvar aortic stenosis, but whether atresia is primary or secondary is not known.

A few patients had ostial stenosis, but whether this was congenital or acquired is unknown. Rarely, the coronary arteries are hypoplastic and may cause death in young adults.

Pathophysiology

With stenosis or atresia of the LMCA, the anterolateral portion of the left ventricular free wall is ischemic and dysfunctional, either reducing stroke volume or increasing left ventricular diastolic volume. Stress intensifies ischemia, and may elicit it even if it is absent at rest.

Clinical presentation

Patients present from 3 months to 60 years of age, most being <20 years of age. Younger patients present with congestive heart failure, and older patients present with angina pectoris or myocardial infarction. Sudden death, sometimes with exercise, is rare. Occasionally there are no symptoms. Signs of anterolateral ischemia or infarction of the left ventricle make one suspect anomalous origin of the left coronary artery from the pulmonary artery that is much more common than atresia.

Diagnosis

This diagnosis can be made when echocardiography or cineangiography fails to show the LMCA arising from the aorta, and when attempts made to catheterize the LMCA from the aorta fail. The distinction between atresia and anomalous origin of the LMCA from the pulmonary artery is that with atresia no flow enters the pulmonary artery from the LMCA as determined by echocardiography–Doppler or cineangiography studies; in particular, failure to fill the anomalous LMCA during a pulmonary angiogram favors the diagnosis of atresia.

Similarly to an atretic LMCA, a single RCA shows a large RCA and no left main coronary artery arising from the aorta or pulmonary artery. However, by angiography the atretic coronary artery anomaly shows collaterals from the RCA entering large major branches of the LCA, whereas in a single right coronary artery, blood flows through progressively smaller arteries as it passes towards the periphery [56].

Treatment

Several reports have described successful coronary artery bypass grafting, with a saphenous vein [59] or an internal mammary artery [55,56,59].

Ectopic origin of one or both coronary arteries from the main or peripheral pulmonary arteries

All coronary arteries from pulmonary trunk

Rarely, both main coronary arteries, or a single coronary artery, arise from the pulmonary trunk; by 1986 only 25 such anomalies had been described. Unless there is a cardiac lesion causing pulmonary hypertension, these children usually do not survive infancy, and even with other lesions survivors are rare [60–62].

Left main coronary artery from the pulmonary trunk

This anomaly, termed ALCAPA (anomalous left coronary artery from pulmonary artery) occurs in 6.5–15.3 per million live births. The first report relating clinical and autopsy findings in a 3-month-old boy was by Bland *et al*. [63], and the anomaly is often called the Bland–White–Garland syndrome. The history of the diagnosis and treatment of this lesion has been described [64].

Pathological anatomy

The RCA is greatly dilated and large superficial collaterals are seen. The LMCA enters the pulmonary artery, usually the left pulmonary sinus but occasionally a branch. Rarely, it is attached to the non-facing sinus [65]. It is usually only 2–5 mm long before it branches. The connection between the LMCA and pulmonary trunk may be narrow or even stenotic. Occasionally the initial portion of the LMCA is intramural.

In infancy, the left ventricle and atrium are dilated and hypertrophied. The anterolateral papillary muscle is atrophic and scarred, and its chordae may be shortened. Sometimes the posterior papillary muscle is similarly affected [13,60].

There may be diffuse endocardial fibroelastosis of the left ventricle, and the anterior mitral valve leaflet is often thickened. The anterolateral left ventricular wall and apex are thinned and scarred from infarction, and there are often mural thrombi. A biopsy of the affected left ventricular free wall at surgery in five patients showed that 51 ± 32% of the wall was fibrotic, and that the remaining muscle fibers, although viable, showed a paucity of contractile fibers [66].

In adults, the LCA is thin walled, resembling a vein. The heart is usually enlarged, but less than in infants, and there is usually no endocardial fibroelastosis. However, there is usually scarring and calcification of the anterolateral papillary muscle, and occasionally even of the adjacent left ventricle [14,67].

Associated lesions

ALCAPA has occasionally been associated with patent ductus arteriosus, ventricular septal defect, tetralogy of Fallot, or coarctation of the aorta [60]. If there is pulmonary hypertension, as with a large ventricular septal defect, left ventricular perfusion may be adequate, but closure of the defect with a fall in pulmonary arterial pressure may be catastrophic [68].

Pathophysiology

In fetal life this anomaly is innocuous. Pressures and oxygen saturations are similar in aorta and pulmonary artery, myocardial perfusion is presumably normal, and there is no stimulus to collateral formation. After birth, however, the left ventricle, with its huge demand for oxygen, is perfused with desaturated blood at low pressures. Collateral vessels between the normal right and abnormal LMCA enlarge, and so does the RCA.(Figure 48.9).

This collateral flow is of little use because most of the collateral flow that enters the left coronary arterial system tends to pass into the pulmonary artery rather than into
Figure 48.9 Left main coronary artery from pulmonary artery. (a) In fetus. (b) In neonate. The light gray apical region indicates the ischemic region. (c) In older infant. The slightly darker gray apical region indicates worsening ischemia, and the very dark central area is the infarct. The gray vessels joining left anterior descending and right coronary arteries are collaterals. The pale gray arrows indicate the direction and approximate magnitude of collateral blood flow and its distribution. The open arrows indicate the direction and approximate quantity of flow in the proximal and distal left coronary artery.
the high resistance myocardial blood vessels (Figure 48.9), as first demonstrated by Sabiston *et al.* [69]. The amount of left to right shunting is small relative to cardiac output, but large relative to coronary flow. Initially, left ventricular myocardial vessels dilate to reduce their resistance and increase flow, but when coronary vascular reserve becomes exhausted, myocardial ischemia ensues. At first, ischemia is transient and occurs only with exertion such as feeding or crying, but further increases in myocardial oxygen demand lead to infarction of the anterolateral left ventricular free wall. This causes congestive heart failure, often made worse by mitral regurgitation secondary to a dilated mitral valve ring or infarction of the anterior papillary muscle [70–72].

In some patients, the connection of the LMCA to the pulmonary artery is restrictive, no steal occurs, and all the collateral flow perfuses the free wall of the left ventricle. These patients may include many of the 15% of patients with these anomalies in whom myocardial blood flow is adequate to sustain myocardial function at rest or even during exercise, and who reach adult life [60,73]. Prolonged

survival is more likely in patients with a dominant right coronary system [73,74].

Natural history
About 87% of children born with this rare anomaly present in infancy, and if untreated 65–85% die before 1 year of age from intractable congestive heart failure, usually >2 months of age [26,60,74,75]. A few improve spontaneously. Others never have symptoms, perhaps because they have extensive collaterals or a restrictive opening between the origin of the left coronary artery and the pulmonary trunk. Nevertheless, even they are at high risk of sudden death [74,76], especially during exercise. Some present as adults with angina of effort or myocardial infarction [67,77,78], arrhythmias [78], or left ventricular dysfunction or even congestive heart failure associated with mitral regurgitation [79,80]. Operation markedly improves function. Whether an operation is required for an adult with this anomaly but no evidence of ischemia at rest or on exercise is unknown. The course without treatment is presented in Figure 48.11.

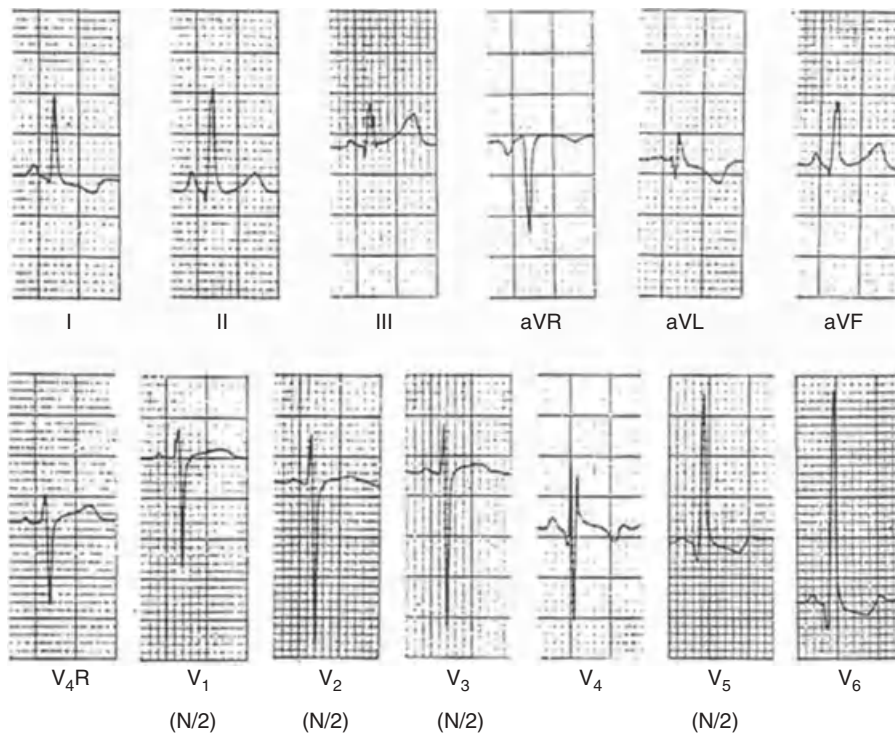

Figure 48.10 Electrocardiogram in ALCAPA. Note abnormal q waves in leads V5 and V6, and also abnormal R wave progression in the precordial leads.

Clinical findings

In infancy, the description by Bland *et al.* [63] still pertains. They wrote:

> Nothing remarkable was noted about the patient until the tenth week; while nursing from the bottle, the onset of an unusual group of symptoms occurred which consisted of paroxysmal attacks of acute discomfort precipitated by the exertion of nursing. The infant appeared at first to be in obvious distress, as indicated by short expiratory grunts, followed immediately by marked pallor and cold sweat with a general appearance of severe shock. Occasionally, with unusually severe attacks, there appeared to be a transient loss of consciousness. The eructation of gas at times seemed to relieve the discomfort and to shorten the duration of the attack which usually lasted from 5 to 10 minutes, and following which the infant might proceed to nurse without difficulty and remain free of symptoms for several days. … It seems probable that in this infant the curious attacks of paroxysmal discomfort … were those of angina pectoris. If this is true, it represents the earliest age at which this condition has been recorded.

Some infants present with signs and symptoms of congestive heart failure. A few children have severe difficulties in infancy and then gradually become asymptomatic. Rarely, this anomaly causes sudden death in infancy. Older children and adults may be entirely asymptomatic, or have dyspnea, syncope, ventricular arrhythmias, or angina pectoris on effort. Sudden death after exertion has been common

[74,76]. Typical myocardial infarctions or congestive heart failure are rare in adults.

On physical examination, there may be signs of congestive heart failure. In infants, the heart is usually enlarged, predominantly the left ventricle. There may be right ventricular enlargement and loud pulmonic closure if left ventricular failure has caused pulmonary hypertension. The first heart sound may be soft or absent (if there is mitral regurgitation), and apical gallop rhythms are common. There may be no murmurs, or the murmur of mitral regurgitation, or at times a soft continuous murmur at the upper left sternal border that resembles the murmur of a coronary arteriovenous fistula or a small patent ductus arteriosus.

Electrocardiography

By the time the infant presents for diagnosis, there is usually an anterolateral infarct, with abnormal q waves (≥ 3 mm deep and ≥ 30 ms duration [81]) in leads I, aVl, and precordial leads V4–V6 (Figure 48.10). There may also be abnormal R waves or abnormal R wave progression through the mid to left precordial leads. Although this pattern occurs in myocardial infarcts from other causes, or in cardiomyopathies, if found, the diagnosis of ALPACA should be considered and evaluated by other means. Even in asymptomatic adults, the resting electrocardiogram is abnormal, and abnormal ischemic responses occur with exercise [67].

Radiological findings

There is marked cardiomegaly, predominantly of the left atrium and ventricle, and pulmonary edema. These features are similar to those of cardiomyopathy, with which this anomaly is often confused.

Thallium uptake can show reduced uptake in the anterolateral ischemic region, but this finding has occurred in some patients with cardiomyopathies [82].

Echocardiography

The abnormal attachment of the origin of the LMCA must be sought in more than one view to avoid problems from lateral drop out. Doppler interrogation shows flow passing from the coronary artery to the pulmonary trunk, so that even if the attachment of coronary artery to great artery is uncertain, the direction of flow is diagnostic. The transverse sinus of the pericardium should not be confused with a normal left coronary artery. False negatives are rare, but one has been described [83]. The echocardiogram also shows the very large RCA and the enlarged collateral arteries. The size and function of the cardiac chambers, particularly the left ventricle, regional left ventricular wall motion abnormalities, and mitral regurgitation are shown. There may be increased echogenicity of the papillary muscle and adjacent endocardium due to fibrosis and fibroelastosis.

Cardiac catheterization

This is used only if echocardiography is not definitive; it may cause death due to arrhythmias. An unnecessary cardiac catheterization however is better than missing a potentially treatable anomaly.

Symptomatic infants have a low cardiac output, high filling pressures, and usually some elevation of pulmonary artery pressures. In asymptomatic older patients, cardiac output is usually normal, but left ventricular end-diastolic pressure may be increased. There may be a left to right shunt at the pulmonary arterial level, but as the amount of shunting may be small its absence does not exclude the diagnosis of ALCAPA. Angiography reveals the dilated left ventricle and atrium with dysfunction of the anterolateral left ventricular free wall, and any mitral regurgitation. Aortic root angiography shows the dilated RCA and, if there are large collaterals, shows filling of the LCA and passage of contrast material from the LMCA to the main pulmonary artery. Main pulmonary arterial angiography often shows reflux of contrast medium into the origin of the LMCA. This anomaly has to be distinguished from the very rare anomaly of an atretic LMCA (see above).

Treatment

Initially, ligating the origin of the LCA was performed to prevent the steal [69]. Most children benefit from this procedure, especially if they have extensive coronary to pulmonary arterial shunting, but late sudden death can occur [67,84–86]. Ligation is performed off cardiopulmonary bypass and is quick, but the circulation cannot be supported if ventricular fibrillation occurs.

Ligating the origin of the left coronary artery and reconstituting flow through it with a subclavian arterial or saphenous venous graft has also been successful [87,88], although clotting or stenosis of the graft has occurred. Late obliterative changes in saphenous vein grafts have occurred [87] and are dangerous, because by ~3 years after successful saphenous vein grafting for this anomaly there is usually a marked reduction of collaterals from the right coronary artery [89,90]. Possibly internal thoracic artery grafts would have longer survival.

Currently, recommendations are to reimplant the origin of the LMCA into the aorta (with a button of pulmonary artery around the origin) [91,92], or create an aortopulmonary window and then fashion a tunnel that directs the blood from the aorta to the left coronary ostium [93–95]. There have been few reports of occlusion of these nongrafted connections, and a short, wide connection is not likely to become occluded. Sometimes the tunnel procedure causes supravalvar pulmonic stenosis, and may need reoperation [96]. The longer the follow-up period, the more the two-artery approach seems better than ligation or bypass grafting [85,97–101].

Occasionally the orifice of the LMCA is far from the aorta, as for example attachment to the non-facing sinus. Then either the LMCA must be connected to the aorta by an interposition graft or a variety of flaps [102–104], tunneled through to the aorta, or else connected by some other technique [65].

The mortality of surgery in the very sick infant is up to 20%, often because of ventricular fibrillation occurring before the sternotomy [105], so some surgeons recommend the less desirable but safer simple ligation procedures (with or without cardiopulmonary bypass) for the sickest infants [105]. Recent reports indicate that satisfactory results are obtained in good centers with even the sickest infants [72,98], although postoperative support with left ventricular assist device (LVAD) or extracorporeal membrane oxygenation (ECMO) might be needed [106,107].

Late results after operation are good, even in adults. The heart becomes smaller, congestive heart failure abates, mitral regurgitation regresses, and left ventricular shortening fraction improves [72,78,84,95,98–102,108]. Symptoms disappear, and exercise tolerance is either normal or slightly reduced [109]. In one study, coronary flow reserve was slightly reduced [109]. The region of hypoperfusion shown by radionuclide scans may disappear or become smaller [107], suggesting that some ischemic tissue was hibernating. Because of the improvement in mitral regurgitation, mitral valve repair is not usually performed during the initial operation [70,72, 92,102,107]; it might, however, be required later [72].

Right main coronary artery from pulmonary trunk

This anomaly (termed ARCAPA) is rare, with ~100 patients reported.

Pathological anatomy

The RCA is attached to the pulmonary trunk, usually the anterior facing sinus, and receives many dilated collateral arteries from the LMCA. Myocardial infarction is rare, and the only grossly abnormal findings are increased size of the LMCA and thinning of the wall of the RCA. The RCA is usually free from atheroma, but its origin may be stenotic.

Associated lesions

This anomaly may be associated with aortopulmonary window, ventricular septal defect, tetralogy of Fallot, and a few other lesions [26,110]. As expected, older patients have fewer of these associated lesions.

Pathophysiology

This is similar to ALCAPA, with collaterals from the LMCA supplying the RCA, and retrograde flow from the RCA into the pulmonary artery. Because of the steal from the LCA, ischemic dysfunction of the left ventricle may occur. Coronary flow reserve is reduced. [111]

Natural history

This is a more benign lesion than ALCAPA (Figure 48.11). Sudden or early deaths are unusual, and only 10% present before 1 year of age [26]; 50% are diagnosed >20 years of age, the oldest being 90 years old [26]. About half of the patients are asymptomatic, but late-onset syncope or cardiac arrest can occur. The proportion of asymptomatic patients decreases with age.

Clinical findings

Most patients are asymptomatic, especially if young. Syncope, cardiac arrest, sudden death, angina pectoris (due to coronary steal), dyspnea, and congestive heart failure have been described [14,110]. The youngest patient reported was 2 months old [110]. There may be a continuous murmur at the left sternal border.

Electrocardiogram

This may be normal, show ischemic changes with exercise, or show signs of left ventricular ischemia at rest.

Echocardiography

This shows the anomalous connection of the RCA to the pulmonary artery, and high-velocity retrograde flow from the RCA into the pulmonary artery. There may be left ventricular dilatation, reduced ejection fraction, and wall motion abnormalities in the most severely affected patients.

Cardiac catheterization and angiography

These are usually unnecessary, but confirm the echocardiographic findings. The Qp/Qs ratio is seldom much elevated, but the proportion of cardiac output due to coronary flow is increased [111].
Figure 48.11 Natural history (survival) in various forms of coronary artery connection to the pulmonary artery.

Treatment

Most patients are asymptomatic, and there is no way of determining which are at risk of sudden death. Some patients managed conservatively have done well. Nevertheless, most cardiologists recommend operation, especially for symptoms or objective evidence of myocardial ischemia. The RCA is reimplanted into the aortic root [112,113].

Left anterior descending or left circumflex coronary artery from pulmonary trunk

These anomalous attachments are rare; ~20 of each have been described [114,115].

Pathological anatomy

The anomalous artery is attached to the main pulmonary trunk, but often an anomalous LCx is attached to a branch pulmonary artery. Left ventricular pathology is similar to that seen in ALCAPA, but usually less extensive.

Pathophysiology

This is similar to that described for ALPACA, with similar dependence of left ventricular wall flow on pulmonary arterial pressure and the adequacy of collateral formation from the normally attached coronary arteries.

Natural history

This is better than that for ALCAPA (Figure 48.11). Apart from a 7-month-old child who died with an anterior myocardial infarct, all the others have been from 7 to 55 years old. Seven had angina pectoris, one an anterior myocardial infarct, and one had mitral regurgitation from papillary muscle dysfunction. One 9-year-old child died suddenly. Congestive heart failure is uncommon.

Clinical features

Most patients had exertional dyspnea, chest discomfort, or frank angina of effort, but many were asymptomatic and detected by chance. Precordial murmurs were common, but there were no specific physical findings.

Electrocardiogram

Most patients had electrocardiographic evidence of ischemia at rest or after exercise, with the site of ischemia depending on the involved artery.

Cardiac imaging

X-rays were normal in about half of the patients and showed mild cardiomegaly in the rest. MRI done in a few patents was diagnostic. Thallium studies with exercise may reveal silent ischemia.

Cardiac catheterization and angiocardiography

These studies are usually unnecessary if the other imaging tests are adequate.

Management

Surgical treatment is recommended even in asymptomatic patients because of the risk of late ischemia. The best choice is reimplanting the anomalous artery into the aorta, but there may not be enough length for this to be done without tension. The alternatives are to ligate the artery, connect it to the aorta with an interposition graft, or ligate the proximal portion and perform a coronary bypass graft to the distal portion [14,115].

Disorders of structure or distribution

The coronary arteries can be involved in many forms of generalized systemic disease, for example, Kawasaki disease (Chapter 63), systemic lupus erythematosus (Chapter 69), and infantile polyarteritis nodosa (Chapter 69). These will not be discussed further here, but certain other abnormalities will.

Calcific arteriopathy of infancy

Fewer than 100 patients have been reported [116].

Pathology

This disease affects mainly the muscular arteries: coronary arteries in 90% of patients, and renal, pancreatic, and splenic arteries in 50%. The internal elastic lamina fragments, and then calcification begins there and extends to the media, where large calcium clumps form and destroy the muscle. Intimal connective tissue proliferation occurs and eventually occludes the lumen [117]. We do not know if there is a single etiology or several different processes with common end results [118]. The disease is unrelated to chronic renal disease, hypervitaminosis D, hyperparathyroidism, and HIV infection, or trisomies 13–15 and 17–18, all of which can show arterial calcification. An inherited genetic disease associated with elastin formation has been suggested because several sets of siblings with the disease have been described [119]. Arterial thromboses may occur, but spare the cerebral arteries [117].

Clinical features

The patients present in congestive heart failure by about 2 months of age, and may have signs of myocardial ischemia and infarction; less often, they have renal failure and hypertension [117,120]. Diagnosis is made by palpating hardened superficial arteries in the neck and limbs, finding calcified arteries on X-ray [121,122], and sometimes by ophthalmoscopy. Most infants die before 6 months of age, but some improve spontaneously [117,122,123]. Diphosphonates have been used therapeutically but their effectiveness has not been proved [119,124].

Myocardial infarction

Myocardial infarction in the fetus or neonate is rare [125,126].

Etiology

Many infarcts are probably due to intrauterine emboli from umbilical, hepatic, or renal veins [125,126], some to coronary arteriopathy [117], a few to severe intrauterine hypoxia and stress, and a few to coagulopathies, but most to unknown causes. Some unusual causes are the antiphospholipid syndrome; collagen vascular diseases, especially systemic lupus erythematosus; takotsubo cardiomyopathy after severe emotional distress; Kounis syndrome (allergic anaphylactoid angina) [127]; hyperlipoproteinemia; and Kawasaki syndrome (see Chapter 63). Occasionally, they occur from postnatal paradoxical embolism, or embolism from material extruded from cardiac catheters, particularly after several changes of guide wires [128]. The risk of coronary embolism may be particularly high in children with cyanotic heart disease. If there is an infarct, it is essential to exclude an anomalous coronary artery arising from the pulmonary artery.

Table 48.2 Etiologies of coronary arterial aneurysms.

1. Congenital
2. Atherosclerotic
3. Inflammatory and infectious causes:
   a. Kawasaki syndrome
   b. Syphilis
   c. Mycotic
   d. Infective endocarditis
4. Trauma, including PTCA
5. Connective tissue disorders:
   a. Marfan syndrome
   b. Ehlers–Danlos syndrome
6. Vasculitides:
   a. Takayasu arteritis
   b. Polyarteritis nodosa
   c. Scleroderma
   d. Systemic lupus erythematosus
7. Miscellaneous: Osler–Rendu–Weber disease, metastatic tumor

Modified from Smith *et al. Cathet Cardiovasc Diagn* 1984;**10**:583–91.

Diagnostic features

The children present with angina pectoris and often have congestive heart failure or shock. Electrocardiography shows evidence of infarction, and echocardiography demonstrates the left ventricular dysfunction. Thallium studies confirm regional ischemia. Because of its rarity, most children with myocardial infarction come to cardiac catheterization and angiography.

Treatment

Pediatric cardiologists see myocardial infarction so rarely that they should consult an adult cardiologist about the use of thrombolytic agents.

Coronary aneurysms

These have been found in 1–5% of coronary angiograms, the difference depending in part on the definition of an aneurysm; the usual definition is a localized dilatation with diameter >50% of the adjacent segments or the patient's largest coronary artery [129,130]. Possible causes are listed in Table 48.2.

The most common cause in children is Kawasaki syndrome (see Chapter 63), and in adults aneurysms are associated with coronary atherosclerosis. All other causes are rare. Aneurysms are usually found while investigating other problems. Occasionally, they appear on X-ray because of calcification. They are shown well by imaging techniques, usually echocardiography or angiography, but better details are often seen with MRI or CT.

Apart from problems pertaining to the underlying disease, aneurysms may thrombose and cause either coronary stenosis or distal coronary embolism, with resulting myocardial ischemia or infarction. Rupture is rare [132]. Treatment ranges from nothing to antiplatelet medication, thrombolytic agents for acute thrombosis, coronary bypass grafting for occlusive disease, and even excision of the aneurysm [132].

Myocardial bridges

The large epicardial coronary arteries are superficial, with only their terminal branches penetrating the muscle, but in 40–50% of people, part of an epicardial artery dips beneath the epicardial muscle (the muscle bridge) for several millimeters [133,134]. These bridges are probably present at birth. Most are over the LAD, predominantly its proximal half [134,135]. In ~75%, the LAD runs in the interventricular groove and may be covered by a few superficial bridging muscle fibers; in 25%, the LAD deviates towards the right ventricle and runs deep in the ventricular septum, where it is crossed by a bundle of muscle extending from the right ventricular apex to the septal muscle [135]. Most bridges are not functionally important, particularly if they are superficial. There are, however, reports of myocardial ischemia [135], infarction [136], or even death [137] associated with them, and of relief of ischemia after myotomy. Symptoms may occur if the bridge is abnormally long or deep, especially if the RCA is small [138].

During coronary angiography, a portion of the coronary artery appears to be narrowed in systole but widely patent in diastole [133,135].

Because myocardial bridges are so common and do not necessarily indicate present or future coronary arterial disease, the decision about myotomy to relieve anginal symptoms depends on demonstrating ischemia, based on lactate production in the regional vein, electrocardiographic changes, or deficient thallium uptake. Ischemia more likely occurs with long, thick bridges that compress the artery and relax unusually slowly so that diastolic filling beyond the bridge is impaired. Disappearance of symptoms and signs of ischemia may follow myotomy. Some patients obtain relief from anti-anginal therapy with β-adrenergic blockade. Myocardial bridges causing ischemia are rare in children; they are more common in children with ventricular hypertrophy, particularly hypertrophic cardiomyopathy [139,140].

Coronary atherosclerosis and atheromatosis

This is one of the major epidemic diseases of the developed world. Although precursors of coronary atherosclerosis appear in early childhood (see Chapter 65), the full-blown disease is rare in childhood. The most common causes of severe coronary arteriosclerosis in children are secondary to Kawasaki disease and to homozygous familial hypercholesterolemia; heterozygotes for familial hypercholesterolemia are also at risk. Children who have had heart transplants

are at risk for diffuse coronary artery vasculopathy as a manifestation of rejection. Other causes include the rare Hutchinson–Gilford syndrome (progeria).

Disorders of termination: fistulas between coronary arteries and cardiac chambers, venous vessels, or pulmonary arteries

A normally originating coronary artery may have a precapillary connection with the atria or ventricles (coronary–cameral fistula) or the coronary sinus, superior vena cava, or pulmonary artery (coronary–arteriovenous fistula). These anomalies constitute 0.2–0.4% of all congenital cardiac anomalies [60,141], with similar incidences in males and females. They are observed in 0.08–0.18% of routine coronary angiograms in adults, and make up 8–13% of the congenital coronary arterial anomalies observed in these studies [4,5].

Embryology

Persistence of wide intertrabecular spaces in the primitive myocardium could lead to coronary–cameral fistulas [142]. On the other hand, fistulas from coronary arteries to pulmonary or bronchial arteries, or the very common tiny communications between the coronary arteries and the pericardial, diaphragmatic, or mediastinal arteries [12] or even the superior vena cava, are probably communications between the primitive coronary arteries and the mediastinal plexus of vessels.

Anatomy and pathology

About 55–60% of the fistulas arise from the right coronary artery and ~5% arise from more than one coronary artery [143]. About 90% drain into the lesser circulation [60,141,143]: the right ventricle in 40%, the right atrium or venae cavae in 22%, and pulmonary artery in 30%. About 1.4% enter the coronary sinus, 5.5% enter the left ventricle, and 1.5% enter the left atrium [143]. Occasionally a complex fistula drains into several sites. The pulmonary artery is a favored site of entry of small fistulas, and most bilateral fistulas enter the pulmonary artery [144].

The fistulous coronary artery may be very small, particularly if it arises from the distal part of the artery [145], or may be dilated up to 40 mm in diameter and tortuous, with variations of diameter along its length. Sometimes there are bundles of small vessels rather than one large fistula. The fistula enters the affected chamber by one or several openings; occasionally plexiform lesions are seen. Saccular aneurysmal dilatation of the fistula can be seen, and these aneurysms are thin walled and often gigantic; some of the largest measured 14 × 12 × 11, 15 × 15 × 10, 8 × 10 × 22, and 17 × 23 × 14 cm. All these giant aneurysms were described in patients over 50 years of age [143].

Associated anomalies

Other congenital cardiac lesions can coexist [60,146], but most coronary artery fistulas are isolated. Connections between myocardial sinusoids and coronary arteries in pulmonary atresia with an intact ventricular septum carry blood into, not away from, the coronary arteries.

Pathophysiology

Small fistulas have no hemodynamic effect. A large fistula, however, causes a left-to-right shunt great enough to cause congestive heart failure. When a fistula enters the low-pressure lesser circulation, the shunt is continuous in systole and diastole. When it enters the left ventricle, the shunt is exclusively diastolic. A significant run-off through the fistula may reduce flow through more distal arteries, and cause a coronary steal and myocardial ischemia [147,148].

Natural history

Fistulas may be detected at any age from birth to the ninth decade [143]. Under 1 year of age, and particularly under 1 month of age, most patients are symptomatic. From 1 to 20 years of age, most are asymptomatic and detected by either a prominent murmur or an echocardiogram done for another diagnosis. After 20 years of age, ~75% of these patients are symptomatic. Asymptomatic coronary fistulas are uncommon in adults.

Because huge aneurysms are found only after 50 years of age, the lesion may progress, at least in some patients. However, very small fistulas, usually between a coronary artery and the pulmonary artery, may never increase in size or cause hemodynamic problems. Fistulas may, however, develop infective endocarditis [143], which usually occurs only in large fistulas. Spontaneous closure of fistulas has been described in >40 patients [143], possibly due to infection in some. Most closed at <15 years of age, and in several series of patients, spontaneous closure occurred in ~13%. Larger fistulas may cause congestive heart failure, dyspnea, fatigue, angina pectoris due to a coronary steal or to accelerated atherosclerosis, or rarely myocardial infarction. They rarely rupture [60,149], which is surprising in view of the massive aneurysmal dilatation of these thin-walled fistulas. Thrombotic occlusion has caused acute myocardial infarction, but rarely in children [26].

Clinical features

History

Those with small fistulas are asymptomatic, but the shunt can be so large that congestive heart failure occurs [60]. Symptoms are rare before 20 years of age [150], but in young adults, atrial fibrillation, fatigue, exertional dyspnea, or ischemic chest pain may appear, and myocardial infarction has been reported [150]. Angina pectoris is rare in children

but present in 80% of these patients >50 years of age [151], due to either coronary atherosclerosis or a coronary steal. About 10% of these patients present with infective endocarditis, even in children [146,152,153].

Physical findings

The cardinal finding is a continuous murmur resembling that of a patent ductus arteriosus but often sounding unusually superficial. The murmur is usually heard best at the mid left or right sternal border, or even the lower sternal border, but may be heard at the upper left sternal border, particularly if the fistula enters the pulmonary artery. The murmur often is louder in mid-diastole than mid-systole when the fistula enters the right ventricle. There may be a thrill, but not if the fistula enters the posterior part of the heart. Continuous murmurs are not heard when the fistula drains into the left ventricle, and fistulas can be silent. Other features include signs of a large left-to-right shunt, congestive heart failure, and occasionally an accentuated pulmonary valve closure.

Electrocardiography

The electrocardiogram is normal with small shunts, shows evidence of chamber enlargement and hypertrophy with large shunts, and occasionally shows evidence of myocardial ischemia.

Radiology

The heart may be normal, or affected chambers are enlarged with increased pulmonary vascular markings due to a large left-to-right shunt. Occasionally, an unusual soft tissue shadow seen on a heart border indicates the tortuous dilated fistula.

Nuclear medicine studies may indicate regional myocardial ischemia, but cannot exclude coronary atheroma as the cause. MRI [154,155] or multidetector CT [156] define these fistulas well.

Echocardiography

Echocardiography with Doppler studies shows the dilated parent artery and the fistula, including its entry into the chamber or vessel. Transesophageal echocardiography has been valuable in large patients [157]. Wall motion abnormalities on exercise indicate myocardial ischemia, but not its cause.

Cardiac catheterization and angiography

Although echocardiography, MRI, and multidetector CT scanning make the diagnosis, cardiac catheterization and angiography are often needed to show fine details of fistula drainage. Because many fistulas are closed by interventional methods, cardiac catheterization is a necessary preliminary procedure.

Treatment

Two comprehensive reviews should be consulted [145,158].

All patients with symptoms probably should have definitive treatment [158], although some older patients with mild angina pectoris have been managed successfully conservatively, with or without with β-blockers. A large fistula, however, should be closed to prevent infective endocarditis, congestive heart failure, myocardial ischemia or infarction, or the occasional rupture. With increasing age, symptoms increase, as do the complications of surgery; the complication rate was 23% >20 years of age and 1.5% for younger patients [151].

Until recently, closure was surgical. The fistula must be ligated near its origin and also near its entrance to the cardiac chamber where there may be multiple entries. Distal ligation alone may be followed by re-establishment of the fistula by collaterals that bypass the site of ligation. Proximal ligation risks ischemia in the territory supplied by normal branches of the fistulous artery. Although surgery can usually be performed without cardiopulmonary bypass, it is often necessary to open the cardiac chamber to find and ligate the points of entry. The risks of surgery are not negligible in older patients: myocardial ischemia or infarction, thrombosis of the parent coronary artery, rupture of the fistula, and ventricular fibrillation have been reported [60]. Surgical mortality, however, is <1% even in older and sicker patients or those with associated cardiac disease.

The long-term results of surgery are excellent, with 95% of the patients being asymptomatic; residual shunts or recanalization are rare, as is death associated directly with the fistula.

Because >90% of these fistulas enter the right side of the circulation, they are candidates for closure by interventional catheterization without risking systemic embolization [159–162]. Devices used include various types of coils and plugs. Occasionally, small or multiple fistulas are closed by microembolization with 300–500 μm diameter poly(vinyl alcohol) foam particles [163] or rapidly solidifying glues (cyanoacrylates) or plastics [164]. In some patients, a covered stent allowed closure of fistulous side branches without compromising flow to the more distal myocardium [165,166].

During the procedure, the operator usually occludes the fistula with a balloon for up to 10 min to make sure that occlusion does not produce ischemia. If it does, then an individual decision to proceed or not must based on the need for closure and the magnitude of the ischemia.

As compared with surgical closure, device closure has a slightly higher incidence of residual shunts, but this incidence is still <10%. Thrombosis of the fistula extending into the normal artery and causing an infarct occasionally occurs. Recanalization after device closure has not been described, but reconstitution of the fistula from small, previously undetected branches can occur. The proximal part of the fistula may remain dilated, especially in older patients.

There is little guidance for treatment of small fistulas in asymptomatic patients. Many of the small coronary to pulmonary artery fistulas cause no symptoms and may not enlarge. These do not have to be closed, but ought to be followed at least annually to determine if they are enlarging. Even if they do not enlarge, there is a risk of infective endocarditis, although this is rare in childhood. It seems reasonable to observe them for several years because some small fistulas may close spontaneously. However, Latson [158] recommended closure of all fistulas that were still clinically apparent after 3–5 years of age.

[3]University Children's Hospital, Tübingen, Germany

Introduction and historical background

Pulmonary arterial sling (PAS) is a congenital anomaly of the left pulmonary artery (LPA), where the LPA arises extrapericardially from the proximal portion of the right pulmonary artery (RPA), passes posteriorly over the right main bronchus, around the right side of the distal trachea, and then courses to the left lung between the distal trachea and the esophagus and anterior to the descending aorta to the left hilus (Figure 49.1). The ductus arteriosus (DA) or the ligamentum arteriosum (lig. art.) passes from the descending aorta along the left side of the trachea to the end of the main pulmonary artery (MPA) at the level of the bifurcation. Hence together the DA or lig. art with the LPA form a sling, compressing the distal trachea and the right or both main stem bronchi.

PAS was first reported 1897 by Glaevecke and Doehle [1]. The first successful operation for this anomaly was published 1954 by Potts *et al.* [2].

Incidence and genetics

PAS is rare. Within the 40 years from 1947 to 1987, only nine patients with PAS were described [3,4]. In the last 20 years, however, nearly 200 patients have been reported. The male-to-female ratio is about 1.5:1 [5,6]. One report of PAS in identical female twins is – as far as we know – the only report of familial occurrence of PAS [7]. Association of 22q11 deletion, trisomy 18 and Mowat–Wilson syndrome have been described in patients with PAS [8–10].

Embryology

The embryologic basis of PAS is unknown, but has been postulated to result from abnormal development of the proximal segments of the left sixth aortic arch [11], leading to the RPA (derived from right sixth aortic arch) vascularizing the undivided primitive lung. With separation of the primitive lung buds, a branch of the RPA passes to the left lung behind the tracheobronchial tree and becomes the LPA. The anterior segment makes no link to the developing vascular plexus of the left lung or else resorbs after the connection [11].

A partial left pulmonary artery sling is rare, with a normal LPA supplying the left upper lobe and an anomalous component arising from the RPA and crossing to the left, behind the airway, supplying the left lower lobe [12]. Airway obstruction also occurs in partial PAS.

Pathologic anatomy and major associated anomalies

The LPA and the ductus ligament form a vascular ring, which compresses the right main bronchus (RMB) and the distal trachea [7,11], leading to tracheomalacia [13–15]. In 30–70% of the patients, complete cartilaginous rings of the trachea can be found [5,13,15–18]; the tracheal cartilage is not "U" shaped with a dorsal pars membranacea, but there is a completely closed ring of the cartilage ("O" shape). As a result, the trachea cannot grow in relation to the child's growth. Increasing airway obstruction and dyspnea result.

Other frequent anatomic findings are the origin of the right pre-eparterial bronchus from the trachea (bronchus suis) or a bridging bronchus (BB), arising from the left main bronchus, crossing the mediastinum to the right, supplying the right middle and lower lobes of the right lung.

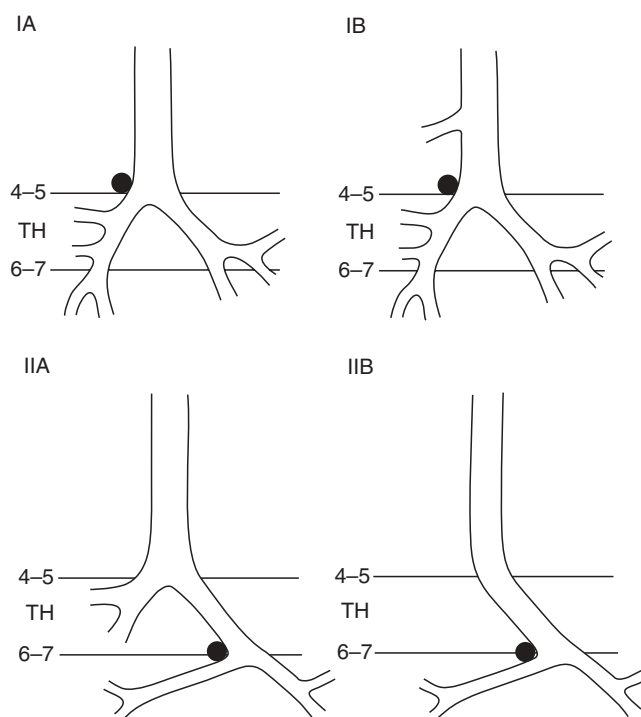
Two forms of PAS are generally distinguished: type IA and B and type IIA and B (Figure 49.2) [18]. In type IA, there is a basically normal bronchial branch pattern and the sling (LPA) passes posteriorly above the RMB and behind the
Figure 49.1 Demonstration of the abnormal course of the LPA between trachea (Tr) and esophagus (Es) in pulmonary arterial sling. Ao, aorta; lig. art., ligamentum arteriosum; LPA, left pulmonary artery; MPA, main pulmonary artery; RPA, right pulmonary artery.


Figure 49.2 Tracheobronchial arborization disorders associated with sling left pulmonary artery (see text). The large black dot indicates the location of the sling relative to the tracheobronchial tree. (Modified from Baden W, Schaefer J, Kumpf M, *et al. Eur Respir J* 2008;**31**: 1125–31, with permission from the European Respiratory Society.)

carina or lower trachea. By imaging techniques the carina projects on vertebral level T4–T5 with normal tracheobronchial angles. Type IB resembles type IA, but there is a bronchus suis, the sling LPA passes to the left between the RMB and

bronchus suis and behind the carina or lower trachea, the carina projecting on T4–T5 as in type I A.

In type IIA and B, a BB has a horizontal course from the LMB to the right middle and lower lobe the origin of the BB from the LMB (pseudocarina) projects on vertebral level T6. In type IIA, there is a right tracheal bronchus (bronchus suis) for the upper lobe, projecting as a true carina on T4–T5. Type IIB resembles type IIA, but the right tracheal bronchus is absent and the right lung may be hypoplastic. The sling LPA passes above the BB and behind the LMB to the left. Patients with PAS type II regularly show tracheal and LMB stenosis and abnormal tracheal and left main bronchial cartilage rings [18].

Associated cardiovascular anomalies

Approximately half of patients have additional congenital heart defects: patent ductus arteriosus, atrial or ventricular septal defect, and persistent left superior vena cava. Rare associations are tetralogy of Fallot, atrioventricular septal defect, coarctation of the aorta, complete transposition, truncus arteriosus, scimitar syndrome, and single ventricle.

Miscellaneous associated non-cardiovascular anomalies

Occasionally, patients with imperforate anus and PAS have been reported, including the triad of imperforate anus, secundum ASD, and persistent left superior vena cava. Absent gall bladder was associated in four patients, one combined with an imperforate anus. Additional less frequent associations are with trisomy 21 and 18, Apert sydrome, Goldenhar syndrome, diaphragmatic hernia, and Hirschsprung's disease.

Pathophysiology

Tracheal and bronchial compression occur as the LPA passes posteriorly and caudally to the RMB and to the left behind the trachea. The course of the anomalous LPA to the right of the trachea deviates the lower trachea to the left, compressing the RMB and lower trachea. This causes airway obstruction that primarily affects the right lung, although compression of the lower trachea and left mainstem bronchus can result in bilateral obstruction. Compression caused by the sling produces obstructive emphysema, atelectasis of the right and left lungs, or both.

Natural history

Because pulmonary artery sling is rare, its natural history remains poorly defined. At least 65% have symptoms within the first year, and 85% by 10 years, but a few asymptomatic adults have been described.

Clinical features

Clinical history

If the trachea is nearly normal and not constricted, patients with PAS can be asymptomatic for a long time. More frequently, the sling is narrow and causes respiratory obstruction soon after birth with expiratory and/or inspiratory stridor and tachypnea leading to emergency intubation. Up to 90% of patients become symptomatic within the first year of life [5] with tachypnea, dyspnea, stridor, apnea, wheezing, and hypoxemic attacks with intermittent cyanosis [17]. Hypoplasia or compression and stenosis of the distal trachea or of RMB and LMB may lead to unequal aeration with obstructive emphysema of parts of the lungs, especially of the right upper lobe [19].

Physical examination

Significant findings on history and physical examination relate either to associated structural heart disease or to respiratory symptoms. In mild forms of PAS, history and physical examination findings are normal. Symptoms and signs of severe respiratory distress or stridor should raise suspicion for this diagnosis. Intercostal retractions may be evident. Prolonged expiratory phase of respiration may be heard.

Electrocardiographic features

There are no specific electrocardiographic features in patients with PAS.

Chest X-ray

The chest X-ray may show an overaeration with hyperexpansion of the right lung in 25–30% of patients and of the left lung in 4%, with displacement of the mediastinum and the distal trachea to the contralateral (mainly the left) side [4,5,16–18]. If displaced to the right side, hypoplasia or aplasia of the right lung has to be considered, as it may be associated with PAS. Dextrocardia with situs solitus also associated with PAS must be considered in the differential diagnosis. Viral or bacterial infections may lead to dystelectasis, atelectasis, or to lobar emphysema in ~28% of patients [20,21]. With more heavily penetrated X-rays taken in the AP projection, narrowing of the distal trachea from the right side and in the lateral view from behind can be seen in 77% of patients.

A horizontal course of the RMB and LMB ("inverted T-sign") and a lower than normal bifurcation on the vertebral level T5–T6 are typical radiographic signs of PAS (type II), but a classification based on the level of the carina is difficult because of different X-ray projections and different air contrast. The position and angles of the carina vary with respiratory cycle, diaphragm level and age.

Barium-filled esophagram

Barium-filled esophagram is the diagnostic procedure of choice and shows an anterior indentation of the esophagus at the level of the bifurcation of the trachea and the fifth dorsal vertebra (Figure 49.3) [20,22]. Anterior esophageal indentation is rare with any other type of vascular ring.

Echocardiography

Echocardiography demonstrates the absence of normal pulmonary artery bifurcation and the anomalous origin of the left pulmonary artery from the proximal right pulmonary artery [4,23,24], if there are satisfactory suprasternal, parasternal, or subcostal windows. Overaeration of the lungs, however, often makes echocardiography difficult. Antenatal detection of PAS has been reported by ultrasound, revealing an echogenic right lung from stenosis of RMB [25].

Cardiac catheterization and angiography

Diagnosis of PAS can usually be established noninvasively. Pulmonary artery angiography can delineate anatomic details prior to surgical correction. Angiography permits diagnosis of variations of the blood supply into the left lung present in some patients. The PAS can be best detected in an anterior–posterior or left-anterior view with cranial angulation.

Other imaging modalities

Assessment of the trachea

Because of the high incidence of tracheal anomalies other than from simple compression by the sling, complete assessment of the trachea should be undertaken. This should include bronchoscopy and at least one other mode of imaging to delineate the severity and extent of tracheal stenosis. This may include computed tomographic scanning or magnetic resonance imaging.

Tracheobronchoscopy is important to exclude associated tracheobronchial anomalies, that is, a complete ring or stenosis of the trachea. In PAS, external dorsal compression of the trachea and compression with pulsations of the right main bronchus (RMB) can be seen. In addition, cartilaginous rings, stenosis of the trachea and the RMB, and abnormal branching of the bronchi can be detected (Figure 49.3). Tracheobronchography with water-soluble contrast is sometimes necessary for long-segment stenosis. Bronchography can produce spectacular imaging of tracheal stenoses but is generally reserved for children who are also undergoing angiography to define vascular anatomy, if unclear from echocardiography alone, or associated cardiac problems.

Multidetector computed tomography (MDCT) allows accurate quantitation of the tracheal luminal diameter and area at various levels and demonstrates complete rings. It is preferred by some centers because of the high quality of the images and short acquisition time, but the radiation dosage is not negligible [26].

With *magnetic resonance imaging* (MRI), the PAS can be diagnosed accurately (Figure 49.4) and noninvasively without radiation exposure [27,28]. MRI is considered the imaging technique of choice to diagnose PAS. However, MRI requires anesthesia, especially in newborns and infants, is expensive, and the acquisition is time consuming.

Differential diagnosis

Other forms of vascular rings, aortic arch anomalies, and respiratory disorders have to be excluded: bronchogenic cysts, lobar emphysema, which can occur even in patients with PAS and with coexisting congenital heart defects [29], and especially foreign body aspiration. Dextrocardia and mesocardia with underdevelopment of the right lung are associated with PAS [4]. Dextrocardia without PAS may also be associated with airway obstruction due to normally related, but deviated, great vessels [30].

Management

Medical

Medical care is only supportive until the patient can undergo operation. Hypoxemia and respiratory distress should be treated with supplemental oxygen and endotracheal intubation if indicated. Pneumonia should be treated with appropriate antibiotics, but respiratory tract infections may be difficult to clear completely before operation because of the difficulty in adequately clearing secretions. Infants without airway obstruction and with minimal symptoms may not require an operation, but this is an exception.

Surgical

Surgery is reserved for children with respiratory symptoms from the sling – the majority of children with PAS. In 1954, Potts and associates described an approach to a PAS through a left thoracotomy with division and translocation of the LPA anterior to the trachea and reimplantation [2]. Frequently, narrowing or occlusion of the LPA has been observed [2,13,31], especially if the LPA was small and hypoplastic or if the anastomosis was under stretch or kinked. The operative mortality has been reported to be as high as 50% [2,13,31,32].

In the early 1980s, repair by reimplantation of the left pulmonary artery was performed through a median sternotomy using cardiopulmonary bypass. None of the previous techniques had dealt directly with the frequently associated tracheal stenosis. Although primary repair of the tracheal anomaly had been suggested previously, it had not been attempted because of fear of early and late tracheal anastomotic problems in the infant. Improved cardiopulmonary bypass techniques, improved sutures, greater familiarity with microvascular techniques, and improved perioperative management strategies [33] have decreased the risk of tracheal anastomosis in infants [34]. Tracheal resection is currently considered an integral part of the repair when the sling is associated with significant localized tracheal stenosis [35–41]. Preoperative studies must identify the details of tracheal compression. Simple compression stenosis of the carinal region may be relieved by translocation of the left pulmonary artery. Localized anatomic stenosis of the trachea (generally associated with complete tracheal rings in this area) is best dealt with by tracheal resection and anterior translocation of the left pulmonary artery. Finally, diffuse and severe narrowing of the trachea related to complete tracheal rings may necessitate an extensive tracheoplasty procedure in addition to relocation of the left pulmonary artery [12,33–39]. Because of associated tracheomalacia, tracheal stenosis, and/or bronchial stenosis, postoperative symptoms of airway obstruction are common, but may resolve

gradually with time. Left pulmonary artery stenosis may occur and can progress.

Long-term history of treated and untreated adults

Surgical survivors may be free of significant symptoms at long-term follow-up. Because many patients demonstrate some degree of persistent airway obstruction, they should be closely observed for both airway and pulmonary artery complications.

50 Abnormalities of Situs

Bruno Marino[1], Paolo Versacci[1], Paolo Guccione[2] & Adriano Carotti[2]

[1]"Sapienza" – University of Rome, Rome, Italy
[2]Bambino Gesù Children's Hospital, Rome, Italy

Introduction

Malposition of the heart is a nonspecific term used to indicate an abnormal position of the heart within or outside the thorax. It gives no specific information about cardiac structure, such as atrial situs, ventricular arrangement, or position of great arteries.

Levocardia indicates a left-sided heart and is the normal position of the heart in individuals with situs solitus; *dextrocardia* indicates a right-sided heart and is the normal position in individuals with situs inversus; *mesocardia* is the midline position of the heart in the thorax. *Ectopia cordis* is the malformation in which the heart is outside the thorax.

Cardiac position is genetically determined and is usually concordant with the ventricular loop; exceptionally, it is discordant.

The embryologic events that result in D-ventricular looping also usually result in levocardia, whereas events producing L-ventricular looping usually result in dextrocardia. When there is concordance between the visceroatrial situs and the position of the heart in the thorax (levocardia in a D-loop and dextrocardia in an L-loop), the pivoting of the ventricle has been complete. On the other hand, the pivoting of the heart is incomplete when discordance between the situs and the position of the heart occurs, resulting in malposition. With atrioventricular discordance, either in situs solitus or in situs inversus, the pivoting of the heart is more often incomplete, resulting in varying cardiac position (levocardia, dextrocardia, mesocardia). The same concept may be applied to patients with asplenia/right isomerism and polysplenia/left isomerism. However, because of ambiguous atrioventricular connections. these conditions preclude designated situs and therefore a concordant or discordant loop. It is not surprising to find a high prevalence of cardiac malposition in situs ambiguus.

The classification of cardiac malposition is difficult, and few discussions have been more controversial than those about the nomenclature of complex cardiac malformations [1–9]. Diagnosis is enhanced by a segmental approach to diagnosis [1,6,8,9] of patients with complex cardiac anomalies and in particular children with malposition of the heart. Because intracardiac anomalies frequently coexist in cardiac malpositions, segmental analysis is essential to understand and describe the cardiac anatomy. Three segments must be considered: (1) atrial situs, (2) ventricular position and connection to the atria, and (3) position of great arteries and connections to the ventricle.

Atrial situs

The first step to understanding the morphology of a heart is determining visceroatrial situs. The left–right orientation of the abdominal organs and of the hearts in vertebrates is a nonrandom and highly conserved phenomenon controlled by several genes [10–23].Visceroatrial situs refers to the relationship between the abdominal viscera and the cardiac atria. The three types of visceroatrial situs are *situs solitus* (normal), *situs inversus* (mirror image of normal), and *situs ambiguus* (similar anatomy of both atria).

Situs solitus

Visceroatrial situs solitus is the usual pattern present and frequently occurs with malformed hearts. In situs solitus, the major lobe of the liver, the inferior vena cava, and the anatomic right atrium are on the right side of the body, as is the trilobed lung and the eparterial bronchus. The stomach, the spleen, the descending aorta, and the anatomic left atrium are on the left side of the body, as is the bilobed lung and hyparterial bronchus.

In individuals with situs solitus, the heart is usually in the left hemithorax. Cardiac malposition in situs solitus includes dextrocardia and mesocardia.

Situs inversus

Situs inversus is the mirror image of situs solitus so that the major lobe of the liver, the inferior vena cava, and the anatomic right atrium are on the left side of the body, as is the trilobed lung and eparterial bronchus. The liver, descending aorta, anatomic left atrium, bilobed lung, and hyparterial bronchus are on the right side of the body.

The heart in situs inversus is in the right hemithorax (dextrocardia), but the cardiac mass may also be "malposed" to the left side.

Situs inversus may be associated with Kartagener syndrome, including bronchiectasis and primary ciliary dyskinesia [10–14].

Situs ambiguus

In any arrangement other than situs solitus or situs inversus, there is random orientation of different organs, a pattern defined as situs ambiguus or heterotaxy and some causative factors have been identified [24–40].

Situs ambiguus consists in all abnormalities of lateralization that show anomalous relationships and unpredictable anatomic relationships between major organs.

Altered left–right asymmetry is accompanied in >90% of instances by severe cardiac malformations and frequently with cardiac malposition, such as mesocardia or dextrocardia.

Other organs, such as the liver, spleen, and intestine, show abnormal morphology and position. In patients with heterotaxy, the genetic message of visceral asymmetry is completely or partially lost and morphologic symmetry of some organs, such as atrial appendages, bronchi, and lungs, is common This aspect prompted some authors to define these conditions as *atrial isomerism* or *isomerism* [33,34] *of the atrial appendages* [36,39,40]. Other investigators [35,37,38,41], although affirming the concept of isomerism as it relates to the heart, believe that it has never been biologically proved, is diagnostically difficult to assess, and is surgically irrelevant. Two forms of situs ambiguus, however, have been defined according to the status of the spleen and the morphology of the atrial appendages, bronchi, and lungs [30–32].

The first subtype of situs ambiguus is the *asplenia syndrome* with *right isomerism* of atrial appendages. In this type of heterotaxy, the spleen is absent (*asplenia*) and the atrial appendages, bronchi, and lungs tend to be mirror images of each other and to show the anatomic features of the right-sided structures (*right isomerism*) [33–40].

The second subtype of situs ambiguus is the *polysplenia syndrome* with *left isomerism* of atrial appendages. In this type of heterotaxy, two or more splenic masses (*polysplenia*) are present along the great curvature of the stomach on the right or the left side of the abdomen. The atrial appendages, bronchi, and lungs tend to be mirror images of each other and to show the anatomy of the left-sided structures (*left isomerism*) [30–35]. In these patients, there may be levocardia, dextrocardia, or mesocardia [42].

Genetics of situs ambiguus

The genetics of cardiac malformations and human situs abnormalities are a complex issue characterized by heterogeneity, gene–environment interaction, variable expression, and reduced penetrance [10–14]. Studies, including familial clustering, detailed descriptions of large series of patients and phenotype/genotype correlations, have improved our knowledge.

Human heterotaxy is usually sporadic, but many families have been described with horizontal recurrence (affected siblings born to unaffected parents), frequent twinning, and spontaneous abortion [10–14]. Consanguineous parents are not rare. This recurrence pattern is consistent with a maternal effect in a significant proportion of patients [28].

Situs ambiguus can be associated with a large number of genetic syndromes, including VACTERL, Alagille, Cantrell, Smith–Lemli–Opitz, oral–facial–digital, Ellis–van Creveld, Bardet–Biedl, Goldenhar, and del22q11.2 [10–15]. In addition, partial or complete trisomies and monosomies, balanced and unbalanced translocations, deletions, and inversions have all been described and show a possible location of genes involved in laterality development [10–14]. Situs ambiguus has also been associated with environmental exposures, such as retinoic acid, maternal diabetes, and first trimester cocaine use [13–26].

Studies of animal models, such as zebrafish, frog, chick, mouse, and shell, have increased our understanding the genetic mechanisms of left–right axis determination [10–25,28].

At present more than 80 genes involved in laterality defects have been detected in model organisms. Many of these genes have a conserved function in humans but relatively few mutations of these genes have been identified in children with situs ambiguus. These include NODAL [16], ZIC3 [20], LEFTYA [21], Criptic [22], ACVR2B [23], CRELD1 [24], and NKX2.5 [25].

The signaling cascade producing left–right asymmetry in humans remains unclear, but an early role of the Sonic Hedgehog gene has been established. Moreover, the NODAL gene encoding a TGFβ family transcription factor induces other genes as LEFTY1, LEFTY2, and PITX2 that are also expressed asymmetrically at the left side of Hensen's node [10–14]. At the level of the node, an asymmetric leftward flow of extraembryonic liquid caused by clockwise rotation of the cilia is involved in the early establishment of left–right asymmetry [10–14]. Mice with situs inversus consistently express NODAL gene in the right side of the node, the opposite side from normal.

Some mutations of genes involved in left–right asymmetry have been identified also in patients with situs solitus

and an isolated cardiac anomaly, such as transposition of great arteries [16,17]. Moreover, recent studies on familial recurrence [18], experimental teratology [19], and genetic mutations [16,17] suggest that isolated transposition of great arteries can be considered a laterality defect consisting only in an abnormality of spiralization of infundibula and great arteries. Nodal signaling, involved in left–right asymmetry and spiralization of great arteries in vertebrates [16], is a conserved gene causing also the normal and abnormal chirality of snail shells [27]. Therefore, these phenotypic and genetic similarities between spiralization of great arteries in vertebrates [16] and spiral pattern of snail shell [27] expand the phylogenetic development horizon of the human heart [28].

Along with the categorization of visceroatrial situs, cardiac malpositions can be classed in three types: with situs solitus, with situs inversus, and with situs ambiguus and heterotaxy.

Cardiac malposition with situs solitus

Dextrocardia

Dextrocardia is the most common type of malposition. Initially described by Fabricius in 1749 [43], dextrocardia simply means that the heart is predominantly in the right hemithorax. The incidence of dextrocardia is one in 12 000 births with a similar number of patients with situs solitus, situs inversus, and situs ambiguus [44]. Numerous classifications of dextrocardia have been proposed. Terms such as mirror-image dextrocardia, false dextrocardia, primary or secondary dextrocardia, dextroversion, and dextrorotation represent attempts to describe and categorize this condition [45,46]. In this chapter, we distinguish dextrocardia and dextroversion. Dextrocardia is the location of the heart in the right thorax with the apex pointing to the right (Figure 50.1), and it is usually due to anomalous pivoting of the ventricles [7]. Dextroversion is the location of the heart in the right thorax with the apex normally pointed towards the patient's left; it occurs in congenital or acquired lesions, such as diaphragmatic hernia or right lung hypoplasia, that push the heart to the right (Figure 50.2).

Dextrocardia with situs solitus

This is the most common type of dextrocardia in reported pathologic series. In dextrocardia but also in mesocardia, the incomplete pivoting of the ventricular septum determines a progressively narrower angle between the atrial and ventricular septa.

Dextrocardia with D-ventricular loop and normally related great arteries {S,D,S}

This is the second most frequent type of cardiac condition in dextrocardia; corrected transposition in situs solitus {S,L,L} is
Figure 50.1 Dextrocardia, thoracic radiograph in posteroanterior projection. The heart is displaced in the right hemithorax with the apex towards the patient's right.

Figure 50.2 Dextroversion of the heart, thoracic radiograph in posteroanterior projection. The major part of the heart is displaced in the right hemithorax because of the enormous dilatation of the right atrium (Ebstein malformation). The apex of the heart is pointed towards the patient's left.

the most common. Several cardiac malformations have been described, in particular septal defects [3,47].

Dextrocardia with normal atrioventricular and ventriculoarterial relations {S,D,S} may be part of a syndrome usually with midline defects, as described by Cantrell *et al.* [48]. Five components are present: (1) midline epigastric abdominal
Figure 50.3 Dextroversion of the heart, scimitar syndrome. (a) Thoracic radiograph, heart in right hemithorax. The right hemithorax is smaller than the left because of the right lung hypoplasia. The right hemidiaphragm is elevated. (b) Pulmonary arteriogram shows hypoplastic vasculature in the right lung.

wall defect, often associated with herniation or omphalocele; (2) defect of the lower sternum; (3) deficiency of the anterior diaphragm; (4) defect of the diaphragmatic portion of the pericardium; and (5) diverticulum of the left or right ventricle with possible intracardiac thrombus [49]. A cardiac malformation often coexists, most frequently tetralogy of Fallot or ventricular septal defect. Although the presentation of Cantrell syndrome varies, one-stage repair of the cardiac defect is usually feasible [50].

Dextroversion of the heart

The malposition of a heart with atrioventricular and ventriculoarterial concordance {S,D,S} in the right thorax with the apex normally pointed towards the patient's left is defined as *dextroversion* (Figure 50.2). This mimic of dextrocardia is generally from a variety of anatomic or functional abnormalities of the lung, diaphragm, or thoracic cage.

These include right lung hypoplasia and dextroversion of the heart [51], usually associated with congenital lesions such as renal abnormalities (oligohydramnios), right bronchial tree abnormalities, deformity of the thoracic spine and rib cage, and left-sided diaphragmatic hernia. Diaphragmatic hernia is the most common cause of congenital dextroversion [51]. Hypoplastic left heart syndrome is commonly observed in fetuses with left diaphragmatic hernia. Fetal echocardiographic studies have shown that preferential streaming of the ductus venosus and inferior caval vein towards the right heart is associated with left heart underdevelopment with left-sided diaphragmatic hernia [51a]. This abnormal flow results from intrathoracic abdominal organ herniation and rightward displacement of the heart.

Acquired lesions resulting in dextroversion are left pneumothorax and pericardial or mediastinal tumor. *Scimitar syndrome* is one well-described anomaly [52] associated with dextroversion. It combines hypoplasia of the right lung, right pulmonary artery, and right bronchus; partial anomalous connection of the right pulmonary veins to the inferior vena cava; and anomalous arterial vessels arising from the descending aorta and directed to the right lung, often associated with bronchopulmonary sequestration (Figures 50.3 and 50.4).

Dextrocardia with D-ventricular loop and transposition of the great arteries {S,D,D}

Transposition of great arteries occurs frequently in dextrocardia (Figure 50.5). Complex forms of transposition of great arteries are more common in dextrocardia than in levocardia, with 75% having a ventricular septal defect and 75% left atrial appendage juxtaposition [47]. Dextrocardia is twice as common in transposition of great arteries with left atrial juxtaposition than in simple transposition of great arteries [53]. Dextrocardia in situs solitus reduces the size of the atrial free wall and may cause difficulties at surgery in creating an atrial baffle [54].

Dextrocardia with D-ventricular loop and L-malposition of the aorta {S,D,L}

Dextrocardia is frequent in this group of rare cardiac malformations that include double-outlet right ventricle with L-aorta and subaortic ventricular septal defect, anatomically corrected malposition of the great arteries, and double-outlet left ventricle.

Figure 50.5 Left ventricular angiogram in a patient with dextrocardia and {S,D,D} and transposition of the great arteries. The pulmonary artery (P) originates from the left ventricle (LV).

A peculiar form of dextrocardia with {S,D,L} arrangement is represented by the crisscross heart [55]. In these patients, the right-sided right atrium is connected to the left-sided right ventricle, and the left-sided left atrium is connected to the right-sided left ventricle, so that the pathways of blood flowing through the atrioventricular valves cross each other. The great arteries are transposed, or both arise from the right ventricle with the aorta anterior and left-sided. In crisscross heart, the tricuspid valve and the right ventricle are always anterior and usually hypoplastic. The right ventricle frequently is superior so that crisscross heart and upstairs–downstairs ventricle (superoinferior ventricle) coexist [55] (Figure 50.6).

Dextrocardia with L-ventricular loop and transposition of the great arteries or double-outlet right ventricle {S,L,L}

This is characterized by discordant atrioventricular connection (L-ventricular loop) and discordant ventriculoarterial connection with anterior and left-sided aorta (L-aorta) (Figure 50.7). Thus, the anatomic features are those of congenitally corrected transposition. In double-outlet right ventricle with L-loop of the ventricles (atrioventricular discordance), both great arteries arise from the left-sided morphologic right ventricle. About 40% of patients with corrected transposition in situs solitus have dextrocardia [7,47]. Frequently, associated anomalies are found (Figure 50.8).

Corrected transposition of great arteries can be included in the group of cardiac defects due to anomalies of lateralization [18,56].

(a) (b)
Figure 50.6 Two-dimensional echocardiography in an {S,D,L} crisscross heart. (a) The right atrium (RA) is connected (arrowhead) with the left-sided right ventricle (RV), which is anterosuperior and gives rise to the aorta (A). Note the horizontal position of the interventricular septum and the superoinferior position of the ventricles. The right ventricle is hypoplastic. (b) In a more posterior plane with respect to (a), the left atrium (LA) is connected (arrowhead) with the right-sided left ventricle (LV). Note the inferior position of the left ventricle compared with the right ventricle. Dextrocardia with L-ventricular loop and inverted related great arteries {S,L,I}

In hearts with situs solitus, atrioventricular discordance and ventriculoarterial concordance, and inverted related great arteries, dextrocardia is common [47]. This rare anomaly is associated with conotruncal anomalies, often tetralogy of Fallot. Atresia of the right superior vena cava with left superior vena cava connecting to the coronary sinus has been reported [57].

Cardiac malposition with situs inversus

Situs inversus with atrioventricular concordance (L-ventricular loop) shows dextrocardia as a frequent feature (Figure 50.9). An L-ventricular loop, "normal" in situs inversus, pivots the heart into the right hemithorax. In situs inversus and dextrocardia, there is alignment between the atrial and the ventricular septa, as in situs solitus and D-ventricular loop. Consequently, malposition of the heart in situs inversus should be defined as in patients with L-ventricular loop and levocardia.
Figure 50.8 Left ventricular angiogram in a patient with {S,L,L} and double-outlet right ventricle (RV). The angiogram shows dextrocardia, situs solitus [the catheter is on the right side of the spine and the aorta (A) on the left], atrioventricular discordance [the morphologic left ventricle (LV) is on the right], and double outlet from the left-sided morphologic right ventricle.
Figure 50.9 Posteroanterior chest radiograph in a patient with dextrocardia and atrial and visceral situs inversus. The liver shadow is in the left upper quadrant of the abdomen and the stomach bubble is on the right. The apex of the heart is pointed towards the patient's right.
Figure 50.10 Angiogram in a patient with situs inversus and levocardia (so-called isolated levocardia). The angiogram demonstrates the innominate vein (IV) and the superior vena cava (SVC) (both on the left) connecting with the left-sided morphologic right atrium (RA). The coronary sinus (arrow) drains into the right atrium.

The expected position of a normal heart in situs inversus, that is, L-ventricular and inverted normal related great arteries (also called mirror-image dextrocardia), is in the right thorax. In contrast, situs inversus and levocardia (Figure 50.10), also called isolated levocardia, is almost always associated with cardiac defect. In publications on malposition of the heart in situs inversus, descriptions of the different positions of the heart in the thorax and the patterns of associated defects are usually included [45,46]. Therefore, we have included these conditions, for example, the normal dextrocardiac heart in situs inversus, although in fact they are not truly malpositions.

Dextrocardia

Dextrocardia with L-ventricular loop and inverted related great arteries {I,L,I}

This represents the normal heart in situs inversus. It is characterized by situs inversus (I), L-ventricular loop (L), and inverted, normally related great arteries (I). Because it might escape clinical detection when there are no associated malformations, its incidence is unknown. The commonly associated anomalies are ventricular septal defect, atrial septal defect, tetralogy of Fallot, double-outlet right ventricle, and pulmonary atresia with intact ventricular septum.

Kartagener syndrome

Kartagener first described a group of children and adults with situs inversus, chronic sinusitis, and airway disease [58]. This triad of symptoms with familial occurrence, known as Kartagener syndrome, appears to be due to ciliary dyskinesia and bronchiectasia [59,60]. Clinical studies indicate

that infertility was present in males as a result of sperm tail motility disorders [59]. Ciliary action is important in the embryogenesis, probably being one of the determinants of the situs [10,14]. Abnormal ciliary motility has been found in some patients with left isomerism [61].

Dextrocardia with L-ventricular loop and transposition of the great arteries {I,L,L}

In situs inversus, this is homologous with complete transposition of situs solitus {S,D,D}. Associated cardiac anomalies are frequent and include ventricular septal defect, hypoplastic left ventricle, and pulmonary stenosis with intact ventricular septum.

Dextrocardia with D-ventricular loop and transposition of the great arteries {I,D,D}

In situs inversus, this is homologous with corrected transposition in situs solitus {S,L,L} and occurs in 5–8% of patients with corrected transposition [62,63]. The segmental description of this anomaly is {I,D,D} and consists of situs inversus (I), atrioventricular discordance (ventricular D-loop), and ventriculoarterial discordance (D-transposition of the great arteries). The combination of atrioventricular and ventriculoarterial discordance allows a normal circulation. In 70% of patients, the heart is in the right thorax; in the remaining 30%, the heart is either mesocardia or levocardia. Associated anomalies are ventricular septal defect (60–100%) [62–66] and subvalvar and valvar pulmonary stenosis or pulmonary atresia (70–100%) [62–66]. Spontaneous or postoperative atrioventricular block appears less common than in patients with corrected transposition in situs solitus [65], perhaps from the more usual location of the conduction tissue [66].

Diagnostic features of malposition of the heart in situs solitus and inversus

On physical examination, the right and left hemithoraces should show symmetric excursion regardless of cardiac location. Reduced excursion of the right hemithorax may be evident in patients with dextroversion from right lung hypoplasia, as in scimitar syndrome, or in patients with diaphragmatic hernia; in these, on percussion, reduced movement of the right hemidiaphragm is noted.

The thoracic radiograph shows the position of the heart in the thorax and abdominal situs. The apex of the heart points downwards and to the left in the normal heart of levocardia, and downwards and to the right in dextrocardia (Figures 50.1, 50.2, and 50.9). In dextroversion, the heart is in the right hemithorax but the apex points towards the left, for example, left pneumothorax or diaphragmatic hernia. The situs can usually be determined by the position of the abdominal viscera. With few exceptions, the anatomic right atrium is almost always on the same side as the main liver

mass. An important radiologic guide to abdominal visceral situs is the gastric air bubble. The thoracic situs corresponds closely to atrial situs and may be determined by bronchial morphology, often evident on the standard or overpenetrated chest radiograph.

The electrocardiogram often allows determination of the situs and the position of the heart in the thorax. The P wave representing atrial activation is initiated from the SA node high in the right atrium. Hence, in situs solitus, the mean P wave vector in the frontal plane is ~+60, whereas in situs inversus it is +120, because the sinus node in the anatomic atrium is on the patient's left. The P wave on the horizontal plane proceeds posteroanteriorly in both types of situs but is towards the left (solitus) or right (inversus).

Using a segmental approach, echocardiography is the best tool for recognizing the cardiac situs and cardiac anatomy. The abdominal aorta and the inferior vena caval relationship, cardiac chamber morphology, their orientation in space, and their connections are easily recognizable by echocardiography, allowing a precise identification of the situs, atria, ventricular loop, and great artery relationship (see Chapter 8).

Magnetic resonance imaging (MRI) can improve the diagnostic accuracy for vascular and extracardiac structures in children and adolescents.

Cardiac catheterization and angiocardiography can be indicated in the preoperative physiologic assessment and in the evaluation of some anatomic details, such as the anatomy of the branch pulmonary arteries, the coronary artery circulation, or the venae cavae.

Surgical treatment of malposition of the heart in situs solitus and situs inversus

A variety of cardiac lesions can coexist in association with malpositioned hearts. The hearts can be divided into those amenable to univentricular palliation and those treatable with biventricular repair. Among the former are single ventricle or severely unbalanced ventricles, and apicocaval juxtaposition (dextrocardia with situs solitus or levocardia with situs inversus), which would be treated with a cava-to-pulmonary artery connection [67,68]. Among those suitable for biventricular repair are balanced biventricular hearts with atrioventricular and ventriculoarterial concordance or with either ventriculoarterial or double (atrioventricular and ventriculoarterial) discordance.

Coexisting atrioventricular and ventriculoarterial concordance is usually associated with a D-ventricular loop and associated anomalies that are amenable to total repair.

For anomalies of ventriculoarterial connection associated with ventricular septal defect and balanced ventricles with an intraventricular repair [69,70], a Rastelli-type [71] or a REV

procedure [72], or an arterial switch procedure (with the construction of a left ventricle-to-pulmonary orifice tunnel) [69,70], can be performed (see Chapters 42 and 44).

With combined atrioventricular and ventriculoarterial discordance and balanced ventricles, double-switch procedures can provide anatomic repair. Double discordance with left ventricular outflow tract obstruction (pulmonary or subpulmonary stenosis) can be treated by combined Senning/Mustard and Rastelli procedures [73,74], whereas patients with unrestricted pulmonary blood flow are best treated by combined atrial and arterial switch [75–77]. Double-switch procedures are usually feasible regardless of the cardiac malposition or atrial situs. Double-switch procedures in patients with situs inversus are more advantageous because of the D-loop arrangement of double discordance and have a lower incidence of atrioventricular conduction disturbances compared with an L-loop arrangement of this cardiac malformation in situs solitus [74].

Isolated ventriculoarterial or, sporadically, atrioventricular discordance can occur in malpositioned hearts. Arterial switch and atrial switch are the procedures of choice.

Biventricular repair has been suggested for crisscross heart [78], which is often associated with dextrocardia. A right ventricular volume >45% of normal and absence of straddling atrioventricular valves are the main requirements for a biventricular repair [79], although a one-and-a-half ventricular repair has been used in those with right ventricular hypoplasia [80].

Cardiac malposition with situs ambiguus

Heterotaxy remains an intriguing condition. The prevalence of these syndromes associated with heterotaxia is estimated to be 1–1.5 in 10 000 live births and accounts for ~3% of cardiac malformations [81–83] and for 30% of patients dying with cardiac malposition [84]. Asplenia/right isomerism is more common in males, whereas polysplenia/left isomerism has an equal gender preponderance [30]. These syndromes are usually sporadic, although several familial occurrences [10–14], in particular in children born of consanguineous parents, have been described [81–85]. Occasionally in the same family heterogeneous laterality defects including situs inversus, asplenia, and polysplenia are found [10–14,85].

Cardiac morphology

Extracardiac and cardiac anomalies are common to both asplenia/right isomerism and polysplenia/left isomerism syndromes, but there are also specific differences between them in the prevalence, anatomic types, and severity of cardiac malformations [86]:

1 The *abdominal organs* are abnormal in shape and position. The liver tends to be symmetric and to occupy a transverse position across the upper abdomen with both lobes showing a "right-like" shape [86,87]. The gallbladder may be absent or hypoplastic. Malrotation of the bowel and of the midgut loop is present [33] and may cause intestinal obstruction [30]. Adrenal and genitourinary tract anomalies have been described [32]. Extrahepatic biliary atresia leading to obstructive jaundice [88] has been found in polysplenia/left isomerism. The spleen is absent in asplenia/right isomerism and multiple in polysplenia/left isomerism, but its characteristics may be discordant with the type of isomerism of the atrial appendages [33,34]. Among extracardiac anomalies, midline defects are particularly frequent (about 40%) [89], and primary ciliary dyskinesia may be present [60].

2 The *thoracic organs* tend to be symmetric [30–33]. In patients with asplenia/right isomerism, the lungs are trilobed and have bilateral eparterial bronchi with the pulmonary artery coursing anterior to the main stem bronchus [32]. In patients with polysplenia/left isomerism, there are bilateral bilobed lungs and hyparterial bronchi; the pulmonary artery courses over and behind the main stem bronchus [30]. Pulmonary arteriovenous fistulas occur in patients with polysplenia/left isomerism [90]. In ~40% of children with asplenia/right isomerism and with polysplenia/left isomerism, cardiac malposition including mesocardia and dextrocardia is present.

3 *Systemic venous connections* are frequently anomalous [30,32,91,92]. In more than half of patients with heterotaxy, bilateral superior venae cavae connect to the respective atria and the innominate vein is absent. If a single superior vena cava is present, it is usually opposite to the cardiac apex. In most patients, the coronary sinus is absent. In patients with asplenia/right isomerism, the inferior vena cava and the abdominal aorta are ipsilateral and lie together on the right or left side of the spine (Figure 50.11). The inferior vena cava connects with the right or left side of the atria. In a few of these patients, the hepatic veins connect separately from the inferior vena cava (Figure 50.12). Interrupted inferior vena cava is extremely rare in patients with asplenia/right isomerism [38,93], but is present in >70% of patients with polysplenia/left isomerism. It connects into the azygos vein and terminates in either the left or right superior vena cava. The hepatic veins connect directly to the left or right side of the floor of the atria. Uncommonly, a small inferior vena cava persists on one side of the abdomen connecting to the atria, and an enlarged azygos vein connects to the superior vena cava on the opposite side. In other patients, the inferior vena cava ascends on one side of the abdomen and crosses to the opposite side at the level of the diaphragm to enter the azygos vein.

4 *Pulmonary venous connections* are often anomalous [29–32,38,40,91–94]. Over 80% of patients with asplenia/right isomerism have total anomalous pulmonary venous
Figure 50.11 Two-dimensional echocardiography in abdominal short-axis view in a patient with asplenia/right isomerism. Note the ipsilateral position of the aorta (A) and the inferior vena cava (IVC) lying together on the right side of the spine (S). The liver (L) presents a symmetric transverse position. L, liver. (Reproduced with permission from Marino and Thieme, *Anatomia Ecocardiografia delle Cardiopatie Congenite*, USES Edizione Scientifiche, Florence, 1990, p. 48.)

connection (TAPVC) and in nearly half of these it is obstructed. TAPVC may be to either a supracardiac or an infradiaphragmatic location [38–40]. Significant hypoplasia of the pulmonary veins may coexist [95]. In polysplenia/left isomerism, the pulmonary veins connect to the atria, and TAPVC is rare. In 40% of these patients, the pulmonary

veins from each lung enter the posterior wall of the atria separately on opposite sides of midline, simulating a partial anomalous pulmonary venous connection [94].

5 *Anomalies at atrial level* and of the atrioventricular valves are frequent [29–32,38,40,91–94,96]. A common atrium with virtually absent atrial septum and bilateral sinus nodes are present in asplenia/right isomerism. The coronary sinus is usually absent. A narrow band, a remnant of the atrial septum, passes in an anteroposterior direction and crosses the midportion of the atria (Figure 50.13). Each atrial appendage shows a broad-based pyramidal morphology with pectinate muscles extending bilaterally round the atrioventricular junctions (right isomerism). In asplenia/right isomerism, the complete form of atrioventricular canal is the rule, with a common atrioventricular valve and left ventricular dominance. The morphology of the common atrioventricular valve differs from complete atrioventricular canal with situs solitus in showing a rudimentary common atrioventricular valve and reduced number of leaflets and papillary muscles which are short and hypoplastic [97]. Moreover, the inlet ventricular septum frequently shows severe hypoplasia, the ventricular septal defect is very large, and the atrioventricular canal is type C of Rastelli's classification [97]. Common atrium is also present in polysplenia/left isomerism (Figure 50.14), but the more frequent pattern is a large ostium primum atrial septal defect, a partial atrioventricular canal, and a cleft mitral valve. The septum primum is frequently displaced either leftwards or rightwards, depending on whether there is levocardia or dextrocardia, respectively. This displacement is responsible for the apparent partial anomalous
Figure 50.14 Two-dimensional echocardigraphy in subcostal four-chamber view in a patient with polysplenia/left isomerism shows common atrium (CA) with biventricular heart, D-loop of the ventricles, and intact ventricular separation. pulmonary venous connection [30,94]. Each atrial appendage is long and narrow, showing the features of a left appendage (left isomerism). This atrial anatomy is similar to that observed in patients with Ellis–van Creveld syndrome [98] and with other postaxial polydactyly syndromes [99].

6 *Anomalies at ventricular level* are also frequent [29–32, 38,40,91–94,100,101]. An L-loop of the ventricles occurs in ~40% of patients with both syndromes. A single ventricle of right ventricular type from malalignment of the atrioventricular canal with a hypoplastic left ventricle is the more frequent pattern, but single left ventricle and biventricular heart are also found. Ventricular septal defect in the setting of complete atrioventricular canal is constant in these children. In contrast, in polysplenia/left isomerism, a single ventricle is less frequent and the biventricular heart (with D- or L-loop ventricle) is common with intact ventricular septum in 20–30%.

7 *Conotruncal defects* and anomalies of the great arteries are usual [29–32,38,40,91–94,100–104]. The classic conotruncal pattern in asplenia/right isomerism occurring in most patients is double-outlet right ventricle with an anterior aorta associated with pulmonary stenosis or atresia, and hypoplasia of the infundibular septum. Transposition of great arteries is also present. Usually there is a bilateral muscular subarterial conus. With pulmonary atresia, the pulmonary arteries are usually confluent with ductus-dependent pulmonary circulation. In those with nonconfluent pulmonary arteries and bilateral ductus arteriosus (Figure 50.15), major aortopulmonary collateral arteries may be present [105]. A correlation between atresia of the

pulmonary valve and obstruction of the pulmonary venous connection [38,93,100,104] may explain the small size of the pulmonary veins [95]. Ventriculoarterial concordance with normally related great arteries is extremely rare [96]. Right-sided aortic arch with mirror-image branching of the brachiocephalic trunk may be present. In contrast, over 70% of children with polysplenia/left isomerism have concordant ventriculoarterial connection [92,101,106]. The great arteries are normally related in patients with D-loop ventricles, or inversely normally related (mirror image) with L-loop ventricles [101,106]. Double-outlet ventricle may be present with infundibular morphology of tetralogy of Fallot, whereas transposition of great arteries is rare. Obstruction of the pulmonary blood flow is present in ~30%, one-third with pulmonary atresia. Left-sided obstructions including mitral stenosis, hypoplastic left ventricle, aortic stenosis, and aortic coarctation are present in 25% of patients.

In summary, in patients with *asplenia/right isomerism*, the cardiac malformations are complex. The classic anatomy includes transverse liver; bilateral trilobed lungs and eparterial bronchi; levocardia, mesocardia or dextrocardia, bilateral superior venae cavae with absent coronary sinus, inferior vena cava coursing with the abdominal aorta on the same side of the spine connecting to the atria, extracardiac TAPVC (frequently obstructed), common atrium, right bilateral morphology of the atrial appendages, complete atrioventricular canal malaligned to a dominant right ventricle, D- or L-loop ventricle, transposition or double-outlet right ventricle with anterior aorta, and pulmonary stenosis or atresia (Figure 50.16).

In patients with *polysplenia/left isomerism*, the pattern of cardiac anomalies is less rudimentary, and they are less complex. The usual morphology includes transverse liver;

bilateral bilobed lungs and hyparterial bronchi, levocardia, mesocardia, or dextrocardia, bilateral superior venae cavae, interruption of inferior vena cava with azygos continuation (Figure 50.17), pulmonary veins draining into the right and left posterior sides of the atria, common atrium or large ostium primum atrial septal defect, left bilateral morphology of the atrial appendages, partial atrioventricular canal, D- or L-loop ventricles with balanced or unbalanced ventricular masses, concordant ventriculoarterial connection, ventricular septal defect (frequent), pulmonary stenosis (possible), and systemic outflow tract obstruction (possible). Some crossover exists, however, with individuals presenting anatomic patterns of asplenia/right isomerism in the presence of polysplenia/left isomerism, and vice versa. Moreover, the heart may be completely normal in patients with polysplenia/left isomerism. An interesting subgroup of patients shows a hypoplastic or rudimentary spleen with many of the features of asplenia/right isomerism but sometimes presenting systemic obstruction [42].

Clinical features and diagnostic approach

Asplenia/right isomerism
The most frequent presentation is of a male neonate with intense cyanosis, respiratory distress, and systolic murmur or no murmur. A right-sided apical impulse, the heart sounds and murmur heard better over the right hemithorax, and the transverse lower hepatic margin are characteristic.

The electrocardiogram is generally abnormal. The P wave axis is directed inferiorly and to the right (90–105°) in patients with levocardia and to the left (75–90°) in those
Figure 50.18 Chest radiograph in a patient with asplenia/right isomerism shows symmetric liver, dextrocardia, and reduced pulmonary blood flow.

Figure 50.19 Chest radiograph in a patient with asplenia/right isomerism shows symmetric liver and mesocardia.

with dextrocardia [107]. The frontal plane QRS axis is usually directed superiorly because of atrioventricular canal.

Clues to the diagnosis of asplenia/right isomerism are often present on the thoracic radiograph, which shows cardiac malposition frequently with mesocardia or dextrocardia and with the cardiac apex discordant with the position of the liver and the stomach. The lower hepatic margin lies horizontally across the upper abdomen. Cardiac size is normal. Pulmonary vascular markings are diminished from pulmonary stenosis or atresia (Figure 50.18) or show pulmonary edema from TAPVC obstruction (Figure 50.19). With tomography or high-kilovoltage radiographs, the bilateral eparterial bronchi may be visualized [108,109].

The diagnosis of asplenia syndrome and of the associated cardiac malformation can be established by two-dimensional echocardiography with color Doppler using the segmental approach [110–114]. With a short-axis subcostal view, the abdominal aorta and the inferior vena cava can be visualized on the same side of the spine (Figure 50.12); with a long-axis abdominal view with color Doppler, the infracardiac TAPVC can be imaged [115]. Furthermore, two-dimensional echocardiography cannot detect a spleen [116]. Isomerism of the atrial appendages is difficult to diagnose by echocardiography. Common atrium, complete atrioventricular canal [113], and single ventricle [112] are well imaged with echocardiography (Figure 50.13), and other details of intracardiac anatomy, including the conotruncal morphology, can be defined. Cardiac malposition (dextrocardia or mesocardia)

or horizontal liver on the chest radiograph (heterotaxy) and the echocardiographic recognition of common atrium, complete atrioventricular canal, single ventricle with anterior aorta, and pulmonary stenosis or atresia are the most precise diagnostic signs of asplenia/right isomerism.

Cine magnetic resonance imaging has improved morphologic diagnosis [117–119]. Because of anatomic complexity and the need for hemodynamic data, particularly of pulmonary vascular resistance, preoperative evaluation by cardiac catheterization and angiocardiography is still indicated in many children [93]. Angiocardiography is particularly useful to delineate the anatomy of pulmonary arteries and the pulmonary blood supply in patients with pulmonary atresia [102,104,120]. Moreover, angiocardiography reveals the site of pulmonary venous connection and the presence of pulmonary venous obstruction, although it might be masked by the pulmonary stenosis or atresia (Figure 50.20). Furthermore, angiocardiography in association with color Doppler echocardiography can quantify the degree of atrioventricular valve regurgitation that in neonates, but in particular in older children, can deeply influence the natural history [121–123].

Polysplenia/left isomerism

The clinical manifestations vary and usually appear later compared with asplenia/right isomerism because the pulmonary obstruction is less severe and the pulmonary veins are
Figure 50.20 Heterotaxy syndrome, right isomerism, pulmonary atresia, ductus arteriosus, confluent pulmonary arteries and mixed pulmonary vein connection. Aortography in the frontal plane. (a) Right aortic arch. Opacification of the ductus arteriosus (white arrow) and of the right and pulmonary arteries. (b) Left pulmonary veins (white circles), right inferior pulmonary vein (solid white arrow) drain in a collector to the superior vena cava (VCS). Right superior pulmonary vein (dashed white arrow) drains separately in the superior vena cava.

Thoracic radiographs may suggest this syndrome, showing dextrocardia or mesocardia with discordance between the position of the heart and the liver and the stomach. Moreover, the absence of an inferior vena caval shadow on the lateral view and an enlarged azygos vein suggests polysplenia/left isomerism [127]. A high-kilovoltage chest radiograph may show a symmetric bronchial branching pattern characteristic of left pulmonary isomerism [108,109].

Echocardiography is the best tool for the noninvasive diagnosis of intracardiac malformations. Interruption of the inferior vena cava with azygos continuation and the pattern of pulmonary venous connection can be identified [110,111], as can malformations of atria, ventricles, and great arteries [101].

A cardiac malposition (dextrocardia or mesocardia) or horizontal liver on the chest radiograph and the echocardiographic recognition of azygos continuation, partial atrioventricular canal, biventricular heart or single ventricle, and normally aligned great arteries (concordant ventriculoarterial connections) are the best diagnostic signs of polysplenia/left isomerism.

Fetal echocardiography can reliably detect heterotaxy [128,129], but prenatal diagnosis seems not to improve neonatal survival [130]. During prenatal life, polysplenia/left isomerism is diagnosed more frequently but also spontaneous abortion occurs more frequently in fetuses with asplenia/right isomerism, probably due to the fetal heart block [129]. The spectrum of fetal cardiac defects in polysplenia/left isomerism seems more complex than found postnatally [131]. Moreover, echocardiography can identify the presence of multiple spleens [116].

Cardiac catheterization and angiocardiography are often required for definitive preoperative anatomic and functional assessment. Interruption of the inferior vena cava often requires a percutaneous approach from the neck to reach the heart directly and avoid the catheter loop in the azygos vein and superior vena cava [132]. A lateral view of a pulmonary arteriogram can demonstrate the superimposed branches of the pulmonary arteries arching posteriorly from the pulmonary trunk, because each has the characteristics of a left pulmonary artery [133].

Natural history

Asplenia/right isomerism

The natural history of asplenia/right isomerism is extremely poor [86], and death occurs in more than one-third of untreated neonates in the first week of life [134]. In a study among 191 patients, the mean age of death was 2.6 months [135]. Hypoxemia from cardiovascular abnormalities is the prominent cause of death, followed by sepsis secondary to the increased susceptibility to infections when spleen is absent [32,136–138].

not obstructed. Cyanosis is present only in children with pulmonic stenosis or atresia. Patients may be asymptomatic or show features of congestive heart failure.

The electrocardiogram shows distinctive features. Because the sinus node is a right atrial structure it may be absent, displaced, or hypoplastic [120]. A leftward and superiorly directed P wave axis and ectopic atrial rhythm are frequently present [107]. Even the QRS axis is superiorly directed because of the atrioventricular canal. Congenital complete atrioventricular block is occasionally present and may progress even in fetal life [124–126].

Polysplenia/left isomerism

The natural history of polysplenia/left isomerism is better than with asplenia/right isomerism [139–141]. Associated cardiac abnormalities are the main cause of death, followed by rhythm disturbances [92,125] and extrahepatic biliary atresia [140,141].

Medical management

Asplenia/right isomerism

Neonates usually develop severe cyanosis with hypoxemia and metabolic acidosis during the first hours of life from either pulmonary stenosis or atresia and/or obstructed TAPVC. Prostaglandin therapy may improve the oxygen saturation provided that the pulmonary venous system is unobstructed. Otherwise, prostaglandin therapy can unmask or increase the degree of pulmonary venous obstruction by increasing the total pulmonary blood flow [121,142,143]. Patients with infracardiac TAPVC should be operated on without delay. In the other neonates, the degree of pulmonary venous obstruction should be carefully evaluated under prostaglandin infusion [143] to provide the best indication for operation.

Because of the susceptibility to infection [136–138], aggressive perioperative antibiotic prophylaxis is important. Antibiotic prophylaxis against encapsulated bacteria with penicillin or amoxicillin is indicated daily. Immunization against pneumococcus is indicated at age 2 years.

Polysplenia/left isomerism

Few patients with polysplenia/left isomerism develop severe neonatal cyanosis because they do not usually have the obstructive lesions so typical of asplenia/right isomerism. If they do, prostaglandin therapy is required. If neonates become symptomatic soon after birth, it is from congestive heart failure and metabolic acidosis secondary to a combination of pulmonary overcirculation and systemic obstruction from severe aortic stenosis, coarctation, or hypoplastic left heart syndrome. Such patients should be managed appropriately [144,145]. Rarely, complete atrioventricular block is the main cause of neonatal symptoms [125]. Most patients become symptomatic some months after birth. Clinical manifestations differ according to the underlying lesions. Cyanosis is usually related to pulmonary outflow tract obstruction, even though it is occasionally associated with pulmonary arteriovenous fistulas [90]. On the other hand, heart failure is usually related to complete atrioventricular canal or isolated ventricular septal defect. Patients with common atrium or partial atrioventricular canal usually become symptomatic later in life, often in association with cardiac rhythm disturbances [146,147]. Biliary atresia can complicate the clinical status [88,140,141].

Surgical treatment of malposition of the heart in situs ambiguus

Single-ventricle repair

Asplenia/right isomerism

Almost all patients are unsuitable for biventricular repair. Such treatment, however, is often affected by pulmonary venous abnormalities, pulmonary outflow obstruction, and/or atrioventricular valve abnormalities [148].

TAPVC can be present in 90% of patients, with 30% having obstructed pulmonary veins. Both early and late mortality for the initial palliative procedure are high, especially in younger age and when TAPVC requires repair [121,122,149–151]. For this reason, in patients with confluent pulmonary arteries, without juxtaductal pulmonary stenosis, and unobstructed TAPVC, a simple initial palliation with a prosthetic shunt is preferred. This postpones pulmonary vein repair until after the first month of life and achieves a better chance of survival [134]. In all other neonates, a more extensive palliation with cardiopulmonary bypass must be performed, especially if pulmonary veins are obstructed. A systemic–pulmonary shunt should be performed in most neonates with patent, although stenotic, pulmonary inflow, to ensure an adequate pulmonary blood supply [149]. Pulmonary vein obstruction and pulmonary outflow obstruction are independent risk factors for earlier mortality. Recurrent pulmonary venous obstruction is common after TAPVC repair in patients with asplenia/right isomerism, and has been associated with the histologic evidence of abnormal development of the pulmonary vasculature, particularly in the veins, even without clinical evidence of pulmonary venous obstruction [150]. Primary sutureless repair of the pulmonary veins has a low incidence of postoperative pulmonary venous obstruction [152].

A major atrioventricular valve anomaly is present in >90% of patients and an independent risk factor for mortality. Common atrioventricular valve regurgitation occurs more frequently in heterotaxy than in other patients and may be amplified by a systemic-pulmonary shunt, especially in right univentricular hearts. Atrioventricular valve regurgitation requires thorough evaluation and aggressive surgical treatment, to be carried out preferably during staging towards Fontan operation [153].

More than 50% of patients with asplenia/right isomerism and single-ventricle physiology die before reaching the stage of Fontan operation. Both morbidity [154–156] and mortality (15–30% depending on the series) at Fontan are higher than those reported for nonisomeric patients [157–159], although dramatically lower than the preliminary experience of most groups. Preliminary reports described also an increased mortality after the Fontan operation in patients with asplenia/right isomerism, compared with patients with polysplenia/left isomerism, mainly due to a prevalence of

right ventricular morphology in asplenia/right isomerism, and the association with anomalous pulmonary venous connections. Such a difference is no longer described [159], and excellent long-term survival has been reported in patients with asplenia/right isomerism provided that anomalous and/or obstructive pulmonary venous return and atrioventricular valve regurgitation are treated aggressively, the Fontan repair is staged, a fenestration is used liberally, and the technique is carefully chosen to minimize the risk of pulmonary venous obstruction [159].

Fontan staging with a bidirectional cavopulmonary anastomosis has been proposed to reduce the risk of the Fontan operation [160]. A bidirectional cavopulmonary anastomosis can be constructed in patients with anomalous pulmonary venous connection with morbidity and mortality that are not different from those in patients with normal pulmonary venous connections [161]. Furthermore, early reduction of the ventricular volume load may be especially beneficial in patients with a common atrioventricular valve to prevent development of incompetence, which occurs more easily when the ventricular end-diastolic pressure is elevated and the atrioventricular valve annulus is dilated [162]. On the other hand, there is some controversy concerning the benefit of a bidirectional cavopulmonary anastomosis alone on an already regurgitant common atrioventricular valve, whose moderate to severe occurrence has been reported as a risk factor for mortality early postoperatively [163].

Modifications of surgical technique have played a crucial role in the improvement of results of surgery in patients with asplenia/right isomerism. A part from the extensive use of extracardiac tube grafts and conduit fenestration for safe direction of inferior vena cava and hepatic venous drainage to the pulmonary arteries [164,165], specific technical modifications have been described for separate drainage of hepatic veins [166], sometimes associated with apicocaval juxtaposition [67,68,167,168]. Such anatomic peculiarities need to be specifically addressed from a surgical point of view, taking into account the distance between inferior vena cava and hepatic veins and their reciprocal relationship with the spine, in order to construct an unobstructed pathway for blood diversion to the pulmonary arterial tree. Evolution of surgical techniques and careful attention to the specific anatomic patterns of the disease may play a crucial role in the improvement of survival of patients with asplenia/right isomerism [169].

Polysplenia/left isomerism

About 50–70% of patients with polysplenia/left isomerism have a cardiac anatomy that is unsuitable for biventricular repair and are consequently candidates for single-ventricle repair [141,170–172]. Initial palliation usually includes a systemic–pulmonary shunt (pulmonary obstruction), a Norwood-type procedure (hypoplastic left heart complex), or a pulmonary artery banding (unobstructed pulmonary

outflow). Pulmonary artery banding may be required at the time of coarctation repair, but may be needed also in patients without aortic outflow obstruction.

Single-ventricle physiology is an independent risk factor for increased mortality among patients with polysplenia/left isomerism. Additional extracardiac and cardiac factors independently affecting survival in patients with single-ventricle physiology, on a par with those with biventricular physiology, are biliary atresia, other gastrointestinal malformations, low birth weight, atrioventricular block, and coarctation of the aorta [141]. In contrast to asplenia/right isomerism, abnormal pulmonary venous connections are not associated with an increased risk, whereas fetal atrioventricular block and coarctation of the aorta are associated with poorer prognosis, the former in spite of pacing [173] and the latter due to its frequent association with aortic outflow obstruction and hypoplastic left ventricle [141].

Staging towards Fontan operation in patients with polysplenia/left isomerism and single-ventricle physiology is accomplished by the Kawashima operation [174], a bidirectional cavopulmonary anastomosis draining to the lungs almost the whole systemic venous return because of the azygos continuation of the inferior vena cava.

Early outcome of Kawashima operation, initially considered a sort of definitive palliation, is affected by an increased occurrence of pulmonary arteriovenous fistulas early postoperatively [90,175,176], due to the exclusion of the hepatic venous blood from the pulmonary circulation. From a theoretical viewpoint, an increased incidence of pulmonary arteriovenous malformations in patients with azygos continuation and bidirectional cavopulmonary anastomosis could be related to other factors, such as polysplenia/left isomerism [90,175–177] or a lesser extent of bronchial collateral flow related to a higher Qp/Qs ratio compared with bidirectional cavopulmonary anastomosis in the absence of azygos continuation. However, their complete regression after baffling the hepatic veins to the confluent pulmonary arteries [178–184] outlines the crucial role of a putative hepatic or splanchnic factor that prevents precapillary channels of the pulmonary circulation from dilating [185,186]. Pulmonary arteriovenous fistulas have been described as increasing early morbidity and mortality after a modified Fontan operation owing to severe arterial desaturation [187]. For this reason, patients with polysplenia/left isomerism who have undergone a Kawashima bidirectional cavopulmonary anastomosis should be strictly followed to assess the early onset of pulmonary arteriovenous fistulas by contrast echocardiography [188] and transcutaneous pulse oximetry and Fontan completion should be performed timely at a relatively short interval.

The mortality with Fontan operations in polysplenia/left isomerism has been reported to range from 0 to 30% [141,156,189], with an improvement over time [156], but with a mortality up to 50% for the extracardiac Fontan

operation. In fact, conduit interposition between the hepatic veins and the pulmonary circulation carries an increased susceptibility to thrombosis due to a genetic hypercoagulable condition of patients with interrupted inferior vena cava (i.e., factor XII deficiency or heterozygous presence of factor V Leiden mutation) [190] and a flow imbalance mechanism between the relatively low upward flow from the hepatic veins and the preponderant downward flow of the Kawashima bidirectional cavopulmonary anastomosis. Improved survival has recently been reported using a hepato-azygos connection, a sort of end-to-side anastomosis between hepatic veins and the nearby segment of the azygos vein, aimed at reproducing the normal anatomic pattern of the systemic venous system [182–184,191,192]. The optimal spatial arrangement provided by direct hepatoazygos connection obviates power dissipation associated with fluid collision [193] and avoids flow stagnation in the hepatic vein–pulmonary artery conduit in the case of conventional Fontan completion after the Kawashima operation [192].

Finally, close attention needs to be paid to atrioventricular valve function in patients with single-ventricle physiology and polysplenia/left isomerism on a par with those with asplenia/right isomerism. About 75% of initial patients receiving the Kawashima bidirectional cavopulmonary anastomosis were reported as receiving concomitant replacement of the incompetent common atrioventricular valve [174]. Furthermore, the degree of preoperative atrioventricular valve regurgitation was described as a significant risk factor for increased mortality rate in heterotaxy patients at the time of the Fontan operation [189]. Accurate evaluation and possible treatment of atrioventricular valve incompetence during staging are mandatory to improve the subsequent candidacy of such patients for the Fontan operation [153].

Despite the good results of the Fontan procedure quoted in recent studies of patients with polysplenia/left isomerism, the incidence of both early and late postoperative arrhythmia remains high, with freedom from late bradyarrhythmia and tachyarrhythmia at 78 and 70%, respectively [153]. Certainly, the extracardiac Fontan modification has led to a general reduction in arrhythmias, by effectively preserving sinus node function [194]. However, in spite of that, both early and late postoperative arrhythmias are more common in patients with heterotaxy syndrome. In particular, 87% of arrhythmias are bradyarrhythmia in patients with heterotaxy, and severe bradyarrhythmia requiring permanent pacemaker implantation is more common in those with polysplenia/left isomerism [172].

Biventricular repair

Asplenia/right isomerism

About 10% of patients with asplenia/right isomerism have a cardiac anatomy suitable for biventricular repair. Criteria [34,195,196] for biventricular repair in heterotaxy patients are the presence of two balanced ventricles of adequate volume and function, associated with septatable atrioventricular valves and venoatrial connections, although some complex associated lesions may still contraindicate biventricular repair even in the presence of favorable prerequisites [152,196,197]. Given the extent of the anatomic variability of these patients, there are no clear criteria to determine suitability for biventricular repair, and each case needs to be considered on an individual basis. Focusing on asplenia/right isomerism, sporadic cases and limited series of complex biventricular repair have been reported with overall satisfactory results and early and late survival [198] of >90% [199]. The most common anomalies are transposition complexes, complete atrioventricular canal defect, double-outlet right ventricle, and pulmonary artery and pulmonary vein anomalies [199–203]. The unfavorable factors noted for the Fontan strategy are also common for biventricular repair, including anomalous venoatrial connections often accompanied by obstruction of the pulmonary venous drainage and hypoplasia of the pulmonary arteries [157,204].

Literature reports indicate that atrioventricular valve regurgitation and, possibly, anomalous pulmonary venous connections do not place a heterotaxy patient at risk for mortality after biventricular repair (as opposed to the Fontan operation). Furthermore, although long-term morbidities, including arrhythmia and reoperation/reintervention, are equivalent to those of Fontan patients, biventricular repair provides better hemodynamics with lower systemic venous pressure than the Fontan procedure and good NYHA status [199]. For this reason, in selected circumstances with suitable morphologic features, biventricular repair should be considered for definitive repair in patients with asplenia/right atrial isomerism [198].

Polysplenia/left isomerism

In contrast to asplenia/right isomerism, biventricular atrioventricular connection has been reported to be present in up to 72% of patients with polysplenia/left isomerism, with two separate atrioventricular valves in 43% [202]. Not all of these patients are amenable to biventricular repair because of abnormalities of atrioventricular concordance or systemic and pulmonary venous connections [205]. However, in recent reports, surgeons have reported their ability to perform biventricular repair in 30–50% of patients presenting with left polysplenia/left isomerism [141,170–172].

Criteria to pursue biventricular repair do not differ from those described for asplenia/right isomerism. The frequent associated concordant ventriculoarterial connection [205,206] and normal outflow tracts [172] may further facilitate the feasibility of repair.

Biventricular repair in polysplenia/left isomerism includes different procedures, namely atrial partition associated with septation of a common atrioventricular valve and closure of a ventricular septal defect (complete atrioventricular canal

defect), suture of a mitral cleft (partial atrioventricular canal defect), ventricular septal defect closure (ventricular septal defect), and interventricular rerouting associated with right ventricular outflow tract reconstruction (tetralogy-type double-outlet right ventricle), depending on the coexisting conditions. Atrial partition may require septation with a straight patch, when systemic and pulmonary veins connect into either side of the atrium independently; intra-atrial rerouting with a tailored baffle, to separate the pulmonary veins from systemic veins; or atrial switch, when the pulmonary veins connect into the functional right atrium or more than two systemic veins connect into the functional left atrium [202]. Multiple lesions may coexist, requiring complex procedures as in the case of atrioventricular canal defect with common atrioventricular valve and double-outlet right ventricle [203].

Results of biventricular repair in polysplenia/left isomerism are excellent, leading to early survival >90–100% [172,199] and very good long-term outcome [171]. The presence of a common atrioventricular valve is a significant risk factor for morbidity leading to reoperation [207], but not for additional mortality. Arrhythmias are typical of polysplenia/left isomerism and may be unrelated to surgery. This can be due to absence, hypoplasia or abnormal location of the sinus node, or abnormalities of atrioventricular conduction system related to associated abnormalities of atrioventricular connection and ventricular architecture [208]. Some studies suggest that atrioventricular block is more common (7–39%) in patients with polysplenia/left isomerism and is four times more common in those with an associated atrioventricular canal defect [209]. Furthermore, progressive slowing of the atrial rhythm is also typical of polysplenia/left isomerism [147], even in the absence of intracardiac abnormalities [172]. However, the incidence of postoperative arrhythmia is significant in patients with polysplenia/left atrial isomerism [199] treated with biventricular repair compared with those undergoing single ventricle palliation [153,169], with an overall incidence of up to 50% [171]. Studies suggest that the types of atrial baffling, atrioventricular valve regurgitation, and systemic and pulmonary venous anomaly are not related to the occurrence of arrhythmia. However, tachyarrhythmia has been reported in association with older age at biventricular repair, whereas the need for right ventricular outflow tract procedures to relieve stenosis has been described in relationship to the development of bradyarrhythmias [199].

Mechanical assistance for malposition of the heart

Recent reports outline the peculiar usefulness of a ventricular assist device and extracorporeal membrane oxygenation in neonatal palliation of cardiac abnormalities associated with asplenia/right isomerism, especially when obstructed total anomalous pulmonary venous drainage coexists [152]. In fact, a ventricular assist device and extracorporeal membrane oxygenation may be used to support the myocardium through a pulmonary hypertensive crisis and can be discontinued after stabilization of pulmonary reactivity.

On the other hand, scattered reports in the literature describe specifically left ventricular assist device implantation as bridge to recovery [210] or in heart transplantation [211] patients with abnormalities of the situs, without particular technical differences compared with patients with situs solitus. However, patients receiving mechanical assist device implantation may become sensitized to a wide variety of leukocyte antigens [212–217] and, therefore, require thorough evaluation and treatment, whenever required, before and after heart transplantation is performed [218,219].

Cardiac transplantation for malposition of the heart

Neonatal cardiac transplantation has been advocated as a primary therapy for some forms of complex cardiac anomalies, such as those associated with asplenia/right isomerism [220,221]. Apart from the general shortage of adequate donors for small recipients, there is general agreement to reserve cardiac transplantation for patients with asplenia/right isomerism, mainly already palliated up to the stage of bidirectional cavopulmonary anastomosis [222], with uncorrectable atrioventricular valve incompetence associated with severe ventricular dysfunction. From this viewpoint, asplenia/right isomerism does not differ from polysplenia/left isomerism or from other cardiac malformations with single-ventricle physiology [223] with/without abnormalities of the situs.

Focusing on particular problems associated with orthotopic heart transplantation in patients with complex cardiac anomalies and abnormalities of the situs, they are mainly related to the position within the recipient's chest of the systemic venous return and to the previous surgery performed.

In fact, when examining the anatomy of cardiac structures for heart transplantation regardless of the situs, the left atrium is a midline structure that receives the right and left pulmonary veins, the pulmonary artery is a midline structure at some point, and the aorta is usually anterior and to the right of the pulmonary artery, regardless of whether it originates normally or is transposed [224]. Abnormalities of the situs, therefore, are mainly characterized by variations up to complete reversal of the anatomic position of the systemic venous return and require particular modification of the surgical technique to deal with them. Several reports have described technical modification of

the standard transplantation technique for patients with situs inversus, reported as being a serious technical challenge due to the complete reversal of the anatomic position of the systemic venous return [224–234]. Reconstruction of the mirror-image systemic venous pathway is generally performed using autologous tissues or prosthetic conduits [224,229,232], and the donor heart is seated in a somewhat clockwise-rotated position with the apex tipped frontwards [133,230] or completely within the recipient's pericardium in dextrocardia [234], according to the technique used. In the subset of patients with heterotaxia, pediatric cardiac transplantation has been reported [223,226,234–236], with a few in patients with situs ambiguus [237,238]. The operative technique in such patients can be complicated by the position of the heart, the abnormalities of systemic and pulmonary venous connections [223,225,235,236,239,240], and the relationship between the great vessels [241,242].

The surgically demanding effects of preliminary palliative procedures on the pulmonary arterial tree and chest adhesions [224,227,236,240] are a less important aspect related to previous surgical procedures. The major problem with heart transplantation in patients who have already undergone previous cardiac operations is the potential development of HLA-directed antibodies allowing allosensitization. In particular, patients who received homograft implantation, blood/platelet transfusions, and/or mechanical assist device implantation may become sensitized to a wide variety of leukocyte antigens [243]. They represent a heart transplant population at high risk of hyperacute rejection and require specific consideration and both pretransplant and postoperative immuno-treatment options [218,219].

Early results of pediatric cardiac transplantation for cardiac malformations showed in the past a significantly increased early mortality compared with idiopathic cardiomyopathy [244,245] because of major operative procedure-related complications. However, increasing proportions of positive results with cardiac transplantation in children with cardiac malformations have progressively been described despite multiple previous cardiac operations [223,224,236,240,246,247]. Under such circumstances, abnormalities of situs do not show a negative impact on both early and late results compared with series of patients undergoing heart transplant for congenital cardiac defects in situs solitus or dilated cardiomyopathy [224,228–230,235,238].

Nowadays, heart transplantation can be considered a safe and highly effective treatment for patients with complex congenital heart defects, irrespective of the situs [225]. In fact, according to the current literature, the outcome in patients with congenital heart disease does not differ from that in patients without such abnormalities [248–250].

Ectopia cordis

Classification

Ectopia cordis is the partial or complete location of the heart outside the thorax. This extremely rare condition occurs in 5.5–7.9 per million live births [251,252]. Anatomic and clinical similarities with Cantrell syndrome are evident [48–50]. Kanagasuntheran and Verzin [253] divided ectopia cordis into five types: cervical, thoracocervical, thoracic, thoracoabdominal, and abdominal. The cervical form was found only in malformed fetuses; the abdominal form is extremely rare, with only one patient described. Hence, for practical purposes, only two types of ectopia cordis need be considered: the thoracic and the thoracoabdominal forms.

The thoracic type is the classic form of ectopia cordis. In these patients, there is a cleft of the sternum that allows protrusion of the heart outside the thoracic cavity, absence of the parietal pericardium, cephalic orientation of the cardiac apex, epigastric omphalocele, diastasis recti, and small thoracic cavity. The thoracoabdominal form is a partial form of ectopia cordis that is characterized by partial absence or cleft of the lower sternum, defect of the parietal diaphragmatic pericardium, midline diaphragmatic defect resulting in free communication between the pericardium and abdominal cavity, and diastasis recti with partial displacement of the ventricular portion of the heart into epigastrium. Many types of cardiac malformations are associated with ectopia cordis: tetralogy of Fallot, ventricular septal defect, atrioventricular canal, common atrium, tricuspid atresia, pulmonary stenosis and atresia, and transposition of the great arteries. There are at least five instances of ectopia cordis without a cardiac anomaly [47].

Oligohydramnios due to amnion rupture causing compression of the heart during cardiogenesis has been hypothesized as a mechanism of both thoracic and thoracoabdominal ectopia cordis [254]. Despite this mechanical explanation, chromosome abnormalities [251,255,256] and associated anomalies such as cleft lip and palate, cranial anomalies, gastrointestinal and renal anomalies, and pulmonary hypoplasia have been identified in some affected patients [47,257,258].

Treatment

A dismal outcome is generally reported in patients with ectopia cordis [257–260], mainly because of associated extracardiac and cardiac anomalies [257,258]. The first successful operative treatment of thoracoabdominal ectopia cordis without cardiac and extracardiac anomalies was performed in 1888 by Lannelongue and reported 22 years later [261]. Major extracardiac problems in the treatment of ectopia cordis include external cardiac compression, lung hypoplasia, and large airway obstruction due to distorted vascular anatomy.

The prognosis is particularly poor in patients with the thoracic form of ectopia cordis. In these patients, even though the thoracic cavity may appear normal in size, the liver occupies much of the cavity and precludes placement of the heart in the thorax. Although the outcome for patients with thoracoabdominal ectopia cordis is considered more favorable than that for patients with the thoracic form, the mortality is still high in both groups. The outcome of a large group of children and infants with ectopia cordis and cardiac anomalies [262] shows that affected infants and children can survive beyond early infancy and undergo successful repair or definitive palliation of their cardiac anomaly.

Thoracopagus conjoined twins

The most common form of conjoined twins shows a fusion in the midportion of the body, and these children are called thoracopagus twins. These patients represent a rare type of cardiac malposition because the fusion involves the anterior chest region and the heart. Conjoined twins occur once in every 50 000 births. Female twins represent more than three-quarters of patients [263,264].

In thoracopagus twins, the livers are conjoined and the sternum is usually partially or totally absent (Figure 50.21). The pericardial and pleural cavities may be either separate or common to both children, and the cardiovascular fusion may be classified into three types [265]: common pericardium but separate hearts, fusion at atrial and ventricular levels, and fusion at atrial level only. Simple or, more frequently, complex cardiac malformations may coexist and may be discordant between the children.

Anomalies of visceroatrial situs are frequent in dicephalus (86%) and in thoracopagus twins (71%), occurring most frequently in the twin on the right side [265]. These laterality defects have been explained by the inhibition of the gene Sonic Hedgehog in the left side of the right twin due to the effect of Activin gene produced at the right side of the left twin [266].

Because anomalies of the visceroatrial situs and discordant atrioventricular and ventriculoarterial connections are frequent [267], the segmental approach to cardiac diagnosis [1,2,6,8] is mandatory in these patients. At atrial level, the most frequent anomalies are single atrium and large atrial septal defect. Venous channels interposed between the superior venae cavae and connecting the systemic venous drainages of the twins are frequent, as is partial or total anomalous pulmonary venous connection. At ventricular level, the most common anomalies are single ventricle and ventricular septal defect [268]; transposition of the great arteries and double-outlet right ventricle are the most common conotruncal defects. Pulmonary and aortic stenosis or atresia occur frequently, and one twin may show one of these conditions and the opposite twin the other [269].

The fetal diagnosis can be made by radiography [270]. Prenatal echocardiographic examination details the intracardiac anatomy [271].

At birth, the diagnosis of separate hearts can be suspected if one twin differs from the other in pulse rate and

(a)   (b)
Figure 50.21 (a) Chest radiograph and (b) computed tomographic angiogram in thoracopagus twins. Note the conjoined livers and the fusion of the chests (twin A is right-sided and twin B is left-sided in the figure).

if they show separate QRS complexes on an electrocardiogram [270]. Echocardiography can diagnose the site and dimension of the heart fusion and the morphology of intracardiac anomalies [269]. Computed tomographic angiography [269,272] may also be useful for the diagnosis, but cardiac catheterization and angiocardiography, although technically difficult in these patients, are usually mandatory to assess the feasibility of separation [269,273]. Aortography and coronary angiography should be indicated to exclude fusion of the coronary vascular beds at ventricular level. Furthermore, the assessment of electromyocardial continuity should be considered in the preoperative work-up [274].

Separation of conjoined twins represents an operative challenge [275–283] and is best delayed until the infants are relatively mature (6–12 months of age). The assessment of the cardiovascular system is fundamental in planning the operative separation, but the evaluation of the liver, pancreaticobiliary tract, gastrointestinal tract, urinary tract, and central nervous system is also important. Therefore, the operative team must include many specialty consultants and surgeons. Moreover, the use of skin expanders and prosthetic mesh is mandatory to facilitate wound closure.

The ethical and legal problems of separation of conjoined twins are important aspects in medical and surgical treatment [282,283]. With conjoined hearts, the possibility of sacrificing one twin, allowing the other to lead a potentially normal life, comes into question [283]. The hospital's ethics committee is helpful in this respect, but obviously the parents always have the right to refuse surgical separation.

There are no reported long-term instances of separation of twins with conjoined ventricles (one patient survived for 3 months) [283] and there were few successes when the junction was at atrial level [276,277].

51 Pediatric Pulmonary Hypertension

Cécile Tissot & Maurice Beghetti
The University Children's Hospital of Geneva, Geneva, Switzerland

Introduction

Pulmonary arterial hypertension (PAH) in children is a life-threatening disease characterized by progressive obliteration of the pulmonary vasculature leading to right heart failure and death if untreated. Prior to the current treatment era, PAH carried a poor prognosis and survival rate [1]. PAH in children may be idiopathic (IPAH) or associated with other diseases (APAH), more commonly with congenital heart disease (CHD). IPAH is diagnosed by excluding other diseases. The first description of PAH associated with CHD was made in 1897 by Victor Eisenmenger, who described the autopsy findings of a 32-year-old man with a large ventricular septal defect and pulmonary vascular disease (PVD). In 1958, Paul Wood's description of the Eisenmenger syndrome (ES) as pulmonary hypertension (PH) at the systemic level due to high pulmonary vascular resistance (PVR) with bidirectional or reversal of shunt is still relevant to our understanding today [2].

The prognosis of PAH has changed dramatically over the past decade since the introduction of new therapeutic agents and the off-label application of adult pulmonary hypertension (PH)-specific therapies to children [1,3–5]. Nevertheless, PH remains serious and extremely challenging to manage. The data in children are often limited by the small number of patients, and extrapolating from adults to children is not straightforward. The degree of pulmonary vasoconstriction relative to fixed pulmonary vascular obstruction is important in children in any form of PH and appropriate therapies must be carefully chosen according to the etiology and pulmonary vasoreactivity. In PAH associated with CHD, pulmonary vasoreactivity is very important in deciding whether the patient is a candidate for surgical repair or not. PAH still has no cure and the treatment aims at prolonging survival by improving quality of life, symptoms, exercise tolerance, and hemodynamics.

Definition and classification

PAH is defined as a mean pulmonary artery pressure (PAP) ≥25 mmHg at rest, with a normal pulmonary capillary wedge pressure (≤15 mmHg). Some authors also include an increased pulmonary vascular resistance index [≥3 Woods Units (WU) m^2] as part of the definition for PAH [6,7]. Exercise criteria have been deleted from the current definition, but some children show an abnormal vasoconstrictor response of the pulmonary vascular bed with increased PAP only with exercise at the early stage of the disease. Measurement of PAP during exercise, however, is extremely challenging in children. Compared with adults, children are thought to have a greater vasoreactive response to hypoventilation with a more pronounced oxygen desaturation [8].

A revision of the classification, including most of the forms of PH encountered in children, was proposed at Dana Point in 2008 (Table 51.1) [9]. A recent article reviewed the clinical presentation of children with PAH and outlined the difficulties of classifying pediatric PH according to this classification [10]. Category 1 includes idiopathic and familial PAH and also PAH related to or associated with various diseases, including CHD. The rationale for including PAH associated with CHD is that the histologies of category 1 PAH diseases are indistinguishable from each other, with the plexiform lesion being the cornerstone of severe pulmonary vascular disease (PVD). The plexiform lesions of patients with idiopathic or familial PAH contain monoclonal proliferating endothelial cells, whereas those of patients with associated PAH contain polyclonal endothelial cell proliferation [11]. The most common forms of associated PAH (APAH) in

Table 51.1 Revised classification of pulmonary hypertension from Dana Point 2008. (Reproduced from Simonneau G, *et al. J Am Coll Cardiol* 2009;**54**(1 Suppl):S43–54, with permission from Elsevier.)

1   Pulmonary arterial hypertension (PAH)
   1.1   Idiopathic PAH
   1.2   Heritable
      1.2.1   BMPR2
      1.2.2   ALK1, endoglin (with or without hereditary hemorrhagic telangiectasia)
      1.2.3   Unknown
   1.3   Drug and toxin induced
   1.4   Associated with
      1.4.1   Connective tissue diseases
      1.4.2   HIV infection
      1.4.3   Portal hypertension
      1.4.4   Congenital heart diseases
      1.4.5   Schistosomiasis
      1.4.6   Chronic hemolytic anemia
   1.5   Persistent pulmonary hypertension of the newborn
1'   Pulmonary veno-occlusive disease (PVOD) and/or pulmonary capillary hemangiomatosis (PCH)
2   Pulmonary hypertension owing to left heart disease
   2.1   Systolic dysfunction
   2.2   Diastolic dysfunction
   2.3   Valvar disease
3   Pulmonary hypertension owing to lung diseases and/or hypoxia
   3.1   Chronic obstructive pulmonary disease
   3.2   Interstitial lung disease
   3.3   Other pulmonary diseases with mixed restrictive and obstructive pattern
   3.4   Sleep-disordered breathing
   3.5   Alveolar hypoventilation disorders
   3.6   Chronic exposure to high altitude
   3.7   Developmental abnormalities
4   Chronic thromboembolic pulmonary hypertension (CTEPH)
5   Pulmonary hypertension with unclear multifactorial mechanisms
   5.1   Hematologic disorders: myeloproliferative disorders, splenectomy
   5.2   Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
   5.3   Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
   5.4   Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

children except CHD are related to chronic lung disease and hemoglobinopathies.

In the new Dana Point classification, venous PH has been renamed PH due to left heart disease and classified in category 2. It is divided into PH related to left ventricular (LV) systolic dysfunction, LV diastolic dysfunction, and left heart valvar disease. Except for restrictive cardiomyopathy, PH secondary to left ventricular diastolic dysfunction is rare in children and the most common causes of PH related to left heart disease

in children are left-sided CHD and cardiomyopathies. Nevertheless, with the emergence of childhood obesity, insulin resistance, systemic hypertension, and survivors of heart transplantation, PH due to diastolic dysfunction will become more frequent in children. The classification of PH does not address adequately the heterogeneity of PVD in children, particularly for two causes of pulmonary venous hypertension: pulmonary veno-occlusive disease (PVOD) is classified in category 1' and congenital pulmonary vein stenosis is not mentioned in this classification. It is still a matter of debate whether a specific pediatric classification should be developed.

Epidemiology and genetics

Data on pediatric epidemiology remain scarce and the exact incidence and prevalence of PH in children are not known. Although there are many registries of adult patients, registries of children with PH are less well established and powered [12–14]. PAH may be idiopathic or heritable with no underlying cause, or associated with a specific disease (associated PAH). Based on available data in children, the etiology of PH is probably more diverse than in adults, with PAH being much more common than pulmonary venous hypertension. In children, the predominant diagnoses are IPAH and PAH associated with CHD and shunt lesions [12]. ES is rarely seen now in developed countries because of early referral and surgical repair. Nevertheless, access to specialist care in developing countries is insufficient, and CHD remains the most common etiology of PAH worldwide [15]. Persistent pulmonary hypertension of the newborn (PPHN) is the most common cause of PH in the neonatal period. PH associated with chronic lung disease and hemoglobinopathies are less common and probably underreported causes of PH in infants and children. Two recent large registries will give important data about pediatric epidemiology in the near future.

PAH appears to be a disease of "predisposed" individuals in whom various stimuli may initiate the PVD process. A genetic trait may account for the variability in expression of different degrees of PH to similar stimuli. A genetic mutation of the bone morphogenetic protein receptor type 2 (BMPR2) on chromosome 2q33, a gene encoding a TGF-β receptor (the PPH1 gene), has been recognized in some patients with familial PAH (>50% of the patients) and IPAH (~20–25%), and in sporadic examples of PAH (26%) [16,17]. BMPR2 mutations are inherited as an autosomal dominant pattern with reduced penetrance and genetic anticipation. Often, the child is the first family member to present with severe disease, and evaluating first-degree relatives reveals milder forms of PAH. The genetics of PAH in children are still unclear but mutations of the BMPR2 gene seem to be involved in some patients [18,19], whereas other children may have a different genetic background [20]. More recently, a study by Rosenzweig *et al.* found that BMPR2 mutation positive

children appeared less likely to respond to acute vasodilator testing than BMPR2 mutation negative children [19]. Mutation in the BMPR2 gene is less common in PAH associated with CHD than in IPAH, but when present, it seems to have a profound impact on outcome.

Pathophysiology

Idiopathic PAH (IPAH)

PAH in adults and children shows many similarities but there are specific differences in children. PAH is a process of pulmonary vasoconstriction and proliferation and remodeling of the pulmonary vascular bed [21,22]. An imbalance in the biosynthesis of prostacyclin and thromboxane A2 [23,24] with increased thromboxane, endothelin, and serotonin and decreased prostacyclin and nitric oxide (NO) has been described [25]. In older children, intimal hyperplasia and occlusive changes and also plexiform lesions are found in the pulmonary arterioles [26]. In contrast to adults, children with IPAH have more pulmonary vascular medial hypertrophy, less intimal fibrosis, and fewer plexiform lesions [27,28]. This suggests that vasoconstriction leading to medial hypertrophy occurs early in the disease and may precede the development of fixed pulmonary vascular changes. This may explain severe acute pulmonary hypertensive crises occurring more often in response to pulmonary vasoconstrictor triggers in children than in adults.

PAH associated with CHD

Increased pulmonary artery pressure (PAP) and/or pulmonary blood flow (PBF) causes an increased pulmonary vascular resistance (PVR) related to active vasoconstriction and pathologic remodeling of the pulmonary circulation consisting of decreased luminal area of the pulmonary arteries ± a diminished number of vessels. This is reflected in the response to pulmonary vasodilatation with a decrease in PVR in patients with CHD [29,30]. Increased wall stress and endothelial shear stress serve as a growth stimulus and increased matrix protein synthesis responsible for the remodeling lesions [31]. In infants with CHD, vasoconstriction is predominant, but even in older children and adults the markedly increased PVR may remain reactive to pulmonary vasodilators. The normal physiologic response to increased flow is vasodilatation and decreased vascular resistance. The increased PVR associated with increased flow from CHD suggests resting vasoconstriction and/or pulmonary vascular remodeling [32].

The distinction between reversible and irreversible PVD and the ability to predict whether the PVR will decrease following surgical correction of CHD is crucial. Indeed, in patients with ES, closure of the pulmonary to systemic connection is associated with a worse clinical outcome than the natural history of the disease [2]. Patients with Eisenmenger syndrome may show a small degree of vasodilatation in response to pulmonary vasodilator testing, thus providing some rationale for therapy [33]. In children <2 years of age with mildly elevated PVR, PVR returns to normal after eliminating the shunt. In older patients with increased PAP and PVR, however, PVD may progress even after surgical correction. Medial hypertrophy is assumed to regress after removal of increased PAP and/or PBF [34].

Some variables have a major impact on the probability of reversal of PVD after surgical repair: the type of CHD, the age of the patient, and the level of PVR at the time of operation. Genetic and environmental factors are responsible for considerable individual variability of the pulmonary vasculature to CHD. The rapidity of evolution of pulmonary vascular remodeling towards irreversible lesions depends on whether the defect is associated with increased PAP, PBF, or both [35]. For patients with a mild increase in PBF, such as atrial septal defect (ASD), the risk of developing PVD is low in those <20 years of age [36]. With more pronounced increase in PBF, such as isolated ventricular septal defect (VSD), if closure is performed in the first 2 years of life, with a few exceptions an elevated PVR becomes normal. Favorable pulmonary vascular remodeling is even better when surgical closure is performed in the first year of life [37]. CHD with increases in both PAP and PBF evolves more rapidly towards severe PVD compared with those with increased PAP or PBF alone. Complex cardiac lesions with increased PAP and PBF together with high pulmonary arterial oxygen saturation (SaO_2), low systemic SaO_2, and polycythemia are at increased risk for the development of early PVD. For example, infants with unrepaired d-TGA and intact ventricular septum may have increased PBF but normal PAP after the early neonatal period and are at risk of developing increased PVR and PVD in the first year or two of life [38]. Infants with d-TGA and VSD or patent ductus arteriosus (PDA) develop early severe PVD in the first year of life, and some patients may develop PVD despite neonatal arterial switch operation [39]. Particular lesions prone to develop early PVD are common arterial trunk or aortic origin of a pulmonary artery [40]. For the latter, pulmonary vascular changes may occur even in the normally connected lung, emphasizing the role of other circulating vasoactive mediators.

PAH associated with hemoglobinopathies

Recently, several publications have reported an increased incidence of PH in children with hemolytic anemia, particularly sickle cell disease (SCD), but also thalassemia and spherocytosis. In a prospective study, Nelson *et al.* reported that 31% of children ≥10 years of age with SCD had evidence of pulmonary hypertension by Doppler echocardiography [41]. Factors associated with suspected PH were male sex and elevated reticulocyte count. In those patients, PH likely results from multiple factors, including high output state related to anemia, left ventricular diastolic dysfunction, and

thromboembolic disease due to hypercoagulability elevating PVR [42,43]. Moreover, intravascular hemolysis releases hemoglobin, which reacts and destroys nitric oxide [44].This reduced NO bioavailability stimulates an increase in endothelin-1, which further exacerbates PH [45].

PAH associated with chronic liver disease

Hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPHTN) are complications of portal hypertension [46]. HPS is defined as pulmonary arteriovenous malformations resulting in intrapulmonary vascular shunting, ventilation-perfusion mismatch, and chronic hypoxemia. There is vasodilatation of pulmonary arterioles and capillaries. In a study by Whitworth *et al.*, intrapulmonary vascular shunting was present in 19% of children with stable cirrhosis or extrahepatic portal hypertension [47]. PPHTN is defined as PH caused by a pulmonary arteriopathy in the presence of portal hypertension, with elevated PAP and PVR [48]. The origin is from several factors: hyperdynamic circulation, increased cardiac output, sheer stress injury to vascular walls, and imbalance of circulating vasoactive peptides, especially endothelin-1, and each has been implicated in the pathogenesis [49].The pathology of those two disorders is completely different with vasodilatation of arterioles and capillaries causing arteriovenous shunting in HPS and intimal fibrosis with endothelial and smooth muscle proliferation leading to increased PVR in PPHTN.

Persistent pulmonary hypertension of the newborn (PPHN)

PPHN is characterized by failure of the pulmonary circulation to achieve or sustain the normal drop in PVR following birth (see Chapter 17). There may be an abnormal transition to the extrauterine life with failure of the pulmonary vasculature to dilate. Strong experimental and clinical data support the role of impaired vascular endothelial growth factor (VEGF) signaling in the pathogenesis of two major clinical disorders of the developing lung circulation: PPHN and bronchopulmonary dysplasia (BPD). These disorders are each characterized by impaired vascular growth, structure, and reactivity, which are at least partly due to endothelial cell dysfunction [50,51]. Laboratory studies have identified the important role of NO–cGMP signaling in regulating the perinatal pulmonary circulation, leading to the development and application of inhaled NO therapy and cGMP-specific phosphodiesterase inhibitors (PDE) such as sildenafil [52,53].

Pulmonary capillary hemangiomatosis (PCH) and pulmonary veno-occlusive disease (PVOD)

PCH and PVOD are both characterized by precapillary PAH and are included in classification category 1. They are characterized by widespread vascular obstruction at either the alvelolar capillary bed (PCH) or the pulmonary venules

(PVOD). These disorders are difficult to diagnose and their treatments are different because pulmonary vasodilators may worsen the patient's status by inducing pulmonary edema [54]. Treatment of PCH and PVOD is frequently unsuccessful and requires lung transplantation.

PH associated with left heart diseases

Left heart diseases may increase pulmonary venous pressure and be responsible for pulmonary venous hypertension (or postcapillary PH). The initial pathophysiologic mechanism is a passive rise in PAP as downstream pressure increases to maintain left heart preload and cardiac output. The hemodynamic data in this setting show a normal transpulmonary gradient (<10 mmHg), a low PVR (<5 WU m^2) and a diastolic PAP equal to the left atrial pressure. Subsequent reflex vasoconstriction of the pulmonary arteries or veins, or both, leads to an increased transpulmonary gradient (>10 mmHg), increased PVR (>5 WU m^2) and diastolic PAP exceeds left atrial pressure. The patients usually respond to pulmonary vasodilators by a decrease in both the transpulmonary gradient and the PVR. Finally, the pulmonary arteries or veins have fixed vasoconstriction and are unresponsive to pulmonary vasodilators. The histopathology shows medial thickening of both pulmonary arteries and veins ("arterialization" of the pulmonary veins) [55]. Lymphangiectasia is seen in both longstanding venous PH and following *in utero* elevation of pulmonary venous pressure (pulmonary vein atresia, total anomalous pulmonary venous drainage, or hypoplasic left heart syndrome with intact atrial septum). Advanced lesions, such as cellular intimal proliferation or plexiform lesions, are not seen. PH regresses if the left heart obstruction or dysfunction is addressed early.

PAH associated with neonatal and chronic lung disease

Bronchopulmonary dysplasia (BPD) is a chronic lung disease in prematurely born or immature infants. BPD is predominantly defined as disruption of distal lung growth with abnormal growth of the alveoli and the pulmonary circulation. The number of small pulmonary arteries is reduced, leading to a reduced alveolar–capillary surface area and impaired gas exchange [56]. PH which presents early in the course of the disease contributes significantly to high morbidity and mortality of neonates with BPD [57]. Abnormalities of the pulmonary circulation in BPD include increased vascular tone and vasoreactivity, hypertensive remodeling, and decreased growth, leading to increased PVR with marked vasoconstrictor response to hypoxia [58]. The reduced vascular surface area implies that even a relatively minor increase in left-to-right shunting of blood through a patent foramen ovale (PFO) or patent ductus arteriosus (PDA) may induce a much greater injury to the lung vasculature than in normal infants. Early closure of shunt lesions should be performed prior to the development of progressive PH. Chronic

sildenafil therapy is well tolerated, safe, and effective for infants with PH related to chronic lung disease [52].

Congenital diaphragmatic hernia presents as PPHN. *In utero* lung growth is compromised by the intrathoracic position of the abdominal contents and leads to pulmonary vascular changes. A recent study by Keller *et al.* has shown that infants with congenital diaphragmatic hernia and poor outcome had higher plasma endothelin-1 (ET1) levels and severity of pulmonary hypertension than infants discharged on room air. The severity of pulmonary hypertension was associated with ET1 levels [59]. The two main factors determining long-term outcome are the degree of lung hypoplasia and the severity of the pulmonary vascular abnormalities [60].

Assessment

Clinical history and physical examination

Symptoms of PAH in children are frequently misleading and the diagnosis may be unrecognized for some time. A high degree of suspicion should be the rule, and PAH should be suspected in any child with undue shortness of breath, exercise intolerance, tiredness, or syncopal episodes. In children with congenital cardiac shunt lesions, feeding difficulties, poor weight gain, and recurrent respiratory tract infections are common signs of high PBF. Recurrent collapse of different lobes or segments of lung can be secondary to dilated proximal pulmonary arteries and airway compression. The signs and symptoms of heart failure usually improve as PVR increases and the patient may become asymptomatic until the shunt reverses and becomes obvious with arterial oxygen desaturation. In children with Eisenmenger syndrome, central cyanosis and digital clubbing are present. Patients with ES are at increased risk of hemoptysis in early adult life. In children with PAH, exercise intolerance is common and can be graded according to the WHO functional classification (Table 51.2).

The physical signs of PAH include a right ventricular lift, an accentuated and palpable second heart sound, and a pulmonary systolic ejection click secondary to a dilated pulmonary trunk. A high-pitched diastolic murmur of pulmonary insufficiency, a holosystolic murmur of tricuspid regurgitation, or gallop rhythm may be audible. The resting systemic arterial oxygen saturation should be normal in the absence of an intracardiac right-to-left shunt. Hepatomegaly with peripheral edema may be present in right heart failure. Even if associated PAH is rare in children except for CHD, all potential etiologies should be evaluated and treated (Table 51.3).

Electrocardiogram (ECG)

ECG findings include right ventricular hypertrophy and strain, right atrial enlargement, and right axis deviation (Figure 51.1). Atrial arrhythmias may be the presenting symptoms of PAH.

Table 51.2 World Health Organization (WHO) functional classification in PH.

Class I	• PH with no limitation of physical activity Ordinary physical activity does not cause undue dyspnea or fatigue, chest pain or near syncope
Class II	• PH with slight limitation of physical activity
	• Comfortable at rest
	• Ordinary physical activity causes undue dyspnea or fatigue, chest pain or near syncope
Class III	• PH resulting in marked limitation of physical activity
	• Comfortable at rest
	• Less than ordinary physical activity causes undue dyspnea or fatigue, chest pain or near syncope
Class IV	• PH with inability to carry out any physical activity without symptoms
	• Signs of right heart failure
	• Dyspnea and/or fatigue may be present even at rest
	• Discomfort is increased by any physical activity

Chest X-ray

Chest X-ray findings in severe PAH are enlarged central pulmonary arteries and diminished peripheral pulmonary vascular markings (Figure 51.2a). Cardiomegaly is usual, secondary to right heart enlargement. In children with PAH related to congenital shunt lesions, the chest X-Ray is reassuringly plethoric when the PVR is sufficiently low to allow high PBF and will show dilatation of the proximal vessels with peripheral hypoperfusion in significant PAH. The chest X-ray in children with venous PH shows obvious pulmonary edema (Figure 51.2b).

Echocardiography

Although cardiac catheterization is necessary for disease confirmation and PAP measurement, echocardiography is a useful noninvasive tool for the diagnosis and follow-up of PAH. In the absence of pulmonary stenosis, echocardiography allows the estimation of the systolic PAP by measuring the peak systolic pressure gradient between the right ventricle and the right atrium using the TR jet and the modified Bernoulli equation ($\Delta P = v^2$, where ΔP is the pressure gradient and v the velocity) and by adding the estimated right atrial pressure (Figure 51.3a). One must be aware that using the TR jet velocity as an estimate of systolic PAP can over- or underestimate the PAP [61]. Echocardiography also allows the estimation of the end-diastolic and mean PAP from the pulmonary insufficiency (PI) flow velocity (Figure 51.3b). Good correlation has been demonstrated between echocardiographic and catheterization estimate of PAP. Echocardiography may reveal right heart dilatation and right ventricular hypertrophy and dilatation with bowing of the interventricular septum to the left (Videoclips 51.1 and 51.2). In children with a shunt lesion, the systolic PAP can also be estimated from the velocity through the shunt using the modified Bernoulli equation. In VSD or PDA, right-to-left shunt or low-velocity left-to-right shunt may suggest an elevated PAP.

Depending on the degree of PH, the interventricular septum may flatten only in systole (mild–moderate PH) or throughout the cardiac cycle (severe PH). The left ventricular eccentricity index (EI) is a measure of the interventricular septal shift towards the LV in end-diastole and is usually >1 in patients with PAH (Figure 51.3c). Marked septal shift can cause underfilling of the left ventricle with redistribution of LV filling from early to late diastole as a reflection of reduced LV compliance and diastolic dysfunction [62]. A pericardial

(a)   (b)
Figure 51.2 *Chest* X-ray (a) in a child with IPAH with enlarged central pulmonary arteries and peripheral hypoperfusion and (b) in a child with pulmonary veno-occlusive disease with obvious pulmonary edema secondary to pulmonary venous hypertension.

effusion is rare in children but is associated with an increased risk of poor outcome [63]. Right ventricular (RV) function can be assessed by echocardiography using the tricuspid annular plane systolic excursion (TAPSE) or the RV fractional area change (RVFAC). In adults with PAH, a TAPSE of <1.8 cm is associated with RV systolic dysfunction and a lower survival rate [64]. (Figure 51.3d). A RVFAC of ≤40% is considered abnormal, reflecting RV systolic dysfunction. A good correlation between RVFAC and EF by cardiac MRI, which represents the gold standard for evaluating RV systolic function, has been demonstrated. A reduced systolic velocity S' obtained by tissue Doppler imaging from the RV free wall at the tricuspid annulus also reflects RV systolic dysfunction.

Cardiac catheterization

Cardiac catheterization is necessary to exclude subtle CHD, such as pulmonary venous obstruction. PAH must be confirmed by catheterization, and pulmonary vasoreactivity testing should be performed, usually with inhaled nitric oxide (NO), but intravenous epoprostenol, adenosine, or inhaled iloprost may also be used [65,66]. Protocols for pulmonary vasodilator testing are center specific, but 20 ppm NO with or without increased oxygen concentration for 10 min usually achieves sufficient pulmonary vasodilatation. Acute responders should show a decrease of ≥10 mmHg in mean PAP with a mean PAP of ≤40 mmHg or a decrease in ≥20% in the mean PAP or PVR with an unchanged or increased cardiac output. It is uncertain if the same definition of vasoreactivity should be applied for adults and children with PAH. Recent data suggest that 7% of children with IPAH and 6% of those with APAH respond to acute vasodilator testing [12].

Cardiac catheterization in children with PAH related to CHD follows different rules and calculation of pulmonary and systemic blood flow and vascular resistance using the Fick principle with measured oxygen consumption is essential [67]. A baseline PVR index <6 WU m^2 with a pulmonary to systemic resistance ratio (PVR/SVR) of <0.3 indicates a favorable outcome following surgical repair. In children undergoing a Fontan operation, a mean PAP of >15 mmHg may be associated with both early and late mortality [68].

The measurement of the transpulmonary gradient (normal TPG <10 mmHg) is essential, particularly in patients with venous PH, and requires an accurate pulmonary capillary wedge pressure (PCWP) measurement. Wedge angiography is helpful in evaluating the severity of PVD (Videoclip 51.3). In patients with severe PAH and PVD, it shows decreased arborization, reduced background opacification and delayed venous filling. The pulmonary arteries may appear tortuous or have segmental dilatation and show abrupt tapering toward the periphery, characteristic of a high PVR [69]. Aortography should be performed at initial diagnosis to rule out aortopulmonary collaterals.

Exercise capacity

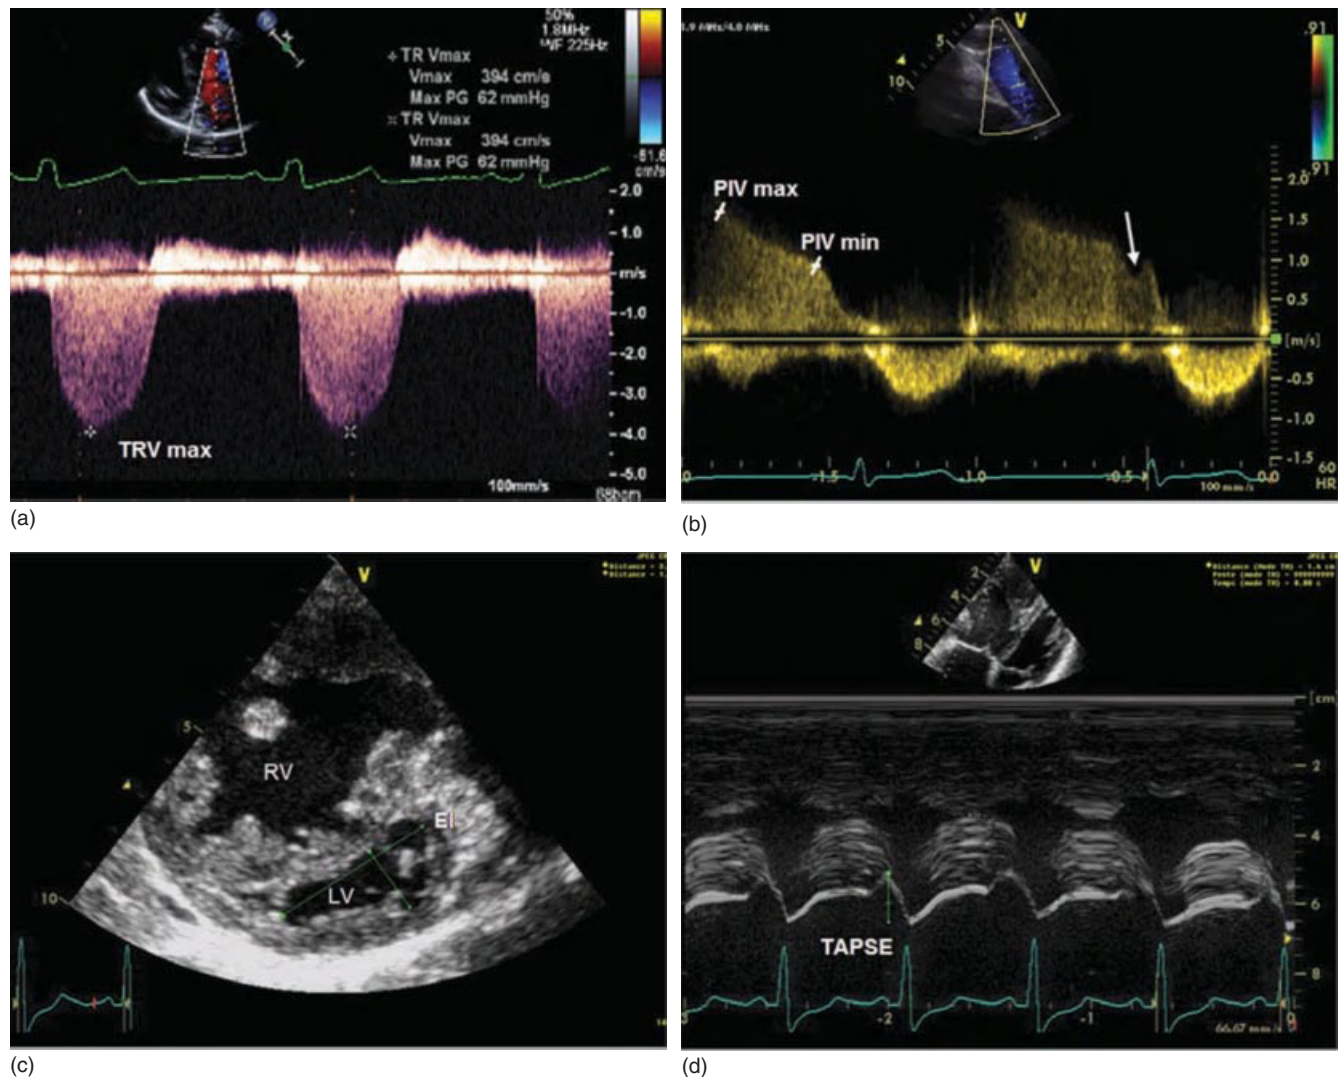
In children aged ≥7–8 years, exercise capacity can be assessed with a 6 min walking test (6-MW test). The 6-MW test remains the standard tool for testing exercise capacity in most clinical trials in adults with PAH [70], but is difficult to standardize in children, even though recent publications of reference values in healthy children are available [71–73]. The 6-MW test has not been validated in children with PAH. In older children, cardiopulmonary exercise testing to determine maximum oxygen consumption (VO_2), work rate, and


Figure 51.3 Doppler echocardiography with high-velocity tricuspid regurgitation (a) allowing for estimation of right ventricular systolic pressure ($RVSP = TRV_{max}^2 + RAP$), and with pulmonary insufficiency (b) allowing for estimation of end-diastolic pulmonary arterial pressure ($PAP\ diast = PIV_{min}^2 + RAP$) and mean pulmonary arterial pressure ($PAP\ mean = PIV_{max}^2$) using the modified Bernoulli equation. (c) 2D echocardiography in a patient with IPAH showing hypertensive and dilated right ventricle with septal shift towards the left ventricular and increased eccentricity index (EI > 1). anaerobic threshold may be useful. Children with PH have significant impairment in aerobic capacity with decreased VO_2 compared with healthy controls [74]. Cardiopulmonary exercise testing can be performed safely in children with PH, with the exception of patients with severe limitation [75].

Cardiac magnetic resonance imaging (MRI)

Cardiac MRI is emerging as a potentially valuable tool for evaluating PH. The measurement of right ventricular volume, muscle mass, and left ventricular septal bowing, the calculation of stroke volume based on PBF, and delayed contrast enhancement suggestive of myocardial fibrosis may have a role in the serial follow-up of children with PH [76].

Nevertheless, cardiac MRI in young children necessitates anesthesia, which is an important consideration. Hence the risk of anesthesia must be carefully weighed against the benefit of additional information.

Brain natriuretic peptide (BNP)

BNP may be a useful tool to assess disease progression. Serial changes in BNP measurements correlate with the change in the functional status, hemodynamics, echocardiographic parameters, and outcome in children with PAH [77–79]. BNP correlates positively with functional status in children with PAH and a value >130 pg ml^{-1} is associated with increased risk of death or need for transplantation [78].

Furthermore, change in BNP over time correlates with change in hemodynamic and echocardiographic parameters in children with PAH. A BNP value >180 pg ml^{-1} predicts decreased survival [77].

Others

Serological studies (HIV, hepatitis) and blood screening for connective tissue diseases and coagulation disorders may help to discover potential causes of PAH. Ventilation–perfusion scan should be performed to exclude chronic thromboembolic disease, including patients with Eisenmenger syndrome because of their known increased incidence of thromboembolic events. An abdominal ultrasound scan should be performed to exclude portopulmonary hypertension. A high-resolution chest CT scan should also be performed before initiating pulmonary vasodilator therapy to exclude pulmonary capillary hemangiomatosis (PCH) or pulmonary veno-occlusive disease (PVOD) (Figure 51.4). Pulmonary function testing shows a mild restrictive pattern in about 20–50% of patients with IPAH and a mild reduction in the diffusion capacity in most of them [80]. Lung biopsy is rarely performed given its relatively high risk, but may be helpful, particularly in small children, to exclude certain diseases, such as PVOD, PCH, or alveolar capillary dysplasia. Those patients respond poorly to treatments currently available for PAH and need a definitive diagnosis for lung transplant listing [81]. In IPAH, the lung biopsy shows the classic features of medial hypertrophy, intimal fibrosis, microthrombi, and plexiform lesions.

Figure 51.5 summarizes the diagnostic algorithm recommended for pediatric patients with pulmonary hypertension.

A suggested work-up (with normal values) for pediatric pulmonary hypertension is presented in Table 51.4.

Table 51.4 Pediatric pulmonary hypertension: suggested work-up (with abnormal values).

Chest radiograph	• Cardiomegaly
	• Enlarged central pulmonary arteries
	• Peripheral pulmonary hypoperfusion
Electrocardiogram	• Right atrial hypertrophy
	• Right ventricular hypertrophy and strain
	• Right axis deviation
	• ST segment changes
Echocardiography	• Right atrial dilatation
	• Right ventricular hypertrophy (free wall >0.5 cm) and dilatation
	• Decreased right ventricular function
	• Fractional area change (FAC) <40%
	• Tricuspid annular plane systolic excursion (TAPSE) <1.8 cm
	• Tissue Doppler S' <10 cm s^{-1}
	• Increased right heart filling pressure (IVC dilatation)
	• TR jet velocity >2.8 m s^{-1}
	• Flattening of the interventricular septum
	• Eccentricity index (EI) > 1
	• Myocardial performance index (MPI) >0.28 ± 0.04 s^{-1}
	• Pericardial effusion
Cardiac catheterization	• Mean pulmonary artery pressure (mPAP) >25 mmHg
	• Pulmonary vascular resistance index (PVRI) >3 WU m^2
	• PVR/SVR >0.3
	• Pulmonary capillary wedge pressure (PCWP) >15 mmHg
	• Right atrial pressure (RAP)
	• Pulmonary vasoreactivity testing (NO ± O_2)
	• Aorto-pulmonary collaterals and/or pulmonary arteriovenous malformations
Liver evaluation	• Liver function tests (ASAT, ALAT, γGT)
	• Abdominal ultrasound (portopulmonary hypertension)
Complete blood count (CBC)	• Anemia or erythrocytosis
	• Abnormal red blood cells
	• Thrombocytopenia
Urinalysis	• Proteinuria
Blood chemistry	• BNP >130 pg ml^{-1}
	• NT-proBNP
Serologies	• HIV
	• Hepatitis profile
Hypercoagulable evaluation	• Disseminated intravascular coagulation (DIC) screen
	• Factor V Leiden
	• Factor II, V, VII, VIII
	• Antithrombin III
	• Prothrombin mutation 22010
	• Protein C and S
	• Von Willebrand Ag
	• Von Willebrand sirtocetin cofactor
	• Anticardiolipin IgM and IgG
Electrophoresis	• Serum protein
	• Hemoglobin
Collagen vascular disease work-up	• Antinuclear antibody (ANA) with profile (DNA, Smith, RNP, SSA, SSB, centromere, SCL-70)
	• Rheumatoid factor (RF)
	• Erythrocyte sedimentation rate (ESR)
	• CH50 complement and components
Thyroid function tests	• TSH and free T4
Genetic	• BMPR2 testing
Lung evaluation	• Pulmonary function tests with DLCO and bronchodilator
	• Sleep study and pulse oximetry

Table 51.4 (cont'd)

Exercise capacity	• *Chest* CT scan • Ventilation/perfusion (V/Q) scan • Lung biopsy[a] • Six-minute walking test (walking distance and saturation) • Cardiopulmonary exercise test (VO$_{2\ max}$, work rate, and anaerobic threshold)

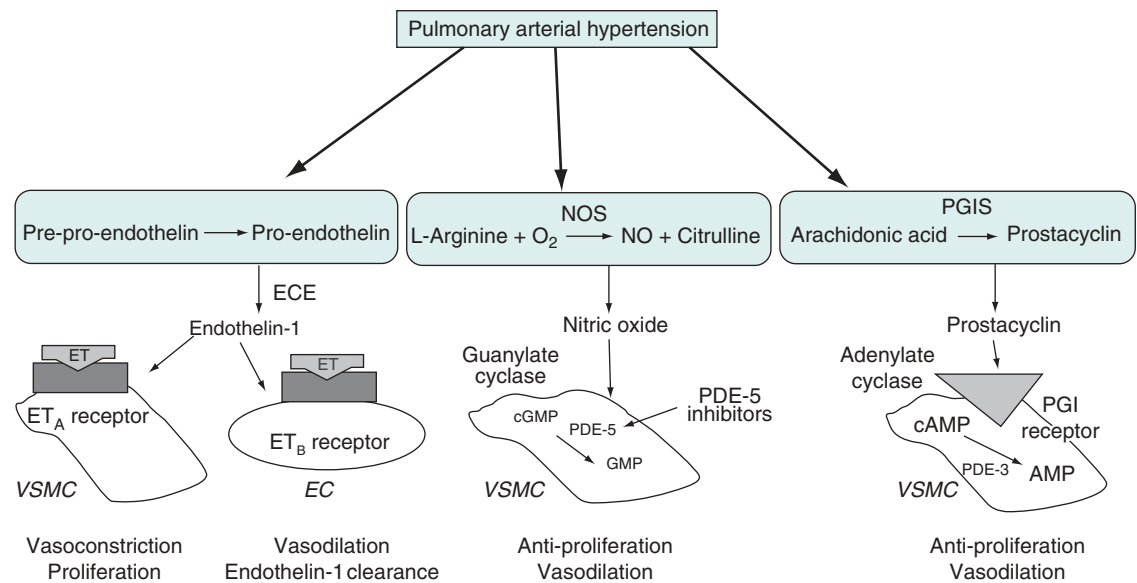
[a]Lung biopsy may be useful in infants with PAH to exclude pulmonary veno-occlusive disease (PVOD), pulmonary capillary hemangiomatosis (PCH). or alveolar capillary dysplasia.


Figure 51.6 Schematic representation of the three pathways involved in the therapeutic approach of PAH. EC, endothelial cell; ECE, endothelin converting enzyme; ET, endothelin; NOS, nitric oxide synthase; PDE, phosphodiesterase type 5; PGI, prostacyclin; PGIS, prostacyclin synthase; VSMC, vascular smooth muscle cell.

Therapeutic approach to PAH

Evidence-based treatment recommendations for children with PAH do not exist, primarily because results from randomized clinical trials are lacking for pediatric patients. The aim of medical treatment is to dilate and reverse the abnormal remodeling of the pulmonary vascular bed and to restore endothelial function, by acting on the prostacyclin, endothelin, and nitric oxide (NO) pathways (Figure 51.6). In practice, the therapeutic algorithm developed for PAH in adults appears to guide treatment of children with PAH [6] (Figure 51.7). Nevertheless, there are some difficulties in applying adult criteria and dosage regimens to children.

The main determinant of treatment is the response to vasodilator testing at cardiac catheterization. Acute responders with IPAH can be treated initially with calcium channel blockers (CCBs). In children with PAH associated with CHD, acute responders are candidates for surgical repair with shunt closure. In nonresponders with right heart failure, the first-line treatment consists of continuous intravenous prostacyclin, whereas in the absence of right heart failure, other targeted therapies (endothelin receptor blockers, phosphodiesterase inhibitors, or prostacyclin analogs) may be tried first. Nonresponders have a very limited survival if not treated with targeted therapies [1,82]. Nonresponders with PAH associated with CHD are also candidates for targeted therapies. These therapies have not been approved for use in children with PAH, except for the pediatric formulation of bosentan, which has been recently approved in Europe [83].

Conventional medical therapy

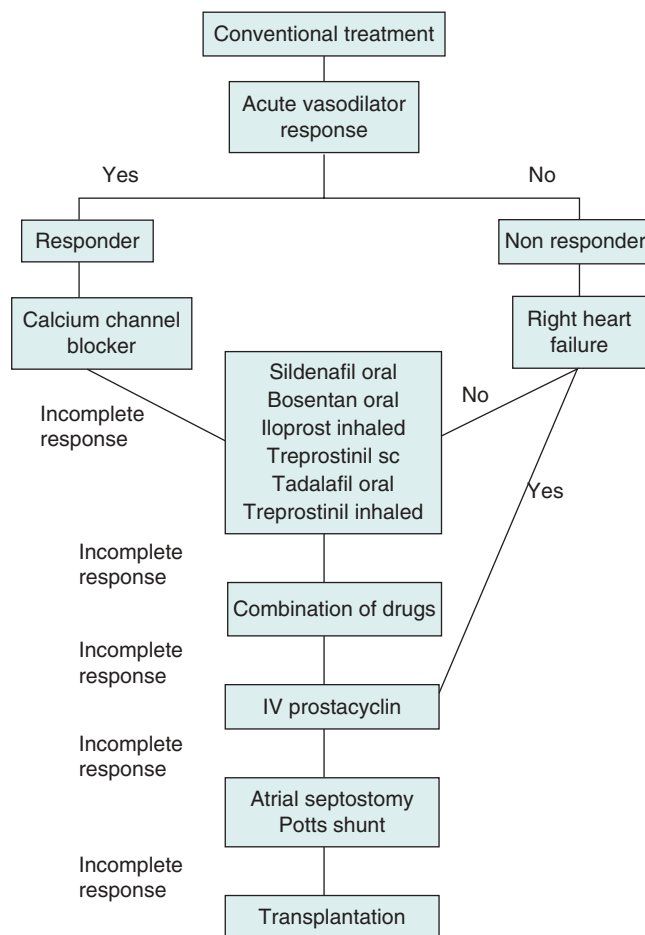
Diuretic therapy may be necessary for children with heart failure, but should be initiated cautiously because children with PAH may be preload dependent to maintain an optimal cardiac output. Although the use of *digoxin* in PAH has not shown clear benefits in children, it is sometimes used for right ventricular failure or arrhythmias [84].


Figure 51.7 Therapeutic algorithm recommended for pediatric patients with PAH.

The benefits of chronic *anticoagulation* have not been widely studied in children with PAH, but may be beneficial in patients with low cardiac output leading to sluggish blood flow through the pulmonary arteries or in those with hypercoagulable states at risk of thrombosis in situ. The risk/benefit of anticoagulation should be weighed carefully, especially in small children prone to hemorrhagic complications. Low-dose warfarin is frequently used to target an INR of 1.5–2 [85]. In younger children, maintenance of an adequate anticoagulation level is frequently difficult and *antiplatelet* therapy with aspirin is sometimes used, even though data are unavailable for children with PAH. For teenagers requiring contraception, oral contraceptive agents without estrogen content are recommended to avoid the risk of thromboembolic events.

Enhanced inspired oxygen is usually not used as a mainstay of therapy in children with normal daytime saturations. Nevertheless, some children may show mild nocturnal hypoventilation and desaturation known to exacerbate PAH, which can be avoided using night-time supplemental

oxygen. Children with PAH should have oxygen supplement available at home for an emergency. They should receive supplemental oxygen during any respiratory tract infection associated with desaturation and also during air travel. For children with RV failure and resting hypoxemia secondary to increased oxygen extraction, chronic supplemental oxygen therapy may be considered. For children with PAH associated with CHD, enhanced inspired oxygen may be beneficial especially for those with hypoventilation or lung disease. Nevertheless, for those with right to left interatrial shunting, oxygen supplement does not usually improve oxygen saturation. A controlled study in patients with Eisenmenger syndrome showed no benefit in survival or level of hemoglobin [86].

Nitric oxide (NO) is a potent vasodilator with selective effect on pulmonary circulation. NO activates soluble guanylate cyclase in the pulmonary smooth muscle cells, increases cyclic GMP, and decreases intracellular calcium concentration, leading to smooth muscle relaxation and vasodilation. NO is useful in all forms of PH [87], and has been beneficial for treating postoperative pulmonary hypertensive "crisis" [88–90]. Rebound PH is problematic and may prolong postoperative NO administration in some patients [91]. The delivery system is a major limitation but chronic home administration of NO can be achieved in children using a pulsed nasal delivery system, which appears to have the same efficacy as the continuous delivery system [92].

Calcium channel blockers (CCBs) inhibit calcium influx into cardiac and smooth muscle cells, causing pulmonary vasodilation. Chronic calcium channel blockade is efficacious in patients who demonstrate an acute response to vasodilator testing. Recent data suggest that ~7% of children with PAH are "responders" and can be effectively treated with oral CCB [12]. In children with IPAH, Barst *et al.* showed that 5-year survival rates improved significantly in acute vasoreactive responders treated with CCBs compared with non-responders [1]. For acute responders treated with CCBs, survival at 1, 5, and 10 years was 97, 97, and 81%, respectively with a treatment success of 84, 68, and 47%, respectively, in IPAH [93].Careful follow-up is essential as some acute responders may become nonresponders with time [93]. Those patients usually deteriorate clinically and hemodynamically and should be switched to other targeted therapies. CCBs are usually not indicated in PAH associated with CHD [6]. Nevertheless, in patients with Eisenmenger syndrome complicating VSD, nifedipine has been shown to improve exercise tolerance and arterial oxygen saturation with exercise [94]. The long-term effect of nifedipine on PVR in children with PAH and CHD still needs to be determined [95]. The major side effect is systemic hypotension. The dosage for children is extrapolated from adult studies and the optimal dose for children still has to be determined.

Targeted therapies

Based on known mechanisms of action and the endothelial dysfunction, three classes of drugs are commonly used to treat children with PAH: prostacyclin analogs, endothelin receptor antagonists and phosphodiesterase inhibitors.

Prostacyclin analogs

Prostacyclin is a metabolite of arachidonic acid endogenously produced by the vascular endothelium. It is a potent pulmonary and systemic vasodilator with antiplatelet activity. Children with severe PAH show diminished NO and prostacyclin synthase expression in the pulmonary vasculature [25].

Epoprostenol, a prostacyclin analog mainly used by intravenous infusion, improves hemodynamics, quality of life, exercise capacity, and survival in adults and children with IPAH and APAH [1,4]. Barst *et al.* have shown improved survival in children treated with long-term IV epoprostenol, with a 4-year survival rate for treated children of 94% compared with 38% in untreated patients [1], and Yung *et al.* have reported a 10-year treatment success rate (freedom from death, transplantation, or atrioseptostomy) of 37% [93]. Epoprostenol lowers PAP and increases cardiac output and oxygen transport. In adults and children with PAH associated with CHD, epoprostenol decreases PVR, improves oxygen delivery, and increases exercise capacity, with a demonstrated effect on survival [96–98]. Tolerance may develop and most children need periodic dose escalation. The optimal dose of i.v. epoprostenol shows a significant patient variability, and should be titrated incrementally, with children usually needing relatively much higher doses than adults. Adverse effects are antiplatelet activity and systemic vasodilation. Diarrhea and jaw pain are common side effects. Epoprostenol has a short half-life (1–2 min), necessitating a continuous intravenous infusion with a permanent central venous catheter. Complications such as line sepsis, local infection, and catheter dislodgement are not unusual [99,100], and can be responsible for life-threatening rebound PAH. Recently, the use of specific closed hub systems has been described in children [101,102] Alternative routes of delivery are attractive but are not as efficacious.

Iloprost is an inhaled prostacyclin analog with a longer half-life. A recent review summarizes its use in pediatric PAH [103,104]. In children treated with iloprost, WHO functional class was improved in 35%, remained unchanged in 50%, and decreased in 15% [105]. Lower airway reactivity is a problem in some children, as is poor compliance with the need for frequent aerosol administrations (6–8 times daily). The short- and long-term efficacy of inhaled iloprost is still controversial [106]. In the critical care of CHD, inhaled iloprost is as efficacious as NO in lowering mean PVR and improves systemic oxygen saturation [107]. Nevertheless, clinical deterioration, side effects, and poor compliance could limit its chronic administration in children [105].

Treprostinil is a prostacyclin analog usually administered by continuous subcutaneous infusion, and is also FDA approved for intravenous and inhaled delivery in adults with PAH. Subcutaneous treprostinil improves exercise tolerance, clinical signs, symptoms, and hemodynamics in adult patients with PAH [108]. Discomfort at the infusion site is common and represents the major limiting factor. No change in exercise capacity was noted in children on changing from intravenous epoprostenol to intravenous treprostinil, but side effects were less [109]. The use of treprostinil in children can be considered for patients who have been on a stable dose of intravenous epoprostenol with clinical improvement. Treprostinil has been studied in inhaled and oral forms [110].

Beraprost is an oral prostacyclin analog, shown to improve hemodynamics and survival in patients with IPAH, including children [111]. Data in children are scarce and beraprost is not available in the United States or Europe but is used in Japan [112].

Endothelin receptor antagonists

Endothelin-1 is a potent vasoconstrictor peptide produced primarily by the endothelial cell. Endothelin-1 expression and plasma levels are increased in patients with PAH and correlate inversely with prognosis. The endothelins are a family of isopeptides consisting of ET-1, ET-2, and ET-3. ET-1 is a potent vasoactive peptide produced primarily in the vascular endothelial cell, but also may be produced by smooth muscle cells. Two receptor subtypes, ET_A and ET_B, mediate the activity of ET-1. ET_A and ET_B receptors on vascular smooth muscle mediate vasoconstriction, whereas ET_B receptors on endothelial cells cause release of NO and prostacyclin (PGI2), and act as clearance receptors for circulating ET-1.

Bosentan is an oral dual endothelin receptor antagonist acting on both ET_A and ET_B receptors [113]. A recent review summarizes its use in pediatric PAH [114]. In children with PAH, Barst *et al.* have demonstrated the beneficial effect of bosentan in lowering PAP and PVR [115]. In an open uncontrolled study in children with PAH, bosentan lowered mean PAP and PVR and improved WHO functional status and survival estimates at 1 and 2 years (98 and 91%, respectively) [116]. Nevertheless, in a study including both children and adults with PAH and a systemic-to-pulmonary shunting, bosentan therapy produced only short-term improvement in WHO functional class and 6-MW test [117]. The beneficial effect of bosentan declined progressively after 1 year, with a more pronounced decline in children, who tended to have more severe disease at baseline. In adults with ES, bosentan has been shown to decrease modestly both PAP and PVR [118] with an increased oxygen saturation at rest and a decreased level of hemoglobin [119]. Common side effects include dose-related hepatotoxicity, teratogenicity, and possibly male infertility [120]. Liver function tests

should be performed monthly. The safety of bosentan therapy in children with PAH has recently been reported by Beghetti *et al.* [120]. Elevated transaminase levels were reported in 2.7% of children compared with 7.8% of patients aged ≥12 years, and the overall discontinuation rate from bosentan was 14% in children compared with 28% in patients aged ≥12 years. In children with ES, bosentan is well tolerated and exercise capacity and hemodynamics improve without compromising peripheral oxygen saturation [118]. A specific pediatric formulation has recently been approved in Europe [83].

Sitaxsentan and *ambrisentan* are oral selective ET_A receptor antagonists with a long half-life. They block the vasoconstrictor effect of ET_A receptors while maintaining the vasodilator effect and clearance function of ET_B receptors. Sitaxsentan and ambrisentan have beneficial effects on exercise capacity and NYHA functional class in adult patients [121–123], but no data are available for children.

Phosphodiesterase inhibitors type 5 (PDE-5)

PDE-5 prevents the breakdown of cyclic GMP resulting in pulmonary vasodilatation. PDE-5 are acute pulmonary vasodilators as efficient as inhaled NO and potentiate pulmonary vasodilatation when used together with NO. They may be particularly beneficial where withdrawal of NO may lead to rebound PAH [124,125].

Sildenafil can be used orally or intravenously but is currently only available orally. Sildenafil has been approved for the treatment of WHO functional class II–IV PAH adult patients [126–128], but the data for children remain limited. In a pilot study of 14 children with PAH [129], oral sildenafil decreased PAP and PVR significantly and improved the mean 6-MW test, but a plateau was reached between 6 and 12 months. In a small study of children with IPAH and PH associated with CHD, sildenafil was well tolerated and safe, with improved oxyhemoglobin saturation and exercise capacity without significant side effects [130]. In children with PAH associated with chronic lung disease, sildenafil improved hemodynamics in 88% of patients, and was well tolerated and safe [52]. Moreover, PDI-5 appears to be highly expressed in the hypertrophied human right ventricle and acute inhibition with oral sildenafil has been shown to improve right ventricular contractility [131]. Side effects include systemic hypotension and penile erection. Preliminary safety and efficacy trials of oral sildenafil are under way in pediatric patients and results are to be expected soon. Intravenous sildenafil has been shown to potentiate the increase in cGMP in response to NO in children with increased PVR related to CHD or to postoperative state. Nevertheless, sildenafil infusion was associated with increased intra-pulmonary shunting and augmentation of hypoxemia related to V/Q mismatch in the postoperative patient [132,133]. In neonates with PPHN associated with congenital diaphragmatic hernia resistant to NO, oral sildenafil improved cardiac output by reducing PH [134]. In neonates with PPHN and an oxygenation index >15, continuous intravenous sildenafil was well tolerated and allowed acute and sustained improvements in oxygenation [135].

Tadalafil is also a selective PDE-5 with a longer duration of action. No data are available for children but tadalafil has been shown to improve oxygenation in an animal model of newborn PAH [136]. Tadalalfil was approved by the FDA in 2009 for adults with PAH. In adults with severe PAH, tadalafil has been used in addition to prostacyclin with some improvement [137].

Combination therapy

As for patients with heart failure, combination therapy is an attractive option to address simultaneously the multiple pathophysiologic pathways present in PAH. Acting on the three different pathways of PAH may be more efficacious than acting on a single one, by additive or synergistic effects. In adult patients with PAH, beginning combination therapy with epoprostenol and bosentan tended to show a greater improvement in hemodynamics compared with epoprostenol alone [138]. In a randomized placebo-controlled trial of initiating sildenafil or placebo at the same time as epoprostenol, the addition of sildenafil to long-term intravenous epoprostenol therapy improved exercise capacity, hemodynamic measurements, time to clinical worsening, and quality of life [139]. A therapeutic approach utilizing bosentan, sildenafil, and inhaled iloprost, by acting on the three pathways, improved survival and lowered the need for lung transplantation and for intravenous iloprost therapy in adult patients with severe PAH [140]. In a pediatric study by Ivy *et al.* [141], bosentan was successfully used in children on long-term epoprostenol therapy, and concomitant use of bosentan allowed for a decrease in epoprostenol dose. If the patient is started on intravenous epoprostenol before the availability of nonparenteral therapy, transition to oral or inhaled therapy for pulmonary arterial hypertension appears safe with efficacy maintained, but needs close follow-up [142].

Whether combination therapy should be used as a first step by simultaneous initiation of two or more drugs, or by addition of a second treatment to a previous therapy once insufficient, is unknown. More studies are needed to establish guidelines. Even if empiric combination of drugs is not uncommon in pediatric patients with PAH, there is a clear lack of studies in this area.

Atrioseptostomy

Atrioseptostomy is beneficial in patients with severe PAH and poor cardiac output, recurrent syncope, and/or intractable right heart failure refractory to vasodilator treatment. Right-to-left shunting through an interatrial defect allows maintenance of cardiac output but with increased hypoxemia. It alleviates signs of right heart failure

by decompressing the right heart [143,144]. Improvement of symptoms and an increase in survival have been reported, but this remains controversial. In a small series of 20 children deteriorating with severe PAH, atrioseptostomy improved symptoms and quality of life [143]. Patients with severe PAH, right heart failure, and markedly elevated PVR may not tolerate atrioseptostomy because of massive intracardiac right-to-left shunting and secondary severe hypoxemia.

Potts shunt

In patients with severe PAH, markedly elevated PVR, and right heart failure who do not tolerate an atrioseptostomy, creating a Potts shunt (anastomosis between the left pulmonary artery and the descending aorta) may decrease right ventricular afterload and improve right ventricular function [145,146]. Because of the high risk of the procedure, it should be reserved and used cautiously for the treatment of children with severe right heart failure resistant to other forms of therapy.

Transplantation

Lung or heart–lung transplantation remains the only available treatment for patients unresponsive to vasodilator treatment or with certain lesions such as pulmonary vascular obstructive lesions [147]. Its use is limited by the shortage of donors and the high incidence of bronchiolitis obliterans, which limits the long-term survival after lung transplantation [148] (see Chapter 70). Therefore, transplantation should be reserved for children with PAH which has progressed despite optimal medical therapy. Children should be listed for transplantation when their probability of 2-year survival without transplantation is ≤50% [149].

Future therapies [22,150]

Platelet-derived growth factor (PDGF) has been implicated in these processes. Altered PDGF signaling may be involved in the vascular remodeling observed in PAH [151] and a PDGF receptor antagonist such as *imatinib* or *sorafenib* could reverse pulmonary vascular disease [152,153]. Studies in animal models have suggested that Rho-kinase and NO synthase play important roles in the regulation of vasoconstrictor tone in physiologic and pathophysiologic states and that pulmonary hypertension can be reversed by agents that inhibit Rho-kinase, generate NO, or stimulate soluble guanylate cyclase [154]. Stimulating the *soluble guanylate cyclase*, a component of the nitric oxide receptor, by *BAY 63-2521* sensitizes the receptor to NO and may reverse right heart hypertrophy and structural lung vascular remodeling [155]. *Vasoactive intestinal polypeptide* (VIP) has a potent vasodilator effect on the pulmonary and systemic circulations and may exert an overall pulmonary vasodilatory effect in adults with PAH [156]. Rho-kinase has been shown to be involved in regulating baseline tone and in mediating pulmonary vasoconstrictor responses.

The 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase inhibitor *simvastatin* inhibits Rho-kinase activity and attenuates and induces regression of chronic hypoxic pulmonary hypertension and reduces pulmonary artery pressure in animal models [157]. In a recent clinical trial in adult patients with PAH, simvastatin added to conventional therapy produced a small and transient early reduction in right ventricular mass and NT-proBNP levels in patients with PAH, but this was not sustained over 12 months [158]. In animal models of PAH, the Rho-kinase inhibitor *Y–27632* attenuated increases in pulmonary arterial pressures in response to vasoconstrictor agents [154]. *Serotonin* is a pulmonary vasoconstrictor and smooth muscle cell mitogen and is thought to be necessary for initiating the development and maintenance of pulmonary vascular remodeling. Complete reversal of PAH by *fluoxetine*, a 5-HT inhibitor, has been shown to reverse those lesions completely in an animal model of PAH [159]. These novel therapies are currently under active investigation either in animals or in preliminary studies in adults and may also be of interest for pediatric patients in the near future.

Management of PAH associated with CHD

Acute responders with PAH associated with congenital shunt lesions are considered candidates for surgical repair. Treatment for patients with CHD and nonreactive PAH (ES) is based on the same selective pulmonary vasodilators as in IPAH, even if data are limited [160,161].

Operability

Most PVD related to CHD may be prevented by correcting the defect at an early age, preventing permanent remodeling of the pulmonary vasculature and irreversible PVD. The window of opportunity for surgical correction and prevention of permanent PVD is wide and essentially lesion specific. Individual, environmental, and genetic susceptibilities also play a role; patients with Down syndrome are prone to early and fixed pulmonary vascular remodeling and have a more reactive pulmonary vascular bed in the postoperative period, being prone to pulmonary hypertensive "crisis." This may be related to the association of chronic upper airway obstruction responsible for alveolar hypoxia, hypercarbia, and acidosis with adverse effect on PVR.

Risk stratification of patients with PVD and CHD is important [67,68,162,163]. As previously mentioned under catheterization, a baseline PVR index <6 WU m^2 associated with a pulmonary to systemic resistance ratio of <0.3 without a vasoreactivity test is interpreted as indicating a favorable outcome following operations resulting in a biventricular circulation. Acute vasodilator challenge using oxygen/NO has been strongly encouraged if baseline PVR index is between 6 and 9 WU m^2 with a pulmonary to systemic

resistance ratio from ~0.3 to 0.5. Although there is no absolute consensus, operability with a favorable outcome is considered likely if the following criteria are met [163]:

- a decrease of 20% in the PVR index
- a decrease of ~20% in the ratio of pulmonary to systemic vascular resistance
- a final PVR index of <6 WU m^2
- a final ratio of pulmonary to systemic resistance of <0.3.

It remains unclear which preoperative pulmonary hemodynamic parameters correlate best with outcomes. Moreover, individual patient factors, such as type of cardiac lesion and genetic predisposition, influence the outcome but are incompletely understood. In children with a VSD, Neutze *et al.* found that those with PVR <8 WU m^2 who showed reactivity (decrease in PVR <7 WU m^2 after pulmonary vasodilatation with isoproterenol) had normal or modestly increased PVR after surgical repair [164]. In children with various types of CHD, Balzer *et al.* showed that a decrease in PVR of <5.3 WU m^2 and in PVR/SVR of <0.27 after pulmonary vasodilatation with 100% FIO$_2$ and inhaled NO was 97% sensitive for identifying patients with good outcome after repair [66].

It should be noted that the above criteria do not apply to patients with single ventricle physiology who are being assessed for a Fontan procedure. In those patients, obtaining accurate hemodynamic measurements can be even more difficult. Ideally, they should have PVR near normal and certainly ≤3 WU m^2. A mean pulmonary artery pressure of >15 mmHg has been associated with increased early and late mortality after the Fontan operation [68].

In general, ASD are repaired by 4–5 years, VSD during the first year of life, complete AVSD, and PDA by 6 months of age and *d*-TGA with VSD and common arterial trunk during the first few weeks of life. For neonates with a single ventricle physiology or complex CHD and unobstructed PBF (no pulmonary protection), the goal is to secure normal PAP with a pulmonary artery banding before proceeding to the cavopulmonary anastomosis.

Pulmonary artery banding

Placing a restrictive band on the main PA can reduce the PAP distal to the band and reverse pathologic pulmonary vascular remodeling [165,166]. Another alternative to PA banding is partial closure of the shunt, allowing for some degree of right-to-left shunting to prevent right heart failure. The use of a fenestrated VSD patch closure has been reported to be beneficial in children with high PVR [167,168].

Immediate postoperative care

In the immediate postoperative period, a child with PAH related to CHD is the most vulnerable. Postoperative pulmonary hypertensive "crisis" is characterized by acute and labile increase in PVR following cardiac surgery, related to heightened vascular reactivity secondary to vasospastic stimuli. Pulmonary hypertensive crisis leads to acute right heart failure, low cardiac output with systemic hypotension and myocardial ischemia, and may be lethal. Patients with extracardiac syndromes (particularly Down syndrome) seem to be at increased risk. In general, corrective surgery in the first 6 months of life decreases the risk of postoperative pulmonary hypertensive crisis, particularly for AVSD and VSD. For high-risk cardiac lesions, such as common arterial trunk or *d*-TGA, surgical repair should be performed at an earlier age [35]. Precipitating factors should be avoided, particularly stressful stimuli such as tracheal suction, pain, and anxiety, and also hypoxia, hypercapnia, acidosis, hyperthermia, or fluid overload. Adequate sedation, hyperventilation, and the use of sodium bicarbonate are useful in the immediate postoperative care of such patients [169].

In general, there is no clear level of PAP indicating the need for postoperative specific pulmonary vasodilator therapy. Patients with a mean PAP >25 mmHg or >50–60% of systemic pressure associated with signs of low cardiac output should be treated. Inhaled NO has become the accepted therapy because of its selective vasodilator effect on the pulmonary vascular bed. There is no optimal dosage but there is little benefit from doses >10–20 ppm [170]. Rebound PH is a common complication upon rapid withdrawal of NO [91] and can be minimized by slow weaning, particularly in the last 5 ppm, and adding oral sildenafil at 0.3–0.5 mg kg^{-1} [125].

Medical therapy

PVD related to CHD may be prevented by early diagnosis and correction. Once permanent pulmonary vascular remodeling is established and nonreactive to pulmonary vasodilator testing, therapy is supportive rather than designated to decrease PVR, even though patients with ES may show some improvement with targeted therapies.

Eisenmenger syndrome (ES)

ES represents the most advanced form of PAH associated with CHD. Treatment options for patients with ES were historically limited to palliative measures and heart–lung transplantation. Treatment most commonly involved the use of digoxin, diuretics, antiarrhythmics, and/or anticoagulants. None of these classes of drugs significantly modifies survival. The efficacy of calcium channel blockers in patients with ES is neither proven nor generally recommended, as their use can result in an acute decrease in systemic arterial pressure and increased right-to-left shunting, which may lead to syncope and sudden death. Patients with ES are at particular risk during cardiac and noncardiac surgery and anesthesia, and as a result of dehydration, chest infections, high altitude, and intravenous lines. They should also avoid strenuous exercise and competitive sports.

Nonoperable pre-Eisenmenger syndrome

These patients have a PVR considered too high for surgical repair but not at a level to diagnose ES. So far, the therapeutic approach for this group is to watch and wait. However, with the upcoming new targeted therapies use to treat PAH, the concept to treat and repair has emerged [171].

In PAH associated with CHD and a large shunt lesion, it is thought that the pressure and/or volume load on the pulmonary vascular bed leads to pulmonary vascular remodeling and lesions. By reducing PVR, the possibility arises that pretreatment with vasodilators can improve a patient's condition and an inoperable patient could be considered operable. Pretreatment may not always be efficacious, depending on the extent and severity of the lesions. Although pretreatment may reduce PVR, PAH could remain postoperatively, resulting in a worse prognosis. Moreover, the reversal of vascular remodeling and lesion formation with pretreatment, leading to an initial decrease in PVR, could actually result in an increase in pulmonary blood flow, re-establishing the propensity towards pulmonary vascular damage and lesions later.

Several reports have described pretreatment with prostacyclins or bosentan being used prior to CHD surgery to prepare borderline patients [172–175]. These reports suggest some benefit in improving hemodynamics and making conditions more favorable for repair. Nevertheless, most of these patients had simple CHD such as ASDs. A retrospective analysis of national registries of this type of data would be required to gain a complete picture.

Persistent pulmonary hypertension late after surgical repair [176]

Acute treatment and survival in the immediate postoperative period do not mean that PH resolves and the patient may present persistent PAH after successful repair. Literature on this subgroup of patients remains scarce, but the hemodynamics and prognosis appear very similar to those in idiopathic PAH [12]. This emphasizes the importance of accurate decision for operability, because survival may be better with a persistent shunt lesion and ES than with a closed shunt and RV failure [177].

Pulmonary hypertension and the Fontan circulation

The Fontan procedure (total cavopulmonary connection) results in a pulmonary circulation very different from physiological conditions, and a small increased in PAP has a profound effect on the passive pulmonary blood flow. As the child ages, PAP may increase and lead to failure of the Fontan circulation over time. For this reason, the idea of treating failing Fontan patients with a therapy that lowers PVR has emerged [178]. Therapies approved for PAH may, therefore, provide benefits in this patient population, but few data have been reported.

Inhaled NO is predominantly effective in patients with central venous pressure ≥15 mmHg and/or a transpulmonary pressure gradient (TPG) ≥8 mmHg [179]. In the early postoperative period, inhaled NO and milrinone are very effective in reducing the TPG [180,181]. The use of prostacyclins in the perioperative course of Fontan is seldom reported, but beraprost reduced mean PAP and PVR in preoperative Fontan candidates with mild elevation in PAP [182], and intravenous epoprostenol prevented the rebound effect after NO cessation in the early postoperative phase [183]. Treatment of late Fontan patients with inhaled NO reduced PVR but had no effect on cardiac index [184], whereas sildenafil improved exercise capacity and hemodynamic response to exercise [185]. The use of bosentan is anecdotal, but has improved functional class, symptoms, exercise capacity, and hemodynamic parameters in a child with plastic bronchitis following Fontan [186]. Given the important role of the pulmonary circulation in the Fontan physiology and the current lack of data, there is a need for clinical studies on the safety and efficacy of those potential therapies.

Outcome

Historically, PAH in children has had a poor prognosis, with a less than 1 year survival in untreated children [187].

For patients with IPAH who responded to calcium channel blockers, Yung *et al.* reported survivals at 1, 5, and 10 years of 97, 97, and 81%, respectively, with a treatment success (freedom from death, transplantation or atrioseptostomy) of 84%, 68%, and 47%, respectively; treatment success decreased significantly when acute responders became nonresponders [93]. For non-responders with IPAH treated with IV epoprostenol, survival at 1, 5, and 10 years was 94%, 81%, and 61%, respectively with a treatment success of 83%, 57%, and 37%, respectively. Since 1995, survival was even better for children with IPAH treated with intravenous epoprostenol with a survival rate of 97%, 97%, and 78% at 1, 5, and 10 years [93]. In children with severe IPAH treated with continuous prostacyclin, Barst *et al.* reported survival rates of 86.9, 72.4, and 63.3 at 1, 2, and 3-years, respectively [1], whereas Haworth and Hislop reported survival rates of 85.6, 79.9 and 71.9% at 1, 3 and 5 years, respectively, for those treated with a combination of intravenous epoprostenol and either bosentan or sildenafil, or both [12]. In APAH, survival rates were 92.3, 83.8 and 56.9% at 1, 3 and 5 years, respectively, with postoperative CHD-associated PAH having the worst outcome. Indeed, in a 5-year retrospective study of children with PAH in the United Kingdom, the subpopulation with postoperative CHD-associated PAH fared far worse than those with PAH associated with complex (unoperated) CHD and ES, and

almost one-quarter of these children died [12]. Children with ES had a greater cumulative survival time by 1.3 years, indicating that surgical repair is not necessarily always the best option.

Conclusion

Advances in the understanding of pulmonary vasculature have led to new therapeutic options and improved survival in children with PAH. In children with CHD, increased PBF is a potent stimulator to both active vasoconstriction and pathologic remodeling of the pulmonary vascular bed leading to increased PVR. With the exception of a few high-risk congenital cardiac malformations, irreversible PVD seldom occur in the first 1–2 years of age. Timely diagnosis is crucial as early surgical repair of congenital shunt lesions and earlier treatment of PAH leads to improved outcome. In children with PAH, an extensive work-up is necessary to determine the etiology, as the most successful strategy involves treatment of the underlying disorder. Initial evaluation includes acute vasodilator testing at cardiac catheterization, which determines initial and long-term therapy. Several novel therapeutic agents are under investigation and evolving clinical research should better define the role of new treatments for children with PAH. Moreover, improved delivery of medical and surgical care in underprivileged areas of the world should reduce PAH associated with CHD.

52 Central Nervous System Complications

Jane W. Newburger

Harvard Medical School and Children's Hospital, Boston, MA, USA

Dramatic improvements in the survival of children with heart disease have been accompanied by the recognition that this population manifests a high prevalence of neurologic and developmental abnormalities, including mental retardation and lifelong language and learning problems [1]. The factors underlying central nervous system (CNS) morbidity in children with heart disease are complex, multifactorial, and probably cumulative. Such morbidities may be mediated by known genetic disorders (e.g., trisomy 21, chromosome 22q11 microdeletion). Developmental abnormalities for which a genetic origin is suspected are common in congenital heart disease (CHD) patients, in whom the prevalence of cerebral dysgenesis ranges from 10 to 29% in autopsy studies and varies with the underlying cardiac lesion [2–4]. Infants with hypoplastic left heart syndrome (HLHS) appear to be at particular risk for associated developmental cerebral abnormalities, ranging in severity from microdysgenesis to gross malformations such as holoprosencephaly [2]. Increasingly, abnormal fetal cerebral hemodynamics are suspected to play a role in adverse neurodevelopmental outcome of children with CHD [5].

Other neurologic abnormalities are acquired postnatally, either as sequelae of congenital heart disease itself or from its therapies. Neurologic complications of open heart surgery have received the greatest scrutiny, in part because CNS protection during cardiopulmonary bypass constitutes a modifiable risk factor. Brain injury among patients with CHD may be caused by pre- or postoperative hemodynamic instability and adverse events, severe chronic hypoxemia or congestive heart failure, episodes of arrhythmia or cardiac arrest, thromboembolic events unrelated to operation, poor nutritional status, and CNS infection.

Not surprisingly, given these risk factors, children with heart disease, compared with a normative sample, have significantly lower scores on IQ and achievement tests, delays in reaching motor milestones, higher frequencies of learning disabilities, use of special services, and speech, language, and behavioral abnormalities [6–14]. In general, outcomes after repair of simple lesions, such as atrial septal defect, are similar to those in the normal population [15], whereas developmental outcomes appear to be worse after biventricular repair of more complex lesions [14,16,17]. Importantly, adverse developmental outcome is most common among those with various forms of single ventricle [7,18,19]. For this reason, children with cardiac disease should undergo periodic neurodevelopmental screening and evaluation to facilitate prompt institution of interventions when needed.

Genetic factors

Wide variance in neurodevelopmental outcomes in CHD patients cannot be explained solely by intraoperative perfusion variables or other obvious risk factors. Hence the relationship of genetic factors to neurologic and developmental outcomes in CHD patients has been subject to increasing investigation.

Genetic factors causing congenital heart defects may also affect brain development. The association of cardiac defects and CNS impairment has long been described in patients with aneuploidy (e.g., trisomy 12, 18, and 21, Turner syndrome) and in chromosomal structural abnormalities, such as monosomy 22q11. The role of single-gene defects in causing CHD and neurodevelopmental impairment has been discovered more recently. For example, JAG1 encodes a ligand for the Notch intercellular signaling pathway, which is of tremendous importance in brain development [20–24]; mutations in JAG1 cause Alagille syndrome, which affects the heart, liver, kidney, and brain. Approximately 10% of

children with facial dysmorphism and multiple congenital anomalies in a series of 373 patients with a normal chromosome analysis had a chromosomal deletion and/or duplication by microarray [25]. More than three dozen genetic syndromes have been associated with single ventricle, a diagnosis particularly notable for its association with neurodevelopmental delays [26–30].

Children with CHD with a genetic or phenotypic syndrome fare worse and have a wider standard deviation in development scores than patients without such genetic abnormalities [31].

Fetal milieu

In some forms of CHD, the fetal circulation is associated with abnormalities of cerebral hemodynamics and brain metabolism. For example, in a fetus with HLHS, the brain is perfused retrograde through the ductus arteriosus. The association of microcephaly in HLVS with a smaller diameter of the ascending aorta suggests that inadequate cerebral perfusion may complement dysgenesis as a cause of abnormally small brain size at birth. Cerebral blood flow characteristics are also abnormal in mid-gestation fetuses with evolving HLHS, suggesting low cerebral vascular impedance [32]. Third-trimester fetuses with complex CHD have smaller gestational age- and weight-adjusted brain volume than normal fetuses and evidence of impaired neuroaxonal development and metabolism [32]. Thus, impaired cerebral perfusion and substrate delivery during fetal life may adversely affect the fetal brain. Furthermore, delayed or abnormal fetal brain development caused by perturbations in cerebral hemodynamics may increase the vulnerability of neonates with CHD to ischemia and reperfusion injury perioperatively [33].

Neonatal intracranial hemorrhage

Perhaps due to hemodynamic instability, the risk period for intraventricular–periventricular hemorrhage [34], characteristic of premature infants, appears to extend further into maturity in infants with a cardiac anomaly (see also Chapter 18). The diagnosis of intraventricular–periventricular hemorrhage in a neonate with CHD complicates operative planning. In these infants, the use of anticoagulants, the increase in fibrinolytic activity [35], and the variation in cerebral perfusion pressure during cardiopulmonary bypass may each predispose to extension of intraventricular–periventricular hemorrhage or hemorrhagic transformation of ischemic lesions. The timing and management of cardiac surgery in infants with intraventricular–periventricular hemorrhage attempt to balance the risks of extension of hemorrhage during a cardiac operation against those of

ischemia–reperfusion injury and further hemorrhagic extension during the persistent cardiorespiratory instability associated with an uncorrected cardiac malformation. The severity of the cardiac anomaly, the expected complexity of the operation, and the severity of the intracranial hemorrhage must be considered. Hemorrhage confined to the subependymal region should not delay operation. It is probably advisable to delay cardiopulmonary bypass for at least 1 week in infants with intraventricular hemorrhage, preferably longer in those with intraparenchymal hemorrhage.

The perioperative period

Acquired brain injury among patients with congenital cardiac anomalies has been well studied among those undergoing palliative and repairative cardiovascular surgery. Bypass-related sources of brain injury include hypoperfusion, macroemboli, and microemboli, both particulate and gaseous. The risk of brain injury related to cardiopulmonary bypass in infants and children may be influenced by many variables, including the duration of total support, the depth of hypothermia, the rate and duration of core cooling [36,37], the type of pH management chosen during core cooling (alpha-stat versus pH-stat) [17,38,39], the degree of hemodilution [40–42], the duration of total circulatory arrest [43–47], the type of oxygenator (bubble versus membrane), the use of arterial filtration, the use of regional cerebral perfusion [48], and other aspects of the biochemical milieu.

Pre- and postoperative risk factors interact with intraoperative vital organ support, with its "planned ischemia and reperfusion injury," in producing CNS injury. In particular, recent data have underscored the frequency and importance of preoperative neurologic state. Miller and colleagues showed that brain metabolism and microstructure, as measures of brain maturation, are abnormal in a high percentage of infants with CHD before they undergo cardiac surgery [33]. Indeed, the imaging findings are similar to those in premature infants. Licht and colleagues studied full-term infants with D-transposition of the great arteries and HLHS, demonstrating that brain maturation was delayed by ~1 month compared with a normative sample without CHD [49]. Thus these term infants had brains that were smaller and less mature prior to cardiac surgery, potentially predisposing to white matter injury. Furthermore, preoperative cerebral blood flow is reduced in neonates with CHD compared with normal infants [50]. In the preoperative period, more than half of infants with critical CHD have abnormalities on neurologic examination [51]. Abnormal preoperative neurological status is an important predictor of adverse longer term outcome in patients with CHD [12,52].

CNS damage may also be caused by early postoperative events, when cerebral vasoregulatory systems disrupted by

hypothermic circulatory arrest and bypass techniques may make the brain more vulnerable to hemodynamic fluxes, such as hypotension [53–56].

Neuropathologic studies of individuals who have undergone congenital heart surgery have demonstrated both diffuse cerebral injury, as might result from ischemia reperfusion injury related to hypoperfusion, and also focal infarctions from thromboembolic events. Among infants who died after reparative or palliative cardiovascular surgery, the most widespread and severe injury occurred in the cerebral white matter, where periventricular leukomalacia and diffuse white matter gliosis were evident [57]. Gray matter injury, however, was also detected. Autopsy series are subject to bias, however, because the most severely ill children are those who succumb.

Magnetic resonance imaging (MRI) has provided a "window" into the CNS in the perioperative period. Mahle and colleagues [58] conducted a prospective MRI study of infants with various types of CHD before and after surgical correction of their cardiac lesions. Periventricular leukomalacia was present in more than half of the subjects postoperatively, but white matter and gray matter injury were already present preoperatively in 15 and 8% of subjects, respectively. Neonates more likely demonstrate evidence of brain injury than infants older than 6 months of age at surgical correction [59]. Furthermore, preoperative magnetic resonance spectroscopy (MRS) showed that more than half of the children had elevated cerebral lactate peaks. In preoperative MRI studies, McConnell and colleagues [60] found enlargement of ventricles and subarachnoid spaces consistent with cerebral atrophy in one-third of their study sample. MR imaging performed on patients with CHD following surgery has revealed findings consistent with both gray matter and widely distributed white matter injury [61]. Taken in aggregate, documentation by MRI of brain abnormalities in children with CHD both before and after cardiac surgery suggest that the preoperative condition of the brain, and also perioperative course, contribute to long-term developmental outcome.

Postoperative delayed recovery of consciousness

Although hypoxic–ischemic reperfusion injury is often associated with postoperative delayed recovery of consciousness, postoperative hepatic or renal impairment resulting in accumulation of toxic metabolites or impaired metabolism or excretion of sedating drugs must be excluded. Prolonged use of neuromuscular blocking agents may delay the recovery of motor function [62–64] and, if severe, may mimic a state of impaired consciousness. As discussed later, a significant minority of infants develop postoperative seizures, which may recur serially and may be clinically silent [65].

A persistent depression of consciousness warrants consideration of occult seizures or a prolonged postictal state.

Postoperative seizures

Seizures are probably the most common neurologic complication of open heart surgery in infants and are clinically manifest in up to 15% of patients in the early postoperative period [65–67]. Prospective long-term video electroencephalographic monitoring has demonstrated a significantly higher incidence of electrographic seizure activity in this early postoperative period, frequently without typical behavioral seizure manifestations [65]. Postoperative seizures may have a number of possible etiologic factors; of greatest concern to long-term outcome are those resulting from hypoxic–ischemic reperfusion injury due to either generalized cerebral hypoperfusion or focal vasocclusive disease. More commonly, however, these early postoperative seizures remain cryptogenic and are often referred to as post-pump seizures. Although post-pump seizures are often assumed to be related to hypoxic–ischemic reperfusion injury, they differ in several respects from other forms of seizures. First, post-pump seizures typically occur later after injury than, for instance, those occurring after birth asphyxia. Whereas most asphyxial seizures have their onset within the first 12 h after birth, post-pump seizures are usually seen first during the second postoperative 24 h. Second, although post-pump seizures are associated with later neurologic and developmental dysfunction [68], they have a less devastating prognosis than asphyxial seizures, in which as many as 50% of infants are left with neurologic disability [69–71]. The delayed onset of post-pump seizures and their more favorable outcome may reflect the neuroprotective effective of hypothermia during cardiopulmonary bypass [72].

The prognosis of postoperative seizures varies with the underlying cause. A prospective study using continuous video electroencephalography demonstrated a significant association between post-pump seizures and worse neurologic and developmental outcome at ages 1 year [68] and 4 years [73]. None of these patients had developed epilepsy by age 4 years, however. Among infants whose seizures had a specific cause, long-term outcome is related to etiology. For instance, if seizures are a presenting symptom of cerebral dysgenesis, poor long-term outcome is nearly universal and subsequent epilepsy is common. If seizures result from a stroke, the risk of subsequent epilepsy ranges from 19 to 28% [74,75]. In these patients, the epilepsy risk relates to age at the time of stroke and the latency to first seizure after the stroke. In a neonate, the risk for subsequent epilepsy is low [76], whereas longer latency to first seizure is associated with greater incidence of epilepsy [75]. These features may guide decisions regarding duration of anticonvulsant therapy.

Movement disorders

Soon after the development of deep hypothermic cardiac surgery, striking movement disorders were reported [77–89]. Although the incidence in different series has ranged from 0.5% [90] to 19% [80], underdiagnosis and underreporting of these dyskinesias are such that the true incidence is unknown. Despite their relative rarity, these movement disorders are often dramatic, frequently intractable, and, if severe, associated with a substantial mortality. Although choreoathetosis is the most frequent form of dyskinesia complicating a cardiac operation, other movement disorders have been described, including oculogyric crises [91] and parkinsonism [92].

The appearance of postoperative movement disorders is typically preceded by a latency period of 2–7 days, during which neurologic recovery from operation appears uncomplicated. The dyskinesia is usually heralded by the subacute onset of delirium, with marked irritability, insomnia, confusion, and disorientation, followed shortly by abnormal involuntary movements. These movements begin in the distal extremities and orofacial muscles, progressing proximally to involve the girdle muscles and trunk; if severe, violent ballismic thrashing may develop. The abnormal movements are present during wakefulness, peak with distress, and resolve during sleep. In addition, an apraxia of oculomotor and oromotor function develops, with a loss of feeding and expressive language skills. A supranuclear ophthalmoplegia often appears, with a loss of voluntary gaze but sparing of reflex extraocular movements; these patients do not appear to look at parents or caretakers and show minimal facial signs of recognition, thereby arousing concerns about blindness. The onset of involuntary movements is usually followed by a period of deterioration lasting about 1 week, a plateau period of 1–2 weeks during which the movements remain relatively constant, and finally a recovery phase of more variable duration.

Diagnosis of postoperative hyperkinetic syndromes is clinical; to date, adjunctive neurodiagnostic tests have been useful primarily to exclude other disorders. Neuroimaging studies, including computed tomography (CT) and MRI, have shown nonspecific changes, most commonly diffuse cerebral atrophy. Focal abnormalities are rare [85–87,89]. Single-photon emission computed tomography (SPECT) functional brain imaging studies have shown a high incidence of both cortical and subcortical perfusion defects even in the absence of structural defects on CT and MRI [93]. Electroencephalographic studies are commonly normal or show diffuse slowing; ictal activity is not seen during these movements. Autopsy studies are limited and the neuropathologic findings are inconsistent [81,94], ranging from normal to extensive degrees of neuronal loss and gliosis, particularly focused in the external globus pallidus [94]. Typical features of infarction are characteristically absent.

The prognosis depends largely on their initial severity. Mild movement disorders tend to resolve within weeks to months, but more severe instances have an associated mortality approaching 40% and a high incidence of persistent neurodevelopmental deficits in survivors [89]. Only ~10% of survivors in the severe group demonstrate normal neurologic outcome [89]. Common residual deficits include generalized hypotonia, developmental delay, and expressive language impairment. However, these reports are anecdotal, and detailed long-term follow-up is lacking.

The mechanisms underlying these movement disorders after a cardiac operation remain elusive [95–97]. Despite the absence of a unifying mechanism, a number of risk factors have been identified. Children at particular risk include those with a cyanotic cardiac malformation, especially with systemic-to-pulmonary collaterals from the head and neck, age at operation older than 9 months, and excessively short cooling periods before attenuation of intraoperative blood flow. Some authors have suggested deep hypothermia itself as a cause [97]. Several reports have cited prolonged use of fentanyl and midazolam as a cause of postoperative dyskinesias. These drug-related dyskinesias tend to be relatively mild and to resolve during a period of weeks [98–100].

Cerebrovascular accident (stroke)

CHD is the most common condition associated with stroke in childhood, being present in 25–30% of affected patients [74,101,102]. Stroke of cardiac origin, that is, cardiogenic stroke, has three broad mechanisms. First, arterial emboli may be generated from an intracardiac source (cardioembolic stroke). Second, emboli may arise from a systemic venous or right-sided heart source and bypass the pulmonary circulation through a right-to-left shunt (paradoxical embolic stroke). Finally, cerebral venous thrombosis may result from a combination of central venous hypertension, venous stasis, and polycythemia. Risk factors for cardiogenic stroke include altered vascular surface, stasis, hypercoagulability, and paradoxical vascular pathways.

Open heart surgery presents multiple risk factors for stroke. During cardiopulmonary bypass, particulate and gaseous emboli originating from the cardiopulmonary bypass apparatus or operative field enter the systemic circulation directly [103–106]. Improvements in bypass circuits, particularly the switch from bubble to membrane oxygenators, have decreased the incidence of macroembolization; reduction in microembolic load is suggested by a smaller total ischemic area as assessed with retinal fluorescein angiography after use of membrane oxygenators compared with bubble oxygenators [107]. Although bypass-related cerebral injury in adults is related primarily to atheromatous emboli or fixed cerebrovascular stenoses, such injury in infants results most commonly from global hypoperfusion

during periods of decreased or arrested systemic blood flow. A further potential mechanism of intraoperative vascular injury may relate to the often marked inflammatory response triggered by the extensive and prolonged exposure between bypass blood and artificial surfaces [108–110]. These factors trigger complex cascades, including endothelium–leukocyte interactions [111–114]. Stroke in the early postoperative period may present with focal motor weakness and speech and visual dysfunction. Seizures are a particularly common presentation of stroke in young infants [74,115].

Patients with CHD are also at risk for stroke from factors outside the operating room. Cardiac catheterization poses a risk of both particulate and gaseous emboli, particularly in cyanotic patients who are at risk for paradoxical embolization. In patients with cardiomyopathy, cerebral emboli can arise from intracardiac thrombus. Similarly, embolic stroke may occur in patients with a left atrial clot who convert to normal sinus rhythm from atrial fibrillation, prompting the recommendation for either transesophageal echocardiography or anticoagulation before planned cardioversions. Vascular surfaces may promote thrombosis secondary to endothelial injury or prosthetic tissue, especially in an area of vascular stasis [59,116,117]. Patients with a left-sided prosthetic valve are at risk for thromboembolic complications. Those with left-sided infective endocarditis may have septic cerebral emboli and occasional intracranial mycotic aneurysms (see later). A number of risk factors for stroke converge in patients who have undergone the Fontan procedure. In a retrospective review of 645 patients after the Fontan operation, the incidence of stroke was reported to be 2.6% [59]. In the Pediatric Heart Network's cross-sectional study of Fontan patients, the incidence of stroke was 2% [118].

Stroke prevention may be regarded as primary (i.e., treatment of high-risk patients to prevent a first stroke) or secondary (i.e., aimed at preventing stroke recurrence) [119]. Most pediatric cardiologists use prophylactic anticoagulant therapy in children with a prosthetic heart valve and intracardiac thrombus identified by echocardiography. The need for stroke prophylaxis in individual patients should consider risk factors such as elevated right atrial pressure, intracardiac prosthetic material, and a right-to-left shunt in children requiring prolonged bedrest. Many pediatric cardiologists administer antithrombotic therapy, either aspirin or warfarin, indefinitely after Fontan surgery and in those with a dilated cardiomyopathy. Secondary stroke prophylaxis aims to balance the risk of recurrent embolism and that of hemorrhagic transformation of a bland cerebral infarction.

Headaches

Headaches in patients with a cardiac malformation commonly require evaluation. Acute severe headache should always raise the concern of a subarachnoid hemorrhage,

particularly in patients with a history of coarctation of the aorta. Patients with severe polycythemia experience more frequent headaches. Raised central venous pressure, as occurs after the Fontan procedure or the bidirectional Glenn procedure, may increase cerebral venous pressure, which by itself may be associated with headaches. Raised central venous pressure may also impair absorption of cerebrospinal fluid, resulting in communicating hydrocephalus [120] elevating intracranial pressure and causing headaches. Headache is the most common presenting feature in the otherwise often subtle clinical presentation of a brain abscess (see later).

Infectious endocarditis

Children with a cardiac anomaly are at increased risk for infectious endocarditis with its protean neurologic manifestations [121]. These include meningitis, brain abscess, seizures, and, most commonly, cerebrovascular injury. Despite modern antibiotic advances, approximately one-third of children with infectious endocarditis have neurologic complications, approximately half of which are embolic in origin [122]. Not only are cerebrovascular complications the most common form of neurologic injury in endocarditis, but they also have the highest mortality, reaching 80–90% with hemorrhage of mycotic aneurysms [123]. The high risk of hemorrhagic transformation of septic infarction or of direct subarachnoid hemorrhage through mycotic aneurysms contraindicates the use of anticoagulation in children with infectious endocarditis and cerebrovascular disease [124].

Brain abscess

Cyanotic cardiac malformations constitute the major predisposing factor for brain abscess [125], with an incidence ranging from 2 to 6% [126]. Conversely, CHD was present in almost half of childhood brain abscess cases in a single-center series [127]. Arterial oxygenation is inversely correlated with the incidence, morbidity, and mortality of brain abscess in CHD [126]. In cyanotic patients with polycythemia, periods of systemic illness and dehydration may critically disturb cerebral microvascular perfusion with subsequent localized areas of ischemia. Organisms bypassing the pulmonary filtration system may gain direct access to the brain, where they breach the disrupted blood–brain barrier, passing into necrotic areas to form focal septic cerebritis and, subsequently, an abscess.

In children with a cardiac anomaly, brain abscess is rare before the age of 2 years [128]. The clinical manifestations of brain abscess result from a combination of intracranial hypertension, focal neurologic injury, and sepsis. Headache is the predominant and usual presenting symptom [127]. The initial presentation is often subtle and the course

progresses slowly . Occasionally, the presentation may be abrupt, for example, a seizure. Headache, a common early symptom, is present in 50% of patients, and is often associated with vomiting, fever, and photophobia [127]. Personality changes and irritability occur early.

The diagnosis of brain abscess is best confirmed by MRI with gadolinium enhancement [129]. Contrast-enhanced CT scans are less sensitive, but can be obtained more quickly in emergency settings. A lumbar puncture should be obtained only after exclusion of a significant mass effect by brain imaging, and may show elevated protein but often only mild leukocytosis.

Brain abscess is usually managed by a combination of antibiotic therapy and surgical drainage (diagnostic and/or therapeutic) [129]. With or without surgery, high-dose antibiotic therapy should be administered for ≥6 weeks, with duration of therapy guided by clinical response and imaging studies. Two or more pathogens were isolated in cultures of 39% of patients in a recent series, and streptococcal species were the most common isolates in patients older than 1 month [127]. In immunosuppressed patients (e.g., after cardiac transplantation), pathogens can include lower virulence organisms and also fungi (e.g., *Aspergillus*) and parasites (e.g., *Toxoplasma*). Therapy should be guided by culture results, when they become available.

Although diagnostic and therapeutic advances have reduced the mortality of brain abscess [130], a minority of survivors return to their premorbid baseline function [127]. Epilepsy develops in as many as one-third of survivors, often after many years [127,131].

Future directions

Reparative infant cardiac surgery, with its necessity for the use of cardiopulmonary bypass techniques and ischemia–reperfusion injury, provides an unparalleled opportunity for prospective clinical trials of improved methods of cardiopulmonary bypass, neuroprotective pharmacologic agents, and postoperative interventions [132]. Standardization of the interpretation of existing neuroimaging techniques and the development of novel neuromonitoring modalities are needed to assess outcomes of new neuroprotective strategies. Finally, as CNS morbidity in cardiac children has moved to the forefront of outcomes research in pediatric cardiovascular disease, multi-center registries and trials should investigate the influence of genetic factors, including the host response to injury, and practice variation on neurodevelopmental outcomes.

53 Adults with Congenital Heart Disease

Anji T. Yetman[1] & Gary D. Webb[2]
[1]Primary Children's Medical Center, University of Utah, Salt Lake City, UT, USA
[2]Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

Over several decades, the life expectancy of individuals born with congenital heart disease (CHD) has increased substantially. Consequently, the population of adults with palliated and repaired CHD has grown, and many of these patients require lifelong subspecialized care. The practice of "Adult Congenital Cardiology" has emerged out of necessity to provide adequate care to these patients who require the expertise of both a pediatric cardiologist and an internist or adult cardiologist.

Demographics

With improved treatment for CHD, the number of patients >18 years of age with CHD has expanded rapidly. The long-term survival of infants born with CHD is ~85–95% [1,2]. Over 1 million adults in the United States have CHD, in addition to an estimated 3 million persons with bicuspid aortic valve [2].

These adults can be categorized by the complexity of their cardiac defect to determine the health burden of this patient cohort to develop and allocate healthcare resources properly. The 32nd Bethesda Conference [3] classified congenital cardiac defects in adults into those of mild, moderate, and high complexity and provided estimates of the prevalence of each (Table 53.1). Recommendations for ongoing care depend on the complexity of the patients' cardiac defect. More complex defects have an increased need for repeat surgical and interventional procedures in adulthood in addition to increased mortality. Such patients require closer surveillance. Although an internist may care adequately for those with relatively simple disease, patients with moderate or highly complex CHD require periodic or regular ongoing subspecialized care.

Transition and transfer of care

The number of adults with CHD who are currently receiving appropriate care in the United States reflects only a small proportion of the total number of patients [3]. Whereas children with CHD receive routine cardiac care, many patients are lost to care in the transition to adulthood. The reasons include lack of, or lack of access to, appropriate healthcare resources, failure to understand the need for lifelong cardiac care on the part of the patient or their pediatric healthcare providers, or the pediatric cardiologist's unawareness of acquired adult co-morbidities [4].

Transition

Transition of care is a process by which adolescents with CHD prepare to take responsibility for their health. This educational process should begin by early adolescence when these patients should receive ongoing, age-appropriate instruction regarding the items listed in Table 53.2. A checklist of age-appropriate topics can accompany each patient's chart, documenting that the topics have been adequately covered. Although such education may be the responsibility of the primary care physician, the pediatric cardiologist may be a better source of information. Education on these transitional issues may directly affect the patient's later cardiac morbidity and mortality [4], so all adolescents should receive adequate education before graduating from the pediatric cardiology clinic. Transitional education may be given by the pediatric cardiologist, clinical nurse specialists devoted to adolescent education, a formalized transition clinic within the pediatric cardiology practice, or through a combined pediatric cardiology–adolescent health facility. Historically, education on important lifestyle issues has not been performed well [4–6].

Table 53.1 Classification of congenital cardiac defects in adults.

Simple CHD	Moderate complex CHD	Severe complex CHD
Care by routine provider	*ACHD clinic visits at least every 2 years*	*ACHD clinic visits at least annually*
Aortic valve abnormalities	Aorto–left ventricular tunnel	Conduits – valved or nonvalved
Mitral valve abnormalities, except parachute and cleft	Anomalous pulmonary–venous connection	Double-outlet right ventricle
	Coarctation of aorta	Eisenmenger syndrome
Patent foramen ovale or small ASD	Ebstein's abnormality	All forms of single ventricle
Small VSD	Significant RVOT obstruction	Fontan
Mild pulmonary stenosis	PDA	Pulmonary atresia
Ligated or occluded PDA	Pulmonary regurgitation – moderate or severe	Pulmonary Vascular disease
Repaired ASD without residua	Sinus of Valsalva aneurysm	Transposition complexes
Repaired VSD without residua	Sinus venosus ASD	Truncus arteriosus
	Aortic stenosis – sub- or supravalvar	Atrioventricular or ventriculoarterial discordance
	VSD with outflow obstruction or valvar abnormalities	

Table 53.2 Educational topics to be covered prior to transfer.

Underlying cardiac diagnoses, preferably by way of pictorial illustration, in order to provide this information to other healthcare providers that they encounter
Importance of any residual cardiac lesions
The need for and rationale behind lifelong cardiac care
Instruction that congenital heart disease is markedly different to other forms of heart disease and that they must follow up with providers specializing in adult congenital heart disease.
Signs and symptoms of cardiac decompensation, where appropriate
The natural history of their disease, including need for eventual cardiac transplantation where appropriate
Insurability
Contraception counseling
Counseling regarding fertility, risks of pregnancy to mother and fetus, and the importance of a pregnancy plan
Career and vocational planning
Safety of recreational activities
Cardiovascular risk factors for ischemic heart disease
Physical fitness
Endocarditis

Young adults often leave a pediatric cardiology clinic without understanding their CHD, their long-term prognosis, or the effect of their disease on childbearing [4–6].

Transfer of care

Currently, >60% of adults with CHD after leaving a pediatric cardiac facility have a significant lapse in cardiac care (median 10 years, range 2–50 years) before establishing care at an adult facility [4]. Delayed transfer is associated with more adverse outcomes and often need for urgent cardiac intervention [4]. Many adults with CHD are cared for by adult cardiologists untrained in CHD, or pediatric cardiologists untrained in adult co-morbidities. Consequently, the patient does not receive the needed comprehensive medical care.

The ideal age to transfer a patient from the pediatric to an adult facility is unclear. Appropriately counseled patients with chronic illness usually can transition to an appropriately designed adult healthcare system when aged 17–19 years. At these ages, increasing maturity, better education, and improved confidence and social skills combine to improve patients' understanding of their condition, their participation in medical decision making, definition of health and life goals, recognition of changes in overall health, and ability to use the medical system successfully.

Although mortality rates associated with CHD have steadily improved, the improvement has primarily affected children [7]. Failure of appropriate transition and transfer is thought to decrease patient survival [4].

Establishing an ACHD service

Adults with congenital heart disease (ACHD) represent a unique clinical challenge. Although pediatric cardiologists understand their complex anatomy and physiology, the acquired co-morbidities of adulthood are often foreign to pediatricians. To address this challenge, regionalized ACHD centers are being developed. The minimal requirements for such a center have been established [3], recognizing that there is not a single optimal design.

Outpatient resources

An ACHD outpatient clinic may be in either a separate location within a children's hospital or an adult hospital. Both models are successful and depend upon the availability of skilled

personnel and high-quality diagnostic testing, including congenital cardiac echocardiography, congenital cardiac MRI and CT, and diagnostic and interventional catheterization.

Inpatient resources

Physicians knowledgeable about both CHD and adult cardiac and noncardiac co-morbidities must care for these patients. Because these patients often present with a variety of medical issues, they need, in addition to cardiologists trained in CHD, other medical and surgical subspecialty services to consult about their problems.

Unless instructed otherwise, patients typically utilize the emergency department affiliated with the location where they receive their outpatient care [8]. Emergency department providers, whether adult or pediatric, must be able to provide immediate medical care to these patients, who may present with problems unrelated to their underlying CHD [8,9]. Although they usually present with cardiovascular problems, such as arrhythmia, heart failure, syncope, aortic dissection, and endocarditis [9], they often need other subspecialty services [9].

Surgical resources

Although children with CHD who undergo an operation have it performed by a trained congenital cardiac surgeon, the same is not true for identical cardiac lesions in adults who often undergo an operation by a surgeon without specific training in congenital cardiac surgery [10]. The surgical results are not as good as for similar patients undergoing the same cardiac operation by a cardiac surgeon who devotes >75% of the time to congenital heart surgery [10]. Morbidity and mortality are often greater in adults than children with the same surgical procedure due to medical co-morbidities, acquired cardiac co-morbidities, or difficulty attaining vascular access for cannulation. Most CHD operations in adults are reoperations. The number of previous reoperations is a risk factor for adverse outcome, as is preoperative cyanosis or congestive heart failure, prolonged cardiopulmonary bypass time, and Fontan revision [11].

Patients with cyanotic CHD have an increased risk of adverse outcome with elective noncardiac surgery. Such operations should be performed in a facility with ACHD services and cardiac anesthesiology.

Preoperative imaging should assess the proximity of conduits or other cardiac structures to the posterior sternum. As vascular access may be required, we routinely assess the patency of the femoral vessels during preoperative MRI, catheterization, or preoperative ultrasound. Because of multiple preoperative co-morbidities, there is increased risk of postoperative morbidity, especially renal and liver dysfunction, endocrine disturbances, and gastrointestinal bleeding. Ready access to multiple medical and surgical adult subspecialties is required.

The ACHD team

The core group of care providers comprising an ACHD team includes a cardiologist with training in both CHD and internal medicine. This training may exist in one individual or by the combined expertise of two or more physicians. Guidelines for ACHD training have been published [12]. In addition to cardiologists trained in ACHD, the core team should include at least one nurse practitioner or physician assistant, at least two echocardiographers experienced and certified in congenital cardiac imaging, and affiliation with a cardiovascular surgical program experienced in operating on adults with CHD. The number of personnel must be adequate to provide both outpatient care and inpatient management.

Immediate access to a wide variety of medical and surgical consultants is required, especially heart failure/transplant services, genetics, pulmonary hypertension, cardiac anesthesia and intensive care, diagnostic and interventional cardiac catheterization, cardiac imaging, electrophysiology, gynecology, and high-risk obstetric/maternal fetal medicine.

Differences between the adult and the child with CHD

Arrhythmias

Ventricular and atrial arrhythmias are more frequent in adults with moderate and high complexity CHD lesions and may not respond well to medical therapy. In patients with tetralogy of Fallot, dextro-transposition of the great arteries (d-TGA) following atrial baffling procedures, and a Fontan connection, the risk of sudden death is significant. Residual hemodynamic lesions should be sought and treated as potential precipitants of arrhythmia. Implantable cardioverter defibrillator (ICD) therapy should be considered in a timely manner, although guidelines for its use are still poor. Predictors of sustained ventricular tachycardia (VT) or sudden death in this group of patients include impaired systemic ventricular systolic function and marked QRS prolongation [13].

Thrombosis

The risk of venous thromboembolism increases with age. Postoperative thromboprophylaxis following cardiac and noncardiac surgery is required in adolescents and adults who will not ambulate for some time. Routine medications associated with thromboses, such as oral contraceptives, should be discontinued during the perioperative period.

Cardiac management

Medical and surgical management guidelines may differ between adults and children having identical cardiac lesions. The natural history of specific cardiac defects differs at various ages, particularly as adults acquire co-morbidities that

affect progression of CHD. Changing operative procedures have produced adults with cardiac repairs, such as atrial baffles, which are no longer performed. Patients following an atrial switch require monitoring for atrial baffle leaks, baffle obstruction, and progressive sinus node dysfunction. Because of the differing natural history of cardiac lesions in adulthood, a comprehensive list of lesion-specific guidelines has been assembled to assist the clinician in the care of these often complex patients [14].

Contraception

Beginning in adolescence, women with CHD should be provided with accurate information about contraception and learn about the implications of their cardiac disease for pregnancy. Many young women do not receive such counseling before becoming sexually active [5,15,16]. Medical personnel with an understanding of the gyneco- logic issues that these women face should perform coun- seling; patients may be told by their cardiologist that pregnancy is contraindicated, when, in fact, it is not [16]. Instructing a patient not to become pregnant is not an effective form of birth control and more specific informa- tion should be provided. Which form of contraception is optimal for the patient depends partly upon the degree of maternal risk associated with pregnancy. Various forms of contraception are associated with different efficacy rates (Table 53.3) [17] and the patient should receive counseling about this.

Combination oral contraceptives

The "birth control pill" (OCP), a common contraceptive, contains estrogen and progesterone. Estrogen has prothrom- botic effects and increases the risk of intracardiac and venous thromboembolism (VTE) by increasing prothrombin and decreasing antithrombin III. Therefore, certain women with CHD should not receive this form of contraception (Table 53.4). Over the years, the dose of estrogen in oral contraceptives has decreased. Whereas first-generation estrogen doses started at 150μg, second-generation dosages decreased to 50μg, and current third-generation doses are now even lower, ranging from 20 to 35μg of ethinylestradiol (EE). The decrease in estrogen dose has led to a decrease in VTE, but current third-generation OCP users still have a risk of developing VTE which is 2–8 times greater than that of nonusers. Risk factors which further increase the risk of thrombosis include age >35 years, smoking, increased weight, and inherited thrombophilias.

Within the general population, women who are over- weight (BMI 25–30kg m⁻²) have an estimated age-adjusted odds ratio of VTE of 11.6 (95% CI: 7.5–18.1) when com- pared with healthy weight women. Women who are obese (BMI ≥30kg m⁻²) have an estimated age-adjusted odds ratio

Table 53.3 Contraceptive methods and their efficacy rates.

Contraceptive method	Annual efficacy rate (%) (typical/ perfect use)
Combined hormonal contraception:	
Oral pill	97/99
Vaginal ring	99.4
Transdermal patch	99.3/99.6
Progestin-only contraception:	
Progestin-only pill (mini-pill)	88/97
Progestin injection (Depo-Provera)	99.7
Progestin implants (Norplant/Implanon)	99.8
Intra-uterine device (Mirena)	99
Barrier methods:	
Male condom	88/97
Male condom with spermicide	99.9
Vaginal spermicide alone	79/94
Female condom	79/95
Vaginal sponge	91
Diaphragm	94
Sterilization	99.6

Table 53.4 Women with cardiac anomalies who should not receive combination hormonal contraception.

Eisenmenger syndrome
Mechanical cardiac valves
Severe systemic ventricular dysfunction
Previous thromboemboli
Intracardiac right-to-left shunting
Pulmonary arterial hypertension
Systemic arterial hypertension
Patients with an atrio-pulmonary Fontan anastomosis

of 23.78 (95% CI: 13.3–42.3) of developing VTE. When considering whether a patient is suitable to receive OCPs, all risk factors for thromboses should be considered [18,19].

If OCPs are not contraindicated but an increased poten- tial for thrombosis exists (atrial dilation with a history of atrial arrhythmias, moderately impaired systemic ventricu- lar function, ASD/PFO with DVT risk factors, nonfenes- trated lateral tunnel, or extracardiac conduit Fontan), a third-generation OCP with the lowest possible effective estrogen dose (20μg EE) should be recommended for women. Preparations containing 20 rather than 30μg of EE have been associated with reduced risk of VTE [18]. In addition, the type of progestogen should be considered, as the newer OCPs containing drospirenone have been associated with an increased risk of VTE when compared with those containing levonorgestrel [19].

Combination nonoral contraceptive hormones

Alternative forms of hormonal contraception include the transdermal patch and vaginal ring. Although these birth control methods are associated with improved compliance, there is no evidence to support a reduced risk of VTE. Hence they remain contraindicated in certain patient groups (Table 53.5).

Progesterone contraception

Progestin-only pills

A lack of consistent and correct use is a common cause of unintended pregnancy with progesterone-only pills [18,19]. In contrast to combined oral contraceptives, progestin-only pills require women to adhere more strictly to the time of day when they take their pills. This form of contraception is not contraindicated in any specific CHD, and is a suitable alternative to combination hormonal therapy in very compliant patients. The most common side effects include menstrual irregularities.

Contraceptive injections or subcutaneous implants

Both intramuscular and subcutaneous progesterone injections (depot medroxyprogesterone) have been approved by the FDA to prevent pregnancy, and in the United States are available under the name Depo-Provera. The perfect-use failure rate for intramuscular Depo-Provera in the first year is 0.3%, with a typical-use failure rate in the first year estimated to be ~3% [18,19]. The most common side effects include menstrual irregularities and weight gain [18]. The use of Depo-Provera is associated with a decrease in bone mineral density that is reversible over time upon cessation of use [20]. When contemplating the seriousness of this side effect, the magnitude of bone mineral density loss is comparable to that sustained during pregnancy and breast feeding [20].

An alternative form of nonoral progesterone-only contraception is the subdermal implant, Implanon. This $4 \times 2\,mm$ progesterone-containing rod is implanted subdermally under local anesthesia. The primary benefit is reliable contraception for up to 3 years after implantation. Local side effects are not uncommon and systemic side effects are similar to those described for Depo-Provera [21].

Intra-uterine devices

For nonpermanent birth control, the newer progesterone-eluting intra-uterine devices (Mirena) are reliable and favored in patients who should not receive oral contraceptives due to risk of thrombosis and in whom pregnancy is not desired or carries associated maternal risk. Although the device may be more easily placed in a woman with a prior pregnancy, nulliparity is not a contraindication. An experienced healthcare provider should insert the device.

Table 53.5 Cardiovascular medications and pregnancy.

Drug	Potential side effects	Risk[a]
Adenosine	None reported	C
Amiodarone	IUGR, prematurity, congenital goiter, hypo-/hyperthyroidism, prolonged QT	D
ACE inhibitors/ARB	Oligohydramnios, IUGR, prematurity, neonatal hypotension, renal failure, anemia, death, skull ossification defect, limb defects	D
β-Blockers:	Fetal bradycardia, IUGR, hypoglycemia	
Acebutolol		B
Labetalol		C
Metoprolol		C
Propranolol		C
Atenolol		D
Sotalol		B
Digoxin	None reported	C
Diltiazem	Major birth defects in small animals	C
Diuretics:		
Furosemide	↓ placental perfusion	C
Spironolactone	1 report of oral cleft	D
Thiazides	Congenital defects, ↓↑ electrolytes	D
Flecainide	Limited data	C
Hydralazine	None reported	C
Lidocaine	None reported	C
Nifedipine	Fetal distress due to maternal hypotension reported	C
Nitrates	Limited data	C
Nitroprusside	Limited data; potential thiocyanate fetal toxicity (avoid extended use)	C
Procainamide	Limited data; none reported	C
Verapamil	Limited data	C

[a]FDA classification: Category B: either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women, or animal reproduction studies have shown an adverse effect that was not confirmed in controlled studies in women. Category C: either studies in animals have revealed adverse effects on the fetus and there are no controlled studies in women, or studies in women and animals are not available. Drugs should be given only if potential benefits justify the potential risk to the fetus. Category D: there is positive evidence of human fetal risk, but the benefits from use in pregnant woman may be acceptable despite the risk. Category X: studies in animals or human beings have demonstrated fetal abnormalities. The risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

Contraception is effective for 5 years from implantation, and fertility may be readily restored upon earlier removal. Reported side effects are rare and include menstrual irregularities [18,19].

Barrier methods

To receive oral or injectable contraception, the patient typically requires a visit to a healthcare provider other than their cardiologist, and must be educated about the correct method of use of the contraceptive and its potential side effects. In contrast, a patient using over-the-counter barrier methods may not have any such instruction. A cardiologist who may be the only medical care provider caring for the patient should not assume that patients know how to use any particular form of contraception effectively.

Pregnancy

Pregnancy causes many physiologic alterations that significantly effect the cardiac status of women with CHD. Although many patients have been repaired before adulthood, residual defects may adversely affect maternal and/or fetal well-being. All women with CHD contemplating pregnancy should be seen in an ACHD clinic for pre-pregnancy counseling. Pregnancy counseling requires a multidisciplinary approach with close communication between maternal–fetal medicine specialists and ACHD providers. Women should be counseled about maternal and fetal risks of pregnancy, the effect of pregnancy on the natural history of their CHD, and the risk of CHD on their offspring. Many women may be receiving cardiac medications during pregnancy and their risks (Table 53.5) should be discussed [22].

Physiology of pregnancy, labor, and delivery

During pregnancy, circulating blood volume and cardiac output increase by 50%, usually peaking between 28 and 32 weeks' gestation. The increased blood volume is due more to increased plasma volume than red blood cell mass. The hemodilution reduces oxygen-carrying capacity. The augmented cardiac output comes from increased stroke volume early in pregnancy, aided by increased contractility, and later a smaller increase in heart rate, averaging 10–20 beats per minute. Because of the uterine circulation and endogenous hormones, systemic vascular resistance and diastolic blood pressure fall to a greater extent than pulmonary vascular resistance, possibly exacerbating an intracardiac right-to-left shunt. Inferior vena caval obstruction from a gravid uterus in a supine position can abruptly decrease cardiac preload and cause symptomatic hypotension, particularly in patients who are preload dependent. During the first stage of labor, contractions are associated with expulsion of 300–500 ml of blood into the general circulation. Women with right or left ventricular dilation and dysfunction may not tolerate this abruptly increased volume. Cardiac output rises by 2.5 l min^{-1}, partly due to anxiety and pain. During the second stage, pushing increases systemic vascular resistance. Cardiac output rises further. After delivery, venous return surges due to removal of IVC obstruction

Table 53.6 Factors associated with worsened maternal adverse outcome.

Prior congestive heart failure, TIA, stroke or arrhythmia
Baseline NYHA functional class ≥II
Baseline cyanosis
Mitral stenosis with MV area <2 cm^2
Aortic stenosis with aortic valve area <1.5 cm^2
Peak left ventricular outflow tract gradient >30 mmHg
Left ventricular ejection fraction <40%
Pulmonary hypertension
Symptomatic obstructive lesions (pulmonary stenosis, aortic stenosis, coarctation of the aorta)
Marfan syndrome with aortic diameter >42 mm
Severe pulmonary regurgitation
Depressed subpulmonary ventricular function

from the gravid uterus and autotransfusion from the contracted uterus. As intra-abdominal pressure falls dramatically, blood flow to the abdominal organs increases significantly and can lead to hypotension and cardiovascular collapse [23,24].

These hemodynamic changes are further accentuated by multiple pregnancy. Compared with a single pregnancy, in a multiple pregnancy maximum cardiac output is 20–30% higher, heart rate increases more by 20–30 beats per minute above baseline, and plasma volume increases by ~67% during pregnancy, in contrast to a 48% increase above baseline seen with singletons [23]. These marked changes need to be considered when counseling women regarding assisted methods of reproduction which are associated with a higher rate of multiple gestations.

Oxygen consumption is increased, as are minute ventilation, tidal volume, and functional residual capacity. The glomerular filtration rate (GFR) increases.

Pregnancy is also associated with a hypercoagulable state from relative decreases in protein S activity, stasis, and venous hypertension. Estrogens can interfere with collagen deposition within the media of the medium and large muscular arteries. Circulating elastase can break up the elastic lamellae and weaken the aortic media during pregnancy. Weakening of the arterial wall may in turn predispose to dissection with or without an underlying connective tissue disorder. Relaxin, an insulin-like growth factor hormone, is detectable in serum during pregnancy and causes a decrease in collagen synthesis, and may predispose to aortic dissection during pregnancy.

Adverse maternal and fetal outcomes

The physiological changes in pregnancy outlined above may be poorly tolerated in patients with certain types of CHD or other maternal risk factors (Table 53.6). Adverse cardiac outcomes include pulmonary edema, arrhythmias, CHF, and

Table 53.7 Maternal factors associated with fetal adverse outcome.

Smoking
Obesity
↑ NYHA class
Use of anticoagulation (warfarin or heparin)
Multiple gestations
Maternal cyanosis
Maternal left heart obstruction
Fontan physiology

thromboembolism. Adverse obstetric outcomes include pre-eclampsia, preterm labor, postpartum hemorrhage, and placental abruption. Couples should be counseled about maternal risk factors and risk factors for adverse fetal outcomes (Table 53.7) [22].

Pregnancy care plan

In coordination with specialists in maternal–fetal medicine, obstetrics, and anesthesia, the ACHD team should develop a plan for delivery. Multidisciplinary conferences prior to delivery are very helpful. The subjects discussed should include timing of delivery, the method of induction (if required), the mode of delivery (Cesarean section versus vaginal delivery versus vaginal delivery with an assisted second stage of labor), the need for and type of cardiovascular monitoring during labor and delivery, fluid management, medication management, and the type of anesthesia, and should be decided upon before the commencement of labor. A care plan should be documented and accompany the patient to the hospital to deal with changes in personnel or location of delivery.

Cesarean section is not necessarily indicated for CHD as it is associated with more deleterious effects on maternal hemodynamics than vaginal delivery. With moderate or high complexity cardiac lesions with sequelae, women may benefit from an assisted second stage of labor. This approach involves early placement of a dense epidural anesthesia followed by a passive second stage of labor without pushing and finally assisted delivery of the infant with forceps or vacuum extraction. Although associated with less hemodynamic alterations, this approach has a greater risk of local maternal injury [24].

Anticoagulation during pregnancy

Women requiring anticoagulation with coumadin or heparin present a challenging problem during pregnancy. Although pregnancy is feasible, they should receive pre-pregnancy counseling with discussion of treatment options and the maternal and fetal risks of warfarin and heparin therapies.

Warfarin crosses the placenta and has been associated with an increased incidence of spontaneous abortion, prematurity, and stillbirth. Warfarin can also cause bleeding in the fetus, and fetal cerebral hemorrhage can complicate labor and delivery, especially if forceps or vacuum extraction is necessary. Warfarin embryopathy (of nasal hypoplasia and/or stippled epiphyses and central nervous system abnormalities) has been described after *in utero* exposure during the first trimester with an incidence ranging from <5 to 67% [22,23]. Clinically significant embryopathy may not occur at doses ≤5 mg per day [26]. The drug is thought to be safe during the first 6 weeks of gestation, but embryopathy may occur if doses >5 mg are taken between 6 and 12 weeks of gestation. Women requiring long-term warfarin therapy who are attempting pregnancy should perform frequent pregnancy tests and, when pregnancy is achieved, switch to low molecular weight heparin (LMWH) therapy for the first trimester unless warfarin doses <5 mg are required. After the twelfth week, warfarin therapy can be restarted but must be discontinued and switched to a heparin several weeks before expected or scheduled delivery regardless of dose.

Unfractionated heparin does not cross the placenta or cause fetal bleeding or teratogenicity. However, in 12–24% of high-risk pregnant women there are maternal thromboembolic complications, including fatal valve thrombosis.

LMWH is associated with increased fetal wastage at rates similar to Coumadin. LMWH does not cross the placenta and fetal teratogenicity does not occur. Maternal thromboembolism and maternal death, however, are more frequent in women receiving LMWH therapy. Studies documenting increased thromboembolism, however, have been criticized because of inadequate heparin dosing and lack of meticulous monitoring. As pregnancy progresses and maternal weight gain occurs, the volume of distribution for LMWH changes. Plasma anti-Xa levels should be measured 4–6 h after the morning dose and the dose of LMWH adjusted to achieve an anti-Xa level of ~0.7–1.2 units ml^{-1}. LMWHs have been used successfully to treat pregnant patients with a mechanical heart valve, but their use remains controversial. An early warning issued by the manufacturer and the FDA in July 2001 describes safety concerns. In 2004, labeling approved by the FDA indicated specifically that the use of LMWH for thromboprophylaxis in pregnant women with mechanical prosthetic heart valves has not been studied adequately.

Aspirin at doses of <100 mg per day is considered safe during pregnancy. A recent meta-analysis found no increased risk of congenital anomalies by using aspirin in the first trimester [22].

Percutaneous and surgical intervention during pregnancy

Women with a hemodynamically significant cardiac lesion should have it addressed prior to conception. However, some pregnant women present with a hemodynamically significant cardiac lesion requiring percutaneous or surgical intervention. Non-emergency interventions are probably

best performed after embryogenesis but before the end of the second trimester (weeks 13–24). There is a trend toward fetal malformations in the first trimester, and to preterm delivery, maternal hemodynamic alterations, and mortality in the third [26]. Cardiac surgery during pregnancy carries a maternal mortality rate similar to that for nonpregnant women with a similar anomaly, but fetal mortality is 20–67%. Risk factors associated with maternal mortality in a cohort of 74 pregnant women undergoing cardiac surgery at a mean gestational age of 22 weeks included repeat sternotomy, emergency surgery, and higher NYHA class [26]. Fetal mortality was related not only to the factors associated with maternal mortality above, but also to anoxic time [26].

Acquired co-morbidities affecting care of the patient with CHD

Coronary artery disease

Adults with CHD have no different risk of coronary artery disease than the general population. Patients should be assessed for and receive counseling about modifiable cardiovascular risk factors of hyperlipidemia, hypertension, diabetes (type I or II), and smoking. Some exceptions are as follows:

1 *Cyanotic heart disease:* The coronary arteries in patients with long-standing cyanosis are atheroma free [27]. Such patients are hypocholesterolemic with a greater reduction in LDL cholesterol than HDL cholesterol. Chronic cyanosis is associated with reduced atherogenic intimal oxidized LDL cholesterol. In addition, upregulated nitric oxide, hyperbilirubinemia, and relatively low platelet counts are independent antiatherogenic factors [27].

2 *Coarctation of the aorta:* Coronary artery disease causes about one-third of deaths in adults with a repaired aortic coarctation. Following operation, these patients have persistent vascular dysfunction with impaired endothelial performance, decreased vascular distensibility, increased carotid intima/media thickness, and increased vascular levels of proinflammatory cytokines [28–31]. Myocardial reserve may be abnormal [32]. These vascular abnormalities are more marked in patients repaired at a later age [28–31], but also occur in normotensive children after repair without residual obstruction. Vascular abnormalities are present despite neonatal repair [28–31]. Although successful repair in childhood is often associated with normal resting blood pressure, exercise-induced hypertension is common and may be a risk factor for later coronary artery disease. The effect of aortic stent placement on vascular properties is unknown.

3 *Turner syndrome:* Mortality due to ischemic heart disease is increased as much as sevenfold in patients with Turner syndrome and may occur at a young age, irrespective of associated CHD. The higher incidence of obesity,

hyperlipidemia, hypertension, and diabetes in these patients likely plays a significant role. Life-long cardiac follow-up is required in this high-risk group of patients [33].

Within the general population, 10-year and lifetime risk calculators have been developed to assess the risk of developing cardiovascular disease based on known risk factors: [35]
- cigarette smoking
- hypertension (BP ≥140/90 or antihypertensive medication)
- low HDL cholesterol (HDL-C) (<40 mg dl^{-1})
- family history of premature CHD (in male first-degree relatives <55 years, in female first-degree relatives <65 years)
- age (men ≥45 years, women ≥55 years)
- with HDL-C ≥60 mg dl^{-1} counting as a "negative" risk factor, removing one risk factor from the total count.

All patients should be assessed for cardiovascular risk factors. Once these data have been obtained, they are entered into the "calculator" [33] that will provide a reliable estimate of risk in patients with two or more risk factors (other than LDL cholesterol) who do not have known coronary artery disease [34]. Although repaired coarctation of the aorta is a risk factor for coronary arterial disease, its weight in calculating risk is unknown, but it should be considered. Recommendations for lifestyle modification or initiation of medical therapy are determined by this calculated risk [35].

Obesity

Obesity has reached epidemic proportions in both children and adults. In adults, overweight and obesity are based on body mass index (BMI) calculations of 25–29.9 and ≥30 kg m^{-2}, respectively. Other indices with greater predictive value include waist circumference, waist-to-hip ratio and waist-to-height ratio [36]. Both general obesity and abdominal adiposity are associated with increased mortality in all patient groups, including those with CHD, placing them at greater cardiovascular risk due to pre-existing CHD or cardiac functional impairment. Obesity's deleterious effect on blood pressure, insulin resistance, and lipid profile is associated with endothelial dysfunction, right and left ventricular systolic and diastolic dysfunction, heart failure, left atrial dilation and atrial fibrillation, pulmonary hypertension, obstructive sleep apnea, and a generalized prothrombotic state [36]. Patients should be counseled from an early age about the importance of a healthy diet and routine aerobic exercise in order to avoid obesity and its attendant risks.

Sleep apnea

In part due to the obesity epidemic, obstructive sleep apnea (OSA) is diagnosed more frequently in adults with CHD. OSA appears to be related to several cardiovascular diseases: systemic or pulmonary hypertension, coronary artery disease (with severe OSA), atrial arrhythmias, and nocturnal bradyarrhythmias. Although isolated systemic hypertension, pulmonary hypertension, or coronary artery disease is not an indication for evaluating possible OSA, they should

prompt the physician to inquire about symptoms of OSA to determine if diagnostic evaluation is warranted [37–39].

Anemia

Anemia, common in patients with heart failure, affects functional capacity and survival [40]. The etiology of anemia is multifactorial, and related to impaired secretion of erythropoietin and neurohormonal activation. Anemia has a prevalence of 13–29% in adults with noncyanotic CHD [41,42]. Independent predictors of anemia include lower mean corpuscular volume (MCV), diuretic treatment, hyponatremia, warfarin treatment, and decreased renal function. Within a group of adults with CHD, anemia was associated with a threefold increased risk of death, even after adjustment for functional class, systemic ventricular function, and other established risk factors [41,42]. Evaluating anemia in adults with CHD should therefore be routine. Only 25% of anemic adults with CHD, however, have an abnormally low MCV. Initial evaluation of normocytic or microcytic anemia should include not only a CBC, but also serum ferritin and iron stores. Occult gastrointestinal blood loss should be sought when serum iron is decreased.

Liver disease

All patients who received blood or blood products prior to 1992 should be screened for hepatitis C. If the hepatitis C antibody screening test is positive, a confirmatory test should be performed. Normal transaminases do not exclude infection with hepatitis C. Most patients infected will develop chronic infection, and 80% develop cirrhosis over 20 years. Most patients will be asymptomatic [43]. Infected patients should be referred to a liver specialist.

Symptomatic liver dysfunction is seen most commonly in adults after a Fontan procedure. Cirrhosis, recognized with increasing frequency in these patients, results from chronic congestion [44]. Provided hepatic synthetic function remains intact, patients may benefit from Fontan revision or cardiac transplantation. If synthetic function is impaired, patients may be eligible for combined heart and liver transplantation [45]. Before either revision or transplantation, patients should be screened for esophageal varices, intestinal bleeding, and hepatocellular carcinoma. Routine screening for cirrhosis in adult Fontan patients has been adopted by many ACHD centers and includes serologic evaluation with measurement of platelet count, serum haptoglobin, α_2-macroglobulin, liver transaminases, protein, albumin, γ-GT, bilirubin, and α-fetoprotein. Further evaluation with ultrasound, CT imaging, or liver biopsy may be warranted.

Renal disease

Renal dysfunction is frequent in adults with CHD, especially cyanotic CHD, despite normal kidneys. Renal dysfunction is an independent predictor of adverse outcome following surgery in an adult with CHD. Nephrotoxic agents and volume depletion should be avoided. Adolescents and adults undergoing Fontan revision have had an acute decline in renal function postoperatively [46]. The need for dialysis should be anticipated, including preoperatively measuring GFR and creatinine. Younger age at initial Fontan procedure, higher preoperative blood pressure, and higher preoperative mixed venous saturation independently predicted better GFR at follow-up [46].

Comorbidities in patients with cyanotic CHD

Erythrocytosis

CHD patients with cyanosis typically have an elevated hematocrit level that increases blood viscosity, particularly with hematocrit >65%. Most have compensated erythrocytosis with stable hemoglobin that needs no management. Patients should avoid even mild dehydration and traveling to higher altitude. Historically, therapeutic phlebotomy was performed in these patients to decrease blood viscosity in the hope of eliminating the risk of stroke. This practice is no longer favored because it depletes iron and causes microcytosis, decreases oxygen carrying capacity and deformability of red blood cells, and increases stroke risk. Current indications for therapeutic phlebotomy include hemoglobin >20 g dl^{-1} and hematocrit >65% with symptoms of hyperviscosity and no evidence of dehydration [47,48]. At these extreme levels, patients may have headache and poor concentration. Removing 500 ml of blood with an equal volume replacement of dextrose or saline relieves symptoms. Before an elective operation, therapeutic phlebotomy may be beneficial to improve hemostasis. Evaluating iron deficiency with a peripheral blood smear, serum ferritin, and serum iron should be performed periodically in all patients with cyanotic CHD [47,48]. Patients should receive iron replacement if indicated.

Hemostasis

Hemostatic abnormalities occur in up to 20% of cyanotic patients. Thrombocytopenia and clotting factor deficiencies may combine to produce a bleeding tendency in these patients, most often epistaxis, gingival bleeding, menorrhagia, and pulmonary hemorrhage. Prophylactic anticoagulation is controversial be cause of increased risk of bleeding, but also increased risk of pulmonary artery thrombosis in patients with Eisenmenger syndrome [48,49].

Hyperuricemia

In chronic cyanosis, renal glomeruli are congested and eventually become sclerotic, reducing GFR, increasing creatinine, and causing proteinuria. Abnormal urate clearance is common, and in conjunction with an increased turnover of red blood cells from erythropoietic stimulation leads to

hyperuricemia (common) and gout (uncommon). Asymptomatic hyperuricemia is well tolerated and rarely requires treatment [48]. Initiating urate lowering therapy can provoke acute gout.

Gallstones

The increased breakdown of red blood cells in chronic cyanosis causes an increased risk of calcium bilirubinate gallstones. Operation is not recommended until patients become symptomatic.

The future

ACHD is a rapidly growing and relatively new medical specialty that has emerged to provide medical care to the ever-increasing number of adult survivors with CHD. The complex nature of these patients dictates that they receive their medical care from physicians with expertise in both adult medicine and pediatric cardiology.

Introduction

The improved life expectancy of children with congenital heart disease (ConHD) has increased interest in their long-term quality of life, and stimulated studies into the psychosocial functioning of adults with ConHD [1–3]. The main question is whether quality of life and psychosocial functioning of adults with ConHD are comparable to those of their healthy peers from the general population. This chapter reviews briefly the outcomes of studies regarding

1 subjective health status and health-related quality of life
2 emotional functioning
3 other psychosocial aspect of living with congenital heart disease at adult age, such as
    a body image
    b feelings regarding the surgical scar
    c relational, psychosexual, and reproductive issues
    d living with an implantable cardioverter defibrillator (ICD).

Subjective health status and health-related quality of life

Although some studies have reported serious restrictions in subjective health status or health-related quality of life in adults with ConHD [4–9], other studies found that, apart from possible physical limitations, the perceived health of adult ConHD patients was comparable to or sometimes even better than that of the general population [10–15].

Table 54.1 indicates the main findings of studies conducted in this field, categorized according to subjective health status and health-related quality of life.

Long-term outcome of subjective health status

Several studies of adults with ConHD used the *Short Form Health Survey (SF-36)* [16], a self-report questionnaire for subjective health status [4,5,11,12,17–20]. The SF-36 assesses eight health concepts: limitations in physical activities due to health problems, limitations in social activities due to physical or emotional problems, limitations in usual role activities due to physical health problems, limitations in usual role activities due to emotional problems, bodily pain, general mental health, vitality, and general health perceptions.

Several other self-report instruments encompassing subjective health status have also been used in studies of adults with ConHD [6,8,10,13–15]. Other studies used the *Duke Health Profile* [19], shortened version of the *Quality of Life Questionnaire of the World Health Organization* (WHOQOL-BREF) [20], *Linear Analog Scale* (LAS), and the *Satisfaction with Life Scale* (SWLS) [21].

Long-term outcome of health-related quality of life

In contrast to the instruments above that assess subjective health status, the *TNO–AZL Quality of Life* instrument (TAAQOL) [22] measures health-related quality of life. Thus, the TAAQOL measures not only the patient's perception of

Table 54.1 Studies of subjective health status and health-related quality of life of adults with ConHD.

Study	Sample size (n)	Age range (years)	Instrument[a]	Rating of results (+/≈/−)[b]	Results
Subjective health status					
Saliba et al. [10]	67	17–49	Duke Health Profile	≈	ConHD sample reported physical, mental, social, general, and perceived health comparable to a reference group from the general population
Kamphuis et al. [4]	78	18–32	SF-36	−	ConHD sample reported more limitations in physical activities due to health problems, more limitations in usual role activities due to physical health problems, lower vitality, and lower general health perceptions compared with a reference group from the general population
Lane et al. [5]	276	16–85	SF-36	−	ConHD patients with inoperable conditions reported a lower subjective health status than the general population in all SF-36 domains
				−	ConHD patients deemed surgically cured also reported a lower subjective health status compared with the general population in nearly all SF-36 domains, except bodily pain
Simko and McGinnis [6]	124	18–59	SIP	−	ConHD sample reported poorer psychosocial and physical health compared with a matched control group
Jefferies et al. [75]	32	18–53	SF-36	−/≈	The rural ConHD sample reported poorer physical function and general health perceptions compared with a healthy rural cohort, but similar outcomes on nonphysical domains (e.g., emotional role, mental health)
Moons et al. [13]	89	20–27	LAS SWLS TAAQOL	+	Good/very good quality of life, general level of satisfaction with their life in Mustard or Senning patients
Simko and McGinnis [7]	124	Mean 26 (SD = 8.5)	SIP	−	ConHD sample, on average, experienced mild disability, especially on the psychosocial dimension (work, sleep, and rest). Patients with single ventricle physiology had poorer SIP outcomes than those with cyanotic anomalies
Immer et al. [17]	154	14–72	SF-36	≈	The total sample of ConHD patients showed normal reports of subjective health status, comparable to a matched control group
				−	A sub-sample of patients with complete AV canal defect reported more limitations in physical activities due to health problems and more limitations in usual role activities due to emotional problems
Daliento et al. [11]	54	Mean 32	SF-36	−	ConHD sample reported more limitations in physical activities due to health problems compared with a reference group from the general population
Rose et al. [8]	111	Mean 33	WHOQOL-BREF	−	ConHD sample reported more restrictions on physical health and to a lesser extent psychologic health compared with a reference group from the general population
Van Rijen et al. [12]	349	20–46	SF-36	−	ConHD sample reported more limitations in physical activities due to health problems compared with a reference group from the general population
				+	ConHD sample reported fewer limitations in social activities due to physical or emotional problems, fewer limitations in usual role activities due to emotional problems, and less bodily pain compared with a reference group from the general population

Study	N	Age range	Instrument	[b]	Findings
Moons et al. [14]	404	18–56	LAS	+	ConHD sample reported more favorable outcome compared with a matched control group of healthy peers
			SWLS	+	ConHD sample reported more favorable outcome compared with a matched control group of healthy peers
Bruto et al. [9]				−	Worse perceived health status
Moons et al. [15]	627	18–66	LAS	+	78% clustered into the good, 20% into the moderate, and 2% into the poor quality of life category
Loup et al. [76]c	345	15–37	SF-36	≈	Outcomes on both instruments comparable to the standard population, without a difference between diagnostic groups (ToF, TGA, and VSD). Frequent disease-specific social problems (e.g., with health insurance: 67%]
Vigl et al. [18]c	332 males	18–59	SF-12	?	Men with erectile dysfunction scored significantly poorer on both the physical and mental sum scale (SF-12) and on depression compared with males without erectile dysfunction (33% versus 3% depressive symptoms, respectively)

Subjective health status, health-related quality of life and exercise

Study	N	Age range	Instrument		Findings
Duffels et al. [77]c	58 (30 without, 28 with Down syndrome)	20–75	IIEF / SF-36		For patients without Down syndrome, Bosentan treatment resulted in longitudinal improvement (up to 18 months follow-up) on SF-36 scales role-physical limitations and vitality
Dua et al. [78]c	61	18–63	SF-12 / SWLS		A gentle graded exercise-training program improved quality of life, exercise capacity, and habitual physical activities in adult patients at all stages of ConHD
Gratz et al. [79]	564	14–73	SF-36		Despite several limitations at exercise, patients only reported reductions on the SF-36 regarding physical functioning and general health, and not psychosocial aspects. This was found in all diagnostic subgroups
Muller et al. [80]	57	8–52	SF 36 (>14 years)		Scores on SF-36 were fairly good, with lower scores on vitality, general health, and physical function

c Other instruments were also used in these studies; for details, see the original articles.

functioning, but also the patient's personal feelings regarding his/her functioning. The 12 domains of TAAQOL are gross motor functioning, fine motor functioning, pain, sleeping, cognitive functioning, social functioning, daily activities, sexual activity, vitality, happiness, depressive moods, and aggressiveness. It has been used in some studies with ConHD adults [22–24].

Summary of long-term outcomes of subjective health status and health-related quality of life

Several studies indicate that the health-related quality of life of adults with ConHD is favorable. When subjective health status and the physical aspects of health-related quality of life are assessed, however, scores of patient groups reflect limitations in physical health and emotional functioning. These limitations are not restricted to patients with the most severe diagnoses, but are also seen in patients with relatively mild ConHD.

For patients with limitations in physical functioning, monitored physical training might help those with poor physical condition to feel more secure about their bodily function.

Regarding limitations in emotional functioning, early screening and psychologic treatment for adult patients with ConHD are recommended.

Emotional functioning

Conflicting results about emotional functioning in adults with ConHD have been reported [3]. Negative outcomes predominate [25–31], but some favorable or neutral outcomes have been reported [32–36]. Cox *et al.* [34] even found a low prevalence of psychopathology in adults with ConHD, but used orthopedic patients as a reference group.

Differences in sample size, sample composition (including different diagnostic groups) and assessment procedures (questionnaires or diagnostic interviews used) make it difficult to compare the results from different studies.

Table 54.2 describes the characteristics and main results of studies of emotional functioning of adults with ConHD. The studies mostly included heterogeneous samples with various types of ConHD. The studies can be divided into

- comparisons with normative samples from the general population
- comparisons with somatic reference samples
- ratings of psychiatric diagnostic criteria
- experimental studies into the relationship between cognitive biases and emotional functioning in adults with ConHD.

Comparisons with normative samples from the general population

In studies comparing emotional functioning of adults with ConHD with normative samples, assessment instruments with different scopes have been used:

- psychopathologic symptoms
- emotional and behavioral problems
- personality traits.

Psychopathologic symptoms

ConHD patients may have a large variety and elevated levels of psychopathologic symptoms compared with normative samples [23,28]. Bromberg *et al.* [26] used the BSI to study a sample of ConHD patients with no apparent symptoms of depression or anxiety. In this apparent symptom-free sample, however, they also found psychopathologic emotional functioning.

Emotional and behavioral problems

Both Utens *et al.* [24] and Van Rijen *et al.* [27] found increased levels of emotional and behavioral problems in adult ConHD patients compared with normative groups. Both studies used the *Young Adult Self-Report* (YASR) [35], a self-report questionnaire with syndrome scales and two broad groupings of syndromes: internalizing problems (anxious, depressed, and withdrawn behavior, somatic symptoms) and externalizing problems (intrusive, delinquent, and aggressive behavior). Van der Rijken *et al.* [33] reported no differences on the YASR between a sample of adult ConHD patients and a normative sample. Balon *et al.* [36] used Ryff's psychologic wellbeing scale [37], and found no differences between patients with simple versus complex malformations. They did not clearly describe the level of psychologic wellbeing of the ConHD patients compared with normative data.

Personality traits

Two studies [30,31] used the *Dutch Personality Questionnaire (DPQ)* [38] and showed favorable outcomes in a cohort of ConHD patients on the personality traits of neuroticism, self-esteem, and hostility, compared with a normative samples. Possibly overcompensation and denial, which have been suggested for adults with ConHD [27,30], underlie the favorable outcomes regarding the personality traits, whereas the existence of concrete emotional and behavioral problems (as described above in the section Emotional and Behavioral Problems) is more difficult to deny.

Comparisons with somatic reference samples

Cox *et al.* [34] used the *Hospital Anxiety and Depression Scale* (HADS) [39] and the *General Health Questionnaire* (GHQ) [40], a more global self-report screening device for minor (non-psychotic) disorders. On both instruments, they found more favorable outcomes for the ConHD patient sample compared with a reference sample of orthopedic patients. These favorable findings might partly be explained by the relatively high prevalence of psychologic problems in the reference sample of orthopedic patients. Miatton *et al.* [41], however, pointed out that finding an appropriate comparison sample is challenging in studies about patients with ConHD.

Table 54.2 Studies into emotional functioning of adults with ConHD.

Authors	Sample size (n)	Age range (years)	Instrument	Rating of results (+/≈/−)[a]	Results
Comparisons with normative samples					
Psychopathologic symptoms					
Brandhagen et al. [23]	168	24–42	SCL-90-R	−	ConHD sample reported higher levels of obsessive compulsive thoughts, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, and psychoticism compared with a normative sample
Bromberg et al. [26]	22	19–60	BSI (global symptom index, and anxiety and depression subscales)		27.3% of the ConHD sample reported pathologic emotional functioning
Geyer et al. [28]	361	14–45	BSI	−	ConHD sample reported higher levels of somatization, obsessive compulsive thoughts, interpersonal sensitivity, anxiety, hostility, and paranoid ideation compared with a normative sample
Emotional and behavioral functioning					
Utens et al. [24]	166	19–25	YASR	−	Proportions of ConHD patients scoring in the psychopathologic range were higher than those in the general population, which was mainly due to scores of 22–25-year-old-males
				−/+	ConHD patients reported more problems in only 2 out of 7 problem areas: more somatic complaints and more strange behavior and ideas (including obsessions and hallucinations) compared with a normative group
Van Rijen et al. [27]	251	20–32	YASR	−	Proportions of ConHD patients scoring in the psychopathologic range were higher than those in the general population
				−	ConHD patients reported more somatic complaints compared with a normative group
			YABCL	−	Proportions of ConHD patients scoring in the psychopathologic range were higher than those in the general population
				−	ConHD patients show more anxious or depressed behavior, withdrawn behavior, somatic complaints, thought problems, attention problems, intrusive behavior, and aggressive behavior compared with a normative group
Van der Rijken et al. [33]	48	18–27	YASR	≈	No differences in emotional and behavioral problems were found between a ConHD sample and normative sample
Balon et al. [36]	163	18–87	Ryff's scale	?	No differences in psychologic wellbeing (positive relations, autonomy, environmental mastery, personal growth, purpose in life, self-acceptance) between patients with simple versus complex malformations
Personality traits					
Utens et al. [30]	278	18–35	DPQ	+	ConHD patients reported fewer feelings of hostility and neuroticism and a higher self-esteem compared with a normative sample
Van Rijen et al. [31]	362	20–46	DPQ	+	ConHD patients reported fewer feelings of hostility and neuroticism and a higher self-esteem compared with a normative sample
Comparisons with somatic reference samples					
Cox et al. [34]	87	17–73	HADS	+	ConHD patients obtained more favorable scores compared with a reference group of orthopedic patients, with borderline significance
			GHQ	+	ConHD patients obtained more favorable scores compared with a reference group of orthopedic patients

Table 54.2 (cont'd)

Authors	Sample size (n)	Age range (years)	Instrument	Rating of results (+/≈/−)[a]	Results
Ratings of psychiatric diagnostic criteria					
Horner et al. [43]	29	26–56	Interview DSM-III-R criteria		4 out of 29 ConHD patients met the criteria for a major depressive disorder, and 5 out of 29 ConHD patients were diagnosed with panic disorder
Popelova et al. [25]	32	19–64	Zung's Questionnaire		Depression was found in 34% of the ConHD patients
Bromberg et al. [26]	22	19–60	Interview DSM-IV-criteria		27.3% of the ConHD sample met the criteria for a depressive episode and 9.1% met the criteria for a anxiety disorder
Kovacs et al. [29]	280	20–43	STAI BDI-II		34% (89/260): elevated anxiety symptoms (STAI) 12%: moderate/severe depressive symptoms (BDI-II)
	58		SCID-DSM-IV interview		50% (29/58) met criteria for a lifetime or mood anxiety disorder Perceived physical health status (SF-36) and social functioning: more predictive of depression and anxiety than medical variables
Experimental studies into the relationship between cognitive biases and emotional functioning					
Rietveld et al. [44][c]	82	17–77	NASSQ (negative thoughts) STAI SF-36		Compared with patients with few or moderate negative thoughts, patients with many negative thoughts scored worse on psychosocial adjustment and subjective health status, irrespective of severity of cardiac disease
Karsdorp et al. [45]	25 patients 24 healthy controls	21–64 19–55	STAI state/trait Perception of heart symptoms Physiology: heart and respiratory rate, blood pressure, arterial partial pressure of CO_2 outcomes	−	A combination of high trait anxiety and ConHD resulted in an increased perception of heart symptoms during a mental stress task (compared with healthy controls)
Karsdorp et al. [46]	26 patients 22 healthy controls	18–59 18–53	STAI state/trait		High anxious patients processed heart-related cues preattentively and in turn showed difficulty shifting attention away from heart-related sensations. The relation between ConHD and perceptual biases for heart symptoms was moderated by trait anxiety
Karsdorp et al. [47]	66 patients 50 healthy controls	18–56 19–53	Interpretation bias (IMIQ) STAI state/trait TAAQOL (e.g., daily functioning)	−	High trait anxious patients with ConHD who also display elevated levels of state anxiety exhibit the most pronounced negative interpretation for ambiguous heart-related sensations and in turn diminished daily functioning
Karsdorp et al. [48]	36 patients 44 healthy controls	19–54 18–54	STAI trait Perception of heart symptoms Physiology: heart and respiratory rate, arterial pressure of CO_2	≈	False heart rate feedback resulted in increased perception of heart symptoms in high trait anxious ConHD that could not be explained by simultaneous cardiac dysfunction

a–cSee footnotes to Table 54.1.

Ratings of psychiatric diagnostic criteria

Popelova *et al.* [25] used *Zung's questionnaire* [42], a self-rating instrument that focuses specifically on depression, and found depression in about one-third of a sample of cyanotic ConHD patients. In two studies [26,43], a structured interview was used to determine how many ConHD patients met the *DSM-III-R* or *DSM-IV* (*Diagnostic and Statistical Manual*) criteria of psychiatric illnesses, respectively. Both studies identified depressive and anxiety disorders in adults with ConHD. Kovacs *et al.* [29] used self-report questionnaires and the SCID–DSM-IV interview (semi-structured clinical interview) to assess the prevalence of mood and anxiety disorders among ConHD patients. They found that 50% of interviewed patients (29/58 patients) met diagnostic criteria for a current of past mood or anxiety disorder. These findings support those of Horner *et al.* [43] and Bromberg *et al.* [26], which showed psychiatric disorders in 28% (8/29 patients) and 35% (8/22 "well-adjusted" patients).

Experimental studies into the relationship between cognitive biases and emotional functioning

Rietveld *et al.* [44] tested the relationship between negative thoughts and adaptation to ConHD. Compared with patients with few or moderate negative thoughts, patients with many negative thoughts scored worse on psychosocial adjustment and subjective health status, irrespective of severity of cardiac disease. Karsdorp and colleagues [45,46]. suggested that high trait anxiety combined with chronic disease may produce stressful, negative experiences with disease and its symptoms. These experiences may be stored in cognitive memory structures, the so-called illness schemes. Perception of cues associated with these illness schemes can elicit processing biases toward disease-related sensations. Examples of such cognitive biases are a tendency to draw attention to disease-related sensations and interpreting ambiguous sensations as disease-related symptoms.

Karsdorp and colleagues [45–48] investigated biases to heart cues and symptoms in several studies by using experimental tasks (Table 54.2).

Summary of long-term outcome of emotional functioning

Emotional and behavioral functioning in adults with ConHD range from no difference from normative groups to positive or negative findings on personality traits. Most often, however, elevated levels of emotional and/or behavioral problems were detected, among which are internalized problems (anxiety, depression, interpersonal difficulties, or withdrawn behavior), externalized problems (hostility, intrusive and aggressive behavior), and even symptoms that may indicate psychotic disorders (see Table 54.1).

Several studies indicated that a combination of high trait anxiety and ConHD resulted in an increased perception of heart symptoms or negative interpretation of ambiguous heart-related sensations. These findings regarding cognitive, perceptual biases could not be explained by simultaneous cardiac dysfunction. Misperception of heart symptoms may unduly result in avoiding physical and social activities and/or unnecessary doctor visits [48]. Psychologic interventions, such as biofeedback training or interpretative bias training, may be beneficial in increasing the accuracy of interpreting heart beat perception and preventing anxiety.

Psychosocial aspects of living with congenital heart disease at adult age

Body image

The overt signs of ConHD (blue cyanotic color, surgical scars, or clubbed fingers) may have a negative influence on the patient's body image [3,49], and hamper adults with ConHD in their attempts to be considered "normal," "healthy," and "the same as others" [50–52]. Geyer *et al.* [53] found that the perception of body image was a stronger predictor for psychopathologic symptoms than limitations of activity and impaired cardiac performance in adult ConHD patients. They suggested that different underlying problems, such as perception of the body as deficient and injured in ConHD males and, to a lesser extent, lack of vitality in ConHD females, may be responsible for increased levels of psychopathology in adult ConHD patients.

Feelings regarding the surgical scar

ConHD adults may dislike or feel restricted by the scar [54,55] or try to conceal the scar by clothing or cosmetics [43,56,57]. Negative feelings regarding the surgical scar may adversely affect emotional and behavior problems [54]. Van Rijen *et al.* [54] found that 40.5% of female patients and 18.9% of male patients felt restricted by the scar. In a Canadian study [56] of 100 patients, 62% of the males and 53% of the females considered themselves disfigured by the scar.

Relational, psychosexual, and reproductive issues

Young adults with ConHD tend to live longer with their parents as compared with "normal" peers [30,57,58]. Favorable outcome regarding marital status has been reported in adults with ConHD [31,58–61], but others reported that patients with ConHD get married less often, or at a later age [57,62]. Offspring rates in adults with ConHD are lower than those in healthy peers [60–62]. Adults with ConHD seem to start families at a later age [31]. Gersony *et al.* [62], however, found no differences in offspring rates or marital status between male and female ConHD patients.

Young adults with ConHD were less sexually active than healthy peers [18,63,64]. Reid *et al.* [64] found that more young adult ConHD females than young adult ConHD males were sexually active, in line with rates of sexual behavior reported in chronically ill youth [65]. An alarming finding was that, among the sexually active patients, 36% of the young ConHD adults and 72% of the adolescent ConHD patients engaged in one or more types of potentially risky sexual behavior (i.e., two or more partners in the past 3 months, questionable birth control, using drugs or alcohol before sex at least sometimes) [64]. These findings underline the need for specific patient education. ConHD females report more sexual problems (not enjoying or being aroused during sex, being insecure) than ConHD males [66]. Vigl *et al.* [18] found that male ConHD patients under the age of 40 did engage less frequently in sexual relationships than peers from the general population. Fears before or during sexual intercourse were present in 9.9%, and also physical symptoms, such as dyspnea (9.0%), feelings of arrhythmia (9.0%), or chest pain (5.1%). About 10% obtained a score on the International Index of Erectile Function indicative of an erectile dysfunction (Table 54.2).

Young females with ConHD are often concerned about fertility, pregnancy, birth control, and genetic transmission [49,58,64]. They may be concerned about their physical ability to raise children. Inability to have children because of cardiac risks can negatively influence a woman's sense of identity and self-worth. Van Rijen *et al.* [31] reported that female patients can feel restricted by their ConHD in their choice of having children. Often, ConHD females are very poorly informed about reproductive matters [49,67], and receive poor or no advice about contraception or pregnancy risks [68], which results in uncertainties.

Living with implantable cardioverter defibrillator (ICD)

Few studies [69–73] have been performed on young patients living with an ICD.

Inappropriate shocks may cause fear of shocks and poor patient acceptance. In a national survey, Sears *et al.* [71] found that ~10–20% of 450 patients implanted with an ICD for <1 year reported difficulty with emotional adjustment to their ICD. ICD recipients receiving more shocks from their ICD, women and younger recipients, reported significantly more adjustment concerns, such as generalized fear, worry, fear of physical exertion, depression, and difficulties managing stress. In a study of 18 young recipients, Dubin *et al.* [72] found diminished social interactions, worry about exercise, problems during sexual activity, and body image concerns. In a study of nine young recipients, Vitale and Funk [73] found abnormal sleep patterns, fear of shock (firing of ICD), and concerns about dying.

In a recent review [69], anxiety was the most serious psychosocial reaction for young ICD patients, as in adult patients. Young ICD patients generally adjust well to life with an ICD, but for a sizeable minority of patients anxiety can be a serious problem.

Clinical implications

We can do better to help our patients adjust to living with ConHD, whether treated or not. The process starts with adequate explanations to parents and child about the anomaly and its likely consequences, both medical and psychosocial, and give them time to ask questions. Frequent repetition of the explanation may be needed, with changes appropriate to any major event. Written material and appropriate Internet references may be useful. Any limitations of physical functioning, as in sports, should be explained and specified and monitored physical training might help patients to feel more secure about their bodily function. Counseling about sexual behavior, fertility, and marriage should be provided early in adolescence by those with appropriate expertise.

Regarding limitations in emotional functioning, early screening and psychologic treatment for adult patients with ConHD are recommended. In our opinion, screening and treatment for psychopathology in adult patients with ConHD should be provided at an early stage, since at younger age these symptoms appear to be less persistent and better treatable [23]. Cardiologists should have the opportunity to refer patients with psychosocial problems to psychologists who specialize in this unique field, to enhance their emotional resilience and styles of coping [74].

Cardiac Arrhythmias: Diagnosis and Management

George F. Van Hare[1] & Anne M. Dubin[2]
[1]Washington University and St Louis Children's Hospital, St Louis, MO, USA
[2]Stanford University, Palo Alto, CA, USA

General considerations

Basic cellular electrophysiology

The potential between the interior and the exterior of a myocardial cell is the transmembrane potential. In diastole the potential is −80 to −90 mV and is termed the resting potential. When the cell is stimulated, an action potential results (Figure 55.1). Rapid depolarization (phase 0) results from rapid sodium influx; the rapid return to near zero potential (phase 1) results from chloride influx. The less negative the transmembrane potential at the onset of depolarization, the slower the rate of depolarization (V_{max}) in phase 0; in turn, reduced V_{max} slows the velocity of propagation of the impulse through the fibers. Antiarrhythmic agents with class I activity (e.g., procainamide, flecainide) block sodium influx, reduce V_{max}, and therefore slow conduction. Phase 1 is followed by a plateau (phase 2) during which slow inward calcium and sodium currents are nearly balanced by potassium leaking out of the cell. Potassium conductance then increases, and potassium efflux causes the potential to become more negative rapidly (phase 3) until the resting membrane potential is reached. During phase 4, sodium is actively pumped out of the cell in exchange for potassium.

Once the action potential has begun, the cell is completely refractory to stimulation until it attains a transmembrane potential of about −55 mV in phase 3, and from this value until it reaches a resting potential of −85 mV in phase 4 the cell gradually regains excitability. Between complete refractoriness and complete responsiveness is the relative refractory period; in keeping with the relationship between V_{max} and transmembrane potential, a stimulus early in the refractory period produces a slow and poorly conducted action potential.

Prolongation of action potential duration and absolute and relative refractory periods occurs with slowing of the rate of depolarization, a long RR interval thus giving a longer refractory period of the next beat. Refractory periods are also prolonged by disease (myocarditis, ischemia) and by some antiarrhythmic drugs (ibutalide, sotalol).

Certain cells have a different pattern. The resting potential starts at about −80 mV but then automatically spontaneously and gradually becomes more positive. When the potential reaches a threshold of about −50 mV, the action potential begins spontaneously; hence these cells are called automatic cells and are said to have automaticity. Normally, only some cardiac muscle cells have automaticity; they may be found anywhere in the heart but are mainly in the SA node, the lower part of the AV node, muscle in the mitral and tricuspid valves, and the conduction system. The repetition rate at which groups of automatic cells depolarize depends mainly on the slope of spontaneous depolarization; the more rapid it is, the sooner the threshold is reached and the faster the heart rate. Catecholamines, vagal blockade, a raised temperature, lowered extracellular potassium or calcium, or a fall in tissue pH or oxygen tension accelerate diastolic depolarization rate and thus tend to increase heart rate. Vagal stimulation, β-adrenergic blockade, increased extracellular potassium, and drugs such as quinidine, procainamide, lidocaine, and phenytoin reduce the diastolic depolarization rate and thus reduce automaticity. The effect of these drugs in reducing automaticity makes them useful in treating many arrhythmias. Various automatic cells have different sensitivities for changes induced by these agents. Thus, phenytoin increases atrial diastolic depolarization but decreases ventricular diastolic depolarization, and lidocaine markedly affects ventricular automaticity but not atrial automaticity.

Figure 55.1 Diagram of typical ventricular muscle cell potential during the cardiac cycle.

−90 mV —

Normally the discharge rate is highest for automatic cells in the SA node, which is thus the usual pacemaker for the heart. Collections of automatic cells (latent pacemakers) lower in the conducting system have slower diastolic depolarization, the slowest being those in the ventricles. Normally these lower (or ectopic) pacemakers are discharged by impulses from the SA node before they can discharge spontaneously and, therefore, they are usually suppressed by impulses from above. The typical discharge rate of each pacemaker varies with age.

Most normal cardiac muscle and automatic cells show rapid depolarization and also conduct rapidly; hence they are known as fast-responding cells, but some cells show a slow response. Their transmembrane resting potential is only about −60 mV, depolarization is slow, as is conduction, and in phase 4 there is an after-depolarization that normally does not reach the threshold for initiating another action potential. Slow-responding cells are found normally in the SA and AV nodes and the AV valves. Ischemia, digitalis toxicity, excess potassium or catecholamines, or chronic dilatation can convert fast-responding cells into slow-responding cells. In these cells the rapid sodium influx of phase 1 is absent, and depolarization is achieved mainly by the slow inward calcium current and can be blocked by calcium channel blockers (verapamil, diltiazem).

The action potential of myocardial cells is controlled by channels that allow or hinder the influx or efflux of ions. The ion exchanges are more complex than shown in Figure 55.1, and a summary is given in Figure 55.2. Almost all the known mutations increase the intracellular positive ions, and most are associated with the long QT syndrome.

Cardiac arrhythmias (both fast and slow) result from abnormal impulse formation, abnormal impulse conduction, or a combination of the two. Abnormal automaticity occurs when ectopic pacemakers compete with the sinus node. Depression of sinus node automaticity may shift the origin of the cardiac impulse to other sites in the heart. Ectopic rhythms may be driven by sympathetic activity or other effects, such as ischemia or stretch. Triggered activity, a form of abnormal automaticity, results from a second depolarization that occurs either during repolarization (early after-depolarization) or after repolarization (delayed after-depolarization). Early after-depolarizations can be associated with hypoxia, ischemia, hypokalemia, cesium, catecholamines, and some antiarrhythmic drugs with proarrhythmic effects, such as the class I agents. Early after-depolarizations may be responsible for torsades de pointes, a type of ventricular tachycardia, especially when associated with antiarrhythmic agents [1].

Abnormal impulse conduction is another mechanism responsible for arrhythmias. Abnormal conduction occurs when it proceeds along abnormal pathways, as in pre-excitation, such as Wolff–Parkinson–White (WPW) syndrome and other re-entrant pathways, or when normal conduction is blocked, as in sinoatrial block or AV conduction block.

Mechanisms of tachycardias

Re-entrant versus automatic tachycardias

For a tachycardia to be termed re-entrant, three conditions must be met. First, an anatomically distinct re-entrant circuit must be present, allowing for the circular movement of excitation conduction. Second, an area of this potential re-entrant circuit must be subject to delay in conduction, or the circuit must be large enough to allow for recovery by the time the next re-entrant wave arrives. Third, unidirectional conduction block must occur, allowing subsequent reversed conduction in that segment.

The common *re-entrant* tachycardias in children include sinoatrial and intra-atrial re-entry, atrioventricular node
Figure 55.2 Diagram of cardiac muscle cell to show many of the known ion channels and some of the mutations that impair their function. Most of the mutations produce lengthening of the QT interval except for Brugada syndrome. The three major causes are shown in large bold italics, the less common defects in plain type. Some of the mutations affect caveolins and ankyrins, proteins that bind to and affect many different ion channels. (Modified with permission from an original diagram published by Viswanathan and Rudy, *Cardiovasc Res* 1999;**42**:530–42.)

re-entry, atrioventricular reciprocating tachycardia involving an accessory pathway, atrial flutter, the permanent form of junctional reciprocating tachycardia, and the re-entrant form of ventricular tachycardia. Tachycardias caused by increased *automaticity* include sinus tachycardia, atrial ectopic tachycardia, junctional ectopic tachycardia, and (automatic focus) ventricular tachycardia. Interestingly, atrial fibrillation was thought to be due mainly to complex multiple re-entrant circuits in the atrium, but now is understood to have its origin from very fast automatic foci in the pulmonary veins and elsewhere.

A major characteristic of the re-entrant tachycardias that allows differentiation from the automatic tachycardias is their tendency to start and stop suddenly. Premature atrial and ventricular contractions may initiate or terminate these rhythms, or they start during normal episodes of sinus bradycardia with junctional escape rhythm. Direct current cardioversion is generally successful in terminating re-entrant tachycardias but not automatic tachycardias [2].

Sinus tachycardia

Sinus tachycardia often masquerades as paroxysmal supraventricular tachycardia in children and is usually secondary to another problem; a careful search for such pro- blems should allow the diagnosis of sinus tachycardia (see Tables 55.1 and 55.2). For example, the gradual slowing of a narrow QRS tachycardia after an intravenous fluid bolus in a patient with dehydration provides strong evidence for sinus tachycardia and not other forms of paroxysmal supraventricular tachycardia. Causes of sinus tachycardia include high fever, pain, hypoxia, hyperthyroidism, seizures, chronotropic agents (isoproterenol or dobutamine), and sedation in paralyzed ventilated patients.

The criteria for *sinus tachycardia* include normal P-wave axis, a normal (not prolonged) PR interval, gradual onset and termination of the tachycardia and a heart rate below 250 beats per minute (bpm). Rates above 250 bpm rule out sinus tachycardia, whereas narrow complex tachycardias below 250 bpm are often, but not always, sinus tachycardia.

Sinus tachycardia must be ruled out, if possible, before antiarrhythmic therapy is instituted. This diagnosis may be fairly difficult in children because the P wave may be hidden in the preceding T wave. Several electrocardiographic leads should be carefully analyzed for deformation of the T wave by a P wave. Vagal maneuvers and other methods for converting supraventricular tachycardia do not terminate sinus tachycardia. Vagal maneuvers may briefly slow the rhythm, but because the underlying cause of sinus

Table 55.1 Common arrhythmias by patient age.

Age	Arrhythmia	Comment
Fetal	Sinus bradycardia (<100 bpm)	Fetal hypoxic stress
	Complete atrioventricular block (<60 bpm)	Isolated, or associated with maternal systemic lupus erythematosus or fetal congenital heart disease. May cause hydrops
	Sinus tachycardia (>180 bpm)	Maternal fever, drugs, fetal stress, anemia
	Supraventricular tachycardia (>200 bpm)	Causes hydrops if sustained
	Atrial flutter (280–450 bpm, conduction delay, 2:1)	Causes hydrops if sustained
	Ventricular tachycardia (>120 bpm)	Rare
		Causes hydrops if sustained
Neonate	Continuation of fetal arrhythmias	
	Sinus bradycardia	Associated with apnea of prematurity as primary event
Infant	Sinus tachycardia (<250 bpm)	Fever, anxiety, shock, dehydration, heart failure, pain
	Supraventricular tachycardia	Primary or sympathomimetic drug administration, fever, myocarditis, trauma
Older child and adolescent	Premature atrial beats	
	Premature ventricular beats	
	Paroxysmal atrial tachycardia	Thyrotoxicosis, idiopathic, atrial enlargement, mitral stenosis, sympathomimetic drugs
	Sinus bradycardia	Trained athlete, vasodepressor syncope
	Sinus tachycardia	As for infant (see above) plus drug abuse (cocaine, amphetamine)
	Various post-cardiac surgery arrhythmias	Surgical scars create lines of block

tachycardia is unaffected by such maneuvers, the rhythm resumes immediately. Therapy should be directed to the likely underlying causes. The response to such measures is likely to be diagnostic.

Accessory pathway tachycardia

An excellent example of a re-entrant supraventricular tachyarrhythmia is the reciprocating atrioventricular re-entrant tachycardia in patients with the WPW syndrome (Figure 55.3). In sinus rhythm, there is pre-excitation in patients with WPW, due to simultaneous conduction down the pathway and the node, forming a characteristic delta wave (Figure 55.4). A premature atrial contraction may block in the accessory pathway but be conducted down the atrioventricular node and the His-Purkinje system, but with significant delay in the atrioventricular node. Impulses arriving in the ventricle are then conducted retrograde via the accessory pathway back to the atrium. The conduction delay in the atrioventricular node allows the accessory pathway and atrium sufficient time to recover and thus establish sustained tachycardia. It is recognized by a characteristic narrow or normal QRS with P waves discernible on the early part of the T wave (Figure 55.5).

Patients with an accessory pathway but without the potential for anterograde conduction are classified as having concealed accessory pathways. A specific form of concealed accessory pathway, AV reciprocating tachycardia, also termed persistent junctional reciprocating tachycardia (PJRT), is mainly seen in children. It presents as a slow narrow QRS

tachycardia with abnormal P waves prior to each QRS. These P waves are characteristically inverted in leads II, III, and AVF (Figure 55.6). Because of the slow rate, the tachycardia may be relatively asymptomatic, but its tendency to be incessant means that it may lead to the development of tachycardia-induced cardiomyopathy [3]. Ventricular dysfunction from the incessant tachycardia may be seen when the patient presents and may be severe, particularly in infants. It generally resolves with successful treatment of the arrhythmia.

Atrioventricular node re-entry tachycardia

Atrioventricular node re-entry tachycardia (AVNRT) is the second common form of re-entrant supraventricular tachycardia. In this condition, so-called dual AV node pathways are demonstrable. Although the normal AV node has one "pathway" with a short conduction time, in AVNRT the AV node is functionally discontinuous with fast and slow AV node pathways. In AVNRT, a premature atrial contraction blocks the fast pathway, which generally has a long refractory period. Conduction proceeds down the slow pathway, producing a markedly prolonged PR interval. If conduction is slow enough, then adequate time is available for the fast pathway to recover and conduct the impulse retrograde, arriving back in the atrium and re-entering the slow pathway anterograde.

AVNRT is less common than accessory pathway tachycardia in younger children, and is rare in infants. It is more common, however, by young adulthood [4].

Table 55.2 Recognition of tachycardia with normal QRS duration.

Diagnosis	Electrocardiographic findings
Re-entrant tachycardias	
Atrial and sinoatrial re-entry	P waves present, precede next QRS complex
	Terminates with QRS rather than P wave
	Variable AV conduction possible AV block does not terminate atrial rhythm
	P wave axis may be superior or inferior, depending on origin
Atrial flutter	Sawtooth flutter waves
	AV block does not terminate atrial rhythm
	Atrial rate 300 in older children, up to 500 in newborns
Accessory pathway-mediated tachycardia (Wolff-Parkinson-White syndrome and concealed accessory pathway)	P waves follow QRS, typically on upstroke of T wave
	Superior or rightward P wave axis
	AV block always terminates tachycardia
	Typically terminates with P wave
	After termination, those with Wolff-Parkinson-White have pre-excitation
Persistent junctional reciprocating tachycardia	Incessant
	P waves precede QRS
	Inverted P waves in II, III, AVF
	AV block always terminates tachycardia
	May terminate with QRS or with P wave
	No pre-excitation after termination
Atrioventricular node re-entry	AV block usually terminates tachycardia
Atrial fibrillation	"Irregularly irregular," no two RR intervals exactly the same
	P waves difficult to see, or bizarre and chaotic
Increased automaticity	
Sinus tachycardia	Normal P wave axis
	P waves precede QRS
	Caused by extrinsic factor, e.g., heart failure, fever, anemia, catecholamine, or theophylline infusion
	Continues in presence of AV block
Atrial ectopic tachycardia	Incessant
	Abnormal P wave axis, which predicts location of focus
	P waves precede QRS
	Continues in presence of AV block
Junctional ectopic tachycardia	Capture beats with no fusion

Figure 55.3 Diagram of the re-entrant circuit in Wolff–Parkinson–White syndrome. Conduction proceeds normally down the normal conduction system, and then in a retrograde manner up the bundle of Kent (accessory pathway to the atrium), to re-enter the normal conduction system. (Reproduced from Van Hare GF. Circulation. In: Rudoph AM, Kamei RK, eds. *Rudoph's Fundamentals of Pediatrics*. Norwalk, CT: Appleton & Lange, 1994: 522.)

discernible P waves. Because of timing, the retrograde P waves are superimposed on the QRS complex (Figure 55.7). In young patients, however, the first part of the P wave may be observed just prior to the onset of the QRS complex. Other forms of AVNRT, such as atypical AVNRT with antero-grade fast pathway conduction and retrograde slow pathway conduction, are unusual in children.

Atrial ectopic tachycardia

Atrial ectopic tachycardia (AET) is a disorder of abnormal automaticity, due to a rapidly firing focus in the right or left atrium. The etiology is generally unknown, although in some patients it is related to myocarditis or dilated cardiomyopathy. Rarely, it is a manifestation of pulmonary disease. In children, it often presents as an asymptomatic incessant tachycardia, which, similarly to PRJT (discussed above), may lead eventually to tachycardia-induced cardi-omyopathy [5]. It is recognized as a narrow QRS tachycardia with a normal to somewhat prolonged PR interval, and abnormal P-wave morphology.

Atrial flutter

Atrial flutter is characterized by a rapid atrial rate of about 300 bpm in older children and adolescents and as high as 450–500 bpm in neonates. In the typical form, a sawtooth configuration of atrial waves (F waves) is seen best in leads II, III, and V$_1$, and there is variable AV block (Figure 55.8). After

These pathways can be detected by programmed stimulation in the electrophysiology laboratory, and may be suspected on electrocardiogram (ECG) inspection. On an ECG, there is a regular, narrow QRS tachycardia without
Figure 55.4 Electrocardiogram in a patient with Wolff–Parkinson–White syndrome. Note the short PR interval with a widened QRS.
Figure 55.5 Lead II rhythm strip showing supraventricular tachycardia with clear P waves superimposed on the early part of the T wave. This is most consistent with accessory pathway tachycardia.

extensive atrial surgery, however, atrial flutter may be atypical without the usual sawtooth F waves. The ventricular rate may be regular or irregular; if regular, the ratio of atrial rate to ventricular rate can range from 2:1 (most frequent) to 8:1. With a reasonable ventricular rate, the arrhythmia is tolerated well for a long time, but with rapid ventricular responses, severe symptoms occur. Initial treatment should be with digoxin to increase the AV block and slow the ventricular rate; if this does not suffice, then propranolol, another β-blocker, or a calcium channel blocker (in older-aged children) can be added. Sometimes this treatment causes sinus rhythm to return, but if it does not, electrical cardioversion may be successful. Atrial flutter is rare in infants and children and is usually associated with structural heart disease, particularly with dilated atria. It sometimes occurs transiently in otherwise normal newborn infants. Because atrial flutter has been implicated in sudden death after a Mustard or Senning repair of transposition of the great

arteries, an aggressive approach to abolishing the arrhythmia has been recommended [6]. Interrupting the flutter circuit by catheter ablation or surgery is usually successful [7].

Atrial fibrillation

Atrial fibrillation is rare in children. It is characterized by disordered atrial activity. The ECG shows no P waves but instead has fine or coarse fibrillatory or f waves. The ventricular response is very irregular and usually rapid; generally it is difficult to find two exactly equal RR intervals. Treatment is initially with digoxin or other agents, such as diltiazem infusion, to decrease ventricular rate. If the atrium is enlarged, atrial fibrillation may be sustained. To restore sinus rhythm, antiarrhythmic agents, such as procainamide, sotalol, or ibutalide, may be employed, but cardioversion is generally more effective. To maintain sinus rhythm after it is restored, sotalol or amiodarone may be used. If the atrial fibrillation keeps recurring, the aim is to
Figure 55.6 Persistent junctional reciprocating tachycardia (PJRT). Normal PR interval with inverted P waves in leads II, III, and AVF, and a relatively slow rate.

control the ventricular rate with digoxin; if ventricular rates still rise unduly with exercise, then propranolol or verapamil may be added. When atrial fibrillation occurs in the presence of an accessory pathway (WPW syndrome), conduction to the ventricle over the pathway may be dangerously rapid with wide QRS complexes. This is thought to be the mechanism of sudden death in this syndrome (Figure 55.9). Because digoxin may shorten the anterograde
Figure 55.8 Atrial flutter with 2:1 atrioventricular conduction. The negative "F" waves are seen best in leads II, III, and AVF.

effective refractory period of the accessory pathway, allowing even faster ventricular rates, it is contraindicated for the acute and chronic treatment of patients of any age with the WPW syndrome, except when an electrophysiological study has documented that digoxin may be used safely [8].

Junctional ectopic tachycardia

An accelerated junctional pacemaker produces a ventricular rate that is faster than the underlying sinus rate. This rhythm occurs most often after surgery near the AV node (such as closure of ventricular septal defect), but there is a congenital form that is incessant and may lead to tachycardia-induced
Figure 55.10 Junctional ectopic tachycardia (JET). Narrow QRS tachycardia with a slower atrial rate. QRS 5 demonstrates a shorter RR interval, due to sinus capture.
Figure 55.11 Ventricular tachycardia. In this tracing, there is no AV dissociation evident.

cardiomyopathy [9]. When an accelerated junctional focus is very fast, it is termed junctional ectopic tachycardia (JET). JET is recognized by narrow QRS tachycardia with AV dissociation (due to the slower sinus rate and lack of retrograde conduction). There may also be capture beats, in which a P wave occurs randomly at a time when anterograde conduction can occur, shortening the RR interval for one beat (Figure 55.10). In the postoperative period intravenous amiodarone is most often employed, along with atrial pacing to restore AV synchrony. Cooling the patient to around 34 °C may also be effective. In the congenital variety, the use of

β-blockers, flecainide, sotalol, and amiodarone has been reported. Catheter ablation is also effective, but with some risk of causing complete AV block [10,11].

Ventricular tachycardia

Ventricular tachycardia is defined as a series of three or more ventricular ectopic beats, often manifesting as a rapid tachycardia with wide QRS complexes (Figure 55.11). Although in children the QRS complex can be relatively narrow, its configuration always differs from the QRS in sinus rhythm. Often there is AV dissociation, with the P waves occurring

less often than QRS complexes; this may be seen by slight variations of the T waves caused by varying superimposition of P waves on them. In half of pediatric patients, there may be retrograde capture of the atria, particularly at slower ventricular rates; this results in a 1:1 relationship between atrial and ventricular contractions. The major differential diagnosis is from supraventricular tachycardia with aberrant conduction. Proof of the ventricular origin of the arrhythmia can be obtained if the QRS complexes resemble typical ventricular extrasystoles in previous ECGs or if ventricular fusion beats are seen.

Ventricular tachycardia may cause severe symptoms and, particularly in patients with structural heart disease, can lead to ventricular fibrillation. It should usually be treated as an emergency. Because most wide QRS tachycardias in children represent ventricular tachycardia, they should be treated as such unless one is certain of a supraventricular origin. Inappropriate treatment of ventricular tachycardia (with digoxin or verapamil, for example) may be fatal. Cardioversion is usually effective. If the patient is hemodynamically stable, amiodarone, lidocaine, or procainamide may be given intravenously. Future attacks may be prevented with propranolol, mexiletine, sotalol, flecainide, or amiodarone. Treatment decisions should always be made with a cardiology consultant. Occasionally, ventricular tachycardia occurs at a rate similar to a normal sinus rate, has a relatively narrow QRS complex, and is called ventricular accelerated rhythm. In the presence of an otherwise normal heart and without circulatory difficulties, it is benign [12]. It usually does not require treatment and, when seen in a newborn, episodes usually disappear within several weeks or months.

Ventricular fibrillation

Ventricular fibrillation produces a recording with no QRS complexes but just a wavy line. P waves can be present. There is no cardiac output, and cardiopulmonary resuscitation should be initiated immediately while preparations are made for electrical defibrillation.

Ventricular fibrillation is often the terminal event in many illnesses. It may follow hypoxemia, hyperkalemia, digitalis or quinidine intoxication, myocarditis, myocardial infarction, catecholamine infusions, anesthetics, and many drugs. It may be seen in patients with dilated cardiomyopathy. It is also a consequence of other arrhythmias, particularly ventricular tachycardia or multiple multiform ventricular ectopic beats.

Ventricular fibrillation may also occur in two other settings. Individuals with complete (third-degree) AV block have episodes of transient ventricular fibrillation that cause syncope (Adams–Stokes attacks) and indicate the need for an artificial pacemaker. Occasionally these attacks occur when the complete heart block is intermittent and is brought on by vagal or other stimuli. In the long QT syndrome, ventricular fibrillation also causes syncope and death. In this syndrome, the arrhythmia starts with an unusual form

of ventricular tachycardia called torsades de pointes; polymorphous QRS complexes seem to rotate around the isoelectric line. Several of these patients have died suddenly of fright or on hearing an unexpected loud noise. Nearly all of the congenital long QT syndromes are related to specific heritable abnormalities in cardiac potassium or sodium channels (Figure 55.2). Multiple specific genes coding for channels may be abnormal because of mutations or deletion, but a significant minority of patients with long QT syndrome have none of the known mutations. Treatment generally requires chronic β-adrenergic blockade. Some patients require an implantable cardioverter–defibrillator, particularly those with a history of aborted sudden death, or continued syncope despite appropriate β-blocker therapy, and or with the sodium-channel mutation (long QT 3) [13].

Mechanisms of bradycardia

Sinus bradycardia

Sinus bradycardia is recognized as a regular, slow atrial rate with normal P waves and 1:1 conduction. Causes include hypoxia, acidosis, increased intracranial pressure, abdominal distention, hypothyroidism, jaundice, and hypoglycemia. Agents such as digoxin, organophosphate pesticides, dexmedetomidine, and propranolol may cause sinus bradycardia. Mild heart rate slowing may also be due to increased vagal tone or cardiac conditioning in a trained athlete.

Atrioventricular block

Complete atrioventricular block may be congenital, surgically induced, or occur suddenly as a result of myocarditis or another infection, such as Lyme disease. It is recognized as atrioventricular dissociation, regular RR intervals, regular PP intervals, an atrial rate greater than the ventricular rate, and the absence of capture beats (Figure 55.12). Associated features of congenital AV block include maternal systemic lupus erythematosus (diagnosed or asymptomatic; anti-Ro antibody positive), whereas associated features of acquired heart block may include those of Lyme disease, Kearns-Sayre syndrome (mitochondrial inheritance, weakness, progressive external ophthalmoplegia, pigmentary retinal degeneration), or myotonic dystrophy (myotonia, weakness). There is an association with atrial septal defect and other congenital heart disease, due to mutations in the transcription factor Nkx 2.5 [14,15].

Second-degree AV block should be classified as Mobitz type 1 (Wenckebach) or Mobitz type 2. Wenckebach conduction is characterized by progressive PR interval prolongation followed by a blocked beat, followed by recovery of conduction (Figure 55.13). Type 2 block lacks this characteristic PR prolongation prior to block and subsequent shortening after the blocked beat. Type 1 generally has a better prognosis than type 2 and responds readily to medication.

Figure 55.12 Complete atrioventricular block. The atrial rate is higher than the ventricular rate and both atrial and ventricular rates are regular and not associated.

(a)
(b)

Figure 55.13 Second-degree AV block. On tracing (a), there is progressive PR prolongation followed by failure of conduction. On tracing (b), a 2:1 relationship is seen.

Other causes of bradycardia include (1) sinus exit block, in which sinus P waves intermittently disappear as impulses are blocked from leaving the region of the sinus node (rare in children), and (2) frequent premature atrial contractions occurring too early to be conducted to the ventricles. This slows the resulting ventricular rate (very common in infants).

Mechanisms of premature beats

Supraventricular premature contractions

Supraventricular premature contractions display narrow and early QRS complexes, but they occasionally are wide as a result of an associated bundle branch aberration. Those originating in the atrium [premature atrial contractions (PACs)]

should be recognizable by finding a premature P wave superimposed on and deforming the previous T wave. This sign may be subtle, and require examination of multiple ECG leads.

Ventricular premature complexes

Ventricular premature complexes (PVCs) are recognizable as wide, often bizarre, early beats, generally without preceding P waves. The differentiation between PVCs and aberrantly conducted supraventricular ectopic beats is sometimes difficult or impossible from a surface ECG. Although, traditionally, premature ventricular beats may be differentiated from supraventricular beats by a full compensatory pause, this sign is unreliable in children. The identification of fusion beats, in which a sinus beat occurs simultaneously with a premature beat, thus creating an intermediate morphology, is helpful and establishes the premature beat as ventricular in origin.

Clinical evaluation

General approach to evaluation

The starting point in the diagnostic evaluation of a cardiac arrhythmia is a careful history and physical examination and the recording of a baseline ECG (i.e., while the patient is not having the arrhythmia). In obtaining the patient's history, one is attempting to determine whether (1) the rhythm abnormality might be caused by a life-threatening problem; (2) the patient is experiencing episodes of tachycardia, premature beats, or bradycardia; (3) the symptoms are exercise related; and (4) there is structural cardiac disease. During the physical examination, structural heart disease can be identified and the cardiac rate and rhythm assessed. On the ECG, obvious evidence of a problem, such as a prolonged QT interval or the WPW syndrome, is sought. The QT interval varies with the heart rate. A corrected QTc interval may be determined by dividing the QT interval by the square root of the preceding RR interval. The normal QTc interval should be less than 0.44 s [16]. A life-threatening problem is suspected if episodes of palpitations are associated with near-syncope, syncope, severe chest pain, or aborted sudden death, or if there is a family history of the long QT syndrome or unexplained sudden death. Patients with a long QT interval are treated with β-adrenergic receptor blocking agents and avoidance of proarrhythmic drugs, which prolong the QT interval. Patients with normal QT intervals but who may have a life-threatening problem are referred for invasive electrophysiologic evaluation, to avoid delay in recording an episode and to initiate appropriate and early treatment of a dangerous arrhythmia.

Patients who do not have obvious evidence of a life-threatening arrhythmia are then differentiated by whether they are experiencing episodes of tachycardia or premature beats or bradycardia. Those with tachycardia proceed to a noninvasive evaluation (discussed later), with the goal of capturing an episode electrocardiographically for the purpose of diagnosis. An echocardiogram is obtained in those with evidence of structural heart disease. With electrocardiographic evidence of WPW syndrome, an echocardiogram is obtained, primarily to rule out associated Ebstein anomaly of the tricuspid valve or, rarely, hypertrophic cardiomyopathy. In patients with likely premature beats or bradycardia but no evidence of structural cardiac disease or an abnormal ECG, noninvasive evaluation is optional and based on symptom severity. If there is structural cardiac disease or an abnormal ECG (e.g., complete AV block), an echocardiogram is obtained, followed by a noninvasive evaluation. An invasive electrophysiologic study may be recommended, depending on the results of the noninvasive evaluation and the severity of the symptoms.

Noninvasive evaluation of the rhythm disturbance involves the use of a variety of diagnostic modalities short of an intracardiac electrophysiologic study. The goal is to capture an episode of the patient's symptom electrocardiographically. Patients whose symptoms are brought on by exercise are referred for exercise testing to attempt to reproduce the abnormal rhythm. If the exercise test is negative or the symptoms are unrelated to exercise, consideration of the frequency of symptoms leads to the use of either a Holter monitor, for those with daily symptoms, or transtelephonic incident recording, for those with less frequent symptoms. If incident recording is used, the correct mode for recording must be chosen. In general, if the episodes last <30 s, it is difficult for the patient or parent to locate the monitoring device, connect it, and make a recording before the symptom resolves. In such patients, a continuous memory-loop recorder is recommended. When a symptomatic episode is recorded, it is important to determine whether the symptom was in fact typical, because benign arrhythmias and sinus tachycardia may coexist with more serious conditions. Recording of multiple episodes increases the reliability of the diagnosis, particularly in patients who do not have a cardiac arrhythmia when they are symptomatic. The only definitive way to diagnose the cause of the palpitations is to record an ECG during the symptom. Nonetheless, information from the patient's history may help in diagnosing the problem and assessing the urgency of reaching a diagnosis.

Clinical history

The patient's description of the sensation is important. Sustained tachycardia is usually described as a "racing" heartbeat, whereas premature beats are usually described as skipping of a beat. For the latter symptom, the sensation of the heart stopping is likely caused by the pause that follows a premature beat. Abrupt onset of palpitations, with equally abrupt spontaneous termination, especially if paroxysmal, suggests supraventricular tachycardia and not sinus tachycardia. The duration and rate of the symptoms should be noted; for sustained fast rhythms, some assessment of likely rate may be obtained by asking the patient or parent to imitate the rhythm by tapping it out. Parents or patients may be taught to take the pulse during such episodes. Patients can usually tell whether the fast rhythm is regular or irregular. Fast rhythms, such as atrial fibrillation and often atrial flutter (with block), are irregular, whereas supraventricular tachycardia and ventricular tachycardia are usually regular.

Symptoms associated with palpitations give clues to the severity of the problem. The most ominous sign is syncope, defined as a sudden loss of consciousness with inability to maintain posture. Syncope occurs as a result of hemodynamic compromise caused by the arrhythmia (rapid supraventricular tachycardia, ventricular tachycardia, AV block). Patients with syncope associated with possible arrhythmia require full cardiac evaluation because of the possibility that future episodes may result in sudden death, depending on the underlying cardiac problem. Patients may complain of transient dizziness or lightheadedness, which suggests lesser hemodynamic compromise. Syncope is discussed in detail in Chapter 56.

Chest pain is occasionally reported but is often due to the strong, rapid heartbeat rather than to any coronary artery

abnormality. The sensation of the pulsations in the neck may signify atrioventricular nodal re-entrant tachycardia or ventricular tachycardia and is caused by contraction of the atria against closed atrioventricular valves, resulting in jugular venous regurgitation (cannon a waves).

Factors that elicit the symptom are important to note. For example, certain forms of ventricular tachycardia are elicited only by exercise [17]. These causes of arrhythmia may depend on sympathetic activity, and "stress" is frequently reported as an eliciting factor. Such patients may respond best to β-adrenergic receptor blocking agents.

Factors identified that terminate the episodes and the manner of termination also help in the diagnosis. Sustained fast heart rhythms that end suddenly are more likely re-entrant tachycardias, whereas those that slow gradually are more likely an automatic tachycardia. Termination by the Valsalva maneuver, gagging, or facial immersion in cold water suggests re-entrant supraventricular tachycardia, although atrial flutter may also terminate with these maneuvers.

The past medical history and review of systems are important, primarily for identifying structural cardiac disease and possible noncardiac causes of palpitations. The most important example of the latter is hyperthyroidism, which may manifest as sinus tachycardia or as atrial fibrillation. A history of deafness (some patients with prolonged QT syndrome), ocular disease (Kearns-Sayre syndrome: progressive ophthalmoplegia, pigmentary retinal degeneration, right bundle branch block or complete AV block), or muscle weakness (myotonic dystrophy: muscle weakness, myotonia, AV block) suggest specific underlying disorders.

Physical examination

Few specific physical findings aid in the diagnosis. Signs of structural cardiac disease are important because, if serious, patients tolerate arrhythmias poorly and are likely to have more complex and dangerous cardiac rhythms. Several specific cardiac abnormalities are strongly associated with arrhythmias. Patients with dilated cardiomyopathy often have a gallop rhythm or signs of heart failure and may have ventricular arrhythmias, including ventricular fibrillation. Those with hypertrophic cardiomyopathy have nonspecific ejection murmurs and an increased apical impulse; they are at risk for ventricular arrhythmias. Arrhythmias are often noted in patients with congenital heart disease both before and after corrective or palliative surgery. If one is fortunate enough to examine a patient in the midst of an episode, the rate, rhythm, blood pressure, and arterial and venous (cannon a jugular waves) pulsations should be noted.

Resting electrocardiogram

In all patients with symptoms suggesting a rhythm disturbance, a resting 15-lead ECG, obtained when the patient is asymptomatic, can indicate a specific diagnosis associated with arrhythmias, but unfortunately cannot exclude arrhythmias *per se.*

The PR interval normally increases with age [18]. Conduction time is shortened when an accessory pathway (WPW syndrome) bypasses the atrioventricular node. A long PR interval indicates prolonged conduction anywhere between the sinus node and the myocardium, but usually indicates atrioventricular node block. Diagnoses evident on a resting ECG include the WPW syndrome, the long QT syndrome, and conduction abnormalities, such as second-degree and third-degree atrioventricular block and premature beats. Nonspecific changes, such as T-wave abnormalities, may suggest a myocardial abnormality, and specific findings, such as left ventricular hypertrophy, may not provide a diagnosis but suggest hypertrophic cardiomyopathy.

Obviously, capturing the arrhythmia on an ECG is very helpful and expedites the diagnostic process.

The electrocardiographic diagnosis of the arrhythmia's mechanism is vital for determining the best treatment, particularly when antiarrhythmic medications are contemplated. Failure to document the tachycardia often leads to inappropriate treatment of patients with benign conditions, particularly sinus tachycardia and premature contractions.

Initially, the QRS duration and morphology during tachycardia are assessed as normal or increased. The "narrow" QRS tachycardias are usually caused by supraventricular tachycardia (Table 55.2). The "wide" QRS tachycardias may be caused by either ventricular tachycardia or supraventricular tachycardia with sustained aberration conduction or bundle branch block; in children, most wide complex tachycardias are ventricular tachycardias (Table 55.3).

Table 55.3 Recognition of tachycardia with prolonged QRS duration.

Diagnosis	Findings on electrocardiogram
Ventricular tachycardia	Often with AV dissociation Capture beats with narrower QRS than on other beats Fusion beats
Supraventricular tachycardia with pre-existing bundle branch block	QRS morphology similar to that in sinus rhythm QRS morphology is that of right or left bundle branch block
Supraventricular tachycardia with rate-dependent bundle branch block	QRS morphology usually similar to that of right or left bundle branch block Rare in small children Difficult to distinguish from ventricular tachycardia in children
Antidromic supraventricular tachycardia in Wolff-Parkinson-White syndrome	QRS morphology similar to pre-excited sinus rhythm, but wider Never with AV dissociation
Atrial fibrillation with Wolff-Parkinson-White syndrome	"Irregularly irregular" wide QRS tachycardia

Next, the relationship between P waves and QRS complexes is determined, if possible; this relationship is often diagnostic. For example, a narrow QRS tachycardia with atrioventricular dissociation and an atrial rate lower than the ventricular rate may be diagnosed as junctional ectopic tachycardia. For rhythms with a 1:1 relationship between P waves and QRS complexes, the relative timing of the respective waves is helpful. If P waves are close to the preceding QRS the diagnosis is likely to be AV reciprocating tachycardia; if close to the following QRS the diagnosis is likely to be either atrial tachycardia or persistent junctional reciprocating tachycardia; or if on top of QRS the diagnosis is likely to be AV node re-entry tachycardia. These characteristics help to differentiate between accessory pathway tachycardia, atrial tachycardia, and atrioventricular node re-entry. Although not completely reliable, an exact electrophysiologic diagnosis may be unnecessary for initial decisions concerning treatment.

Holter monitoring

Twenty-four-hour ambulatory monitoring (*Holter monitoring*) is commonly used to capture the rhythm abnormality on the ECG when symptoms occur. With Holter monitoring, the ECG is continuously recorded digitally (or on to magnetic tape) for 24h, capturing as many as three separate leads simultaneously, for later playback and analysis. The patient keeps a diary of events and symptoms. The Holter recording is examined at these times to determine the existing heart rhythm during the symptom. If symptoms occur daily, Holter monitoring is the most efficient method of diagnosis. It is particularly valuable in patients with frequent symptoms (many times per day) that are not clearly the result of an arrhythmia. In such patients, the recording of many symptom episodes that show no electrocardiographic abnormality provides strong and reassuring evidence against a dangerous cardiac arrhythmia. From the Holter recordings, additional information about cardiac conduction, average heart rates, response of sinus rates to normal daily exertion, and the prominence of atrial ectopy, or ventricular ectopy (premature beats), is obtained and may be useful diagnostically if an episode of palpitations is not captured.

Echocardiography

Echocardiography is helpful in diagnosing structural cardiac disease. Because many of the structural abnormalities (congenital heart disease, hypertrophic cardiomyopathy, rhabdomyoma, mitral valve prolapse) associated with arrhythmias are difficult to diagnose on physical examination and electrocardiography, certain patients require echocardiography. Patients with worrisome symptoms (syncope, chest pain, dyspnea, prolonged duration) and who may have life-threatening episodes of tachycardia should have an echocardiogram. In most patients with arrhythmias, the echocardiogram is normal.

Transtelephonic incident monitoring

When symptoms do not occur daily, Holter monitoring is inefficient, because several consecutive Holter recordings may be needed to capture a single episode or may not detect them. Transtelephonic incident recorders are small, battery-powered devices that the patient carries for 1 month or longer. When the symptom occurs, the patient makes a recording by placing the device on the chest or connecting it to wrist or chest electrodes. A single ECG lead is recorded into the device's memory for 60–120s. The patient then plays the recording back over the telephone to the clinician's office or monitoring center. The unit generates a series of signals that are decoded at the monitoring center into the ECG. For very transient symptoms, devices are available that are connected to the patient as with a Holter monitor and continuously record the heart rhythm in a memory loop. When a symptom is experienced, the patient presses a button, which causes the device to store an ECG for the 30–45s before and for a short period after the button was pushed.

For patients in whom the symptoms are very severe but very infrequent, and in whom standard loop recording has failed to capture an episode, implantable loop recorders are available [Reveal (Medtronic, Minneapolis, MN, USA), SJM Confirm (St. Jude Medical, St. Paul, MN, USA)]. These very small devices are implanted in the upper chest, like a pacemaker, and automatically capture arrhythmias. They can also be activated by the patient or a family member using a hand-held device. Stored electrograms are available for electronic downloading later [19,20].

Exercise testing

In some patients, an exercise test helps to elicit an episode of tachycardia or irregular heart rhythm and is a reasonable approach when symptoms are exercise related. The patient's ECG and blood pressure are monitored while the patient runs on a treadmill or rides a stationary bicycle (see Chapter 11). During the test, the work load is increased in discrete steps. The ECG is monitored during both exercise and recovery. Formal exercise testing, however, does not reproduce the type of exercise stress experienced by athletes, particularly the competitive stress. The failure to induce an arrhythmia with exercise testing does not exclude exercise-related arrhythmias.

Electrophysiology study

History of electrophysiology study

The His bundle was first recorded in 1969 and the technique was quickly adopted for use in children. In 1970, programmed stimulation techniques were incorporated with His bundle recordings and the electrophysiology study was developed [21–23]. This has become a powerful diagnostic tool and can be extremely helpful in determining arrhythmia risk and mechanism.

Principles and technical considerations

Education and family preparation are crucial when performing an invasive electrophysiology study. These studies are usually performed with conscious sedation or general anesthesia. In general, most patients who receive conscious sedation will receive a narcotic (such as fentanyl) and a benzodiazepine (midazolam). Midazolam is a good choice in electrophysiology studies because it lacks electrophysiologic effects [24]. A designated person monitors the patient's status and vital signs when using conscious sedation for EP studies. General anesthesia is being used more often as studies have become more complicated and smaller children are being studied. Propafol is a good anesthetic choice. Dexmedetomidine, commonly used as a sedation agent for cardiac catheterization, is not a good choice for electrophysiology studies, owing to its vagotonic effects [25].

Patients undergoing an EP study are usually positioned for a long procedure. The arms are positioned alongside the thorax to decrease brachial plexus injury. A full 12-lead ECG is placed. Oxygen saturation and blood pressure are continuously monitored. Defibrillation pads are routinely placed, to allow for rapid emergency defibrillation. Catheters are then inserted, usually via a femoral vein. Other approaches use the internal jugular vein or subclavian vein.

Catheter sizes come in a variety of sizes. Traditionally, 5 Fr catheters are used in young children and infants whereas 6 and 7 Fr catheters are used in older children and adolescents. The electrodes on this catheter vary in number and interval spacing. Most electrophysiology catheters are in a quadripolar configuration; however, 8, 10, and even 20 pole catheters are commonly used for mapping large areas.

Catheters are placed using fluoroscopy. Biplane fluoroscopy is helpful for precise catheter manipulation while mapping. Radiation exposure to the patient and staff must be carefully monitored and limited. The use of modern pulsed fluoroscopy with pulse rates of ≤ 7.5 pulsess^{-1} and proper shielding significantly decreases radiation exposure. Once catheters are in place, the tracings are displayed and recorded, usually in a bipolar manner. Most laboratories have an optical disk computer system which allows for recording and pacing of several signals simultaneously. This permits on-line measurements with a freeze-scope capability. The recording speed can be manipulated to allow for analysis of both tachycardias and bradycardias. A stimulator is also necessary to pace the heart at different cycle lengths.

Basic intracardiac study

Catheters are placed in four standard recording and stimulating positions within the heart: the right atrium, the right ventricular apex, the coronary sinus, and in the His bundle region. From these locations, electrograms can be recorded and the heart stimulated, allowing for the diagnosis of most arrhythmias. A variety of measurements and a formalized stimulation protocol are performed. Both surface ECG measurements and baseline measurements of the atrial–His (AH) and His–ventricular (HV) intervals are made. The AH interval may be prolonged in patients with AV nodal disease, receiving antiarrhythmic medications, or with increased vagal tone. HV interval prolongation usually reflects intrinsic His–Purkinje disease, or exposure to antiarrhythmic agents. A short HV is commonly present in patients with WPW syndrome.

EP testing usually consists of two basic pacing maneuvers performed in the atrium and ventricle. This first is rapid pacing at a set cycle length. This can determine AV block cycle length when performed in the atrium, and can occasionally elicit either atrial or ventricular arrhythmias. The other maneuver is programmed extrastimulation. An eight-beat drive train at a conventional cycle length is followed by premature stimuli. This sequence is repeated with the premature stimulus gradually shortened by 10 ms intervals until it fails either to conduct or to excite cardiac tissue. This interval indicates the effective refractory period for the site.

Although sinus node dysfunction is diagnosed by noninvasive testing and history, it can be formally evaluated by several pacing maneuvers. The two most common measurements are sinus node recovery time (SNRT) and sinoatrial conduction time (SACT). Sinus node recovery time measures the time for the sinus node to recover automaticity following overdrive suppression via atrial pacing. In a patient with a normal healthy sinus node it is short, but fairly prolonged (several seconds) in a patient with a diseased sinus node. Atrial pacing in the right atrium is performed for 30 s. The pacing is abruptly terminated, and the time for the sinus node to recover is then measured. This maneuver is repeated at faster pacing rates, and the maximum SNRT is recorded. The patient's concomitant sinus cycle length is then subtracted from the maximum SNRT to give a corrected sinus node recovery time (CSNRT). In children, CSNRT is usually <275 ms [26]. The SACT estimates conduction time through perinodal tissue. This is a measure of the time required for premature stimulus to penetrate into the SA node and reset the timing for the next normal sinus beat [27]. Single premature atrial contractions (PACS) are delivered either in sinus rhythm, or after an eight-beat drive train, and the coupling interval is made progressively shorter by 10 ms until atrial refractoriness is reached. The time from the paced beat to the next spontaneous beat is then measured (A2–A3). As the premature beat becomes more and more premature, the sinus node enters a "reset zone" where the extra beat penetrates the perinodal atrial tissue and resets the sinus node. At this point the A2–A3 reaches a plateau. Thus, during the reset zone, the A2–A3 represents three events, the conduction time of A2 into the sinus node, the spontaneous cycle length of the sinus node, and the conduction time out to the surrounding atrial muscle. Hence the SACT is calculated by subtracting the sinus cycle length from the A2–A3. The normal value for this is <200 ms [28].

The AV node and His–Purkinje system can also be examined during an EP study. The effective refractory period of the AV node is commonly measured. Dual AV nodal physiology can often be identified with atrial programmed stimulation, and is defined as an abrupt increase in the AH interval of 40–50 ms in response to a 10 ms decrease in S2 (a single induced premature beat). This can be a sign of AV nodal tachycardia. Occasionally in patients with His–Purkinje disease, block below the His bundle can be seen as two components – an S1 S2 This is usually considered a pathologic finding.

In a patient with SVT, an electrophysiology study serves several purposes. First, the SVT mechanism can be identified for a suitable target for ablation therapy (see below). If ablation cannot be performed, drug testing allows the prediction of a suitable anti-arrhythmic agent.

Second, SVT substrate can occasionally be identified by measuring the baseline intervals. In patients with WPW syndrome, a short HV interval diagnoses pre-excitation. The anterograde ventricular activation pattern can localize the accessory pathway in this situation, especially in patients with a left-sided pathway.

An atrial protocol is then performed, consisting of single premature stimuli that are shortened down to atrial refractoriness. This evaluates effective refractory periods, which can be very useful in patients with AVN re-entry tachycardia. Rapid atrial pacing can also be performed. These maneuvers can be repeated with an isoproterenol infusion to aid in inducing the arrhythmia. Finally, ventricular pacing can be performed to evaluate retrograde (VA) conduction and demonstrate eccentric atrial activation, suggesting an accessory pathway.

When ventricular tachycardia is suspected, programmed stimulation in the ventricle is often performed. The EP study can differentiate a wide complex SVT from VT, determine if a sustained VT can be elicited, and guide therapy, either ablative or medical. A ventricular protocol consists of pacing the ventricle with delivery of a single premature beat (S2) at several different cycle lengths. The S2 is progressively decreased by 10 ms increments until the effective refractory period of the local ventricular muscle is reached. Following this, double extra stimuli (S2, S3) and triple extra stimuli (S2, S3, S4) are delivered until the coupling intervals become too short to capture. This protocol is performed at two different ventricular locations, usually the right ventricular apex and right ventricular outflow tract. This is often repeated with the addition of a catecholamine, such as isoproterenol, to mimic stress/exercise.

Several responses to a ventricular protocol are commonly seen in a child. One is a short run (0–4 beats) of ventricular beats of the same morphology as the paced beats, which is commonly termed a repetitive ventricular response. This is likely due to bundle branch re-entry and is not believed to be a pathologic rhythm. Another is nonsustained ventricular tachycardia, defined as any ventricular arrhythmia which lasts from >4 beats to 30 s. If the arrhythmia lasts >30 s, or requires pacing or cardioversion for treatment, it is considered sustained ventricular tachycardia. These rhythms are further characterized as monomorphic, polymorphic, or ventricular fibrillation depending on QRS morphology and cycle length. These sustained rhythms are predictive of sudden death in children with congenital heart disease [29].

Advanced mapping techniques

Arrhythmia mapping has undergone major changes in the last decade. Several computer-based methods allow three-dimensional visualization of electrical and anatomic information. Complex arrhythmias in congenital heart disease can be mapped better with less fluoroscopy time. A noncontact mapping system uses electrical signals in the blood pool of a chamber to derive an inverse solution for the signals on the endocardial surface (EnSite, St Jude Medical) [30,31]. This system is particularly attractive in patients with nonsustained tachyarrhythmias or those with hemodynamically unstable rhythms. Electroanatomic mapping systems (CARTO, Biosense-Webster, Baldwin Park, CA, USA, and Nav-X, St. Jude Medical) use a set of magnets to identify catheter location and orientation in three-dimensional space [32]. Three-dimensional activation, propagation, and voltage maps can be constructed. Both systems currently allow integration of other imaging modalities, such as CT and intracardiac echocardiography, to their systems to allow for better anatomic visualization. One of their potential advantages is the ability to perform EP studies and ablations with less fluoroscopy, a major concern in a developing child [33].

Therapeutic EP interventions

An invasive "cure" for re-entrant SVT was first described in 1969 when Sealy *et al.* surgically ablated the aberrant pathway in a patient with WPW syndrome [34]. This began for many arrhythmias an era of invasive procedures which has progressed from open chest operations and uncontrolled higher energy direct current (DC) shocks through a catheter to routine controlled elective radiofrequency and cryoenergy catheter ablation in children [11,35–37]. At present many arrhythmias can either be cured or modified with the catheter techniques, including re-entrant rhythms, such as AVRT, AVNRT, atrial flutter, automatic atrial tachycardias, and ventricular tachycardias [38,39].

Either of two major energy sources is commonly utilized for destruction of myocardial tissue: radiofrequency and cryoenergy. Radiofrequency current heats tissue to destroy myocardial cells. Huang *et al.* attempted a closed-chest ablation of the AVN using catheter-delivered radiofrequency energy in 1987 [40]. This technique was quickly adopted, with reports of use for both AV node and pathway ablation appearing soon after [41]. The mechanism behind the cell destruction has been delineated [42,43]. Cell death results from protein denaturation and dehydration. Lesion size

grows exponentially with time. Temperature decreases hyperbolically with distance from the catheter tip [42]. Radiofrequency ablation quickly became the primary modality for therapeutic arrhythmia management.

Cryoablation has become established as an alternative for a subset of arrhythmic substrates. Cryoablation uses circulating nitrous oxide through the catheter tip to cool tissue to a temperature of –75 °C. Hypothermia causes myocardial cells to become more acidic, secondary to slower ion pump transportation, and slowing metabolism [44]. These effects are transient if the exposure to hypothermia is brief. However, with ice crystal formation, permanent tissue injury occurs. The ice crystals initially damage mitochondria and distort cellular membranes [45,46]. This is followed by hemorrhage and inflammation secondary to dehydration and ultimate necrosis of the cell [47,48]. Cryolesions tend to be well circumscribed with distinct borders and have less thrombogenic potential than do radiofrequency lesions [49]. This has led many centers to use cryoablation in patients with arrhythmogenic foci near the AV node. Successful cryoablation in the septal region has been reported with no episodes of incidental heart block [35,50].

Transesophageal study

Transesophageal pacing is useful in both diagnosis and therapy of a wide range of arrhythmias, particularly in the differentiation and therapy of supraventricular rhythms. It has been especially beneficial in small children because of its ease of use and relatively noninvasive nature.

History

Max Cremer was the first to record a transesophageal electrogram in 1906, when he persuaded a sword swallower to swallow an electrode under fluoroscopic guidance. In the 1960s, low-energy defibrillation of the atrium and emergency ventricular pacing were performed via the esophagus [51,52]. In the 1980s, esophageal pacing was reported as a therapeutic tool in AVNRT and atrial flutter [53–55]. This technology can predict the recurrence of SVT and drug efficacy in neonates with some success [56]. It is accepted for diagnosis and therapy in pediatric electrophysiology, especially in young infants where a more invasive electrophysiology study may be difficult.

Technical considerations

Adequate education and preparation of the patient and family are important before performing pediatric transesophageal pacing. Usually mild sedation is all that is required to maximize patient cooperation and comfort while performing a transesophageal study. Intravenous midazolam (0.05–0.1 mg kg^{-1}) and/or fentanyl (0.5–1.0 μg kg^{-1}) are often used. It is important to consider a sedation/pain strategy, as it is extremely difficult to perform a study in an uncooperative and anxious patient.

A transesophageal study can be performed in both inpatient and outpatient settings. A surface ECG and oxygen saturation monitoring should be used. A DC cardioverter–defibrillator should be present and personnel should be well versed in sedation monitoring and advanced life support.

Three major components are necessary for performing transesophageal pacing studies: the electrode catheter, the recording equipment, and the stimulator. There are several different models of transesophageal catheters, ranging in size from 4 to 10 Fr with differing interelectrode distances (2–30 mm) and differing number of electrodes (bipolar to hexapolar). Interelectrode distance has no significant effect on pacing thresholds regardless of age or size [57].

Placement of the catheter is similar to that of a nasogastric tube, and involves lubrication (lidocaine gel can be helpful). The catheter is placed through the nares and advanced through the posterior pharynx to the esophagus. Optimal catheter position is determined by patient height and can be facilitated by fluoroscopic visualization. Minor adjustment may be necessary to achieve the optimal pacing location. The catheter is then secured with tape to the patient's face.

A simple ECG machine can act as the recording equipment. A three-channel continuous recording ECG may be configured for two surface leads while the unipolar esophageal lead can be connected to one of the precordial leads (V1) This allows for comparison of the P waves on the surface leads with the esophageal electrograms. Recording during pacing can occur without recording of the atrial esophageal electrogram. Alternatively, a bipolar recording system may be used. The advantage of this system is that more reproducible and reliable electrograms can be produced. This system requires a preamplifier which can be set with a high-pass filter at 20 Hz.

The stimulator ideally should be able to deliver a pacing stimulus with a long pulse width (10–20 ms) and a high current (up to 50 mA). Pulse widths greater than the standard 2 ms used in intracardiac pacing are required to capture the atrium from inside the esophagus. Usually successful atrial pacing can be accomplished with a pulse width of 6–10 ms and a current of 10–15 mA [57,58]. Patient discomfort is often reported with currents >15 mA (at a constant pulse width of 10 ms) [57,58]. Successful pacing with minimal discomfort can be achieved in >90% of pediatric patients [53,54,59,60].

Pacing protocols are usually limited to atrial pacing for practical reasons. The protocols can include sinus node testing by measuring sinus node recovery times. AV conduction can be assessed with atrial overdrive pacing to measure AV block cycle length and determine AV nodal and atrial tissue refractory periods with premature atrial extrastimulation. SVT mechanisms can be identified by assessing means of inducibility, termination, and VA conduction. Drug therapy can be tested by SVT provocation before and after drug administration.

Complications of transesophageal pacing are rare and mostly minor [61]. Trauma to the mucosa from insertion of the catheter and discomfort are the most frequently reported. Rarely, inadvertent ventricular pacing can result in ventricular arrhythmias which may require cardioversion.

Emergency treatment

Tachycardia

Immediate treatment of patients with sustained symptomatic tachycardia starts with an assessment of the patient's hemodynamic status. Patients with signs of shock require immediate cardioversion, whatever the mechanism of tachycardia. Other modalities may be tried first in patients who are less symptomatic. Patients with a wide QRS during tachycardia should probably undergo electrical cardioversion because of the high likelihood that the rhythm is ventricular tachycardia. Intravenous lidocaine may be used alternatively, provided that the diagnosis of ventricular tachycardia is certain and the hemodynamic status is stable (Table 55.4). In uncertain diagnoses, intravenous procainamide may be effective in ventricular tachycardia and most forms of supraventricular tachycardia.

In patients with a normal QRS duration, maneuvers to increase vagal tone should used initially. Older children may be coached through a Valsalva maneuver or facial immersion in ice water, whereas younger children may have gagging induced, have rectal stimulation, or, more often, have an ice bag applied to the face. Although these measures often work, a time limit should be set so that the patient's hemodynamic status does not deteriorate during prolonged unsuccessful attempts. If maneuvers fail, the administration of adenosine intravenously is the preferred approach (Table 55.4) with continuous electrocardiographic monitoring in a room with a cardioverter-defibrillator available. Adenosine is given by very rapid intravenous injection at an initial dose of 0.05 mg kg^{-1}, and the ECG is observed for 10–15 s. If there is no effect, the dose is repeatedly doubled until a dose of 0.40 mg kg^{-1} is reached (maximum 24 mg in adolescents and adults). In patients with tachycardia involving the atrioventricular node (accessory pathway tachycardia, atrioventricular node re-entry), adenosine should terminate it by stopping atrioventricular conduction for 1–2 s. In patients with sinus or atrial tachycardia or atrial flutter, adenosine causes a short episode of atrioventricular block, and the underlying atrial rhythm is revealed on the continuous ECG recording. If the diagnosis is shown to be atrial tachycardia or flutter, patients >6 months old may receive intravenous verapamil. Those <6 months old should never receive verapamil; instead, they may undergo pace conversion using esophageal pacing or cardioversion, or may receive intravenous procainamide.

Many patients may not require long-term treatment if the episodes are not severely symptomatic and are either self-limited or easily converted with vagal maneuvers. If suppressive drug therapy is indicated, depending on the likely diagnosis, various medications may be used, including digoxin, β-blockers, verapamil, flecainide, sotalol, and amiodarone (Table 55.5). The last three agents are more potent

Table 55.4 Intravenous antiarrhythmic agents.

Agent	Dosage	Comments
Verapamil	0.1–0.2 mg kg^{-1} i.v., 5–10 mg maximum	Beware of hypotension Definitely contraindicated under 6 months of age, probably under 12 months of age Do *not* give with β-blockers
Esmolol	500 µg kg^{-1} over 1 min, then 50–250 µg kg^{-1} min^{-1} continuous infusion	Monitor pulse, blood pressure Contraindicated in those with asthma and those with congestive heart failure Do *not* give with verapamil
Procainamide	10–15 mg kg^{-1} i.v. over 30 min	May cause hypotension; continuous monitoring is essential Cardiology guidance is recommended
Digoxin	10 µg kg^{-1} i.v. as initial load Second dose in 6 h, third at 24 h	Do not use in hypokalemia or if digoxin toxicity is suspected
Lidocaine	1–2 µg kg^{-1} i.v. over 15 min	Continuous infusion 30–50 µg kg^{-1} min^{-1}
Phenylephrine	0.02 mg kg^{-1} i.v. slowly	Used for raising blood pressure and eliciting a baroreceptor vagal reflex
Adenosine	Starting i.v. dose: 0.05 mg kg^{-1}; double dose repeatedly until effect is seen, to maximum of 0.4 mg kg^{-1}	Contraindicated in pre-existing second- or third-degree AV block without pacemaker Use with caution in severe asthma; half-life is 10 s in serum

Table 55.5 Oral antiarrhythmic medications.

Agent	Dosage[a]	Comments
Propranolol	0.25–1 mg kg^{-1} p.o. every 6 h	Observe for wheezing and symptoms of hypoglycemia
Atenolol	0.5–2 mg kg^{-1} per day p.o. divided every 8 h	
Procainamide	50–100 mg kg^{-1} per day p.o. divided every 8 h	Monitor both procainamide and *N*-acetylprocainamide levels
Quinidine sulfate	30–60 mg kg^{-1} per day p.o. divided every 6 h	
Flecainide	50–200 mg m^{-2} per day p.o. divided every 12 h or 6.7–9.5 mg kg^{-1} per day divided every 8 h	Flecainide levels >1.0 mg ml^{-1} correlate with toxic effects
Mexiletine	1.4–5.1 mg kg^{-1} p.o. every 8 h	
Digoxin	10 mg kg^{-1} p.o. as initial load Second dose in 6 h, third in 24 h; reduce dosage in premature infants	Do not use in hypokalemia or if digoxin toxic reaction is suspected
Sotalol	2–8 mg kg^{-1} per day p.o. divided every 8 h	Torsades de pointes is likely with hypokalemia. Monitor ECG for QT prolongation
Amiodarone	5 mg kg^{-1} p.o. b.i.d. × 2 weeks, then 2.5 mg kg^{-1} p.o. b.i.d.	Monitor thyroid and pulmonary function

[a]b.i.d., twice per day; p.o., orally.

antiarrhythmic agents than the others and are associated with increased risk of side effects.

Intracardiac catheter ablation techniques during cardiac catheterization using radiofrequency energy are available for pediatric patients with nearly all forms of abnormal tachycardia and may be offered to ease life-threatening tachycardia. In older children this treatment may be used as an alternative to long-term medication therapy, or in younger children it may be used when medication fails to control the tachycardia.

Finally, in selected patients who are found to have life-threatening ventricular arrhythmias not amenable to ablation and not reliably prevented or controlled by medication, the use of implantable cardioverter–defibrillators may be appropriate. These devices are implanted in a procedure similar to that used for pacemaker implantation, and they detect and terminate dangerous ventricular arrhythmias either by rapid pacing or by the delivery of a high-voltage shock to the heart.

Bradycardia

The hemodynamic effect of a slow heart rate depends on the difference from the patient's usual heart rate. Sudden heart rate decreases may be poorly compensated by increases in stroke volume, particularly in those with limited cardiac function. Moderate sinus bradycardia in normal children rarely necessitates treatment. Underlying causes, such as hypothyroidism, should be corrected. Patients with third-degree AV block and those with severe sinus node dysfunction may require permanent artificial cardiac pacing. The occurrence of symptoms (over and above the symptom of palpitations) such as syncope, exercise intolerance, or dizziness prompts pacing. With severe sinus node dysfunc-

tion, pacing may be required if the patient is to be given antiarrhythmic agents to suppress episodes of tachycardia because of the danger that such medications will worsen sinus node dysfunction. Patients with persisting complete AV block as a result of cardiac surgery generally require pacing, even in the absence of symptoms. Prophylactic cardiac pacing may be recommended in completely asymptomatic patients with complete congenital AV block who are at greater risk for progressing to syncope or sudden death.

Therapy for specific tachyarrhythmias

Accessory pathway tachycardia (including Wolff-Parkinson-White syndrome)

Acute and chronic treatment can be directed at either the anterograde AV node conduction or the retrograde accessory pathway conduction. β-Blockers, digoxin, or calcium channel blockers affect the anterograde limb of the re-entrant circuit. The retrograde accessory pathway conduction is affected by procainamide or flecainide [62]. Long-term management depends on the severity of the problem and the frequency of the attacks. For children with rare, mildly symptomatic attacks of supraventricular tachycardia that are easily terminated, we advise no treatment at all. Infants and children with more frequent or symptomatic attacks are treated initially with β-blockers. Digoxin is used only if there is no evidence of pre-excitation in sinus rhythm. About one-third of adults with pre-excitation treated with digoxin have a shortening of the anterograde ERP of the accessory pathway, which could be dangerous if atrial fibrillation develops. Although atrial fibrillation is uncommon in infants and digoxin has been used for years to treat children with

pre-excitation, with few if any documented problems, some reports suggest the possibility of sudden death in infants treated with digoxin [63].

Transcatheter ablation of the accessory pathway is increasingly being used as first-line therapy in children. Its use in infants is still limited because of complications of perforation, AV block, and damage or occlusion of major coronary arteries. In addition, the natural history of accessory pathway tachycardia in infancy is favorable: 75–90% have spontaneous resolution of tachycardia by 12 months of age [64]. Ablation is reserved for patients with life-threatening, medically refractory tachycardias, as in those with PJRT and dramatically compromised left ventricular function.

Atrioventricular node re-entry tachycardia

Short-term treatment of AV node re-entrant tachycardia is directed at achieving a brief episode of AV block. Neonates might respond to vagal maneuvers or rectal stimulation. If vagal measures fail, the first choice of medication is intravenous adenosine. Other effective treatments include intravenous esmolol or digoxin, and esophageal or intracardiac atrial overdrive pacing is effective. Neonates with refractory AVNRT also respond to electrical synchronous cardioversion.

The natural history is unknown, but the condition may well disappear with time. Therefore, it is reasonable to treat such infants with antiarrhythmic medications for several years with the hope of avoiding transcatheter ablation.

Persistent junctional reciprocating tachycardia

Treatment of children with PJRT is challenging. In addition to the techniques and drugs used for children with WPW syndrome, amiodarone is often effective, and spontaneous resolution is occasionally observed [3].

Atrial flutter

Therapy is directed towards either converting the flutter to sinus rhythm or limiting the ventricular response. Vagal maneuvers can convert the rhythm. Digoxin, propranolol, or esmolol can slow the ventricular response and assist in converting the tachycardia.

Procainamide can convert the tachycardia, but may slow the atrial rate without converting the rhythm. If the faster atrial rate is associated with variable AV conduction, the slower rate can allow 1:1 AV conduction, paradoxically increasing the ventricular rate. For this reason, procainamide should be used only after a drug, such as digoxin, that limits AV conduction has been given.

If immediate tachycardia conversion is necessary, the first choice is esophageal atrial overdrive pacing. This method is effective, particularly in small children, and does not require anesthesia. In postoperative cardiac surgical patients, temporary atrial pacing wires can be used. If this method fails or is unavailable, electrical cardioversion with deep sedation or anesthesia will be effective.

For long-term treatment, the first choice is oral digoxin or propranolol. If this therapy fails, sotalol, is given three times per day [65]. Other choices are flecainide, two or three times per day, or propafenone, three times per day.

Atrial flutter in the newborn period often disappears within the first 6 months of life. Traditionally, such infants have been treated with digoxin for 1 year; after conversion they can probably be followed without medication.

Atrial ectopic tachycardia

Treatment of AET is difficult, and rate control may be the only achievable response to therapy. The atrial focus may be slowed by β-blockers, flecainide, or propafenone or by class III agents, such as sotalol and amiodarone. The goal of treatment is to protect against the subsequent development of tachycardia-induced cardiomyopathy. Intervention to cure the tachycardia, either by radiofrequency ablation or cryoablation, or by surgical cryoablation, should be performed at the earliest echocardiographic signs of reduced cardiac function [5].

Junctional ectopic tachycardia

The pharmacologic approach to AET can also be effective in treating JET. Although no agent is reliably effective in treating this arrhythmia, amiodarone is often effective. In selected patients, transcatheter ablation can eliminate the junctional focus. In very small infants, the proximity of the JET focus to the AV node increases the risk of causing complete AV block at the ablation. This risk is likely lower with cryoablation. Permanent pacemaker implantation is used in the sickest infants who have not responded to antiarrhythmic agents [10].

Postoperative JET is usually seen in infants with low cardiac output. JET could be caused by the poor cardiac output or could contribute to the hemodynamic compromise. Intravenous amiodarone is widely used for JET. Surface cooling can slow the junctional rate, allow effective AV sequential pacing, and restore AV synchrony, which often improves the cardiac output. Unlike congenital JET, postoperative JET is transient and resolves as the myocardium recovers [66].

Ventricular tachycardia

Pharmacologic suppression of ventricular tachycardia, when induced by catechol stimulation, includes the use of moderate to high doses of β-blocking medications. When unsuccessful, or when the ventricular tachycardia does not depend on catecholamine stimulation, class I agents, such as mexiletine, and flecainide can be used. Class III agents, such as sotalol and amiodarone, might also be effective. Infants with accelerated ventricular rhythm probably do not require treatment, because the tachycardia rate is not fast enough to produce hemodynamic compromise and the rhythms usually resolve by several months of age [12].

Premature beats

Premature beats of any kind without tachycardia rarely need treatment. Ventricular premature contractions may occasionally require treatment when

1 The contractions are multiform.

2 The contractions occur in couplets or in short runs of ventricular tachycardia.

3 The contractions follow a recently converted ventricular tachycardia.

4 The contractions exhibit the "R on T" phenomenon (i.e., they fall repeatedly on the early part of the T wave of the preceding beat).

Decisions concerning treatment of premature beats are difficult and should be made in consultation with a cardiologist. Possible inciting factors, such as drugs, hypoxia, and acidosis, should be corrected. If ventricular premature contractions require emergency treatment, the agent of choice is lidocaine, given by a continuous intravenous infusion. Bretylium has also been used to terminate ventricular tachycardia.

56 Syncope

John R. Phillips & Larry A. Rhodes

Robert C. Byrd Health Sciences Center, West Virginia University College of Medicine, Morgantown, WV, USA

Syncope, a transient loss of consciousness, is a common disorder affecting ~35% of the population at least once in their lives [1,2]. Symptoms often begin during adolescence and are recurrent [3], so that syncope is a common pediatric problem causing anxiety and concern for patients and parents alike. Vasovagal (neurocardiogenic) syncope is by far the most common cause of syncope in the community [4]. Syncope is best defined as a transient, self-limited loss of consciousness and postural control with a relatively rapid onset and recovery. More often than not, the syndrome is benign but may be a harbinger of complex medical problems, such as cardiac arrhythmias, structural heart disease, or neurologic disorders. In many circumstances, syncope may be the first symptom indicating those at risk for sudden cardiac death. Physicians must differentiate benign syncope from more life-threatening conditions. This chapter reviews the differential diagnosis of syncope in children and adolescents and concentrates on evaluating and treating vasovagal syncope.

Incidence and age at presentation

Several studies have attempted to identify the incidence and age at presentation of syncope. Syncope most often presents during adolescence with the age centered about 13 years [3]. In 1997, Driscoll *et al.* reported that patients seeking medical attention for syncope had an incidence rate of 125.8 per 100 000 with a peak age range between 15 and 19 years [5]. The incidence in girls (166.3 per 100 000) was higher than that in boys (92.9 per 100 000). A study of medical students under 22 years of age found a modal age of first syncope of 13–15 years [1]. Very few patients in either study were <7 years of age at onset of syncope. Lifetime prevalence of syncope has been reported to range from 7% [6] to 39% [1],

again with females affected more often than males. Studies of military personnel in early adulthood suggest a prevalence of 20–32% [7,8].

Causes of syncope

The brain requires an adequate supply of oxygen and glucose to function normally. Decreases in the steady supply of oxygen and glucose to the brain may lead to syncope or presyncope. The causes of syncope are numerous and can be categorized as circulatory, metabolic, or neuropsychologic (Table 56.1). Metabolic and neuropsychologic disorders that cause syncope are beyond the scope of this chapter. We concentrate on circulatory abnormalities leading to syncope.

Cardiac syncope

The mechanism of cardiac syncope is decreased cardiac output and, subsequently, blood flow to the brain. Cardiac syncope results from severe obstructive lesions, myocardial dysfunction, and arrhythmias. Obstructive lesions include severe aortic or pulmonary stenosis, obstructive hypertrophic cardiomyopathy, and pulmonary hypertension. Although rare, myocardial ischemia or infarction secondary to coronary artery anomalies, Kawasaki disease, and congenital or acquired cardiomyopathies may cause myocardial dysfunction and produce decreased cardiac output and cardiogenic syncope. Extreme tachycardia or bradycardia can decrease cardiac output and lower cerebral blood flow, causing syncope. Cardiac structure and function are often normal in young people with arrhythmias but congenital channelopathies, such as long QT syndrome and Brugada syndrome, predispose patients to malignant ventricular tachyarrhythmias. Conversely, severe bradycardia, as in congenital complete heart block and congenitally

corrected transposition of the great arteries, may also decrease cardiac output.

Unlike vasovagal syncope, a cardiac cause of syncope should be considered particularly if syncope occurs with the patient recumbent, during exercise, or is associated with chest pain. Furthermore, a cardiac etiology should be considered if the patient has a history of repaired or unrepaired congenital heart disease or family history of sudden death. Pacemaker malfunction should be considered where appropriate.

Extracardiac syncope

Extracardiac causes of syncope include vasovagal syncope, orthostatic hypotension, situational syncope (after swallowing, urination, coughing, or defecation), carotid sinus hypersensi-

tivity, failure of venous return, and cerebrovascular occlusive disease including subclavian steal. Of all causes of syncope, vasovagal syncope, also called vasodepressor, neurocardiogenic, or common syncope, is by far the most common. It results from inappropriate output from the autonomic nervous system leading to symptomatic changes in blood pressure and heart rate. These changes typically occur while the patient is standing but may develop during emotional stress (e.g., speaking performances or standing at the altar), or after noxious stimuli such as phlebotomy or an unpleasant sight. A prodrome of dizziness is common. Others complain of an aura, such as flashing lights, changes in hearing (rushing sound), tunnel vision, or nausea. The blood pressure falls, the heart rate slows, and the subject becomes pale and loses consciousness. Injury from falling is rare. Repeated myoclonic jerks are common, and may lead to the misdiagnosis of epilepsy. True tonic–clonic seizures are rare if the patient is supine, and there is no incontinence.

Despite years of investigation, a complete understanding of the pathophysiology of vasovagal syncope remains elusive. Several mechanisms have been proposed. The first is that vasovagal syncope occurs as the result of an abnormal physiologic response to venous pooling in the lower extremities while standing. To understand this, consider the normal response to venous pooling in the legs. In a normal adult, ~500 ml of intravenous volume is displaced into the lower extremities during standing [9]. This is equivalent to ~10 ml per kilogram in a child [10]. With venous pooling, the central venous volume is decreased, as is left ventricular preload. The decreased ventricular filling reduces the stretching of mechanoreceptors in both atrial and ventricular tissues [5,9]. The resultant decreased signaling from the C fibers reflexly increases sympathetic tone and, subsequently, elevates heart rate and peripheral vascular resistance [11–13]. The atrial afferents are myelinated and arise from the junction of the vena cava and pulmonary veins within the atria [12]. They appear to be sensitive to central volume changes and insensitive to myocardial contractility [11,13]. The ventricular afferents are unmyelinated, slowly conducting C fibers sensitive to contractility and end-diastolic pressure [12]. With decreased stretching, there is less signaling from C fibers to the brain stem, leading to a reflex increase in sympathetic output [11–13].

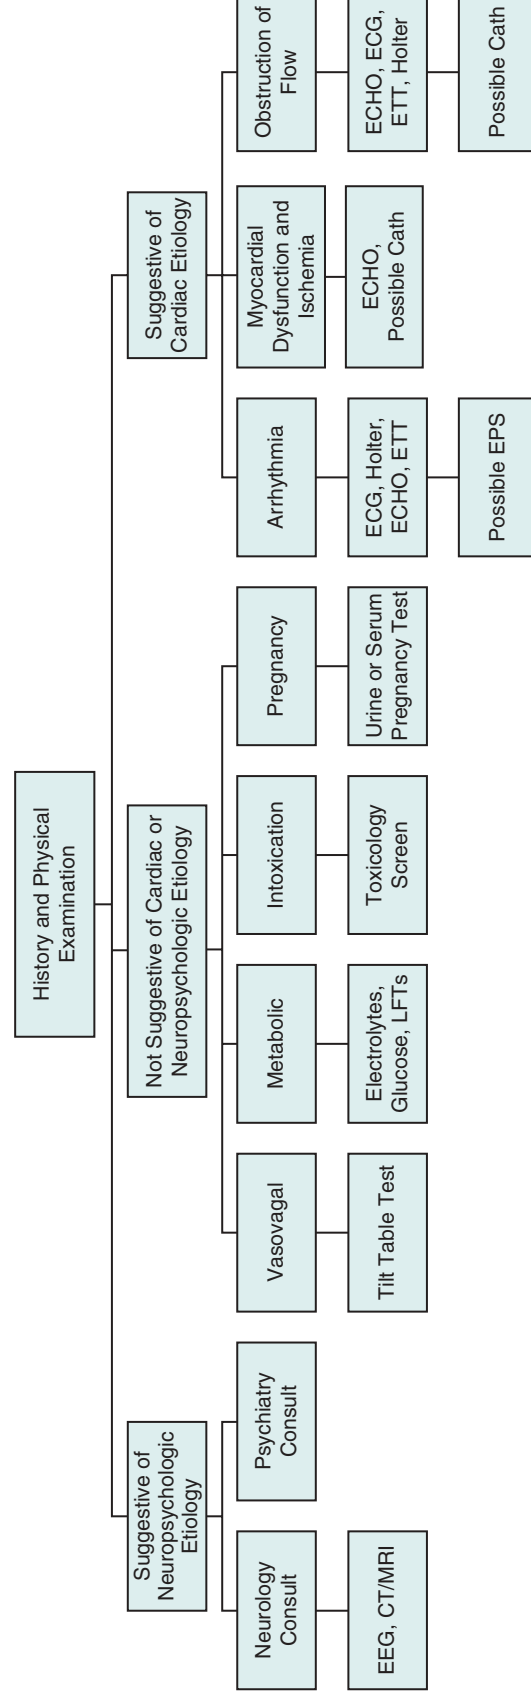
In patients with vasovagal syncope, this reflex is abnormal. These patients experience a decrease in sympathetic tone and an increase in parasympathetic tone leading to hypotension and bradycardia [11]. The exact abnormality in the reflex is not fully understood. One proposed mechanism is that a decrease in left ventricular preload increases contractility, which then raises the intracavitary pressure. This pressure increase stimulates the left ventricular mechanoreceptors and in turn elevates parasympathetic tone [11]. The role of left ventricular mechanoreceptors in this reflex has been demonstrated in work by Oberg and Thoren [14]. They


Figure 56.1 Scheme for the evaluation of the patient with syncope. Cath, catheterization; CT/MRI, computed tomography/magnetic resonance imaging; ECG, electrocardiography; ECHO, echocardiography; EEG, electroencephalography; EPS, electrophysiologic study; ETT, exercise tolerance testing; LFTs, liver function tests.

documented an initial decline followed by a marked increase in ventricular mechanoreceptor activity in cats subjected to experimental hemorrhage or occlusion of inferior vena cava blood flow leading to decreased ventricular filling [14]. They proposed that the underfilled left ventricle became distorted, activating the mechanoreceptors, which in turn fed back to the brain stem, causing a reflex withdrawal of sympathetic tone and an increase in parasympathetic tone [14]. Similar mechanisms may operate in the syncope that occurs in some patients with left or right ventricular outflow obstruction. A variation of this hypothesis suggests that there may be an initial increase in sympathetic tone contributing to this reflex. This is supported by the finding that patients with vasovagal syncope often have an increase in heart rate and arterial blood pressure immediately before syncopal episodes [15–17], in addition to increased levels of urinary catecholamines before the event [18].

The heart rate and blood pressure responses that accompany standing have also been evaluated in children [19]. In normal children, standing leads to an initial decrease in systolic and diastolic blood pressures followed by an increase in both pressures and an increase in heart rate. As the child continues to stand, the systolic blood pressure returns to baseline with the diastolic blood pressure and heart rate remaining elevated for as long as 2 min. In individuals susceptible to syncope, standing produces an exaggerated decrease in systolic and diastolic blood pressure and, in some, a paradoxical decrease in heart rate.

A second possible mechanism for vasovagal syncope may involve central triggers that lead to bradycardia and hypotension. Neurohormonal agents other than catecholamines may play an important role in leading to the depressor response in neurally mediated syncope. Increased levels of β-endorphin were found in patients with vasovagal syncope [20] and in hemorrhagic shock [21,22]. Evans *et al.* found that hypotension could be prevented in hemorrhagic shock by giving naloxone intracisternally [21]. Serotonin, a central mediator, may also play a role in vasovagal syncope. Animal studies have suggested that serotonin may lead to the depressor response in hemorrhage [23]. In a study by Abboud and Thames, intracerebrovascular serotonin induced hypotension and changes in renal sympathetic nerve activity and may have acted centrally to inhibit sympathetic activity [12].

Recently, implantable loop recorders (ILRs) have been placed in adults to establish the mechanism of vasovagal syncope. The International Study of Syncope of Uncertain Etiology (ISSUE) evaluated adult patients without structural heart disease or identifiable causes of syncope and negative or positive tilt-table testing with ILRs [24]. The most frequent finding was prolonged asystolic pauses preceded by progressive bradycardia recorded in 46% of tilt-negative patients and 62% of tilt-positive patients. Bradycardia without pauses was observed in 8 and 12% of patients, respectively. Another study of ILR showed that 69% of patients

had bradycardia during syncope [25]. These studies offer insight into the predominant cardiac rhythm during syncope but not an understanding of the pathophysiology of the bradycardia.

Evaluation of the patient with syncope (Figure 56.1)

History

Evaluating a child or adolescent with syncope begins with a thorough medical history that should include a precise, detailed account of the events surrounding the episode, including the type of activity engaged in prior to the episode. In particular, the occurrence of syncope during or immediately following exercise is a very important observation, as it strongly suggests a cardiac etiology. Important points include any prodromal symptoms, such as nausea, vomiting, palpitations, visual aura, auditory changes, or dizziness. A complete history may be difficult to obtain from a patient because of amnesia around the event. If so, efforts should be made to obtain eye-witness accounts. Helpful information includes an assessment of the patient's appearance, such as pallor or cyanosis before and during the event. An estimate of the duration of the syncopal episode is important. In general, vasovagal syncope is brief, in contrast to cardiac syncope. Abnormal movements, seizure activity, or abnormal posturing during the period of unconsciousness should be documented. The patient's mental status after an episode may help in developing a differential diagnosis. Other important historical data are illness around the time of the event, oral intake in the preceding 24 h, medications taken, and previous similar episodes.

A key element of the past medical history is a careful account of drugs that the patient may be using, including over-the-counter, recreational, and prescription medications. History of prior medical problems including cardiac and psychological illness should be obtained. A complete review of systems with special concentration on the cardiovascular and neurologic systems should be made. Finally, and perhaps most importantly, a detailed family history should also be elicited, particularly of congenital heart disease, arrhythmias, sudden death, and neurologic or psychologic disorders. In addition, specific questioning regarding hypertrophic cardiomyopathy, long QT syndrome, drowning, and pacemaker or defibrillator placement should be made. A social history is important in ascertaining the possibility of substance abuse, pregnancy, or factors leading to a conversion reaction.

Physical examination

A complete physical examination is performed. When examining the patient during and immediately after syncope, document heart rate, blood pressure, respiratory effort, and motor movements consistent with seizure activity. After a syncopal

event, evaluate blood pressure and heart rate with the patient supine and standing to exclude orthostatic hypotension or tachycardia. Signs of trauma or drug abuse are sought. Neurologic examination should be complete, including looking for papilledema or other signs of increased intracranial pressure. Cardiovascular examination includes palpation of the patient's pulses for rhythm and quality. A thorough auscultatory examination evaluates rhythm, characteristics of the heart sounds, and murmurs. This portion of the examination should be performed with the patient both sitting and supine, and with use of standing, squatting, and the Valsalva maneuver to enhance findings of mitral valve prolapse or hypertrophic cardiomyopathy. Particular attention should be given to the second heart sound to identify pulmonary hypertension.

Subclavian steal is an exception because it produces local cerebral ischemia with a normal cardiac output and blood pressure. The occurrence of syncope with arm exercise, especially in a patient with a Blalock–Taussig shunt, suggests this diagnosis. A blood pressure difference between the two arms is confirmatory.

Laboratory tests

Further testing is directed towards the patient's specific symptoms and physical examination findings. If a neurologic cause is being considered, a complete evaluation by a pediatric neurologist is indicated. If substance abuse or intoxication is suspected, a toxicology screen is performed. Other possible laboratory evaluations include serum electrolyte, blood urea nitrogen, creatinine, and glucose determinations as a screen for metabolic abnormalities. Serum or urine concentration of human chorionic gonadotropin β subunit can exclude pregnancy. Abnormal laboratory values of dehydration may not be found with the patient having a normal BUN, hemoglobin, or urine specific gravity.

A 12-lead electrocardiogram is reviewed for heart rate, rhythm, and conduction abnormalities, such as heart block and pre-excitation. PR, QRS, and corrected QT intervals should be measured. If syncope is associated with exercise, an exercise stress test may be performed, and the origin of the coronary arteries must be established by echocardiography or other imaging modality, to exclude a coronary artery anomaly. If an arrhythmia is suspected, 24 h ambulatory monitoring (Holter) or event monitoring (external or implanted) should be performed. A complete electrophysiologic study is considered if the Holter monitoring suggests an arrhythmia. In patients with a history of recurrent or atypical syncope, a tilt-table evaluation may be performed.

Tilt testing

Over the past decade, the use of tilt-table testing in evaluating patients with syncope has declined significantly, owing to inconsistency in tilt protocols and concerns about the sensitivity and specificity of the test. Protocol variations include the length of the study, the inclination of the table, the type of blood pressure monitoring (invasive versus noninvasive), the measurement of serum catecholamines, and the use of provocative medications, such as isoproterenol or epinephrine. Previously, the type of response to tilt testing was important in the management strategy. Determining the exact mechanism of noncardiac syncope may not be necessary to treat the patient successfully. Many cardiologists use tilt-table testing only for patients with a history inconsistent with a vasovagal mechanism or who have failed conventional therapy. It may help if a patient reports the same sensations as occurred before the syncopal event.

Treatment

This section discusses the treatment of children and adolescents with vasovagal syncope. Fortunately, most patients with vasovagal syncope require only lifestyle modification by increasing daily salt and fluid intake to treat their symptoms [26]. The remainder may need other measures, including dietary modification, physical training, medication and even pacemaker implantation. A recent review of current treatments by Kuriachan, Sheldon, and Platonov nicely outlined treatment effect, rated that effect, and summarized the evidence to substantiate their claims [27]. Their recommendations are outlined below.

Physical and lifestyle treatments

Increased salt and fluid

A 64 oz intake of noncaffeinated fluid per day and liberalizing dietary salt are primary therapy for vasovagal syncope. Up to 90% of adolescents with a previously positive tilt test who receive oral fluid therapy are free from recurrence [26]. Most patients with an initial positive tilt test have a negative repeat test after receiving increased fluid and salt supplements. The usual adult dose of salt tablets is 6–9 g per day. Side effects of salt tablets include stomach upset and bloating. Salt supplements are contraindicated in those with hypertension, renal dysfunction, or cardiac dysfunction. For those without contraindications to salt therapy, recommending salty foods, such as a bag of salted pretzels, may be sufficient.

Recommendation: In the absence of contraindications, liberalization of fluid and salt should be undertaken. This therapy is probably helpful with a moderate amount of evidence to support the claim [27].

Exercise training

Although exercise training acutely increases blood volume, there is limited evidence that shows improvement of syncope.

Recommendation: The benefits of exercise are well known and should be encouraged. The evidence in support a benefit of exercise in preventing syncope is weak [27].

Physical counterpressure maneuvers

Physical counterpressure maneuvers consist of isometric muscle contractions performed by presyncopal patients to prevent syncope. Leg crossing, pulling apart gripped hands, or squats are such maneuvers that increase cardiac output and arterial blood pressure while reducing peripheral resistance. Patients practicing these techniques decrease the number of subsequent syncopal episodes [28]. Although some patients have insufficient prodromal symptoms to perform counterpressure maneuvers, these maneuvers are easy to teach, without side effects, and free.

Recommendation: All patients should be taught these techniques to prevent syncope. Counterpressure techniques are probably helpful with good evidence to support the claim [27].

Tilt-test training

Because the reproducibility of tilt testing is inconsistent, researchers speculated that a training effect may be the cause [29]. To test the theory, patients were either tilted daily until tilt testing was negative or asked to stand against a wall at home for 30–60 min daily. Some studies demonstrated an encouraging effectiveness of the training with up to 82% freedom from recurrent syncope over 43 months. Other randomized trials, however, failed to corroborate these findings, and the compliance of long-term home training was brought into question.

Recommendation: Whether poor results are due to poor compliance or inefficacious therapy, orthostatic training in not currently recommended for routine use. Evidence suggests that it is probably unhelpful [27].

Pharmacological therapy

Fludrocortisone

Fludrocortisone is a mineralocorticoid steroid that stimulates the retention of sodium chloride and intravascular volume. Fludrocortisone prevented syncope in 90% of children and adolescents in one study [30]. With the use of salt, fludrocortisone, and increased fluid intake, significant changes in serum electrolyte concentrations, especially hypokalemia, may require monitoring and possible intervention. Hypertension and weight gain associated with the additional salt and fluid retention may result. This change in body weight may be secondary to normal growth of adolescence or related to increased fluid intake and retention, and may hinder successful treatment in this age group as they are sensitive to even minor increases in weight. More recently, a randomized, double-blinded, placebo-controlled study found that children receiving fludrocortisone were *more* symptomatic than children treated with placebo [31]. A randomized, controlled clinical trial is under way to evaluate the effectiveness of fludrocortisone in treating adults with syncope [32].

Recommendation: Fludrocortisone may be prescribed in frequently symptomatic patients but the effect is debatable and the evidence for its use is weak [27].

β-adrenergic blockers

A second treatment approach is β-adrenergic blockers. Theoretically, the negative inotropic effect of β-blockers may offset increased ventricular contractility seen as part of the abnormal reflex in vasovagal syncope or block the effect of circulating epinephrine, a possible central trigger of the abnormal vasovagal reflex. β-Blockers are well tolerated in children but must be used with caution in patients with reactive airway disease and depression. Side effects include depression, decrease in school performance, and fatigue.

Initially, the efficacy of β-blockers in preventing recurrent syncope in adults was encouraging, ranging from 71 to 100% [33–37]. Later, the results of five randomized clinical trials on the efficacy of β-blockers for the prevention of syncope were basically negative [38]. In 2006, a randomized, placebo-controlled, double-blinded trial assessing the usefulness of metoprolol in preventing syncope showed no benefit compared with placebo [39].

Recommendation: There is good evidence to show that the use of β-adrenergic blockers is probably unhelpful and they should not be used as first-line therapy [27].

Midodrine

α-Adrenergic agonists, such as midodrine, are another class of medications used to treat vasovagal syncope in young people. Decreased venous return to the heart while standing may be related to venodilatation and venous pooling. α-Adrenergic agents increase venous tone by direct sympathetic stimulation. Arterial vasoconstriction leads to increased systemic vascular resistance, blocking systemic hypotension [40]. These potential advantages have been verified in children and adults with vasovagal syncope. A randomized, open-label trial of children with at least three syncopal episodes per year showed a recurrence rate of 20% in those receiving midodrine compared with 80% in the control group [41]. A randomized crossover placebo-controlled study of midodrine reported a reduction in symptoms and positive tilt testing in adults receiving midodrine compared with the placebo group [38].

The use of midodrine in children and adults shows both short- and medium-term therapeutic success. The drug is well tolerated, with side effects including supine hypertension, nausea, scalp paresthesias, piloerection, and rash. The side effects are dose related and reversible. Midodrine is contraindicated in patients with hypertension or heart failure.

Recommendations: There is good evidence to show that midodrine is probably helpful in adult and pediatric patients with frequent syncope and should be used as a first-line therapy [27].

Selective serotonin uptake inhibitors (SSRIs)

The final class of medications prescribed in treating vasovagal syncope is the serotonin uptake inhibitors, including fluoxetine hydrochloride (Prozac) and sertraline hydrochloride (Zoloft). These agents have antidepressant properties and have been used in patients with vasovagal syncope refractory to conventional medications [42]. The abolition of the vasodepressor response by depletion or receptor blockade of serotonin has been well described in animal models of acute hemorrhage [22,43]. Although the exact mechanism of action of serotonin uptake inhibition in the treatment of vasovagal syncope is not fully understood, it is probably related to a similar decrease in the serotonin-mediated vasodepressor response. On the basis of findings in patients with clinical depression treated with fluoxetine hydrochloride in whom vasovagal syncope was alleviated, Grubb *et al.* studied the effects of sertraline hydrochloride therapy in pediatric patients with vasovagal syncope whose conventional therapy had failed [42]. A beneficial response to treatment with sertraline hydrochloride was found in 53% of the patients. Side effects included nausea, diarrhea, headache, and mild insomnia. A more recent randomized, placebo-controlled study reported equal effects between fluoxetine, propranolol, and placebo [44]. Therefore, the evidence suggesting that SSRIs are useful in the treatment of vasovagal syncope are mixed at best.

Recommendations: The evidence supporting the use of SSRIs in treating vasovagal syncope is debatable, with a moderate amount of evidence suggesting that SSRIs should not be used as initial treatment for vasovagal syncope [27].

Pacemaker therapy

A final therapeutic option is the use of cardiac pacing in patients with recurrent syncope. Pacing patients with vasovagal syncope is a class IIb indication as described by the American College of Cardiology/American Heart Association/Heart Rhythm Society 2008 guidelines [45]. The guidelines state: "Permanent pacing may be considered for significantly symptomatic vasovagal syncope associated with bradycardia documented spontaneously or at the time of tilt-table testing." The guidelines state that pacing is a class III indication and *not* indicated for "situational vasovagal syncope in which avoidance behavior is effective and preferred." Whether the subset of patients with vasovagal syncope associated with asystolic pauses would benefit from pacing remains unknown and is being studied [46]. It should be noted that even though pacing may prevent the bradycardia, it will have no effect on marked arteriolar vasodilatation caused by sympathetic inhibition.

Recommendation: Permanent pacemakers should not be used routinely to treat vasovagal syncope. The clinician may consider pacing in highly symptomatic patients failing drug therapy with documented asystole during syncope.

Conclusion

For the most part, particularly in children and adolescents, vasovagal syncope is benign and improves with time. First-line therapy is directed at liberalization of fluids and increased dietary salt. An intake of 64 oz of noncaffeinated fluid per day and increased salt intake were suggested [27]. The patient should be instructed that the goal of therapy is to keep the urine clear and avoid the sensation of thirst. Since syncope is common in the adolescent, a letter allowing the patient to carry a water bottle to school and allowing frequent restroom breaks is recommended to ensure compliance with the protocol. Counterpressure measures including leg crossing and squatting should be advised to all patients, particularly those with extended prodromal symptoms. For patients requiring pharmacologic management, midodrine is likely the most efficacious first-line therapy based on available evidence. Routine use of β-blockers, SSRIs, fludrocortisone, and pacemakers is discouraged. In patients with recurrent and refractory syncope or an atypical presentation and history, the clinician must consider those diagnoses that place the patient at increased risk for sudden cardiac death.

57 Cardiovascular Disease, Sudden Cardiac Death, and Preparticipation Screening in Young Competitive Athletes

Barry J. Maron

Minneapolis Heart Institute Foundation, Minneapolis, MN, USA

During the past several years, interest and concern have heightened considerably in the medical community and the lay public regarding the causes of sudden and unexpected death in young trained athletes [1–17]. The risks associated with participation in organized competitive sports are diverse and range from sudden collapse due to underlying (and unusually unsuspected) cardiovascular disease [8–23] to non-penetrating and often innocent appearing chest blows triggering ventricular fibrillation in the absence of structural cardiac disease [24–26]. Recognition that athletic field deaths may be due to a variety of detectable cardiovascular lesions has also stimulated intense interest in defining the most practical and effective strategy for preparticipation screening of largely high-school and college-aged [7–15,27–39] (but also professional) athletes [40], and also in the criteria for eligibility for and disqualification from competitive sports [3,11].

Definitions

A competitive athlete has been defined as one who participates in an organized team or individual sport requiring regular competition against others as a central component, places a high premium on excellence and achievement, and requires vigorous and intense training in a systematic fashion [41]. This definition can be regarded as somewhat arbitrary in that many individuals participate in "recreational" sports [42] in a truly competitive fashion.

Causes of sudden death in young athletes

Autopsy-based studies have documented the cardiovascular diseases responsible for sudden death in young competitive athletes [19–23]. These structural abnormalities are independent of the normal physiologic adaptations in cardiac dimensions evident or in many trained athletes, usually consisting of increased left ventricular end-diastolic cavity dimension, or occasionally mild wall thickening [43–46].

About 70% of sudden deaths in young athletes (aged <35 years) are due to a variety (more than 20) of primarily congenital cardiovascular diseases (Figures 57.1 and 57.2) [20–22]. Indeed, virtually any disease capable of causing sudden death in young people may potentially do so in young competitive athletes [5,6]. Although these conditions may be relatively common as causes of young athletes dying suddenly, each is uncommon within the general population [5,6].

Hypertrophic cardiomyopathy

In several autopsy-based studies, the single most common cardiac abnormality among the causes of sudden death in young athletes is hypertrophic cardiomyopathy (HCM) [19–22], usually without outflow obstruction under resting conditions [47–49], accounting for about one-third of such catastrophes (Figure 57.2).

HCM is a primary and familial cardiac malformation with heterogeneous clinical and morphologic expression, complex pathophysiology, and diverse natural history [47–49], for which >1000 mutations in 11 or more genes encoding proteins of the cardiac sarcomere have been reported [50]. HCM is the most common of the genetic heart diseases, occurring with phenotypic expression in about 1 in 500 of the general population [51].

Sudden death in HCM is most common in children and young adults, usually in previously asymptomatic individuals [48,49]; therefore, such catastrophes are often the first clinical manifestation of unsuspected disease. Although most patients die while they are sedentary or during mild exertion, an important proportion collapse during or just after vigorous physical activity [21]. This observation, and also the evidence that athletes with HCM usually have
Figure 57.1 US National Registry for Sudden Death in 1866 Young Athletes [21]. Cardiovascular diseases are the predominant causes of sudden deaths in athletes, accounting for about 70%.
Figure 57.2 Cardiovascular causes of sudden death in young competitive athletes, with HCM the most common. [a]Includes congenital heart disease (n = 8); myocardial infarction (n = 6); Kawasaki disease or related conditions (n = 5); sickle cell trait (n = 5); sarcoidosis (n = 4); stroke (n = 3); cardiac tumor (n = 1); conduction system disease (n = 2); and miscellaneous (n = 2). [b]Regarded as possible (not definitive) evidence for HCM at autopsy with mildly increased LV wall thickness [18 (SD 4) mm] and heart weight [447 (SD 76) g]. Ao, aorta; ARVC, arrhythmogenic right ventricular cardiomyopathy; AS, aortic stenosis; CM, cardiomyopathy; CAD, atherosclerotic coronary artery disease; LAD, left anterior descending; MVP, mitral valve disease; WPW, Wolff–Parkinson–White.

events during training or competition [20–22], supports the view that intense physical activity represents a trigger for ventricular tachyarrhythmia-related sudden death, and disqualification of athletes with HCM from intense competitive sports is prudent [3,11] (Figure 57.3).

Clinical diagnosis of HCM is based on the most characteristic morphologic feature of the disease, namely asymmetric thickening of the left ventricular (LV) wall associated with a nondilated cavity in the absence of another cardiac or systemic disease capable of producing the magnitude of hypertrophy present (e.g., systemic hypertension or aortic stenosis) [48,49]. Although most HCM patients may demonstrate obstruction to LV outflow (at rest or with physiologic exercise), dynamic gradients are not required for diagnosis [52].

On the basis of echocardiographic, cardiovascular magnetic resonance (CMR), and necropsy analyses in large numbers of patients, the HCM disease spectrum is characterized by vast structural diversity with regard to the patterns and extent of LV hypertrophy [47,53]. Indeed, virtually all possible patterns of LV wall thickening have been reported in HCM, and no single phenotypic expression can be considered classic or typical of this disease. Nevertheless, the HCM phenotype is not invariably expressed as a greatly thickened LV, and a few genetically affected adults even have normal thicknesses (≤12 mm) [48–50].

Some young athletes with segmental hypertrophy of the anterior ventricular septum (wall thicknesses 13–15 mm), consistent with a relatively mild morphologic expression of HCM, may be difficult to distinguish from extreme expressions of physiologic LV hypertrophy, which represents an adaptation to systematic training (i.e., athlete's heart) [4,43–46]. In asymptomatic, trained athletes within this morphologic gray zone, the differential diagnosis between physiologic athlete's heart and HCM can often be resolved by clinical assessment and noninvasive testing (Figure 57.4).

Congenital coronary anomalies

Second in importance and frequency to HCM as a cause of athlete sudden death is a spectrum of congenital vascular malformations of the coronary arterial circulation (responsible for about 15–20% of young athlete deaths), the most common of which is anomalous left main coronary artery from the right (anterior) sinus of Valsalva, and less frequently anomalous right coronary from the left sinus [20–22,54]. Such coronary artery anomalies are difficult to detect clinically because they are not consistently associated with ECG abnormalities, or because the index of clinical suspicion is not sufficiently high. However, these anomalies are now recognized with increasing frequency due to penetration of CMR and CT angiography into clinical cardiovascular practice [55]. Such diagnostic considerations are particularly important since these malformations are rarely identified during life, but nevertheless are amenable to corrective surgery.
(a)
(b)

Figure 57.3 Hourly distribution of sudden cardiac deaths. (a) Histogram showing competitive athletes with either HCM (dark portion of bars) or a variety of other predominantly congenital cardiovascular malformations (light portion of bars). Time of death was predominantly in the late afternoon and early evening, corresponding largely to the time of training and competition. (b) In contrast, histogram for non-athlete HCM patients demonstrating a prominent early morning peak between 7 a.m. and 1 p.m. and a secondary peak in the early evening (most evident between 8 p.m. and 10 p.m.). (Reproduced from Maron *et al. JAMA* 1996;**276**:199–204, with permission from the American Medical Association.)

Other diseases

Less common causes of sudden death in young athletes are responsible for about 5% or less of athlete deaths and include myocarditis, dilated cardiomyopathy, aortic dissection and rupture due to Marfan syndrome, sarcoidosis, mitral valve prolapse, aortic valve stenosis, atherosclerotic coronary artery disease, long QT syndrome, and arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D) [20–22] (Figure 57.2).

Of note, ARVC/D has been cited as the most common cause of sudden death in athletes in the Veneto region in northeastern Italy [56]. Although this disease is also a component of the US experience with athletic field deaths, its frequency is <5% in autopsy-based reports from the United States [19–22]. The explanation for such a discrepancy

between the United States and Italy remains incompletely resolved, although it is possible that the difference reflects a unique genetic substrate for ARVC/D in Italy. The relatively low frequency with which HCM is apparently responsible for sudden death in Italian athletes may however be due to the long-standing and systematic Italian national program for the cardiovascular assessment of competitive athletes [12,13,57]. which likely disqualifies disproportionate numbers of trained athletes with HCM, compared with ARVC/D (which is much more difficult to identify clinically).

On occasion, athletes may die suddenly without evidence of structural cardiovascular disease, even after careful gross and microscopic examination of the heart. In such instances (about 2% of autopsy cases) (Figure 57.1) [19–22], it may not be possible to exclude noncardiac factors (e.g., drug
Figure 57.4 Clinical criteria used for differential diagnosis to distinguish hypertrophic cardiomyopathy (HCM) from physiologic athlete's heart when the left ventricular (LV) wall thickness is within the shaded gray zone of overlap (13–15 mm), consistent with both diagnoses. [a]Assumed to be the nonobstructive form of HCM because substantial mitral valve systolic anterior motion would confirm the diagnosis of HCM in an athlete. [b]May include a variety of abnormalities, including heterogeneous distribution of left ventricular hypertrophy (LVH) in which asymmetry is prominent, and adjacent regions may be of greatly different thicknesses, with sharp transitions evident between segments and areas of hypertrophy are non-contiguous, in addition to patterns in which the anterior ventricular septum is spared from the hypertrophic process and the region of predominant thickening may be in the posterior portion of the septum, or the anterolateral or posterior free wall, or left ventricular apex. ↓ = decreased; CMR, cardiovascular magnetic resonance; LV, left ventricular. Medical history[a]

Personal history

1. Exertional chest pain/discomfort
2. Unexplained syncope/near-syncope[b]
3. Excessive exertional and unexplained dyspnea/fatigue, associated with exercise
4. Prior recognition of a heart murmur
5. Elevated systemic blood pressure

Family history

6. Premature death (sudden and unexpected, or otherwise) before age 50 years due to heart disease in ≥1 relative
7. Disability from heart disease in a close relative <50 years of age
8. Specific knowledge of certain cardiac conditions in family members: hypertrophic or dilated cardiomyopathy, long-QT syndrome or other ion channelopathies, Marfan syndrome, or clinically important arrhythmias

Physical examination

9. Heart murmur[c]
10. Femoral pulses to exclude aortic coarctation
11. Physical stigmata of Marfan syndrome
12. Brachial artery blood pressure (sitting position)[d]

[a]Parental verification is recommended for high school and middle school athletes.
[b]Judged not to be neurocardiogenic (vasovagal).
[c]Auscultation should be performed in both supine and standing positions (or with Valsalva maneuver), specifically to identify murmurs of dynamic left ventricular outflow tract obstruction.
[d]Preferably taken in both arms.

abuse) as responsible for the catastrophe, or to determine whether careful inspection of the specialized conducting system and associated vasculature (which is not part of the standard medical examiner protocol) would have revealed occult but clinically relevant abnormalities. Some of these deaths may be due to primary ventricular tachyarrhythmias unassociated with cardiac structural abnormalities, such as Wolff–Parkinson–White syndrome or ion channelopathies such as long QT syndrome, possibly exercise-induced coronary spasm, or undetected segmental forms of ARVC/D.

Left anterior descending coronary artery tunneled within LV myocardium (i.e., "bridging") may constitute a potentially lethal anatomic variant in otherwise healthy young individuals during exertion [20–22,58]. Indeed, tunneled or bridged left anterior descending coronary artery completely surrounded by myocardium for at least a portion of its course (about 1–3 cm) was present in about 5% of the athlete field deaths in the US registry, in the absence of any other structural anomaly that could be assigned as the cause of death. On the other hand, bridged coronary arteries appear to play little role in promoting risk for sudden death in patients with HCM [58,59]. Also, the chronic ingestion of drugs (such as cocaine) may have adverse cardiovascular consequences, resulting in the clinicopathologic profiles of acute myocardial infarction and myocarditis [60].
Figure 57.5 Number of cardiovascular, blunt trauma-related, or other sudden death events in 1866 US young competitive athletes, tabulated by year from the US National Registry. Other causes of these deaths include commotio cordis, heat stroke, illicit drugs, and pulmonary disease. (Reproduced with permission from Maron *et al*. *Circulation* 2009;**119**:1085–92.)

Prevalence and significance of the problem

Sudden unexpected death due to cardiovascular disease during competitive sports is rare in high-school students participating in organized interscholastic sports (i.e., about 1 per 220 000 participants per academic year or 1 per 70 000 participants during a 3-year high-school period [61]. In the large national US registry, the absolute number of cardiovascular sudden deaths in young athletes was relatively low with a rate of <100 per year [21] (Figure 57.5). Notably, the cardiovascular diseases responsible for sudden death in about one-third of these athletes would not likely be suspected or detected by screening (even with ECGs).

Somewhat higher estimates of the risk for sudden death have been reported for apparently healthy males, joggers, and marathon runners, usually due to atherosclerotic coronary artery disease [62,63]. Such estimates suggest that the intense and persistent public interest in these tragic events is perhaps disproportionate to their numerical significance in the general population. However, the emotional and social impact of athletic field catastrophes understandably remains high.

Despite its relatively low event rate, sudden death in young athletes continues to represent an important medical issue [1–3,5,6]. Indeed, it is an important responsibility of the medical community to create a fully informed public and also, when it is prudent and practical, to pursue early detection of the causes of catastrophic events in young athletes and initiate preventive measures. Because such events are uncommon relative to the vast numbers of athletes participating safely in sports, information about athlete field deaths should not raise undue anxiety among youthful athletes and their families and thereby inhibit participation in sports [7,8].

Demographics

On the basis of data assembled largely from broad-based US populations [19–22], a profile of young competitive athletes who die suddenly has emerged. Such athletes participate in a large number and variety of sports, the most frequent being basketball and football (about 70% combined), not only reflecting the high participation level in these popular team sports but also the intensity of competition. Most athletic field deaths occur in men (about 90%); the relative infrequency in women probably reflects a lower participation level, sometimes less intense levels of training, and the fact that some diseases most commonly accounting for sudden death in athletes may be recognized less frequently in women (e.g., HCM). Most athletes are of high-school age at the time of death (about 60%); however, not uncommonly, other sudden deaths have been reported in young athletes who have achieved collegiate or even professional levels of competition.

Most athletes who die suddenly, regardless of their particular underlying disease, have been free of symptoms and usually are not suspected of harboring a cardiovascular abnormality. Sudden collapse usually occurs with exercise, predominantly in the late afternoon and early evening hours, corresponding to peak periods of competition and training, particularly in organized team sports such as football and basketball (Figure 57.3). This observation for athletes with HCM contrasts sharply with prior reports in HCM patients who are not competitive athletes, for whom a bimodal pattern of circadian variability was evident, including a
Figure 57.6 Cardiovascular deaths in athletes according to race. The data include 690/1866 total deaths that were proved to be due to cardiovascular causes and are shown with respect to the number of white and non-white athletes with each disease. ARVC, arrhythmogenic right ventricular cardiomyopathy; HCM, hypertrophic cardiomyopathy; CAD, coronary artery disease; MVP, mitral valve prolapse.

prominent early- to mid-morning peak, similar to that reported in patients with coronary artery disease and acute myocardial infarction or sudden death (Figure 57.3) [64].

Although most sudden deaths reported in competitive athletes have been in white men, a substantial proportion (>40%) were African-American athletes (Figure 57.6) [21,22]. This substantial occurrence of HCM-related sudden death in young black male athletes contrasts sharply with the infrequent identification of HCM in hospital-based populations. These data emphasize that it is less common for young African-American men to receive a cardiovascular diagnosis such as HCM (which requires echocardiography) than their white counterparts and, consequently, they are less likely to be disqualified from competition in accordance with the recommendations of the 36th Bethesda Conference [3] to reduce the risk for sudden death.

Mechanisms of SD and AEDs

Although the precise mechanism ultimately responsible for sudden death in young athletes depends on the particular disease state involved, in most victims (including athletes with HCM), cardiac arrest results from electrical instability and ventricular tachyarrhythmias. The most common exception is Marfan syndrome, in which death is usually due to ruptured aorta [19–22].

Automated external defibrillators (AEDs) represent an important and effective impetus to secondary prevention of sudden death in trained athletes with cardiovascular disease, and deserve greater dissemination, accessibility and penetration into the sports arena [65–70]. Several studies of early defibrillation using public access AEDs have demonstrated a survival benefit for out-of-hospital cardiac arrest [66,67,70]. The available AED literature suggests that the use of AEDs by trained or untrained bystanders and nontraditional responders produces survival rates of 40–75% when CPR is provided and defibrillation is rapid within 5 min of collapse. Particularly relevant is the recent study of Drezner *et al.* [70] surveying 1710 high schools with onsite AED programs; 2% of the high schools reported a sudden cardiac arrest either in student athletes, employers, or spectators, and 64% of these events had restoration of sinus rhythm and survival to hospital discharge, including athletes with cardiomyopathies, such as HCM and ARVC.
Figure 57.7 Comparison of state preparticipation screening questionnaire forms, 1997 versus 2005, for US high school athletes, analyzed with respect to American Heart Association recommendations. Screening forms could be assessed for 43 states in the 1997 and 48 states in 2005. (Reproduced from Glover *et al. Am J Cardiol* 2007;**100**:1709–12, with permission from Elsevier.)

Screening and preparticipation detection of cardiovascular abnormalities

General perspectives

The detection of pre-existing cardiovascular abnormalities with the potential for significant morbidity or sudden death is an important objective of the widespread practice of preparticipation screening of high-school and college-aged athletes (Figure 57.7). There is a general consensus within a benevolent society that a responsibility exists on the part of physicians to initiate prudent efforts to identify life-threatening diseases in athletes to minimize the cardiovascular risks associated with sport [1–3,5,7,8,11–13,71]. Screening recommendations are predicated on the probability that intense athletic training is likely to increase the risk for sudden cardiac death (or disease progression) in trained athletes with underlying structural heart disease, although it is currently not possible to quantify that risk with precision, or to know prospectively to which individual athletes these considerations will apply with certainty.

However, there are two major limitations to mass population screening for competitive athletes. First is the rarity of those lesions responsible for sudden cardiac death in young healthy people. The several largely congenital malformations most relevant to athletic screening (including HCM) [17,21] account for a combined prevalence of only about 0.3% or less within the general competitive athlete population [4,49,51]. The second consideration is the large reservoir of competitive athletes who are eligible for preparticipation screening, which in the United States is probably in the range of at least 10–15 million each year [8,21,28,31].

Customary practice and legal considerations

Two American Heart Association expert consensus panels [7,8] have recommended a standard, systematic preparticipation screening strategy to raise the suspicion (or detect) potentially lethal cardiovascular abnormalities with history and physical examination. However, no available screening design can detect all important lesions or affected athletes, and medical clearance for sports with history and physical examination does not necessarily imply the absence of cardiovascular disease [7,8]. US law enables the medical profession to establish the bounds of appropriate management of athletes by the physician [2,33,71]. Indeed, the medical standard is ultimately translated into the legal standard for malpractice purposes [2,33,71]. Although educational institutions and professional teams are required to use reasonable care in conducting their athletic programs, there currently is no clear legal precedent regarding their duty to conduct preparticipation screening of athletes for the purpose of detecting medically significant abnormalities. In the absence of binding requirements established by state law or athletic governing bodies, most institutions and teams at present rely on the team physician (or other medical personnel) to determine the appropriate medical screening procedures [33,71,72].

A physician who has medically cleared an athlete to participate in competitive sports is not necessarily legally liable for an injury or death caused by an undetected cardiovascular condition [71]. Malpractice liability for failure to discover a latent, asymptomatic cardiovascular condition requires proof that a physician deviated from customary or accepted medical practice in his or her specialty in performing the preparticipation screening of athletes and furthermore that the use of established diagnostic criteria and techniques would have disclosed that medical condition [72].

Some form of medical clearance by a physician or other trained healthcare worker, consisting of a history and physical examination, appears to be customary for most high-school and college athletes [71,72]. However, currently, there are no universally accepted standards for the screening of athletes in the United States, nor are there approved certification procedures for the healthcare professionals who perform such screening examinations [29,30,72]. Indeed, in

a number of states, non-physician healthcare workers are sanctioned to perform athletic screening examinations, including advanced nurse practitioners or physician assistants and even chiropractors. Standards may be mandated by state legislative action or rest with individual state high-school athletic associations or school districts. There is no agreement among the states, however, as to the precise format of preparticipation medical evaluations. Indeed, a small minority of states still have no standard history and physical forms to serve as a guide to the examiners of high school athletes, and in others the medical clearance forms have been criticized as generally inadequate when evaluated against the specific screening recommendations proposed by the 2007 American Heart Association consensus panel [8] (Table 57.1). However, over the last several years, largely in response to a highly visible critique [29], the history and physical examination forms have been improved substantially in many states [30], undoubtedly increasing the number of athletes diagnosed with cardiovascular disease (Figure 57.7). Nevertheless, it is not possible to ascertain with precision the extent to which such changes have enhanced identification of disease.

Expectations

Most of the lesions considered here as potentially responsible for sudden death in young athletes are challenging to detect by screening, even with echocardiography, ECG, or other noninvasive tests incorporated into the process, for example, congenital coronary anomalies, particularly anomalous origin of left main coronary artery from the right sinus of Valsalva. Despite its limitations, history and physical examination screening alone can be effective in raising suspicion of certain cardiovascular diseases such as HCM in some at-risk athletes [73]. Indeed, other genetic heart diseases, such as Marfan syndrome and ARVC/D, and also premature atherosclerotic coronary artery disease, can be suspected by family history or by prior transient symptoms. Physical examination may identify the stigmata of Marfan syndrome, mitral valve prolapse, or left ventricular outflow obstruction by a heart murmur (e.g., in aortic valvar stenosis and some patients with HCM), or systemic hypertension. Indeed, about 5% of the young patients referred to our center for HCM have been initially identified through preparticipation sports screening [73].

Electrocardiogram

The 12-lead ECG has been proposed as an effective alternative to echocardiography for population-based screening [9,10, 12–14,27,37,39,74,75]. Indeed, the ECG is abnormal in about 75–95% of patients with HCM [76–78] and is an effective tool for the detection of this disease in an Italian athlete population [12,18], and also will usually identify long QT syndrome. However, the ECG has low specificity as a screening test in athletic populations because of the high frequency of ECG alterations associated with the normal physiologic adaptations

to training ("athlete's heart") [4,7–9,15,31,36,38,79–81]. In mass preparticipation screening, about 10–20% of athletes examined have an ECG pattern that ultimately triggers echocardiographic study [4,7,8,13,15,28,31,44,81,82].

Finally, elite trained athletes not infrequently demonstrate distinctly abnormal ECG patterns indistinguishable from pathologic conditions, in the absence of structural heart disease [81,82]. These largely false-positive test results complicate efforts to use the 12-lead ECG as a primary screening tool in athletic populations [7,8,28,33,75,76,81–83], although occasionally they may be early markers of cardiomyopathies [16]. Notably, race also unavoidably impacts US screening specificity/sensitivity and reliability, as African-American athletes without heart disease may show distinctively abnormal ECG patterns [83] and thicker LV walls than white athletes [45]. Finally, even primary echocardiographic screening of athletes for HCM has resulted in a low yield of disease detection in the United States [32] and United Kingdom [17].

Screening strategies: US versus italian models

The preparticipation cardiovascular screening process of young trained athletes is time honored in the United States, Italy, and much of Europe, and generally conceded to be a desirable aspiration with potential benefits for public health [5,7–16,27,28,31,33,36,37,74,75,79,80,84]. However, controversy has emerged regarding the most effective strategy for examining large populations of competitive athletes [7,8,12–15,28,33,80,84]. At present, high school and college-aged athletes in the United States (and many other parts of the world) are screened by a personal and family medical history and physical examination performed by designated examiners with varying levels of cardiovascular training [7,8]. However, in Italy, a unique mandatory national preparticipation screening program has been employed for over 25 years, routinely consisting of a 12-lead ECG (in addition to history and physical examination) and administered by a select cadre of accredited sports medicine physicians dedicated to this process [13,28,57].

The Italian screening model with routine ECGs has achieved considerable visibility over the last several years and has been promoted as the standard by the European Society of Cardiology [13], the International Olympic Committee [27], and others [9,10,13,14,27,37,74]. In addition, studies from the Veneto region have documented identification of HCM in athletes [18] and most recently have reported a 90% decrease in athlete sudden deaths over the past 25 years which was attributed to the national screening program [12]. In contrast to the European zeal for mass screening with ECGs [12,13,27,37,84,85], the AHA consensus scientific panels have persistently discouraged such a program for the United States as impractical and possibly counterproductive, while alternatively supporting self-sustaining regional or local initiatives [7,8].
Figure 57.8 Plot comparing annual mortality in competitive athletes per 100 000 person-years in the Veneto region (Italy) and Minnesota (United States). Arrow denotes the beginning of the Italian national preparticipation screening program. (Reproduced from Maron *et al. Am J Cardiol* 2009;**104**:276–80, with permission from Elsevier.)

Obstacles in the United State to the Italian model of mandatory and routine athlete ECG screening include the lack of professional resources (without an established and dedicated group of sports medicine examiners, such as exists in Italy), and cost-efficacy considerations, in addition to the expected high proportion of false-negative (and particularly false-positive) results, which would create chaos for secondary testing. Furthermore, and perhaps most importantly, limiting systematic population screening to a select segment of the general youthful population would be regarded as both exclusionary and discriminatory. Therefore, US screening for cardiovascular disease would probably be acceptable ethically only if extended to the entire youthful population, involving up to about 30 million people annually, likely an impossible proposal.

Critics of the AHA position cite the Italian program and its apparent benefits, resulting in very low mortality rates in athletes over the most recent years, and implying that the US screening strategy (with only history and physical examination) could be responsible for an excess of cardiovascular deaths in athletes [33,84]. However, a comparison of published data from the Veneto region and from the United State (i.e., the demographically similar state of Minnesota) does not support this view [23]. Despite the different screening strategies employed (Veneto, history, physical examination and ECGs; Minnesota, history and physical examination alone), there was no significant difference evident in the incidence of athlete sudden deaths between Veneto and Minnesota over the most recent decade (Figure 57.8). In the period 1994–2004, when the two athlete populations could be compared directly in time, mortality rates were very low in both, relatively constant, and similar to that previously reported in US high school and college athletes [21,23,61], and were not significantly different in statistical terms. This observation supports data from other sources that cardiovascular sudden death in young athletes is in fact a low event rate (albeit tragic)

phenomenon [21,28,61]. Recognition of this principle is the basis for the decision not to screen competitive athletes systematically in Denmark [34,85].

Eligibility considerations for athletes with known cardiovascular disease

When a cardiovascular abnormality is identified in a competitive athlete, the following considerations arise: (a) the magnitude of risk for sudden cardiac death associated with continued participation in competitive sports; and (b) criteria to be implemented for determining whether individual athletes should be withdrawn temporarily or permanently from sports competition to reduce risk. Recommendations for athletic eligibility or disqualification are available in the 36th Bethesda Conference [3], and also in ESC guidelines [11], considering the severity of the cardiovascular abnormality and the nature of the sports training and competition. These recommendations are predicated on the principle that intense athletic training and competition increase the risk for sudden cardiac death (or disease progression) in trained athletes with clinically important underlying structural heart disease, although it is not possible at present to quantify that risk in precise terms.

Cincinnati Children's Hospital, Cincinnati, OH, USA

Introduction

Cardiomyopathies are major causes of morbidity and mortality. The term was introduced in 1957 to identify a group of myocardial diseases not attributable to coronary artery disease [1]. The definition has since been modified and now refers to structural or functional abnormalities of the myocardium not secondary to hypertension, valvar or congenital heart disease, or pulmonary vascular disease. Over the past 20 years, our understanding of the major forms of cardiomyopathy has improved, largely from advances in genetics and genomics. Clinical understanding of childhood forms of cardiomyopathy has also improved by the longitudinal follow-up gained from the NIH–NHLBI-funded Pediatric Cardiomyopathy Registry (PCMR) [2–4]. New forms of cardiomyopathy have been described and classified, and further subdivided into genetic/inherited forms and acquired/noninherited forms [5]. Each form occurs in childhood, although ARVC (see below) is almost always identified in adolescents or young adults.

The five classified forms of cardiomyopathy are as follows [5]:

1 Dilated cardiomyopathy (DCM), previously called congestive cardiomyopathy, demonstrates left ventricular or biventricular dilation and depressed systolic function. Systolic dysfunction is a main clinical feature resulting in signs and symptoms of congestive heart failure.

2 Hypertrophic cardiomyopathy (HCM), formerly known as idiopathic hypertrophic subaortic stenosis, is characterized by left ventricular hypertrophy that may be asymmetric. Systolic function is usually preserved. Symptoms result from left ventricular outflow tract obstruction, diastolic dysfunction, or arrhythmias causing sudden death.

3 Restrictive cardiomyopathy (RCM) has impaired diastolic filling, but with generally normal ventricular dimensions and systolic function. It is recognized by markedly dilated atria,. Symptoms result from pulmonary and right-sided systemic venous congestion. Syncope may be a presenting feature.

4 Arrhythmogenic cardiomyopathy, formerly known as arrhythmogenic right ventricular dysplasia (ARVD) or arrhythmogenic right ventricular cardiomyopathy (ARVC), is a disease affecting both ventricles, with arrhythmias usually prominent. It is characterized by substantial fibrosis, with or without fatty replacement of the ventricular myocardium. Sudden death and heart failure are prominent.

5 Left ventricular noncompaction (LVNC), originally called spongy myocardium, is the newest classified form of cardiomyopathy [5], and is characterized by abnormal left ventricular trabeculations. It is clinically heterogeneous, taking on the features of other forms of cardiomyopathy or congenital heart disease. Important clinical features include heart failure, sudden death, and strokes.

Dilated cardiomyopathy

Dilated cardiomyopathy (DCM) is the most common form of cardiomyopathy, accounting for ~55% of patients [4–6]. In the United States, the mortality rate due to cardiomyopathy is >10 000 deaths annually, with DCM being the major contributor [6]. In 2009, the estimated cost of treating heart failure patients in the United States was >$39 billion [7].

Over the past 15 years, clinical features have been identified and multiple causative genes discovered. These genes appear to encode two major subgroups of proteins, cytoskeletal and sarcomeric proteins [8–11], and also sarcomeric genes encoding Z-disk proteins [12–15], ion channel

Table 58.1 Dilated cardiomyopathy (DCM) genetics.

Another form of DCM, viral myocarditis, has the clinical features of DCM including heart failure, arrhythmias, and conduction block [19]. The most common causes of myocarditis are viral, including the enteroviruses (coxsackie viruses and echovirus), adenoviruses, and parvovirus B19, among other cardiotropic viruses, and the predominant related virus appears to alternate every decade [20]. Viral myocarditis and DCM (genetic) seem to have similar disease mechanisms based on the proteins targeted.

Epidemiology and etiology

DCM is the most common form of cardiomyopathy in adults, with an annual incidence of 2–8/100 000 in the United States and Europe and an estimated prevalence of 36/100 000 population [21]. In adults with DCM and congestive heart failure, the most common causes are idiopathic (47%), myocarditis (12%), coronary artery disease (11%), and other identifiable causes (30%) [21]. In a study of 1426 children with DCM enrolled in the PCMR, the annual incidence of DCM in children <18 years old was 0.57/100 000 per year [4], was higher in boys than in girls (0.66 versus 0.47/100 000; $p < 0.001$), in blacks than in whites (0.98 versus 0.46/100 000; $p < 0.001$), and in infants than in children (4.40 versus 0.34 /100 000; $p < 0.001$). Most children (66%) had idiopathic disease. The most common known causes were myocarditis (46%) and neuromuscular disease (26%). The 1- and 5-year rates of death or transplantation were 31 and 46%, respectively. Independent risk factors of DCM for subsequent death or transplantation were older age, congestive heart failure, lower left ventricular fractional shortening, Z score, and cause of DCM ($p < 0.001$ for all). In two earlier studies of children of various ages with DCM, 2–15% had biopsy-proven myocarditis, whereas in 85–90% no cause was identified [22]. In 24 children <2 years old who presented with DCM, 45% had myocarditis, 25% had endocardial fibroelastosis, and the remainder had no identified cause [23]. Familial forms occur in 20–50% of patients with DCM [24–26].

Pathology

The chief morphologic feature is biventricular dilation; the atria are generally enlarged [27]. Mural thrombi may be present in the cardiac chambers. The heart is globular; the myocardium is pale and sometimes mottled. The endocardium is usually thin and translucent [28]; however, focal sclerosis may be seen. The heart weight is increased, indicating hypertrophy, and the coronary arteries are normal. Histologic features classically include myocyte hypertrophy and degeneration, with varying degrees of interstitial fibrosis [27,29]. Occasional small clusters of lymphocytes may be present [30]; if so, this disorder must be differentiated from myocarditis, in which the lymphocytes are associated with areas of myocyte damage and necrosis [31]. Electron microscopy shows nonspecific ultrastructural changes in the mitochondria, T tubules, and Z bands.

Pathophysiology

Depressed contractile function is shown by decreased shortening fraction, ejection fraction, and cardiac output. This decline in systolic function increases end-diastolic volume, end-diastolic pressure, and ventricular filling pressure [27]. To maintain an adequate cardiac output, the ventricles dilate and the myocardium hypertrophies. The dilation increases wall tension, thereby increasing oxygen consumption and decreasing myocardial efficiency. As cardiac output diminishes, renal blood flow decreases. As these features typically progress slowly, mild pulmonary edema and systemic venous congestion occur. In children with acute decompensation, significant pulmonary edema and systemic venous congestion occur. Neurohumoral mechanisms are increasingly activated, particularly the renin–angiotensin system and sympathetic nervous system. Activation of these systems contributes to peripheral vascular changes and the clinical picture of congestive heart failure (see chapter 70).

Ventricular myocardial fibrosis may occur and produce irritable foci causing ventricular arrhythmias [32,33] and contribute to systolic and diastolic dysfunction. The associated arrhythmias may occur from ion channel dysfunction.

Clinical presentation

If an adequate cardiac output cannot be maintained, signs and symptoms of congestive heart failure develop [4,5,8,32,34]. Initially these may be subtle with decreasing exercise tolerance and dyspnea with exertion. Infants may have tachypnea that is more pronounced with feeding, resulting in decreased oral intake and failure to thrive. Signs and symptoms may be unmasked by a superimposed infectious illness that causes further cardiac decompensation. Palpitations and syncope or near-syncope are reported in >13% of children [4,5,8,32,34]. Obtaining a thorough family history and echocardiograms from first-degree relatives is important to verify familial inheritance [24].

Figure 58.1 Chest film of a young child with dilated cardiomyopathy. The cardiac size is enlarged (cardiomegaly) with mildly congested lung markings.

Physical examination

A wide range of findings is found on physical examination [34–36]. Griffin *et al.* [37] reported that 70–80% of patients present with signs of congestive heart failure. Tachypnea and tachycardia are frequent. The skin appears pale. Cyanosis is uncommon unless circulatory collapse is imminent. Peripheral pulses are often weak with normal to low blood pressure and a narrow pulse pressure. The extremities may be cool with decreased peripheral perfusion.

Auscultation of the lungs may reveal diminished breath sounds posteriorly on the left if there is atelectasis from compression by an enlarged heart. Rales may occasionally be heard over an area with atelectasis, but otherwise they are rare in infants and small children even with pulmonary edema on chest radiography. Mild to marked intercostal retractions may be present.

The cardiac apical impulse is displaced laterally. The heart sounds may be muffled, and a prominent diastolic filling sound produces a gallop rhythm (S_3). Murmurs may be absent, but mitral regurgitation (due to a dilated mitral valve annulus or papillary muscle dysfunction) may be heard. Hepatomegaly is common. Other signs of systemic venous congestion include neck vein distention and peripheral edema, which are more common in an older child or young adult than in infants.

Diagnostic studies

Radiography

Chest films typically reveal cardiomegaly due to left atrial and left ventricular enlargement. Pulmonary venous congestion is often present and may progress to frank pulmonary edema (Figure 58.1). Atelectasis of the lower lobe of the left lung may occur because of compression of the left main stem bronchus by the dilated left atrium. Pleural effusions may be present.
Figure 58.2 Echocardiogram of a child with dilated cardiomyopathy. This apical four-chamber view shows a dilated left ventricle with thin walls. In real time, left ventricular systolic function is depressed.

Electrocardiography and Holter monitoring

Most patients have sinus tachycardia. Nonspecific ST-T wave changes, left ventricular hypertrophy, right and left atrial enlargement, and right ventricular hypertrophy are common [32,34–36]. On Holter monitoring, one study [32] found arrhythmias in 46% of the children with DCM with atrial arrhythmias being more common than ventricular arrhythmias, but another study [36] found ventricular arrhythmias to be more common. The finding of fragmented QRS (fQRS) on 12-lead ECG, which represents myocardial conduction delays perhaps from myocardial scar, is a predictor of arrhythmic events in adults with ischemic and nonischemic heart disease [38]. Similar studies in children have not been reported.

Echocardiography

Echocardiographic features of DCM include dilation of the left ventricle (Figure 58.2) with systolic dysfunction represented by decreased shortening and ejection fractions [34]. Regional wall motion abnormalities may also be seen. In patients with DCM, the coronary artery origins should be identified to exclude anomalous left coronary artery arising from the pulmonary artery. Pericardial effusion may be present, and intracardiac thrombi also occur. Color and pulse Doppler echocardiography frequently demonstrate mitral regurgitation, which may be associated with a dilated left atrium. Decreased aortic flow velocity from diminished cardiac output and abnormal mitral inflow patterns due to diastolic dysfunction may be seen.

Cardiac catheterization and biopsy

Because DCM can be diagnosed by echocardiography, cardiac catheterization, angiography, and biopsy are sometimes deferred until the patient is stable or is being evaluated for transplantation [34]. Catheterization can be useful (1) to exclude anomalous left coronary artery as this is occasionally missed by echocardiography, (2) to predict etiology and prognosis if the biopsy shows myocarditis or metabolic abnormalities, or (3) to evaluate for cardiac transplantation, including measuring pulmonary vascular resistance. Hemodynamic measurements generally show elevated left ventricular end-diastolic, left atrial, and pulmonary capillary wedge pressures, a widened A–V oxygen difference, and usually diminished cardiac output. Angiography demonstrates left ventricular dilation and reduced ejection fraction, normal coronary artery origins, and mitral regurgitation.

Endomyocardial biopsy typically shows variable degrees of myocyte hypertrophy and fibrosis, without significant lymphocytic infiltrate [39–41]. Biopsies can detect myocarditis in addition to mitochondrial or infiltrative diseases, by either histologic examination or polymerase chain reaction (PCR). The findings may have a significant effect on prognosis and treatment [29–43].

Blood and urine studies

In infants and young children, other types of studies may help identify the etiology [4,8,10,18,34]. Examining urine for organic and amino acids, may be useful, particularly if 3-methylglutaconic aciduria is found (i.e., Barth syndrome) [8,18,34]. Blood studies for lactate, calcium, magnesium, carnitine/acylcarnitine, pyruvate, blood urea nitrogen, creatinine, and electrolyte determinations are useful diagnostically and for assessing metabolic function secondary to cardiac failure. In addition, B-type natriuretic protein (BNP), creatine kinase with isozymes (CK), and cardiac troponins have become increasingly useful in predicting disease course, risk stratification, and longitudinal follow-up of patients and family members [44–46]. Viral serology for myocarditis diagnosis has been questioned [47], with myocardial PCR now becoming standard [42]. Molecular analysis for the genetic basis of cardiomyopathies have also become standard [8,9,48–50].

Clinical genetics of dilated cardiomyopathy

Dilated cardiomyopathy was initially considered inherited in a small percentage of patients until Michels *et al.* [24] showed that ~20% of patients had family members screened by echocardiography who showed evidence of DCM. More recently, inherited familial DCM (FDCM) has been shown to occur in 30–50% of patients [49,51]. Autosomal dominant inheritance is the predominant pattern of transmission; X-linked, autosomal recessive, and mitochondrial inheritance are less common.

Molecular genetics of dilated cardiomyopathy

Progress in understanding the genetic etiology of FDCM was made in the early 1990s studying X-linked forms of DCM, and in the past decade studying autosomal dominant forms of DCM (Table 58.1). Three X-linked forms of DCM have been well characterized: X-linked cardiomyopathy (XLCM)

presenting in adolescence and young adults [52], Barth syndrome, most frequently identified in infancy [53], and Danon disease, which commonly presents with hypertrophic cardiomyopathy in boys, later becoming DCM and affecting female carriers with late-onset DCM [54].

X-linked cardiomyopathies

X-linked dilated cardiomyopathy (XLCM)

First described in 1987 by Berko and Swift [52] as DCM occurring in males in the teen years and early twenties and showing rapid progression from CHF to death due to VT/VF or transplantation, these patients are distinguished by elevated serum creatine kinase muscle isoforms (CK-MM). Female carriers develop mild to moderate DCM in the fifth decade and the disease is slowly progressive. Towbin *et al*. identified the disease-causing gene and characterized the functional defect [55]. The dystrophin gene was shown to be responsible for the clinical abnormalities by immunoblotting demonstrating severe reduction or absence of dystrophin protein in the hearts of these patients. The findings were confirmed [56] when a mutation in the muscle promoter and exon 1 of dystrophin was identified in another family with XLCM. Subsequently, multiple dystrophin mutations have been identified in these patients.

Dystrophin is a cytoskeletal protein that provides structural support to the myocyte by creating a lattice-like network to the sarcolemma [57]. In addition, dystrophin plays a major role in linking the sarcomeric contractile apparatus to the sarcolemma and extracellular matrix [57–60], and is involved in cell signaling, particularly through its interactions with nitric oxide synthase. The mutated dystrophin gene is also responsible for Duchenne and Becker muscular dystrophy (DMD/BMD) [61].These skeletal myopathies present early in life (DMD is diagnosed before age 12 years and BMD is seen in teenage males >16 years of age) and most patients develop DCM before the 25th birthday. In patients with DMD/BMD, CK-MM is elevated as in XLCM; in addition, female carriers develop disease late in life, similarly to XLCM. Furthermore, immunohistochemical analysis demonstrates reduced levels (or absence) of dystrophin, as in the hearts of patients with XLCM.

Murine models of dystrophin deficiency demonstrate disturbed muscle physiology based on membrane structural support abnormalities [62]. In addition to the dysfunction of dystrophin, mutations in dystrophin secondarily affect other proteins. At the amino-terminus (N-terminus), dystrophin binds to the sarcomeric protein actin, part of the thin filament of the contractile apparatus. At the carboxy-terminus (C-terminus), dystrophin interacts with α-dystroglycan, a dystrophin-associated membrane-bound protein involved in the function of the dystrophin-associated protein complex (DAPC), which includes β-dystroglycan, the sarcoglycan subcomplex (α-, β-, γ-, δ-, and ε-sarcoglycan), syntrophins,

and dystrobrevins [63–65]. In turn, this complex interacts with α$_2$-laminin and the extracellular matrix [66]. Like dystrophin, mutations in these genes lead to muscular dystrophies with or without cardiomyopathy, supporting the contention that this group of proteins is important to the normal function of the myocytes of the heart and skeletal muscles [66,67]. Mechanical stress [62] appears to play a significant role in the age onset-dependent dysfunction of these muscles. The information gained from the studies on XLCM, DMD, and BMD led us to hypothesize that DCM is a disease of the cytoskeleton/sarcolemma that affects the sarcomere [11], a "final common pathway" of DCM [68]. We suggested that dystrophin mutations play a role in idiopathic DCM in males, when we showed that 3/22 boys with DCM had dystrophin mutations and all were later found also to have elevated CK-MM [69]. In addition, eight families with DCM and possible X-linked inheritance were also screened and in three of the families dystrophin mutations were noted; CK-MM was elevated in all subjects carrying mutations [70]. Therapeutically, the efficacy of angiotensin-converting enzyme (ACE) inhibitor therapy and β-blockers has been shown [71,72]. Jefferies *et al*. [71] also suggested that age of onset and severity of DCM were associated with a specific mutation area: the 5′ area (encodes the N-terminus) of dystrophin, when mutated, leads to early onset DCM whereas the 3′ end (C-terminus) has later onset DCM. Whether this responds differently to therapy is unknown.

Barth syndrome

Initially described as X-linked cardioskeletal myopathy with abnormal mitochondria and neutropenia by Neustein *et al*. [73] and Barth *et al*. [53], this disorder typically presents in male infants as CHF associated with neutropenia (cyclic) and 3-methylglutaconic aciduria [74]. Mitochondrial dysfunction is noted on electron microscopy and electron transport chain biochemical analysis. Abnormalities in cardiolipin have also been noted [75]. These infants typically have echocardiographic evidence of left ventricular dysfunction with left ventricular dilation, endocardial fibroelastosis, or a dilated hypertrophic left ventricle. Some infants succumb from CHF/ sudden death VT/VF, or sepsis due to leukocyte dysfunction. Most children survive infancy and do well clinically, although DCM usually persists. Some require cardiac transplantation. Histopathologic evaluation typically demonstrates the features of DCM, although endocardial fibroelastosis may be prominent and the mitochondria are abnormal in shape and abundance.

The genetic basis of Barth syndrome was first described by Bione *et al*. [76], who cloned the disease-causing gene, G4.5. This gene encodes a novel protein called tafazzin (TAZ), whose gene product is an acyltransferase which when defective results in cardiolipin abnormalities [75]. Mutations in G4.5/TAZ result in a wide clinical spectrum, including classic DCM, hypertrophic DCM, endocardial fibroelastosis (EFE), and left ventricular noncompaction [18,77].

Autosomal dominant dilated cardiomyopathy

The most common form of inherited DCM is the autosomal dominant [8]. Patients present with either classic "pure" DCM or DCM associated with conduction system disease (CDDC). In the latter form, patients usually present in the third decade of life with mild conduction system disease that can progress to complete heart block over decades. DCM usually presents late in the course but is out of proportion to the degree of conduction system disease [78]. The echocardiographic and histologic findings in both subgroups are classic for DCM, although the conduction system may be fibrotic in patients with CDDC. In both groups of DCM patients, VT, VF, and torsades de pointes occur and may result in sudden death.

Genetic heterogeneity exists for autosomal dominant DCM with more than 15 genes identified for FDCM and for CDDC. The identified genes include those encoding cytoskeletal and sarcomeric proteins, although some ion channel genes and others have also been identified [8,9,79,80] (Table 58.1).

Mechanistically, cytoskeletal proteins (desmin, δ-sarcoglycan, metavinculin, MLP), are thought to cause defects of force transmission resulting in the DCM phenotype, and defects of force generation have been speculated to cause sarcomeric protein-induced DCM [81]. Purevjav *et al.* recently showed that the mutation in a gene may disrupt protein-binding partners and, depending on this interaction, differential phenotypes and severity occur [14].

Muscle is muscle: cardiomyopathy and skeletal myopathy genes overlap

Interestingly, nearly all of the genes identified for inherited DCM are also known to cause skeletal myopathy in humans and/or mouse models. Dystrophin mutations cause Duchenne and Becker muscular dystrophy whereas δ-sarcoglycan mutations cause limb girdle muscular dystrophy (LGMD2F). Lamin A/C causes autosomal dominant Emery–Dreifuss muscular dystrophy (EDMD) and LGMD1B and actin mutations are associated with nemaline myopathy. Desmin, G4.5/TAZ, α-dystrobrevin, Cypher/ZASP, MLP, α-actinin-2, titin, and δ-sarcoglycan mutations also have associated skeletal myopathy suggesting that cardiac and skeletal muscle function are interrelated. Possibly the skeletal muscle fatigue of patients with DCM may be due to primary skeletal muscle disease rather than cardiac dysfunction. Perhaps the function of these muscles has a "final common pathway" and both cardiologists and neurologists should consider evaluating both sets of muscles.

Further support for this concept comes from studies of animal models. Mutations in δ-sarcoglycan in hamsters cause cardiomyopathy whereas mutations in all sarcoglycan subcomplex genes in mice cause skeletal and cardiac muscle disease. Mutations in other DAPC genes and also dystrophin in murine models also consistently demonstrate abnormalities of skeletal and cardiac muscle function. Arber *et al.* [82]

produced a mouse deficient in muscle LIM protein (MLP), a structural protein that links the actin cytoskeleton to the contractile apparatus. The resultant mice develop severe DCM, CHF, and disruption of cardiac myocyte cytoskeletal architecture. Murine mutations in titin, cypher, α-dystrobrevin, desmin, and other proteins all demonstrate cardiac and skeletal muscle disease. Finally, the DCM that develops after viral myocarditis has a mechanism similar to the inherited forms [83]. Using coxsackievirus B3 (CVB3) infection of mice, the authors showed that the CVB3 genome encodes for a protease (enteroviral protease 2A) that cleaves dystrophin at its third hinge region, resulting in force transmission abnormalities and DCM. In addition, Xiong *et al.* [84] showed that abnormal dystrophin increases susceptibility to viral infection and resultant myocarditis. Interestingly, a similar dystrophin mutation that affects the first hinge region of dystrophin in patients with XLCM was previously reported by our laboratory, demonstrating a consistent mechanism of DCM development, abnormalities of the cytoskeleton/sarcolemma and sarcomere. Finally, we have shown that N-terminal dystrophin is reduced or absent in hearts of patients with all forms of DCM (ischemic, acquired, genetic, idiopathic) and that reduction of mechanical stress by use of left ventricular assist devices (LVADs) results in reverse remodeling of dystrophin and of the heart itself [85,86].

Differential diagnosis

The causes of DCM are varied (see Table 58.2) and the differential diagnosis depends on age. In infants and young children, DCM is typically more severe than in older children and adults and more frequently includes other systemic abnormalities.

Treatment

Targeted therapies based on mechanism in DCM

Once the mechanism(s) of disease have been identified and understood, targeted instead of symptom-based therapies can be considered and developed. To date, only a small number of successes have been defined. Because the "final common pathway" involved in DCM is the link between the sarcomere and sarcolemma, mechanical stress is a key secondary component to consider [11,68,80]. Reducing mechanical stress and stretch might favorably remodel the heart. In testing this hypothesis, LVAD therapy reduces LV size, myocyte hypertrophy, and fibrosis, ultimately improving systolic function and overall ventricular performance [85,86]. In a subset of patients, significant improvement of LV size and function led to removal of mechanical support and resumption of normal or near-normal cardiac function. This may also be a key mechanism in β-blocker and ACE inhibitor therapy in some patients. In addition, the recent discovery of the regulatory effects of the transforming growth

factor-β (TGF-β) pathway on the development of myocardial fibrosis and the inhibitory and protective effects of bone morphogenic protein-7 (BMP-7) on this pathway and the effects of TGF-β-induced fibrosis may offer an approach to therapy [87,88].

Other targeted therapies exist. Endocardial fibroelastosis (EFE) in infancy was shown to occur from intrauterine mumps virus infection [89]. The successful use of vaccinations has reduced the occurrence of mumps and the incidence of EFE subsequently dropped to essentially zero. Furthermore,

the key causes of HIV-related DCM are enteroviral and adenoviral infection of the heart, not HIV [90]. Coxsackievirus (an enterovirus), the most commonly identified viral genome in these hearts, cleaves dystrophin by the use of endogenous enteroviral protease 2A, leading to DCM [83,84]. Protease inhibitor use, a mainstay in HIV therapy, has limited the development of coxsackieviral myocarditis and hence reduced the incidence of heart disease in these patients.

Current medical therapy

If no identifiable and treatable cause of the DCM is found, therapy is supportive and consists of an anticongestive regimen, control of significant arrhythmias, and minimizing the risk of thromboembolic complications. Critically ill children frequently require intubation and mechanical ventilation. The mainstay of acute decompensated heart failure therapy is discussed in Chapter 70 [91–97]. The use of dobutamine and dopamine is limited because of the concept of mechanical stress relationship to disease worsening and its correlation with arrhythmia triggering. When used, dopamine is typically begun in renal doses to enhance renal perfusion and diuresis. Myocardial phosphodiesterase inhibitors, such as milrinone, are useful. In adults, reports of associated ventricular arrhythmias has tempered enthusiasm for this drug, but this complication has not been observed in childhood DCM. Nitroprusside can also be used for afterload reduction but may have a greater blood pressure effect in these at-risk patients and must therefore be used with caution. Correction of anemia is important [98]. For children, oral therapy is instituted as intravenous inotropic agents are weaned [91–93] (see chapter 70).

Arrhythmias are common in children with DCM [32,34]. Sometimes the only treatment required is medical management to improve cardiac function and normalize electrolyte imbalances. If significant arrhythmias persist, antiarrhythmic therapy is warranted [99]. Many antiarrhythmic drugs adversely affect ventricular function and may be proarrhythmic. For significant arrhythmias, amiodarone is effective and relatively safe in children. Temporary pacing of symptomatic bradyarrhythmias may be necessary during the acute phase of illness. Permanent pacing occasionally may be necessary. Elective pacing to optimize atrioventricular synchrony and ventricular filling remains investigational. implantable defibrillators (ICDs) are becoming the standard of care when systolic function is significantly depressed and life-threatening arrhythmias occur.

The utility of immunosuppressive agents in DCM, including steroids, cyclosporine, and azathioprine, remains unproven. Intracavitary thrombus formation and systemic embolization occur in young patients with DCM, and anticoagulation should be strongly considered [100]. If a thrombus is identified, patients are usually anticoagulated with heparin and then converted to warfarin. If a thrombus is not seen, antiplatelet drugs (aspirin, dipyridamole) may be useful in preventing thrombus formation.

In children with a metabolic cause of DCM, careful attention to biochemical derangement is important [4,8,10,34,101]. Correcting associated metabolic acidosis and diagnosing the underlying causes are paramount. Oral feeding should be reduced or discontinued until stabilization has occurred, with intravenous fluid and dextrose replacement used to provide energy and reduce the ongoing catabolic process, and total parenteral nutrition (TPN) used for nutrition.

Surgical

Despite maximum medical therapy, some patients continue to deteriorate [102]. Children with acute and severe decompensation may require mechanical circulatory support (MCS) therapy with a ventricular assist device (VAD), intra-aortic balloon counterpropulsion, or extracorporeal membrane oxygenation (ECMO) (see Chapter 14). In children, MCS commonly is a bridge to transplantation. It occasionally helps to remodel the heart favorably, allowing device removal. Typically, it is meant to stabilize children and reduce other end-organ damage while awaiting transplantation. Unlike in adults, where MCS may be used as "destination therapy," that approach is rarely considered in children. The other surgical approach is cardiac transplantation, which is used when children are unable to maintain functional stability and end-organ stability (see Chapter 70). The data on childhood transplantation have been stable for the past decade, with a median survival for infant transplant of 18.3 years and an adolescent transplant mean survival of 11.1 years [103].

Prognosis

In infants and children presenting with DCM, there are four possible outcomes [4,5,32,34]: complete resolution, improvement, death, and cardiac transplantation. Review of the available studies in children suggests that approximately one-third die, one-third improve but have some residual cardiac dysfunction, and one-third recover completely. In children, 1-year survival ranges from 63 to 70% and 5-year survival from 34 to 66%; 10–11-year survival is 50%. Mortality is highest during the first 1–2 years after presentation. Congestive heart failure is the most common cause of death, although sudden death also occurs. The time from presentation to ~6 months after diagnosis appears most critical in terms of defining outcome. In those who are going to recover or improve, signs of improvement are generally seen during the initial 6 months, although continued improvement may occur beyond 2 years. Most deaths occur in the first 6 months, with survival declining gradually thereafter. The persistence of congestive heart failure despite maximum medical therapy, and persistently low functional echocardiographic parameters on echocardiography, should prompt consideration of cardiac transplantation.

Myocarditis

Myocarditis is characterized by inflammatory infiltration of the myocardium associated with necrosis or degeneration of adjacent myocytes that differs from the ischemic damage associated with coronary artery disease [19,31,33]. The cause may be infectious, toxic, associated with connective tissue disorders, or other processes; the commonest cause is viral, but almost any organism can be the cause (see Table 58.3). Myocarditis is believed to be a significant cause of idiopathic DCM.

Epidemiology

Although epidemics have been reported, the disease is usually sporadic [4,10,19,20,33,34]. Over the years, different viruses have been dominant in a population and a shifting demographic of viral etiology occurs approximately every decade [20,43]. In the 1960s–1980s, the enteroviruses, particularly coxsackievirus B, were the most common causal agents, although the virus was rarely recovered from the heart. Coxsackievirus B is spread by the fecal–oral or airborne route and is most common in the spring and summer. Young children, particularly infants, are most commonly affected. In the 1990s, we showed that adenovirus was the most common cause of myocarditis in children during that decade [42,104]. Adenovirus infections occur sporadically throughout the year and in epidemics during winter, spring, and early summer. The outcomes for children with adenoviral myocarditis differed slightly from those for coxsackievirus, but in both instances most children improved. We were the first to show that parvovirus B19 was a significant cause of childhood myocarditis [105], and during 2000–2010 it became the predominant viral cause of myocarditis [20,42,106–108]. Parvovirus B19 infects the endothelium, unlike adenovirus and coxsackievirus, which both infect the cardiomyocyte [108]. Because of its attraction to the endothelium, parvovirus B19 inflames arteries, particularly the coronaries, leading to coronary insufficiency, myocardial injury, ischemia, and infarction. Currently, coxsackievirus is beginning to become more common again.

Clinical presentation

Children commonly present with signs and symptoms of congestive heart failure that may rapidly lead to cardiovascular collapse [10,19,109]. Infants usually are pale and clammy, irritable or somnolent, and have increasingly uncomfortable respiratory effort. On examination, they are tachypneic and tachycardic at rest. The cardiac examination demonstrates a gallop rhythm, and perhaps a mitral regurgitant murmur. The pulses are typically thready, and perfusion is poor. Commonly, there is moderate hepatomegaly. Rales are usually absent in small children. Older children generally present with breathlessness and signs of heart failure. Syncope may occur. Some children and adolescents present

with signs of ischemia, particularly in parvovirus B19 infections or fulminant myocarditis [107]. There may be a history of recent viral-type illness, although many have not been ill. Infectious contacts may not be known.

Diagnostic studies

Chest radiography

Cardiomegaly and pulmonary venous engorgement, with or without evidence of pneumonitis, are common. If the child improves, the chest radiograph becomes normal.

Electrocardiography

Classically, the surface electrocardiogram demonstrates low voltage of the QRS complexes in the limb leads (<5 mm total amplitude) with inverted T waves and absent or small Q waves

Table 58.4 Dallas criteria.

Type	Definition
General definition	Myocardial cell injury with degeneration or necrosis with inflammatory infiltrate not due to ischemia
Active myocarditis	Both myocyte degeneration or necrosis and definite cellular infiltrate with or without fibrosis
Borderline myocarditis	Definite cellular infiltrate without myocyte injury
Persistent myocarditis	Continued active myocarditis on repeated right ventricular endomyocardial biopsy
Resolving/resolved myocarditis	Diminished or absent infiltrate with evidence of connective tissue healing

Figure 58.3 Histologic appearance of lymphocytic myocarditis in this right ventricular endomyocardial biopsy specimen obtained from the child with new-onset heart failure. Note the lymphocytic inflammatory infiltrate and myocyte necrosis.

in leads V_5 and V_6. Sinus tachycardia is the rule, although bradycardia may be evident. Premature ventricular complexes and supraventricular tachycardia are the most common rhythm disturbances, although ventricular tachycardia, and complete atrioventricular block also occur [10,19,34,109–113].

Echocardiography
The echocardiogram demonstrates left ventricular dilation and depressed ventricular function. The atria (particularly the left atrium) may also appear mildly dilated. A pericardial effusion may be found. Doppler and color Doppler evaluation may demonstrate mitral regurgitation.

Cardiac catheterization and endomyocardial biopsy
Hemodynamic evaluation typically shows elevated ventricular end-diastolic pressures and reduced cardiac index [33,39]. Endomyocardial biopsy is used for histopathologic evaluation by light microscopy and electron microscopy, culture, and molecular analysis. Histopathologic analysis typically follows the Dallas criteria (Table 58.4), which rely on the amount of lymphocytic infiltrate, fibrosis, myocyte necrosis, and edema (Figure 58.3) [19]. Unfortunately, this approach is diagnostic in only 50% of patients [114–117]. Imaging approaches, including cardiac MRI, have replaced biopsies as the diagnostic modality in many patients and institutions. [117].

Viral culture and serology
Viral, bacterial, and fungal cultures are usually obtained from nasopharyngeal and stool specimens and also from the myocardium. Blood cultures are generally useless for viral diagnosis because the virus has usually cleared before clinical presentation [47]. If the culture is positive from a peripheral site, a presumptive etiologic diagnosis may be rendered but
is commonly incorrect. Serologic identification requires a fourfold increase in antibody titers on serial analysis.

Molecular methods
In the 1980s, Bowles *et al.* [118] first described the use of *in situ* hybridization studies using probes designed for sequences of coxsackievirus to analyze myocardium. There were >50% hybridization-positive samples, suggesting that coxsackievirus was indeed a common cause of myocarditis. They also showed coxsackievirus probe hybridization in patients with idiopathic DCM and inferred that a previous subclinical infection caused the cardiomyopathy [118,119] Since the early 1990s, PCR has been used to analyze endomyocardial biopsy and autopsy specimens for viral sequences [120,121] This rapid amplification process is highly sensitive and has identified viral sequences in 30–50% of myocardial specimens studied over the past 20 years [19,20,33,42,43,89,90,104,105,117,120,121].

Therapy
Patients with myocarditis and acute decompensated heart failure require anticongestive therapy as described above. Therapy should be given intravenously and may include milrinone and diuretics. Intubation and mechanical ventilation may be necessary. VAD or ECMO support or intra-aortic balloon pump may be needed for circulatory support. In stable patients, oral therapy with afterload-reducing agents, such as captopril or enalapril, and diuretics are used. For persistent ventricular dysfunction, carvedilol or metoprolol are added. Therapy for treating the inflammatory response is controversial. Some centers advocate steroids and other centers use immunosuppressive agents such as cyclosporine or azathioprine [19,33,122–126]. Intravenous immunoglobulin (IVIG) has been used and appeared to have favorable results [19,33,43,117,127–129].

Future directions

Diagnosis

PCR analysis of myocardium is currently commercially available. Cardiac MRI with gadolinium late enhancement, applied in adults to diagnose myocarditis, is beginning to be used in children. Mechanical circulatory support is being used for a short-term bridge to recovery and appears useful in remodeling the heart.

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is defined by its wall thickening [130–132] and is the most common cause of sudden death in young, healthy athletes [133–136]. It can cause heart failure [137–139] due to either diastolic factors or the development of systolic dysfunction, "burned out" HCM [137–138].

In children, the underlying etiologies of HCM and the variable age of onset differentiate the childhood form from the adult counterpart [8,101,131,139]. In infants, ventricular hypertrophy associated with systolic dysfunction is more the rule. Overlap disorders in which HCM coexists with atypical features are more common in children, further confounding the presentation, treatment, and outcome compared with adult disease.

Clinical aspects

HCM is a primary myocardial disorder with an autosomal dominant pattern of inheritance characterized by hypertrophy of the left (± right) ventricle with histological features of myocyte hypertrophy, myofibrillar disarray, and interstitial fibrosis [130–132,135,139]. HCM is one of the most common inherited cardiac disorders, with a prevalence in young adults of one in 500 [130,131]. HCM is also called hypertrophic obstructive cardiomyopathy (HOCM) and idiopathic subaortic stenosis (IHSS), names reflecting "classic" features of asymmetric septal hypertrophy and left ventricular outflow tract obstruction (Figure 58.4). This early disease description was based primarily on patients with severe symptoms seen in tertiary referral centers. Epidemiologic studies now suggest that a wide range of clinical manifestations, severity, and prognosis are present in the community. The first clinical description of HCM was in 1869 [140] and it was identified as a genetic disorder in the late 1950s. During the last 15 years, molecular genetic studies have given important insights into the pathogenesis of HCM and have provided a new perspective for the diagnosis and management of patients with this disorder [141,142].

Genetics of familial hypertrophic cardiomyopathy

The first gene for familial hypertrophic cardiomyopathy (FHC) was mapped to chromosome 14q11.2-q12 using genome-wide linkage analysis in a large Canadian family
Figure 58.4 Gross pathology in hypertrophic cardiomyopathy. Note the very thick interventricular septum and small left ventricular cavity. The septum is significantly thicker than the free wall, consistent with asymmetric septal hypertrophy.

[143]. Soon afterwards, FHC locus heterogeneity was reported [144] and subsequently confirmed by mapping the second FHC locus to chromosome 1q3 and the third locus to chromosome 15q2 [145,146]. Since then, a large number of loci and genes have been identified with approximately 27 gene mutations reported to date.

Gene identification in familial hypertrophic cardiomyopathy

Most of the identified disease-causing genes code for proteins that are part of the sarcomere, the "final common pathway" of HCM [68]. The sarcomere is a complex structure with an exact stoichiometry and multiple sites of protein-protein interactions [141,147]. These include three myofilament proteins, the β-myosin heavy chain (β-MyHC), the ventricular myosin essential light chain 1 (MLC-1s/v), and the ventricular myosin regulatory light chain 2 (MLC-2s/v); four thin filament proteins, cardiac actin, cardiac troponin T (cTnT), cardiac troponin I (cTnl), and α-tropomyosin (α-TM); and one myosin-binding protein, the cardiac myosin binding protein C (cMyBP-C) [139,141,142,147]. Each protein is encoded by multigene families which exhibit tissue-specific, developmental, and physiologically regulated patterns of expression [148]. The giant protein titin [149] and its interactive Z-disc protein, muscle LIM protein (MLP), have also been identified [150], as have multiple other Z-disc-encoding genes including CARP, NEBL, and nexillin (NEXN) [14,151–153]. In addition, the gene located on chromosome 7q3 associated with HCM and Wolff–Parkinson–White (WPW) syndrome was identified as AMP kinase (AMPK), which may play a role in energy metabolism and

cause infiltration of a glycogen-like substance similar to Pompe disease [154–156]. This was further supported by identifying mutations in LAMP-2, the gene responsible for Danon disease [157–160].

Genotype–phenotype relations in familial hypertrophic cardiomyopathy

The pattern and extent of left ventricular hypertrophy in patients with HCM vary greatly even in first-degree relatives and a high incidence of sudden death is reported in selected families. Since the description of the first HCM-causing mutation, investigators have attempted to correlate genotypes with particular clinical phenotypic expressions. Stemming from earlier pedigree studies, specific missense mutations were associated with a markedly unfavorable prognosis whereas others had an uneventful natural history. These observations resulted in specific mutations being designated as either "malignant" or "benign." Several concepts have been published for mutations in the MYH7, TNNT2, and MYBPC3 genes. For MYH7, the prognosis for patients with different mutations varies. Watkins *et al.* [161 described mutations in MYH7 found in 12/25 families with HCM and concluded that the MYH7-R403Q mutation was associated with a significantly shorter life expectancy, and therefore considered a "malignant" mutation. In contrast, a noncharge change mutation (V606M) was associated with nearly normal survival and therefore was considered "benign." In 2003, Woo *et al.* analyzed mutations in functional domains in 15/70 MYH7-positive probands and concluded that there may be prognostically informative domains. [162]

Initial reports on the clinical expression from another common subtype of HCM with MYBPC mutations showed a slower progressive disease course, with later onset and milder disease characteristics [163–165]. Investigators in The Netherlands and South Africa discovered founder mutations in MYBPC3 with mild phenotypic expression present in >30% of their patients [166]. Certain genotype–phenotype correlations were attributed to TNNT2 (troponin T) mutant forms of HCM. Far less common than MYBPC or MYH7 forms, TNNT2 affects <5% of patients, is associated with less severe LV wall thickness, and has a higher incidence of premature sudden cardiac death [167–169]. Generally, patients who suddenly died had less hypertrophy and fibrosis, but more myocyte disarray, which may have provided the substrate for malignant arrhythmias [169].

These observations were made from studies of small cohorts involving larger families with penetrant disease expression whereas genotype–phenotype studies involving large cohorts of unrelated patients have indicated that great caution must be exercised when assigning particular prognostic significance to any particular mutation. [170–172]. Studies have demonstrated that the two most common forms of genetically mediated MYH7 and MYBPC3 are phenotypically indistinguishable [173].

Despite the inconsistent findings regarding outcomes based on genotype–phenotype correlations, several phenotype–genotype relationships have emerged. Recently, echocardiography-guided genetic testing has been explored [174]. Over two decades ago, Lever *et al.* noted a predominance of sigmoidal HCM among the elderly and suggested a strong age dependence with the various septal morphologies of HCM [175].They suggested a morphologic classification of septal morphology as reverse curve, sigmoidal, apical, and neutral contour HCM. Solomon *et al.* observed that patients with mutations in β-myosin heavy chain (MYH7) generally had reversed curvature septal contours (reverse curve HCM) [176].

Subsequently, a large genotype–phenotype analysis correlating the septal morphology with the underlying genotype was conducted in >400 unrelated patients, and demonstrated that sigmoidal HCM (47% of cohort) and reverse curve HCM (35% of cohort) represented the two most prevalent anatomic subtypes of HCM. They showed that the yield of genetic testing for myofilament HCM was 80% in reverse curve HCM, but only 10% in patients with sigmoidal HCM, and that septal contour was the strongest predictor of a positive HCM genetic test, regardless of age [174].

Therapy in hypertrophic cardiomyopathy

The mainstay of therapy in children with HCM has been pharmacologic approaches with β-blockers and calcium-channel blockers [177–182]. In small children, propranolol is our drug of choice due to ease of access, liquid formulation, and low side-effect profile. Therapy is monitored by heart rate response, with goal of ~80–100 beats per minute. Typically dosage ranges from 2 to 5 mg kg^{-1} per day divided three times daily. Verapamil has been used with good outcomes. In older children, we typically treat with atenolol; in those with excessive hypertrophy and severe outflow tract obstruction, we occasionally use combination therapy (β-blocker plus calcium-channel blocker), although this has risk. The risk:benefit ratio must be determined for each patient.

When standard pharmacologic therapy fails, there are limited options. In small children, myectomy is the only proven option, but has risks [183–186]. In older patients, pacing protocols have been used but are controversial [187–190]. In adults, alcohol septal ablation has been used, but this has not yet been adopted in children because of uncertainties regarding long-term outcome associated with creating an infarct in a young individual [191–195].

In patients with syncope, ventricular arrhythmias, or other presumed high-risk factors, ICD implantation should be considered [196–199]. In some patients, pacing is also necessary. Heart failure in HCM occurs from either diastolic or systolic dysfunction. In the latter, therapy is similar to that for DCM, including ACE inhibitor plus β-blocker therapy, with or without diuretic and digoxin [139,199,200]. Enalapril plus carvedilol is the most common ACE inhibitor–β-blocker combination used. With diastolic dysfunction, heart failure,

and preserved systolic function, combination therapy with ACE inhibitors and diuretics, with or without angiotensin II receptor blockers such as candesartan or losartan, is commonly used. In these patients, β-blockers, calcium-channel blockers, and pacing are also considered, along with surgical relief [139,199,200].

Finally, in children with metabolic or mitochondrial dysfunction underlying the HCM, metabolic therapies have occasionally been successful. Similarly to the therapy in DCM caused by these deficiencies, carnitine, coenzyme Q10, riboflavin, and thiamine may be considered [101,139].

Infiltrative forms of hypertrophic cardiomyopathy

A variety of disorders with apparent left ventricular hypertrophy and features of hypertrophic cardiomyopathy occur from infiltrative disorders. The classic infiltrative disease is Pompe disease, which typically presents in the first weeks of life [101,201]. Other infiltrative diseases, with later onset, have been identified, such as Fabry disease [202,203], Danon disease [157–160], and left ventricular hypertrophy due to mutations in AMP-activated protein kinase (AMP-K) encoded by the PRKAG2 gene [154–156,204]. These disorders, along with those caused by mitochondrial abnormalities and genetic dysmorphism syndromes, are caused by abnormalities not primarily affecting the sarcomere [205]. Therapy is similar to that for the sarcomeric form of the disease, unless systolic dysfunction occurs, when heart failure therapy should be instituted.

Pompe disease (Type II glycogen storage disease)

Genetic deficiency of acid α-1,4-glucosidase, an enzyme involved in the breakdown of glycogen to glucose, results in a wide clinical spectrum ranging from the rapidly fatal infantile onset to a slowly progressive adult-onset myopathy [101,201]. The infantile-onset form (Pompe disease) typically manifests during the first 5 months of life, and patients usually die before their second year of life unless they receive enzyme replacement therapy [206]. This rare inborn error of glycogen metabolism occurs in <1/100 000 births. Massive glycogen accumulation occurs, leading to an enlarged tongue, striking hepatomegaly, hypotonia with decreased deep tendon reflexes, and cardiomyopathy (usually HCM) with congestive heart failure. The glycogen accumulation can be noted histologically in the skeletal muscles, liver, and heart. The diagnosis may be suspected from the classic electrocardiogram (ECG) in which gigantic QRS voltages are notable, typically with a short PR interval [101,201]. The disease has autosomal recessive inheritance; the gene coding for the defective lysosomal enzyme resides at chromosome 17q23-q25 [101]. Prenatal diagnosis is possible by amniocentesis or chorionic villus sampling by assay of α-glucosidase. Enzyme therapy with Myozyme (alglucosidase alfa) is now possible and, in some patients, appears to reverse the cardiac phenotype [206].

Fabry disease

An X-linked recessive disorder with mild expression occasionally seen in carrier females is caused by deficiency of the enzyme α-galactosidase (α-Gal) and found in 1/40 000 people [203]. Deposits of glycosphingolipids in various tissues, particularly the kidneys and coronary arteries, cause the most important disease manifestations – renal failure and myocardial infarctions in young adult males. Fabry disease usually begins in adolescence with sensations of burning pain in the hands and feet [202,203] associated with fever, heat, cold, and exercise. With increasing age, multiple angiokeratoma become noticeable, especially around the umbilicus and genitalia. Corneal opacities are often noted. Progressive renal failure develops. CNS manifestations include seizures and headaches, and also hemiplegia associated with an increased risk of stroke. Primary cardiac manifestations in affected males are hypertrophic cardiomyopathy and mitral insufficiency. Diagnosis depends on echocardiography [203]. The left ventricular myocardium and mitral valve are regions of greatest storage of lipid material [203,206–208]. On electrocardiogram, the PR interval is usually short. Deposition of sphingolipids in the coronary arteries leads to myocardial ischemia and infarction. The disease-causing gene is localized to Xq22 and encodes the α-Gal gene [203,206–208]. Enzyme replacement therapy with recombinant human α-galactosidase A (algasidase) is promising but expensive.

Danon disease

Danon disease is an X-linked dominant disorder characterized by intracytoplasmic vacuoles containing autophagic material and glycogen in cardiac and skeletal muscle cells. The major manifestations relate to cardiomyopathy with or without conduction defect, WPW syndrome, skeletal myopathy, or mental retardation [54,157–160]. The abnormality affects lysosomal function due to mutations in the lysosomal associated membrane protein 2 (LAMP2). The clinical phenotypic expression of Danon disease varies. Charron *et al*. screened 50 patients with HCM for LAMP2 mutations and identified mutations in two patients with HCM and skeletal myopathy [159]. Both individuals presented as teenagers and other affected individuals in the family were identified as young as 7 years of age. WPW syndrome and high-voltage QRS complexes on electrocardiogram were notable along with elevated creatine kinase plasma levels. LV dilation and dysfunction occurred late with symptoms of heart failure. Atrial and ventricular arrhythmias and conduction disease were notable along with death during the twenties. Visual acuity abnormality from choriocapillary ocular atrophy is common. This disease appears under-recognized and may be a significant cause of heart failure and LVH in childhood [160].

AMP-activated protein kinase (AMP-K)

AMP-activated protein kinase (AMP-K), encoded by the γ2 regulatory subunit of the PRKAG2 gene on chromosome

7q31 [209], is an enzyme that has been thought to modulate glucose uptake and glycolysis [210,211] and regulate energy homoeostasis [204]. AMP-K is expressed in many tissues, including the heart and vasculature. It is activated in response to stresses that increase the cellular ratio of AMP to ATP caused either by inhibiting ATP production (i.e., anoxia or ischemia) or by accelerating ATP consumption (i.e., muscle contraction or fasting). In the heart, AMP-K activity increases during ischemia and functions to sustain ATP, cardiac function, and myocardial viability [204]. Dominant gene mutations have been identified [154,155] in patients with hypertrophic cardiomyopathy, WPW pre-excitation, and atrioventricular block. Blair *et al.* [155] argued that mutations in AMP-K resulted in HCM due to compromise of energy production and utilization, but Arad *et al.* [156] provided evidence that this disorder is a form of glycogen-storage disease. Cardiac pathology, however, differed from other forms of HCM in that there was pronounced vacuole formation in which glycogen-associated granules were noted and no myocyte or myofibrillar disarray was seen. The myocytes were enlarged and interstitial fibrosis was minimal. Utilizing a yeast system in which a similar enzyme is functional, Arad *et al.* introduced the same mutations found in the patients and showed that the enzyme activity is persistent (i.e., does not turn off), leading to glycogen accumulation. They confirmed these findings by developing a murine model which mimics the human disorder [156].

Energy-dependent forms of hypertrophic cardiomyopathy

Mitochondrial cardiomyopathies

The human mitochondrial genome is a small, circular DNA molecule that is maternally inherited. Mitochondrial DNA (mtDNA) encodes 13 of the 69 proteins required for oxidative metabolism, 22 transfer RNAs (tRNAs), and two ribosomal RNAs (rRNAs) required for their translation [212–214]. Because mtDNA has much less redundancy than the nuclear genome (in which essentially identical information is received from both parents), and tRNAs and rRNAs are present in multiple copies, the mitochondrial genome is an excellent target for mutations giving rise to human disease. Mitochondria enjoy a symbiotic relationship with the cell. These subcellular organelles depend on nucleocytoplasmic mechanisms for most structural components, but do contribute vital peptides that are central to cellular respiration. Mitochondria contain a permeable outer membrane and a highly restrictive inner membrane that guards the chemical microenvironment of the matrix compartment. Adaptive mechanisms exist for the passage of large and small molecules across the inner membrane. Translocases shuttle monocarboxylic acids, amino acids, acylcarnitine conjugates, small ions, and other metabolites in and out of the mitochondrial matrix. Energy is required for importing proteins into the mitochondria because the nuclear gene-synthesized mitochondrial proteins are precursor molecules that require presequence cleavage. The 13 mtDNA genes are located in the respiratory chain [212–214] and include seven complex I subunits (ND1, -2, -3, -4L, -4, -5, and -6), one complex III subunit (cytochrome *b*), three complex IV subunits (COI, -II, and -III), and two complex V subunits (ATPase 6 and 8). Coordination must exist between nuclear and mitochondrial genomes to permit assembly of the complex holoenzymes. Each cell contains numerous mitochondria and each mitochondrion contains multiple copies of mtDNA. This genetic material derives exclusively from the female gamete and any mutation must be passed from female parent to all progeny, male and female. The replicative segregation of mutant mtDNA copies within the cell determines whether this biological disadvantage is expressed. In most mitochondrial disorders, patients carry a mix of mutant and normal mitochondria, a condition known as heteroplasmy, with the proportions varying from tissue to tissue and from individual to individual within a pedigree in a manner correlating with severity of phenotype [212–215].

Mitochondrial diseases often produce disturbances of brain and muscle function, presumably because these two organs are so metabolically active, and therefore the metabolic demand is high during growth and development [213–216]. Cardiac disease is most commonly seen with respiratory chain defects [212]. Ragged red fibers are present in muscle biopsy specimens almost invariably when the molecular defect involves mtDNA (except in infants). These defects represent the genetics of ATP production. The diverse clinical syndromes associated with various respiratory chain complexes are thought to result from involvement of tissue-nonspecific (generalized) subunits in other cells, and the residual enzyme activity in affected tissues. The cardiac diseases associated with mitochondrial defects include both hypertrophic cardiomyopathy and dilated cardiomyopathy, and LV noncompaction [217].

Kearns–Sayre syndrome

This mitochondrial myopathy is characterized by ptosis, chronic progressive external ophthalmoplegia, abnormal retinal pigmentation, and cardiac conduction defects, in addition to DCM [212,218]. Approximately 20% of Kearns–Sayre syndrome patients have cardiac involvement and the majority have conduction defects causing progressive heart block [219]. These patients generally have large, heterogeneous deletions in the mitochondrial chromosome. Poulton *et al.* [220] showed germline deletions of mtDNA in a family with Kearns–Sayre syndrome with a deletion in muscle mtDNA and at low levels in blood that was identical with that found in the mother and sister. The probands, however, had more deleted DNA, correlating with more severe symptoms. Other mutations have also been described [214].
Figure 58.5 (a) Apical four-chamber echocardiographic view of a child with restrictive cardiomyopathy. Note the extremely dilated atria and normal-sized ventricles (which appear to be small because of the large atrial dimensions). The electrocardiographic strip at the bottom demonstrates a giant P wave as well. (b) Echocardiogram (parasternal long-axis view) in a child with restrictive cardiomyopathy. Note the giant left atrium and normal-sized left and right ventricles. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

MERRF syndrome

This syndrome is characterized by myoclonic epilepsy with ragged red muscle fibers (MERRF) and is caused by a single nucleotide substitution in tRNA LYS that apparently interferes with mitochondrial translation [212,214,216,221]. This abnormality causes decline in ATP-generating capacity, with onset of disease that includes cardiomyopathy. Other reports outline various disease-causing mutations [222–224].

Restrictive cardiomyopathy

Restrictive cardiomyopathy (RCM) is a rare form of heart disease (<5% of cardiomyopathies in children) [225–228] characterized by "normal or decreased volume of both ventricles associated with biatrial enlargement, normal left ventricular wall thickness and atrioventricular valves, impaired ventricular filling with restrictive physiology, and normal (or near normal) systolic function" (Figure 58.5) [5].

Epidemiology

In children in the United States and Australia, RCM accounts for 2.5–5% of the diagnosed cardiomyopathies, with most having no specific identified cause [3,225–227,229]. In Australia, RCM accounted for 2.5% of the cardiomyopathies in children <10 years of age [229] and in the United States it accounted for 3% of the cardiomyopathies in patients <18 years of age. [3] The estimated annual incidence in children in the United States and Australia is 0.04/100 000 and 0.03/100 000, respectively [3,229].

Etiology and pathology

Multiple causes of RCM described in adults and children are listed in Table 58.5. The pathology and histology vary with the underlying disease process [230,231]. Histochemical stains show variable degrees of myocyte hypertrophy, interstitial fibrosis, and myocytolysis. Both sporadic and familial examples of RCM are reported. Worldwide, the most common etiology is endomyocardial fibrosis, which affects ~10 million people, most often children and adolescents [232,233]. Some inherited instances of RCM have autosomal dominant transmission, mostly caused by mutations in sarcomere-encoding genes such as troponin I, troponin T, β-myosin heavy chain, and actin [225,231]. RCM has also been associated with atrioventricular block and skeletal myopathy, and caused by mutations in desmin [225,231].

Clinical presentation and diagnostic evaluation

The common presenting symptoms in children with RCM include dyspnea that is frequently exacerbated by an intercurrent respiratory illness or "asthma," fatigue, exercise intolerance, syncope, and sudden death [225,230,234,235]. Abnormal findings on physical examination include hepatomegaly, ascites, elevated jugular venous pulse, a loud pulmonary component of the second heart sound (P2), and an S_3 or S_4 gallop. Chest radiography usually reveals

Table 58.5 Etiologies of restrictive cardiomyopathy.

Genetic	Mixed	Acquired
Sarcomeric mutations	Amyloidosis	Endomyocardial fibrosis
Troponin I	Endocardial fibroelastosis (EFE)	Myocarditis
Troponin T		Cardiac transplant
α-cardiac actin		*Pseudoxanthoma elasticum*

cardiomegaly and pulmonary venous congestion (an indicator of poor prognosis). The electrocardiogram is abnormal in ~98% of patients [236]. The most common abnormalities are right and/or left atrial enlargement; however, ST segment depression and ST-T wave abnormalities are frequent (Figure 58.6). Right and/or left ventricular hypertrophy and conduction abnormalities may be present. Arrhythmias are found in ~15% of pediatric patients and include both atrial and ventricular tachyarrhythmias, including torsades de pointes and WPW syndrome, and various degrees of heart block. Symptomatic sinus bradycardia requiring pacing has also been reported [234].

The most striking finding on echocardiography is massive atrial dilation with normal AV valves.(Figure 58.5) [225]. In children, findings consistent with restrictive filling and increased left ventricular end diastolic pressure include elevated E/A ratios, short mitral deceleration times, increased pulmonary vein atrial reversal velocity and duration, and pulmonary vein atrial reversal duration greater than mitral A duration [237–239]. Some systolic dysfunction may be present and deteriorate with time [225,230,236,237]. Some concentric increase in septal and left ventricular posterior wall thickness is present in many patients otherwise fulfilling the criteria for RCM. The ventricular cavity sizes are usually normal.

Cardiac catheterization should be performed. It shows elevated left and/or right ventricular end diastolic pressures, and frequently pulmonary hypertension [225,237,239]. The pulmonary vasculature may remain reactive, but 40% of patients had elevated and nonreactive pulmonary vascular resistance when evaluated for cardiac transplantation [240]. The major hemodynamic problem in RCM is restricted ventricular filling. The diastolic pressure curve generally shows one of two patterns: (1) the pressure is elevated at the onset of diastole and rises further with ventricular filling; (2) a prominent *y* descent occurs in early diastole, followed by an abrupt rise during the rapid filling phase, producing the "square root" or "dip and plateau" pattern. The first pattern can also be seen in cardiac tamponade, and the second may be seen in constrictive pericarditis (see also Chapter 59). Elevated pulmonary artery pressure is common, and markedly elevated pulmonary vascular resistance can occur within 1–4 years of diagnosis. Endomyocardial biopsy reveals myofiber hypertrophy and mild to moderate interstitial fibrosis.

Treatment

Treatment of RCM is nonspecific and directed at alleviating symptoms. In general, medical therapy does not improve survival [234,236,237,240]. Diuretics are usually helpful in reducing pulmonary and systemic venous congestion. Because there is restriction on ventricular filling, care must be taken to avoid excessive reduction of preload. Afterload-reducing agents, calcium-channel blockers, and inotropic agents have not been beneficial Adrenergic agonists and phosphodiesterase inhibitors can improve left ventricular relaxation, but they are effective only in patients with concurrent systolic dysfunction. Chatterjee and Alpert [241] reported that in patients with RCM and severe heart failure, pharmacotherapy is ineffective and cardiac transplantation is the most effective therapy. Atrial thrombi or embolic events occur often, so anticoagulation or antiplatelet therapy appears warranted. ICD implantation has theoretical advantages but there are limited data to support its use. Transplantation remains the treatment of choice. Contemporary outcomes from transplantation far exceed the natural history of this disease, causing some groups to recommend listing for transplantation when the patient presents, even if asymptomatic. Progressive elevation of pulmonary vascular resistance should lead to early consideration of transplantation. Elevated pulmonary vascular resistance usually normalizes after transplantation.

Prognosis

The prognosis for children with RCM is poor [225,230, 234,236–240,242], with half dying or undergoing transplant within 3 years of diagnosis [225,230,234,236–240]. Sudden cardiac death is common [225,230,234,236–240], especially in those with signs and symptoms of ischemia, such as syncope and chest pain. Deaths from heart failure are the most common, with poor prognostic factors being cardiomegaly and pulmonary venous congestion on chest X-ray, age <5 years, thromboembolism, and elevated pulmonary vascular resistance [225,230, 234,236–240].
(a)

(b)

Figure 58.6 (a) This electrocardiogram demonstrates large P waves in addition to T-segment abnormalities consistent with ischemia. (b) Electrocardiographic strip demonstrating ventricular tachycardia. This occurred after the development of sinus tachycardia, which led to worsening ischemic abnormalities on electrocardiogram.

Arrhythmogenic cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC), first reported in 1978 [243], has areas of fibrofatty replacement, inflammatory infiltrate, and fibrosis, predominantly in the right ventricular but also the left ventricular free wall. A spectrum of right ventricular involvement occurs. Classically, the patients present with syncope or palpitations secondary to ventricular tachycardia of left bundle branch block morphology, originating from the areas of fibrofatty replacement [244–246].

Pathology

Pathologically there is some right ventricular enlargement, frequently with aneurysms and thinning of the right ventricular free wall in the region of the infundibulum, apex, or inferior wall (known as the "triangle of dysplasia") associated with fibrosis with or without fatty replacement (Figure 58.7) [247,248]. These areas of replacement are white, thickened, and sclerotic on the endocardial surface. The left ventricle is also often affected. Histologic sections show a variable reduction in myofibrils and inflammation associated with interstitial infiltration by histiocytes and lymphocytes. The few remaining
Figure 58.7 Histologic examination in arrhythmogenic right ventricular dysplasia shows fibrofatty infiltration within the right ventricular tissue. Note the fatty infiltration and the fibrous tissue surrounding the islands of cardiomyocytes.

Table 58.6 Arrhythmogenic RV cardiomyopathy genetics.

Locus name	Inheritance	Map position	Gene
ARVD1	AD	14q23	TGFB3

Naxos	AR	17q21	Plakoglobin (JUP)
Carvajal	AR	6p24	Desmoplakin (DSP)

myofibrils are hypertrophied or show signs of degeneration. It is the fibrosis and fatty infiltration that are most characteristic of ARVC; all layers of the free wall are affected [246],

Prevalence

It is difficult to assess the prevalence of ARVC, because clinically evident right ventricular dysfunction is uncommon, and the reporting is based primarily on the arrhythmia and not right-sided failure. The estimates range from 1/1000 to 1/5000 population [249–251].

Etiology

Two etiologic factors for ARVC have been defined [252]. An inflammatory process, possibly infectious, has been implicated because infection with coxsackievirus B3 and adenovirus has been reported [253]. In susceptible individuals, a preceding viral infection could gradual destroy myocytes and cause fatty infiltration. Familial occurrence is recognized and genes encoding proteins of the desmosome or desmosome interacting proteins have been described.(Table 58.6) [252].

Clinical findings

The clinical picture seems to be independent of age [245,246,252]. The typical patient is male and in the third decade of life, but the ages range from the first year of life to the ninth decade. Athletic teens and 20–30-year-olds are the most at risk. Typically the patient presents abruptly with syncopal episodes, palpitations, or ventricular tachycardia, often associated with exercise. Sudden death may be the initial (and final) presentation. The physical examination is usually normal. When findings are abnormal, diastolic filling sounds are most frequent (20%), and prominence of the left anterior thorax occurs in <10%. An irregular rhythm is usually found on physical examination. Presentation with right ventricular failure occurs in <2% of patients [245,246,252–254].

Diagnostic studies

Chest radiography

The chest radiograph is normal in the absence of right ventricular failure. Although a cardiothoracic ratio of >50% occurs in many older patients, it is normal in children. Pulmonary vascular markings are usually normal.

Electrocardiography

The electrocardiogram is helpful [245,246,252]. It usually shows sinus rhythm, with frequent ventricular premature depolarizations of left bundle branch block morphology. The QRS, P wave, and T wave frontal plane axes are normal. Although precordial QRS morphology is normal, a pattern of incomplete right bundle branch block is seen in >30% of patients. The most striking and constant feature is the inversion of T waves in leads V_1–V_4. Whereas this sign is highly suggestive of ARVD in the adult, it may be normal in children <12 years old. Ventricular post-excitation waves, so-called epsilon waves, are found in the ST segments of the right precordial leads in 30% of adult patients. By increasing the gain or by using signal-averaging techniques, these potentials – which arise from areas with markedly delayed depolarization – can be made visible. Epsilon waves are considered a marker for risk of re-entry tachycardia. When present, ventricular tachycardia is characterized by a left bundle branch block morphology, a rate in the range 170–300 beats per minute (average 250), with a QRS axis that is normal to rightwards.

Noninvasive imaging

Noninvasive evaluation of ventricular morphology and function is helpful but may not detect all patients in childhood [255,256]. Cardiac MRI can visualize the anatomic abnormalities, myocardial fibrosis, and inflammation. Echocardiographic imaging can show right ventricular outpouching, diffuse dysfunction, or dilation. Global dysfunction and regional wall motion abnormalities may also be identified by radionuclide angiography [246,252,256].

Cardiac catheterization

If ARVC is suspected (e.g., ventricular tachycardia in a "normal heart") and not found on MRI or echocardiography, cardiac catheterization (especially with angiography) should be considered [245,252,257]. The pressures may be normal in each cardiac chamber. If abnormal, the most common finding is an elevated right atrial *a* wave, which in patients with severe right ventricular dysfunction may exceed the pulmonary artery diastolic pressure. A right ventriculogram usually shows dyskinesis and dilation in adults but less commonly in children. Children show segmental dilation with paradoxical motion of the outflow tract. The hallmark of the disease is systolic bulging of the right ventricular free wall. The "triangle of dysplasia" includes the anterior infundibulum, the right ventricular apex, and the diaphragmatic free wall. Hemodynamic and angiographic assessment of left ventricular function should also be done. Endomyocardial biopsy of the right ventricular septum should be performed, because classic pathologic changes are seen in >90% of patients [245,252,257]. Analysis of the biopsy should include histology with appropriate staining for fibrosis and adipose/lipid infiltration, PCR analysis for viral genome, and immunohistochemistry for desmosomal and gap junction proteins.

Electrophysiologic study

Invasive electrophysiologic investigation is usually not needed for diagnosis [257–259]. Atrial and atrioventricular node conduction times are often prolonged minimally and epsilon waves can be recorded in only half the patients. Electrophysiologic testing can confirm that the tachycardia originates in the right ventricle, map the location of initiation, and evaluate response to antiarrhythmic agents. An ICD can be implanted when appropriate during the electrophysiologic study [258].

Treatment

Treatment focuses on control of the arrhythmias [257–259]. Propranolol, sotalol, procainamide, disopyramide, and amiodarone have been effective in some patients. ICD implantation has become standard in adults but has been used only in symptomatic children [258].

Natural history

The natural history of ARVC requires further study [246,252,257,258]. Although sudden death occurred in ~5%
Figure 58.8 Echocardiogram of a child with left ventricular noncompaction. This apical three-chamber view shows an apparently thick left ventricle with small left ventricular chamber. Note the apical "fill in" and the strips of muscle (trabeculations) at the free wall with intertrabecular recesses between the trabeculations (arrows). RA, right atrium; RV, right ventricle; LV, left ventricle.

of the reported patients, most were either untreated or undiagnosed. Sudden death in childhood occurs, as does death from congestive failure, but it is uncommon. There is debate whether antiarrhythmic treatment will reduce the incidence of sudden death. The usual course appears to be one of slow deterioration of right ventricular function and reduction in the efficacy of antiarrhythmic treatment.

Overlap disorders

Left ventricular noncompaction

This disorder has been named spongy myocardium, fetal myocardium, and noncompaction of the left ventricular myocardium [77,260–262]. It may represent an arrest in the normal process of myocardial compaction, the final stage of myocardial morphogenesis. The result is persistence of multiple prominent ventricular trabeculations and deep intertrabecular recesses at the LV apex and at times the free wall and septum (Figure 58.8). This cardiomyopathy may be difficult to diagnose unless there is a high level of suspicion during echocardiographic evaluation. In fact, on careful review of echocardiograms and other clinical data, it appears that left ventricular noncompaction is relatively common in children and adults [8,77].

Left ventricular noncompaction (LVNC) is a clinically heterogeneous disorder that may present with multiple different
Figure 58.9 Echocardiograms of children with left ventricular noncompaction. These apical four-chamber views show the heterogeneous phenotypes that can occur in left ventricular noncompaction. (a) LV noncompaction associated with normal LV size, thickness, and function. Note the apical and free wall trabeculations in the LV. (b) LV noncompaction associated with a dilated LV and poor systolic function (DCM form of LVNC). Note the inappropriate apical and free wall thickening in this otherwise dilated LV. (c) LV noncompaction associated with a hypertrophic LV and hyperdynamic systolic function and diastolic dysfunction (HCM form of LVNC). Note the asymmetric septal hypertrophy with midseptal bulge, apical hypertrophy/trabeculations, and free wall trabeculations. (d) LV noncompaction associated with a dilated atria and normal LV size, thickness, and systolic function (RCM form of LVNC); (e) LV noncompaction associated biventricular trabeculations. The apex of both ventricles show hypertrophic "fill in" with trabeculations and the LV free wall is also heavily trabeculated, giving the appearance of a hypoplastic LV.
Figure 58.10 Echocardiograms of a child with left ventricular noncompaction associated with congenital heart disease. The associated CHD lesion in this case is Ebstein's anomaly; note the apically displaced tricuspid valve (arrow).

features (Figure 58.9) including the following [8,77, 263,264]:

1 LV noncompaction associated with normal LV size, thickness and function occurs in ~25% of LVNC. The patients are asymptomatic and features do not change.

2 LV noncompaction associated with a dilated LV and poor systolic function (DCM form of LVNC).

3 LV noncompaction associated with a hypertrophic LV and hyperdynamic systolic function and diastolic dysfunction (HCM form of LVNC).

4 LV noncompaction associated with a hypertrophic and dilated LV with systolic dysfunction (HDCM form of LVNC).

5 LV noncompaction associated with a dilated atria and normal LV size, thickness and systolic function (RCM form of LVNC).

6 LV noncompaction associated with congenital heart disease, commonly right-sided but with a variety of other lesions (Figure 58.10).

All leads ¼ standard
Figure 58.11 Electrocardiogram in a neonate with the dilated, hypertrophic form of left ventricular noncompaction. Note the extreme mid-precordial QRS complex voltages and the short PR interval. The voltages are set at one-quarter standard.

In the isolated form and that associated with congenital heart disease, metabolic derangements may be notable. [217,261]

Clinical features of left ventricular noncompaction

Towbin recently suggested that patients with a trabeculated left ventricle be subgrouped into phenotypes and that this subdivision is important in predicting outcome [264]. In approximately 25% of patients, the size, thickness, and function of the LV are normal, and these subjects, provided that they are arrhythmia free, appear to show a benign course. The other forms are dependent on the other features regarding outcomes. When LVNC coexists with another type of cardiomyopathy as defined above, many present in infancy with signs and symptoms of heart failure but others are identified later, even in adulthood. Pignatelli *et al.* [77] reported 36 children with a median age at presentation of 90 days (range 1 day–17 years). About 40% of these children presented with low cardiac output or congestive heart failure and only one child presented with syncope. Most of the other patients (42%) were asymptomatic, but had electrocardiographic or radiographic abnormalities. In an infant with LVNC, the ECG may show giant QRS complexes sometimes with pre-excitation (Figure 58.11). In addition, 14% of the 36 children had associated dysmorphic features and 19% of affected children had first-degree relatives with cardiomyopathy. The children who died each had a systemic disease and died in the first 3 months of life. Thromboembolic phenomena, including stroke, also occur in patients with LVNC [263]. Whether the disease in adults differs from that in children is unknown [265].

Genetics of left ventricular noncompaction

LVNC commonly has X-linked recessive or autosomal dominant inheritance [5,8,263,264]. In X-linked LVNC, female carriers do not develop frank clinical disease and their echocardiograms are normal. Consistent with X-linked inheritance, no male-to-male transmission of the disease occurs. In most patients with LVNC associated with CHD, autosomal dominant inheritance is seen in familial instances and less often in LVNC without CHD. When LVNC is associated with CHD, the CHD may be heterogeneous in families. In some of these, affected members may be identified with "minor" forms of CHD, which have spontaneously improved, whereas others have severe CHD. Penetrance may be reduced in some families and both autosomal dominant and X-linked inheritance have been described [263].

Molecular genetics of left ventricular noncompaction

A genetic cause of isolated LVNC was initially described by Bleyl *et al.* [18] when they identified mutations in the gene G4.5/TAZ in patients and carrier females. This gene, known as G4.5 or tafazzin (TAZ), encodes a novel protein family (tafazzins) with unclear function, and is also responsible for Barth syndrome (BTS) [76] and other forms of infantile cardiomyopathies [266,267]. BTS, a clinical association of myocardial dysfunction with a number of other features [53,73,74,268], was discussed above. It is an X-linked disorder and may be allelic to several phenotypically different disorders on Xq28 [269,270] such as LVNC and dilated cardiomyopathy. Congenital heart defects have not been associated with BTS or other G4.5-associated disease.

For autosomal dominant LVNC, multiple genes have been identified, including mutations in α-dystrophobrevin [271],

mutations in the Z-line protein encoding ZASP, located on chromosome 10q22 [12], mutations in sarcomere-encoding genes, mutations in β-myosin heavy chain (MYH7), α-cardiac actin (ACTC), and cardiac troponin T (TNNT2) [272], sarcomere-encoding genes and the cytoskeleton, and mutations in the sodium channel gene, SCN5A [273]. A cytoskeletal protein associated with LVNC is dystrophin in Duchenne and Becker muscular dystrophy [274]. Skeletal muscle biopsy has, in some patients, identified mitochondrial abnormalities, suggesting a nuclear import protein as the primary abnormality. Genetic testing can identify a disease-causing mutation in ~40% of these patients [275,276].

Therapy and outcome

The specific therapy [277–279] depends on the specific clinical and echocardiographic findings of the phenotypic subtype of LVNC [264], and these have been discussed above under the specific type of cardiomyopathy. In patients with forms of noncompaction with associated mitochondrial or metabolic dysfunction, some investigators add a "vitamin cocktail" to the cardiac therapy, with coenzyme Q10, carnitine, riboflavin, and thiamine commonly used alone or in combination [8,34,102,217,264].

In patients with associated congenital heart disease undergoing catheter intervention or surgical repair [280], the cardiac functional abnormalities must be understood, evidence of thrombi (which should be treated with anticoagulation) sought, cardiac rhythm disturbances addressed [264], and the metabolic status of the patient attended to.

59 Pericardial Diseases

Jonathan N. Johnson & Frank Cetta

Mayo Clinic College of Medicine, Mayo Clinic, Rochester, MN, USA

Introduction

Normal anatomy and physiology

The normal pericardium has two primary layers, the visceral pericardium and the parietal pericardium. The visceral pericardium, or epicardium, is a single serous layer covering the surface of the heart and proximal great vessels (Figure 59.1). The parietal pericardium has three layers, the innermost serous layer being continuous with the serous visceral pericardium. The space between the two serous layers is termed the pericardial space or cavity, and contains a small amount of serous fluid for lubrication (<20–30 ml in adults). The middle layer of the parietal pericardium is fibrous tissue and the outer layer is epicardial connective tissue, largely collagenous. The pericardium obtains its arterial blood supply from the internal mammary artery and descending aorta, and is innervated by the phrenic and vagus nerves. It is anchored within the thoracic cavity with attachments inferiorly to the diaphragm and a portion of the inferior vena cava, and posteriorly to the esophagus, aorta, pulmonary veins, and thoracic vertebrae [1].

The pericardium provides a mechanical barrier for the heart, protecting it from the spread of inflammatory, infectious, and neoplastic diseases from contiguous structures. The small amount of normal pericardial fluid allows free movement during the cardiac cycle. The pericardium limits acute distension of the heart, and therefore diastolic volume. It also allows diastolic coupling of the two ventricles, whereby filling pressure abnormalities of one ventricle affect the other. Slow accumulation of fluid within the pericardium is well tolerated by stretching and growth of the parietal pericardium, but rapid accumulation of even a small amount of fluid is typically poorly tolerated.

This chapter discusses the clinical features and etiology of acute pericarditis and associated pericardial effusion, congenital anomalies of the pericardium, and constrictive pericarditis.

Acute pericarditis

Clinical history

Children and adolescents with acute pericarditis of any etiology commonly present with precordial or substernal chest pain that is described as squeezing, sharp, or dull. It is typically worse when supine and the patient may refuse to lie down for the examination, preferring to sit upright and lean forward. The pain is worse with inspiration, coughing, and movement [2]. Younger children may present without typical chest pain symptoms. Respiratory distress is uncommon unless cardiac tamponade or pulmonary disease is present. Abdominal pain is rare, but can result from hepatic distension in patients with a fast-accumulating effusion and tamponade.

Physical examination

The pathognomonic physical finding of acute pericarditis is a friction rub, a high-frequency, scratching/sandpaper-like sound caused by friction between the inflamed pericardial surfaces. The rub is heard in systole and diastole, may be intermittent, and is best heard at the left sternal border or the apex. It is loudest when the heart is closest to the chest wall as when the patient leans forward, kneels, and/or inspires [2]. The absence of the rub does not exclude pericarditis, particularly with a large effusion, and then the heart sounds may be muffled. Fever, if present, is largely nonspecific.

Cardiac tamponade is compression of the heart from the fluid-filled pericardial cavity, restricting atrial and ventricular

Figure 59.1 Cadaveric heart specimen, showing the heart within the pericardial cavity (left) and the bilayered pericardium with the heart removed (right). (Courtesy of Dr. William D. Edwards, Division of Anatomic Pathology, Mayo Clinic, Rochester, MN, USA.)

filling and decreasing cardiac output [3]. Tamponade may result from either a sudden increase in pericardial volume or from gradual increases in pericardial volume beyond the point of potential pericardial distention. On physical examination, tamponade is characterized by Beck's triad of hypotension, distant heart sounds, and elevated central venous pressure with jugular venous distension [3]. Patients also have tachycardia, tachypnea, narrow pulse pressure, and pulsus paradoxus. Initially, cardiac output is maintained by increasing heart rate and ejection fraction. As the tamponade worsens and these mechanisms no longer maintain cardiac output, systemic vascular resistance increases to maintain blood pressure, narrowing pulse pressure and compromising systemic perfusion. Ultimately, coronary perfusion pressure falls, causing decreased myocardial function, decreased cardiac output, and hypotension [3].

Pulsus paradoxus in tamponade is an exaggerated decrease in blood pressure of >10 mmHg during inspiration. During normal inspiration, the systolic blood pressure decreases slightly because of increased capacity of the pulmonary venous bed and decreased intrathoracic pressure. With a significant pericardial effusion, the left ventricular diastolic volume and output are restricted by increased pericardial pressure, decreased pulmonary venous return, and shifting of the intraventricular septum to the left; consequently, blood pressure decreases to a greater extent in inspiration. (The paradox is that with inspiration in severe tamponade, the pulse may disappear but the cardiac impulse indicates a heart beat.) To measure pulsus paradoxus, the patient is placed supine. A blood pressure cuff is inflated until the radial pulse is no longer palpable. With slow release of cuff pressure, the initial Korotkoff sounds are listened for. With inspiration, the Korotkoff sounds disappear, particularly if pulsus paradoxus is present. Cuff pressure should be slowly released until the Korotkoff sounds are heard throughout the respiratory cycle. The pressure difference between when the auscultator hears the first Korotkoff sound and when it is heard on each heart beat is the pulsus. Normally, the pressure difference is ~5 mmHg during inspiration. If the pressure difference exceeds 10 mmHg, pulsus paradoxus is present.

Chest radiography

A normal heart size does not exclude pericarditis or pericardial effusion; tamponade can occur in patients with a "normal-sized" cardiac silhouette. With a large effusion, the cardiac silhouette commonly assumes a triangular or "water-bottle" shape, with normal pulmonary vascular markings (Figure 59.2). Chronic pericarditis may show pericardial calcifications (Figure 59.3). The chest radiograph may suggest a cause of pericarditis, with findings of bacterial pneumonia, tuberculosis, or neoplastic disease.

Electrocardiography

Electrocardiographic changes in pericarditis can be secondary to either direct inflammation of the epicardium, or pressure exerted on the epicardium by pericardial fluid. Acute pericarditis is the most frequent cause of ST segment elevation in children. Low QRS voltages can be seen in all leads with chronic pericarditis or a large pericardial effusion. Electrical alternans, a cyclical variation of the QRS amplitude, may occur secondary to the pendular motion of the heart with a large pericardial effusion (Figure 59.4).

Four stages of electrocardiogram (ECG) changes in pericarditis have been reported [4]. Stage 1 consists of ST segment elevation in the lateral leads (I, II, AVF, V4–V6), thought to be due to subepicardial myocarditis (Figure 59.5). A ratio of ST segment elevation (mm) to T-wave amplitude (mm) greater than 0.25 is predictive of pericarditis, and helps differentiate pericarditis from myocardial infarction [5]. Reciprocal ST depression occurs in leads AVR and V1. The T-waves remain normal, and PR depression can occur if atrial tissue is inflamed. In stage 2, the ST segment becomes isoelectric, and the amplitude of the T-wave diminishes. The PR segment becomes more depressed. In stage 3, the ST segment remains normal, but the T-waves become inverted in the lateral leads. Stage 4 shows normalization of the ECG, although some T-wave changes may persist.

Echocardiography

Echocardiography is the primary tool for diagnosis and monitoring pericardial effusions, which appear as an echo-free space adjacent to the heart [6] (Figure 59.4). Fibrinous strands may be noted in the pericardial space on two-dimensional imaging, and can be seen in postmortem specimens (Figure 59.6). Additionally, echocardiography helps detect other structural and myocardial causes of cardiomegaly. Pericardial effusions may be detected by fetal echocardiography, and are associated with hydrops fetalis [7].

With a supine patient, a small effusion is commonly seen posteriorly, and only be detectable in systole. A tiny pericardial
Figure 59.2 Chest radiogram of a 2-year-old female with immune deficiency after she presented with tachypnea, including the AP (a) and lateral (b) views. The patient required an emergency pericardiocentesis, after which (c) her cardiothymic silhouette had markedly decreased in size.
Figure 59.3 Chest radiogram of an adult patient with chronic pericarditis and resultant calcification of the pericardial space. (Courtesy of Dr. William D. Edwards, Division of Anatomic Pathology, Mayo Clinic, Rochester, MN, USA.)

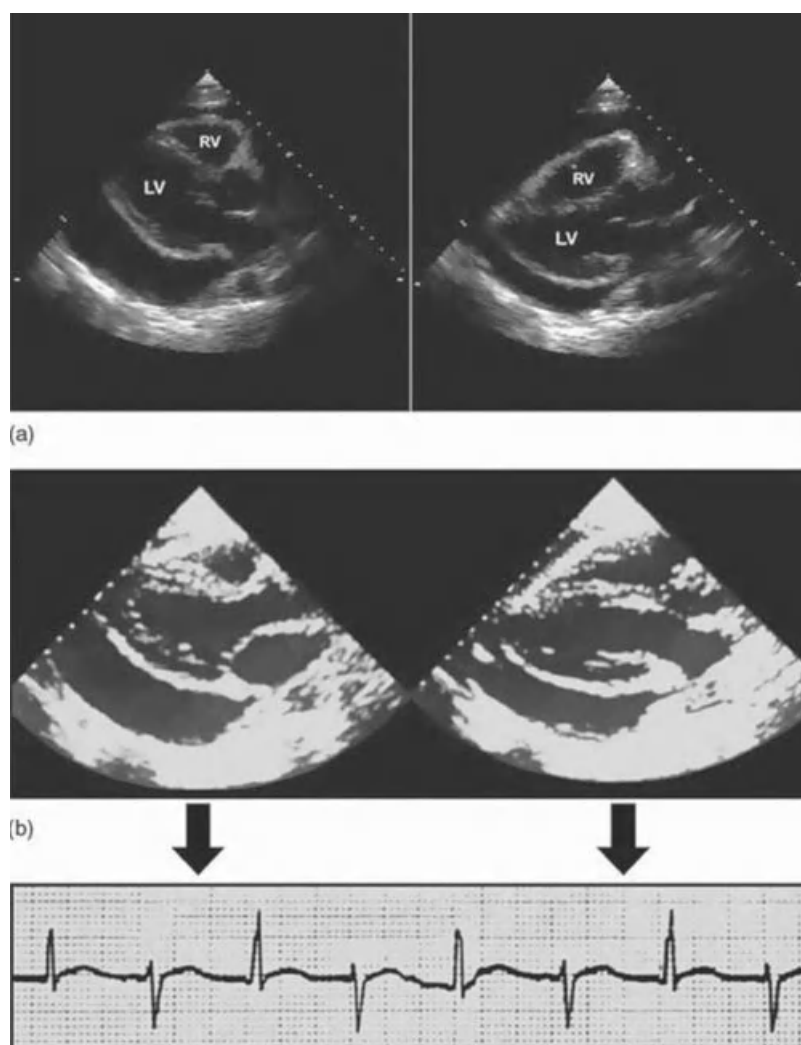
space posteriorly in systole may be completely normal. In an adult, an effusion >25 ml is observed in both systole and diastole (Figure 59.7) [8]. With a larger effusion volume, fluid may be detected both anteriorly and posteriorly. In large effusions, the heart may swing to-and-fro within the pericardial cavity (Figure 59.4, Videoclips 59.1 and 59.2). This swinging motion may also be seen on M-mode echocardiography (Figure 59.8). The first sign of the hemodynamic impairment in tamponade is collapse of the right ventricular free wall in early to mid diastole (Figure 59.9) [8]. The right


Figure 59.4 Parasternal long-axis echocardiographic views, demonstrating (a) a large effusion with swinging motion of the heart. This swinging motion may be an ominous sign of cardiac tamponade. (b) When the left ventricle is close to the sternum, the QRS voltage increases on the ECG, but it decreases when the left ventricle swings away from the surface, producing electrical alternans. ECG, electrocardiogram; LV, left ventricle; RV, right ventricle. (Adapted from Oh *et al.*, *The Echo Manual*, 2006, with permission from Lippincott Williams & Wilkins.)

atrium may invert in late diastole. The inferior vena cava may be dilated without normal inspiratory variation, and the ventricular septum may have abnormal motion described as a "bounce," where the septum shifts leftwards with right ventricular filling during inspiration. It then shifts back rightwards with expiration with the improved left ventricular filling.

Clues about etiology may be discovered. A clot in the pericardial space suggests hemopericardium. Air in the pericardium (pneumopericardium) can occur in patients with esophageal perforation. Adhesions or metastases may also be seen in the pericardial space.

Doppler echocardiography of the heart provides an excellent understanding of tamponade physiology (Figure 59.10). During inspiration, there is an exaggerated decrease in the mitral inflow velocity (E velocity) and velocity–time integral by an average of 35%, with a relatively increased atrial component (A velocity). Conversely, there is an exaggerated increase in tricuspid inflow velocity (tricuspid E velocity) and velocity–time integral by an average of 80% during inspiration [9]. The aortic and pulmonary outflow changes mirror those of their respective AV valves.

Cardiac catheterization

With large accumulations of pericardial fluid, diastolic pressures rise in all four chambers of the heart, and ultimately equalize. Right ventricular and pulmonary artery pressures may be elevated. Pulsus paradoxus can be seen on femoral artery and right atrial tracings [10]. The role of cardiac catheterization in differentiating between constrictive pericarditis and restrictive cardiomyopathy is discussed below.

Other imaging modalities

In assessing pericardial effusion, computed tomography (CT) and magnetic resonance imaging (MRI) may not add substantially to the evaluation. However, CT is helpful in evaluating constrictive pericarditis, as it can identify calcification, pericardial thickening, or other pericardial masses, including
Figure 59.5 Electrocardiogram of a 17-year-old male several days after atrial septal defect repair. Note the diffuse ST segment changes including ST segment elevation in the lateral precordial leads.
Figure 59.6 Cadaveric adult heart specimen, showing the heart within the pericardial space with a large effusion. Fibrinous stranding can be seen within the pericardial space. (Courtesy of Dr. William D. Edwards, Division of Anatomic Pathology, Mayo Clinic, Rochester, MN, USA.)

neoplasias. Additionally, MRI and CT are valuable in evaluating pericardial cysts and absence of the pericardium [11].

Management of tamponade

If a child presents with cardiac tamponade, intravenous fluid should be given immediately to increase the diastolic filling pressure temporarily and provide stabilization. Medications that lower systemic pressure, including vasodilators and diuretics, should be avoided. Pericardiocentesis should be performed in patients with clinical tamponade (low cardiac output, hypotension, or pulsus paradoxus >10 mmHg), and in those with suspected bacterial pericarditis, immunocompromised hosts, or for diagnosis when the etiology of an effusion is unclear [12,13].

Pediatric Cardiovascular Medicine
Figure 59.8 M-mode echo image showing a large pericardial effusion (*) anterior and posterior to the heart. Note the swinging motion of the heart evident in the M-mode signal.

Figure 59.9 Right ventricular collapse in early diastole in a patient with tamponade. Note that in the upper echo image in systole (a), the full four-chamber view is noted, and in the lower echo image in diastole (b), the right ventricular free wall is compressed (arrows).

Ideally, pericardiocentesis should be performed either in an intensive care unit, operating room, or cardiac catheterization laboratory. The patient should be placed in a 30° head-up position and be sedated, with continuous heart rate, blood pressure, and pulse oximetry measurements. The needle is introduced subxiphoid and advanced towards the left shoulder. Echocardiographic guidance allows for more accuracy, but is unnecessary in an emergency [13]. In most patients, a drainage catheter should be placed for at least 48 h due to the likelihood of recurrence of effusion [12]. Potential risks of the procedure include arrhythmias, myocardial puncture, coronary artery or vein laceration, hemopericardium and recurrent tamponade, pneumothorax, aortic or internal mammary artery injury, hepatic laceration, and death [13].

Aspirated pericardial fluid should be analyzed for cell count with differential, glucose and protein concentrations, Gram and acid-fast bacilli stains, bacterial, viral and fungal cultures, and microscopic analysis. Specific bacterial or viral-specific antigens may be assessed with polymerase chain reaction (PCR) studies and latex agglutination studies. A high triglyceride level is diagnostic for a chylopericardium. An adenosine deaminase activity level can be obtained if there is concern about tuberculous pericarditis [14].

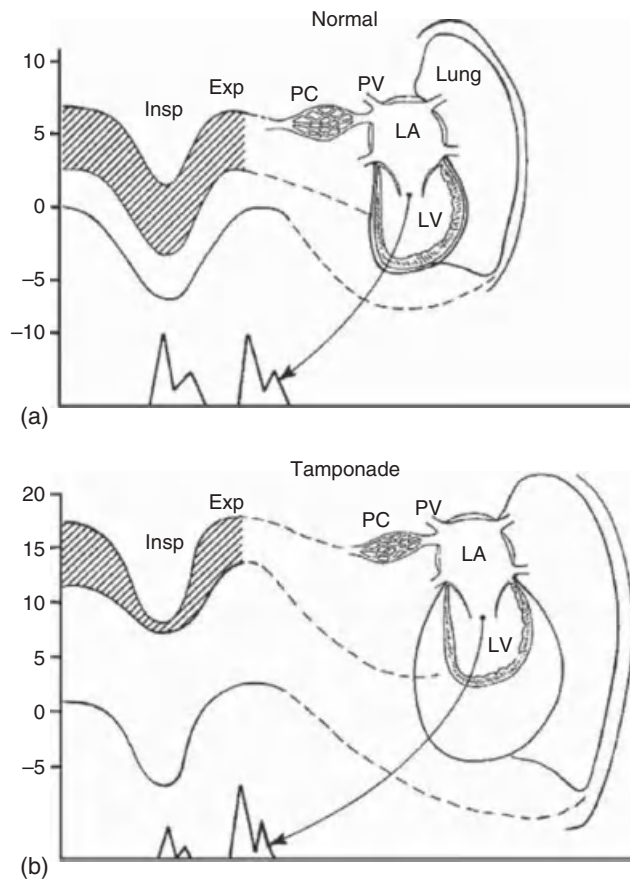
Sometimes the purulent material may be too thick to drain, or may be loculated. Then, instead of attempting a repeat pericardiocentesis, an operation should be performed. The surgical approaches (thoracotomy, subxiphoid, and thorascopic) and the extent of pericardium removal (complete/partial pericardiectomy or pericardial window) vary, but all are effective [15].


Figure 59.10 Diagram of intrathoracic and intracardiac pressure changes with respiration in (a) normal and (b) tamponade physiology. The shaded area indicates left ventricular filling pressure gradients (difference between pulmonary capillary wedge pressure and left ventricular diastolic pressure). At the bottom of each drawing is a schematic mitral inflow Doppler velocity profile. In tamponade, there is an inspiratory decrease in left ventricular filling because the pressure decrease in the pericardium and left ventricular cavity is smaller than the pressure drop in the pulmonary capillaries. Left ventricular filling is restored after expiration. LA, left atrium; LV, left ventricle; PC, pulmonary capillaries; PV, pulmonary vein. (Adapted with permission from Sharp, JT et al. Am J Med 1960;**29**:640–646.)

Etiology

Viral pericarditis

Viral pericarditis is the most common form of childhood pericarditis. Patients commonly present 10–14 days following an upper respiratory or gastrointestinal infection, with classic precordial chest pain and friction rub. Fever is typically present, and patients may complain of abdominal pain. Patients with viral pericarditis generally appear less toxic than those with bacterial pericarditis; however, concomitant myocarditis may worsen the clinical picture of a patient with a viral etiology. Tamponade is rare; however, patients should be monitored closely after initial diagnosis. The most common viral causes of pericarditis are listed in Table 59.1.

Table 59.1 Viral causes of pericarditis.

Enterovirus (primarily Coxsackie B)	Measles
Adenovirus	Cytomegalovirus (CMV)
Influenza virus (A and B)	Respiratory syncytial virus (RSV)
Rubella	Herpes simplex
Mumps	Hepatitis B
Epstein–Barr	HIV

Pericardial fluid is typically serous or serosanguineous, and shows a predominance of lymphocytes, although neutrophils are more common in early stages of pericarditis. Viral cultures can be obtained from pericardial fluid, nasopharynx, or stool, and PCR studies may assist in determining a specific viral cause. Coxsackievirus is the most frequently isolated virus in children with pericarditis, although numerous enteroviruses have been implicated (Table 59.1). [16].

Treatment is symptomatic, including bed rest and oral nonsteroidal anti-inflammatory drugs (NSAIDs). If anti-inflammatory agents are insufficient, steroidal therapy may be considered, but only if bacterial causes have been excluded. Resolution typically begins in days and is complete in <1 month. A few patients relapse and improve with retreatment. Constrictive pericarditis is a rare late sequela.

Bacterial pericarditis

Bacterial pericarditis, although less common, is serious and life-threatening. It occurs most commonly before 2 years of age [17]. Patients present with classic symptoms of precordial chest pain, friction rub, and muffled heart sounds, but often are in extremis, with decreased cardiac output. Markedly elevated fever is common and associated with dyspnea, tachypnea, and tachycardia out of proportion with the degree of fever. Often bacterial pericarditis results from a disseminated infection, either by a hematogenous route or by direct contact, most commonly from the lung. Septic arthritis, osteomyelitis, meningitis, or soft-tissue infection may also be the source [17,18].

The pericardial fluid shows a marked predominance of neutrophils, and cultures are typically positive for the causative organism. If antibiotics have been given before procuring a sample, latex agglutination studies of the pericardial fluid, serum, or urine may help diagnose the organism. *Staphylococcus aureus* is currently the most common bacterium isolated in bacterial pericarditis, accounting for half of these episodes [17], and is the most common cause of bacterial pericarditis occurring within 3 months of a cardiac operation. Anaerobic bacteria should be considered in children with an associated lung abscess, abdominal infection, or blunt chest trauma. Potential bacterial causes of pericarditis are listed in Table 59.2.

Antibiotic treatment alone is not sufficient for cure; all patients with evidence of bacterial pericarditis should

Table 59.2 Bacterial causes of pericarditis.

Staphylococcus aureus	Chlamydia psittaci
Haemophilus influenzae	Nocardia asteroides
Streptococcus pneumoniae	Brucella
Other Streptococcus species	Yersinia
Neisseria meningitidis	Salmonella
Neisseria gonorrhoeae	Actinomyces
Campylobacter fetus	Mycobacterium tuberculosis
Pseudomonas aeruginosa	Escherichia coli
Mycoplasma pneumoniae	Listeria monocytogenes
Mycoplasma hominis	Pasteurella multocida
Legionella	Klebsiella
Francisella tularensis	Anaerobes

undergo percutaneous or surgical drainage of the pericardial cavity. A surgically created window or pericardiectomy is necessary if the purulent pericardial fluid cannot be aspirated via pericardiocentesis [15]. Intrapericardial streptokinase may improve drainage [19]. Broad-spectrum antibiotics directed towards the most commonly affecting organisms, *Staphylococcus aureus* and *Haemophilus influenzae*, should be administered, and should include an intravenous penicillinase-resistant penicillin (nafcillin or oxacillin) or vancomycin in patients at risk for methicillin-resistant *S. aureus*, in addition to a third-generation cephalosporin (ceftriaxone, cefotaxime). An aminoglycoside can be added in immunocompromised patients. Specific therapy is designated once specific culture and sensitivity results are known. Most patients require 3–4 weeks of intravenous antibiotic treatment [19].

Survival in patients with bacterial pericarditis has improved considerably, and mortality is currently <10% [19,20]. Risk factors for a poor outcome include delay in diagnosis, failure to initiate early surgical intervention, inadequate drainage, myocardial involvement, tamponade, septicemia, younger age, and staphylococcal disease [19,20]. Constrictive pericarditis occurs rarely after recovery [18,19], most commonly following *S. aureus*, *H. influenzae*, or *Streptococcus pneumoniae* infection.

Tuberculous pericarditis

Once a common cause of pericarditis in the United States, *Mycobacterium tuberculosis* pericarditis now occurs primarily in developing countries. The onset is typically insidious, with weight loss, malaise, low-grade fever, night sweats, dyspnea, and chest pain. The presentation may also be subacute, complicated by pericardial tamponade. Tuberculous pericarditis often occurs secondary to miliary tuberculosis with direct extension or lymphatic spread into the pericardium. Hematogenous spread may occur without obvious pulmonary infiltrates.

Most patients have a positive Mantoux skin test. The pericardial fluid is typically serosanguinous or hemorrhagic, with a lymphocytic predominance. Acid-fast bacilli may be seen on auramine–rhodamine fluorescent-stained smears, but are present in <50% of patients [14]. Pericardial biopsy is useful and provides histologic confirmation of tuberculous infection. Elevated pericardial adenosine deaminase levels >50 U l⁻¹ may be diagnostic [14]. Mycobacterium cultures often take up to 6 weeks to grow, hence treatment must begin before culture confirmation of diagnosis. For pulmonary tuberculosis, PCR techniques, which have been developed, can make the diagnosis rapidly and with a high degree of sensitivity and specificity.

Multi-drug therapy is the mainstay of treatment, because of the risk of drug resistance. A regimen of rifampicin, isoniazid, pyrazinamide, and ethambutol for ≥2 months, followed by isoniazid and rifampicin for a further 4 months, is highly effective. A 1–2-month course of steroid therapy may be used to reduce inflammation and increase resorption of pericardial fluid. Tuberculosis is a common cause of chronic pericardial effusion. Tuberculous pericarditis is one of the leading causes of constrictive pericarditis worldwide [14]. Pericardiectomy may be difficult because of diffuse inflammatory and caseous material. Some surgeons delay pericardiectomy for at least 6–12 weeks, although this is controversial.

HIV and other infections

Pericardial effusions have been reported in 25% of children with HIV infection [21], but rarely cause tamponade. Pericardial fluid cultures are usually negative. Pericardial effusions commonly coexist with pleural effusions and ascites. Patients with a compromised immune system, including those with HIV, are at risk for fungal or parasitic pericarditis (Table 59.3). In the developing world, concurrent infection with HIV and tuberculosis is common, and HIV is a major risk factor for developing tuberculous pericarditis with effusion [14].

Other causes of pericardial effusion

Renal failure

Pericarditis is observed in 10% of patients with chronic renal failure [22]. The levels of creatinine and blood urea nitrogen (BUN) do not predict the likelihood of pericarditis. It occurs more commonly with concurrent systemic lupus erythematosus (SLE) or treatment with hydralazine for hypertension. Most effusions resolve with efficient dialysis [22]. Pericardial fluid is typically serous, but with heparinization may be bloody from pericardial hemorrhage that can result in tamponade. NSAIDs can be given for chest pain, but typically do not reduce effusion size. Pericardiocentesis should be performed for the usual indications. If dialysis fails to

Spirochetal	Syphilis, leptospirosis
Rickettsial	Typhus, Q fever
Fungal	*Candida, Aspergillus, Blastomyces, Coccidioides, Histoplasma, Cryptococcus*

resolve the effusion, surgery may be indicated, particularly if constriction develops [22].

Kawasaki disease

During the acute phase of Kawasaki disease, one-third of patients have a pericardial effusion, but this typically resolves within 2 weeks and is unlikely to progress to tamponade [23].

Drug-induced pericarditis

A lupus-like drug reaction occurs in some patients treated with specific medications, most commonly hydralazine, isoniazid, procainamide, and phenytoin. Antinuclear antibodies are commonly elevated in these patients. Rarer causes are cyclosporine, methysergide, and chemotherapeutic agents such as cyclophosphamide, doxorubicin, and dactinomycin. Pericarditis occurs with the inflammatory reaction but rarely progresses to tamponade [24]. Treatment includes removal of offending medications and giving NSAIDs. Anticoagulants and thrombolytics may cause pericardial hemorrhage in an inflamed pericardial cavity, and lead to adhesions and eventual constriction. Hypersensitivity reactions to penicillin and cromolyn sodium have been associated with pericardial effusion [25,26].

Hypothyroidism

Pericardial effusion occurs in 80% of patients with myxedema, but rarely with mild hypothyroidism [27]. It is generally asymptomatic. Tamponade is rare because of the slow fluid accumulation [27]. Unlike others with a pericardial effusion, these patients are bradycardic. The pericardial fluid shows elevated protein and mucopolysaccharides [27]. With thyroid hormone replacement, the effusion resolves gradually.

Chylopericardium

Chylous pericardial effusion occurs following congenital heart surgery, especially with trauma to the thoracic duct or elevated central venous pressures [28]. Other causes are mediastinal masses obstructing lymphatic drainage, cystic hygromas, radiation therapy, and pancreatitis, or it may be idiopathic. There is often a concurrent chylous pleural effusion. The pericardial fluid is milky colored, having markedly elevated triglyceride and protein levels. Treatment includes a low-fat or medium-chain triglyceride diet, started after a period of parenteral nutrition without oral intake to allow resolution of the effusion. Treatment of the underlying cause should be applied, including therapy to lower the central venous pressure if this is causing the effusion. Persistent chylous effusions can be treated using thoracic duct ligation, or palliated with a pericardial window, pericardiectomy, or placement of a pericardio–peritoneal or pleuro–peritoneal shunt [28]. Intravenous octreotide has been used with some success in patients with chronic chylous pleural effusions [29].

Trauma

Blunt and penetrating cardiac trauma can cause a hemorrhagic pericardial effusion. The usual Beck's triad of symptoms rarely occurs. Echocardiography is diagnostic. Symptomatic trauma patients require emergency pericardiocentesis. Hemopericardium can also occur with placement or passage of catheters, pericardiocentesis, and placement of pacemaker leads. These types of pericardial trauma require an operation to identify and repair the rupture in the cardiac wall.

Neoplastic disease

Primary pericardial tumors are rare in children and include lymphoma, malignant teratoma, mesothelioma, and angiosarcoma. Metastatic tumors are more common and include Hodgkin disease, non-Hodgkin lymphoma, leukemia, neuroblastoma, Wilms tumor, and sarcomas of the soft tissue and bone [30].

Several non-malignant congenital intrapericardial lesions exist. These include pericardial cysts, extra-lobar pulmonary sequestrations, cystic lymphangioma, bronchogenic cysts, and pericardial teratomas [31,32]. Teratomas in particular can be large and cause hydrops fetalis. Surgical excision of these large tumors is typically curative [32].

Pericardial effusions may occur with a malignancy, independent of the primary tumor. This may be due to infectious causes, or secondary to metastatic invasion of pericardial lymphatics. Pericarditis can occur after treatment with certain chemotherapy agents. Pericardial involvement after chemotherapy is more common in patients receiving mediastinal irradiation. Pericardial fluid, if available, should be sent for cytologic analysis and culture.

Treatment regimens for Hodgkin disease and breast cancer have traditionally used mediastinal radiation. Up to 5% of patients who have received mediastinal irradiation develop pericarditis from 2 months to 2 years after the treatment, an effect that is dose related [5]. The pericarditis may be asymptomatic or lead to fulminant constrictive pericarditis. Most resolve with NSAIDs, but pericardiocentesis may be needed. Pericardiectomy or steroids may be required for recurrent effusions [33].

Postpericardiotomy syndrome

Postpericardiotomy syndrome is characterized by low-grade fever beyond the first week following intracardiac or pericardial surgery, although it may recur weeks to years later. Pericardial and pleural inflammation and effusions cause typical chest pain. Postpericardiotomy syndrome occurs as a single episode in up to 40% of patients following operation [34]. Children <2 years old, although rarely affected, show irritability, malaise, decreased appetite, and arthralgias. There is a friction rub, tachycardia, and fluid retention indicated by weight gain and hepatic congestion. Tamponade is rare, but must be considered and ruled out.

Postpericardiotomy syndrome is likely due to an autoimmune reaction. Similar pericardial effusions have been noted after blunt cardiac trauma, pacemaker lead placement, and in Dressler syndrome (postmyocardial infarction syndrome) [35]. Postpericardiotomy syndrome may occur after any cardiac surgery, but is more frequent after repair of tetralogy of Fallot, ventricular septal defect, and atrial septal defect [34]. It also occurs in half of children after cardiac transplantation [36]. Laboratory evaluation reveals nonspecific indicators of inflammation, including elevated erythrocyte sedimentation rate, C-reactive protein, and white blood cell count. Echocardiography may reveal an effusion that typically reaches maximum size by postoperative day 10 [34].

Postpericardiotomy syndrome is a benign, self-limited illness. Treatment consists of diuretics for fluid retention and anti-inflammatory medications, with pericardiocentesis performed for a symptomatic effusion [37]. Aspirin remains the primary anti-inflammatory medication, typically 30–75 mg kg^{-1} per day in four divided doses for 4–6 weeks, and then tapered. In patients with a large effusion or refractory to NSAIDs, prednisone (2 mg kg^{-1} per day, maximum dose 60 mg daily, for 1 week with a 3–4 week taper) can be effective. Although tamponade is rare, patients may require pericardiocentesis, and pericardiectomy in those with recurrent effusions [37].

Autoimmune and connective tissue diseases

Pericarditis and pericardial effusions occur in many autoimmune and connective tissue diseases. Approximately 25% of patients with systemic lupus erythematosus and 10% with juvenile rheumatoid arthritis develop pericarditis. Less common causes include dermatomyositis, periarteritis nodosa, mixed connective tissue disease, Wegener granulomatosis, Takayasu arteritis, inflammatory bowel disease, and spondyloarthropathies. Oral NSAIDs are effective treatment. Pericardiocentesis may be needed [38]. Short courses of steroids may also assist in resolving symptoms [39]. Pericarditis may develop in patients with acute rheumatic fever [40] (see Chapters 61 and 62).

Recurrent and chronic pericarditis

Recurrent pericarditis is intermittent pericardial inflammation due to relapsing of the underlying disease, or reaccumulation of pericardial fluid after discontinuing medical therapy [41]. It occurs most commonly with postpericardiotomy syndrome, juvenile rheumatoid arthritis, or systemic lupus erythematosus. Treatment includes NSAIDs, colchicine, and oral steroids. Patients improve with immune modulators including azathioprine and cyclophosphamide. Pericardiectomy may be performed for numerous recurrences.

Chronic pericarditis refers to symptoms lasting >3 months, typically with heart failure or systemic inflammatory disease (see above). Standard medical and surgical treatment is used for symptomatic patients [42]. Intravenous immunoglobulin has been used with encouraging results.

Congenital abnormalities of the pericardium

Absence of the pericardium

Complete or partial absence of the pericardium is rare, and usually identified incidentally at autopsy or surgery. Most patients with partial absence have a left-sided defect [43]. One-third of patients have an associated cardiac or pulmonary (sequestration, or bronchogenic cyst) anomaly. Although typically asymptomatic, patients may have nonspecific symptoms including chest pain, lightheadedness, or dyspnea. Sudden death due to herniation of the left atrium, left atrial appendage, or right atrium through the defect is rare [43]. Compression of a coronary artery and torsion of the great vessels may also occur.

Physical examination is nonspecific, but may demonstrate a leftward shift of the apical impulse. Chest radiography reveals leftward shift of the heart. Echocardiography will not delineate the exact diagnosis, but may show unusual scanning windows, cardiac hypermobility, and abnormal ventricular motion [44]. The entire heart is shifted to the left, and thus the right ventricular cavity appears enlarged from the standard parasternal windows [8]. CT and MRI are diagnostic because they can delineate the absence of pericardial tissue [11].

Treatment depends on symptoms and the defect's anatomy. In patients with herniation of atrial tissue, or a small defect where future herniation is possible, surgical repair is indicated [43]. The defect can be either closed or enlarged. Complete absence of the pericardium usually causes no symptoms and requires no treatment.

Pericardial cysts

These are congenital anomalies resulting from failure of fetal lacunae to coalesce into the pericardial coelom. Most patients are asymptomatic, and cysts are usually discovered
Figure 59.11 Chest radiography (a) and computed tomography scans (b–d) of a patient with a coarctation of the aorta and incidentally discovered pericardial cyst (arrow, *).

incidentally on chest radiography. They can occur anywhere on the pericardium, and can become infected or compress bronchi. Rarely, patients present with chest pain, dyspnea, or cough [45]. Due to the benign nature of the lesion, no treatment is indicated. Because they present as a thoracic mass, neoplasm or infection must be excluded. CT and MRI help confirm the diagnosis (Figure 59.11) [11]. On echocardiogram, they appear as echo-free spaces adjacent to the heart (Videoclip 59.3).

Constrictive pericarditis

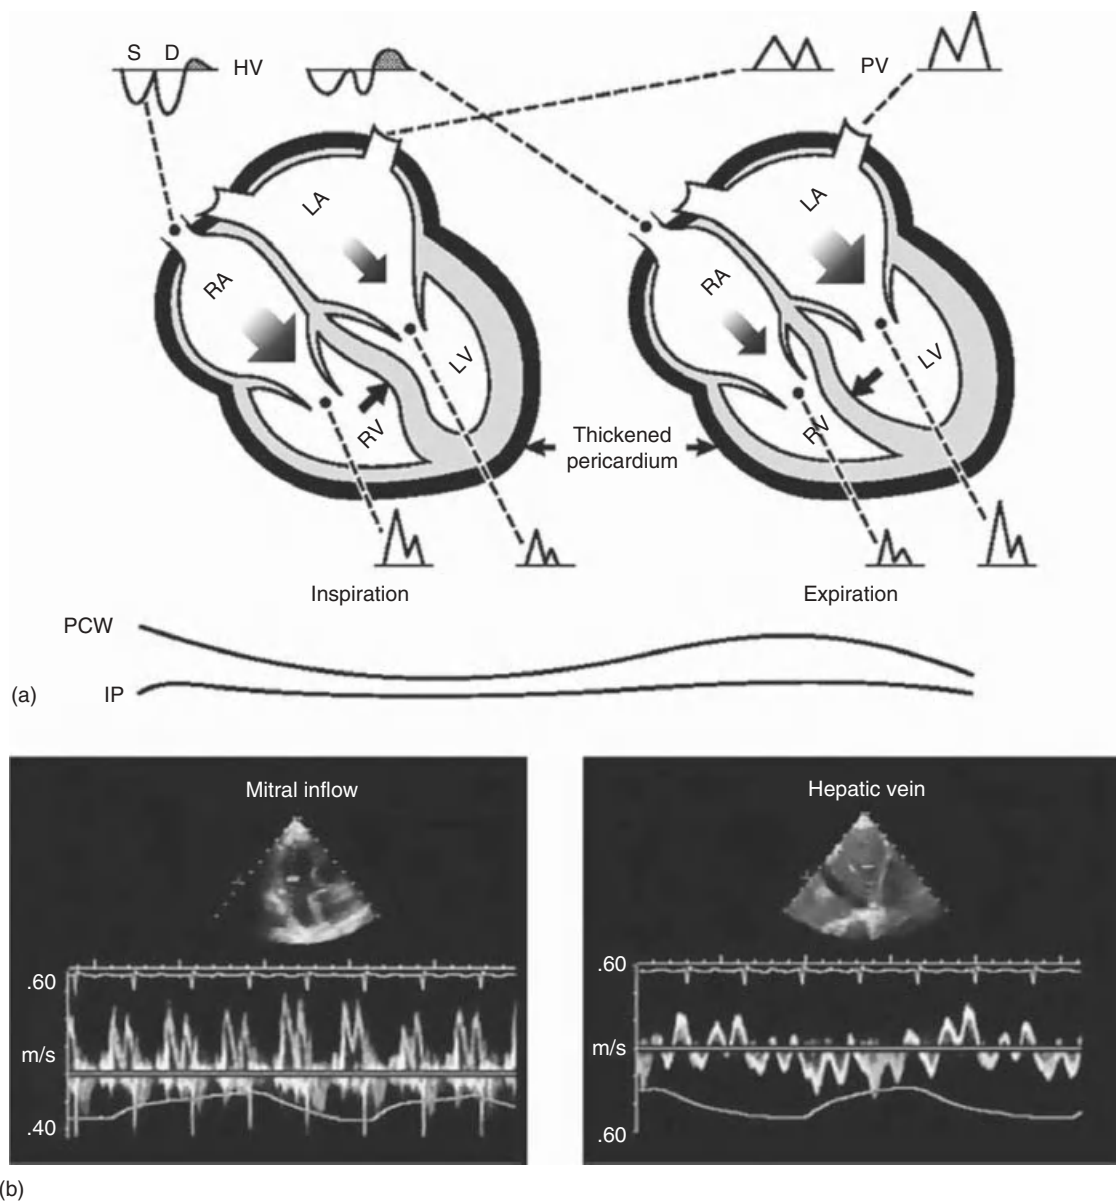
Constrictive pericarditis is characterized by a thickened and fibrotic pericardium that restricts ventricular filling (Figure 59.12). Calcification of the pericardium occurs in only 25% of patients [8]. The constrictive process usually involves the entire pericardium, but focal constriction occurs. Constrictive pericarditis may develop without obvious cause or as the end-stage of any form of pericarditis [46]. In some patients with bacterial or viral pericarditis, a transient form of constriction has occurred with eventual resolution [47].
Figure 59.12 Severe constrictive pericarditis. Note the markedly thickened pericardium in this ventricular short-axis slice. (Courtesy of Dr. William D. Edwards, Division of Anatomic Pathology, Mayo Clinic, Rochester, MN, USA.)


Figure 59.13 Hemodynamic filling patterns in constriction. (a) These diagrams illustrate a patient with constrictive pericarditis and (b) the corresponding Doppler echocardiographic patterns with inspiration and expiration. Bottom line on echocardiograms is a respiration trace, with inspiration shown by a rising line. Mitral inflow signals vary with respiration, with increased flow velocities on inspiration compared to expiration. Conversely, with inspiration, increased right ventricular filling causes hepatic vein diastolic forward flow to increase. In expiration, hepatic vein diastolic forward flow decreases, and significant flow reversals in diastole may be present. The width of the shaded arrows indicates relative flow. HV, hepatic vein; IP, intrapleural pressure; LA, left atrium; LV, left ventricle; PCW, pulmonary capillary wedge pressure; PV, pulmonary vein; RA, right atrium; RV, right ventricle. (Adapted from Oh *et al.*, *The Echo Manual*, with permission from Lippincott Williams & Wilkins.)

With constriction, ventricular systolic function generally remains normal, but diastolic expansion of the ventricles is limited. Early diastolic filling is normal, but mid and late diastolic filling are limited. Pulmonary wedge and central venous pressures are increased secondary to elevated filling pressures [48]. Patients complain of exercise intolerance, dyspnea, fatigue, weight gain, or syncope. Physical examination demonstrates hepatomegaly, splenomegaly, jugular venous distension, edema, or ascites.

During auscultation, one may hear a precordial knock, a diastolic filling sound corresponding to abrupt cessation of ventricular filling.

Chest radiography may be normal, or demonstrate pericardial calcification (~25%) (Figure 59.3). The electrocardiogram is nonspecific, but may show low-voltage QRS complexes and abnormal ST segments or T-waves. Echocardiography reveals paradoxical septal motion with a septal "bounce." Both vena cavae may be dilated. Doppler

500 ms

Figure 59.14 Catheterization tracing of a patient with constriction physiology. Note the equalization of LVEDP and RVEDP, creating the "square root sign" (**). Ao, Aorta; LV, left ventricle; RV, right ventricle. X axis is time, and Y axis is pressure in mmHg.
Table 59.4 Differentiating constrictive pericarditis and restrictive cardiomyopathy.

Finding[a]	Constriction	Restriction
Echo: septal "bounce"	Common	Typically absent
Echo: atrial size	Normal or mildly enlarged	Significantly enlarged
Echo: systolic function	Typically normal	Normal or mildly decreased
Echo: wall thickness	Normal	Normal or increased
Echo: Doppler changes with inspiration/expiration	Significant and common	Rarely occurs
CT: pericardial thickening	Common	Typically absent
Catherization: RVSP	<50 mmHg	>50 mmHg
Catherization: LVEDP – RVEDP	<4 mmHg	>4 mmHg
Catherization: wedge pressure – RA pressure	<4 mmHg	>4 mmHg
Catherization: RVEDP/RVSP	>0.33	<0.3
Catherization: systolic area index	>1.1	<1.1
History of cardiac surgery	Common	Uncommon

[a]RVSP, right ventricular systolic pressure; RVEDP, right ventricular end-diastolic pressure; LVEDP, left ventricular end-diastolic pressure; RA, right atrium.

echocardiography shows significant respiratory variation of both left- and right-sided flows (Figure 59.13) [49]. With inspiration, there is an exaggerated decrease in the mitral inflow velocity and an exaggerated increase in tricuspid inflow velocity (tricuspid E velocity) [49]. CT and MRI may reveal thickening and calcification of the pericardium [11]. Cardiac catheterization demonstrates equalization of left and right ventricular end-diastolic pressures, left and right atrial mean pressures, and mean pulmonary capillary wedge pressure. The "square root sign" may be noted, describing the early diastolic drop in pressure followed by a plateau phase, secondary to rapid early diasto-

lic filling with abrupt cessation (Figure 59.14). Definitive treatment is total pericardiectomy, which is safe and effective in children [42].

Differentiating constrictive pericarditis and restrictive cardiomyopathy

Restrictive cardiomyopathy is typically caused by an infiltrative process, including amyloidosis, hemochromatosis, endomyocardial fibrosis, and eosinophilic cardiomyopathy. It may be idiopathic [50]. Because it also is characterized by significantly abnormal diastolic function and preserved systolic function, differentiation from constrictive pericarditis is

(a)

(b)
Figure 59.15 Catheterization tracings in constrictive physiology (a) and restrictive cardiomyopathy (b). Note that both patients have early rapid filling and elevation and end-equalization of the left ventricular (LV) and right ventricular (RV) pressures at end expiration. In constrictive pericarditis, there is an inspiratory increase in the area of the RV pressure curve (orange shaded area) compared with expiration. The area of the LV pressure curve (yellow shaded area) decreases during inspiration as compared with expiration. In restrictive cardiomyopathy, there is an inspiratory decrease in the area of the RV pressure curve (orange shaded area) as compared with expiration. The area of the LV pressure curve (yellow shaded area) is unchanged during inspiration as compared with expiration. (Adapted from Talreja et al. [48] with permission from Elsevier.)
(a)

(c)

Figure 59.16 Tissue Doppler imaging of the septal mitral annulus in (a) constriction and (b) restriction. Note the relative normal or increased mitral septal annulus velocity (E′ velocity) in constriction, compared to the decreased E′ velocity seen in restriction. When comparing constriction with amyloidosis and restrictive cardiomyopathy in adults (c), there is a clear differentiation between the average E′ velocities. (Adapted with permission from Ha JW et al. *Am J Cardiol* 2004;**94**:316–19.)
Figure 59.17 Diagram of Doppler velocities from mitral inflow (MV), mitral annulus velocity, and hepatic vein (HV) and the ECG and respirometer recordings indicating inspiration (i) and expiration (e). D, diastolic flow; DR,diastolic flow reversal; DT, deceleration time; S, systolic flow; SR,systolic flow reversal; blackened areas under curve, flow reversal. Typically, mitral inflow has respiratory variation, but not always. (Adapted from Oh *et al.*, *The Echo Manual*, 2006, with permission from Lippincott Williams & Wilkins.)

difficult [48]. Differentiation is important, as the definitive treatments for these disorders are disparate (pericardiectomy versus transplant). A list of potential differentiating factors is shown in Table 59.4.

A recently proposed catheterization-based method of differentiation involves calculating the *systolic area index*, defined as the ratio of the area under the right ventricular pressure curve to the area under the left ventricular pressure curve in inspiration versus expiration (Figure 59.15). A systolic area index value >1.1 was found to be 97% sensitive and 100% specific for diagnosing constrictive pericarditis [48]. This study was performed only in adults, and requires validation in children, who have different heart rate, respiratory rate, and filling pressures.

Echocardiographic differentiation between constrictive pericarditis and restrictive physiology includes those factors listed in Table 59.4. Visualization of the septal "bounce" is more common in constriction, whereas significant atrial enlargement is more common in restriction. Doppler velocities, including mitral inflow, tricuspid inflow, and pulmonary venous inflow, are affected by respiration in constriction. With inspiration, decreased left ventricular filling allows increased right ventricular filling, which causes hepatic vein diastolic forward flow to increase (Figure 59.13). In expiration, hepatic vein diastolic forward flow decreases, and significant flow reversals in diastole may occur. The use of a respirometer during the echocardiogram is critical in timing the flow patterns. Patients with restriction rarely present with such respiration-induced changes in Doppler velocities. Tissue Doppler imaging can also be helpful. The early diastolic septal mitral annulus velocity (E' velocity) tends to be higher in patients with constriction, often greater than $8\,cm\,s^{-1}$

(Figure 59.16). A reduced E' velocity is seen in restrictive cardiomyopathy, similar to other cardiomyopathies [8]. Figure 59.17 shows Doppler velocities from mitral inflow (MV), mitral annulus velocity, and hepatic vein (HV) and the ECG and respirometer recordings.

Introduction

The evaluation and management of the child with infective endocarditis (IE) continues to be a challenge for pediatric cardiologists and other providers of children's healthcare.

IE is an infection of the endothelial (endocardial) surface of the heart and involves valvar structures, mural endocardium, or great vessels. It can complicate intracardiac patches, prostheses, central catheters, surgically constructed shunts and conduits, and indwelling devices of various types. IE is caused not only by bacteria but also by fungi, rickettsiae, and viruses. With current antimicrobial and surgical therapies, mortality rates have been reduced to 10–20%, although morbidity and long-term sequelae are serious issues for many more. Even in the current era of advanced imaging technology, surgical treatment, and expanding antibiotic capabilities, IE remains a serious disease.

Epidemiology

In most developed countries, including the United States, IE has historically been seen most often in patients with an underlying structural cardiac abnormality [1]. Recently, however, new data have indicated an emerging trend towards an increasing proportion of children admitted to hospital for IE without pre-existing heart abnormalities [2]. Reported hospitalization rates for IE continue to vary widely but remain at approximately one in every 1300–2000 admissions annually [2]. Regardless of the specific hospitalization rate, the frequency of IE in children appears to have increased over the past several decades. Reasons for this increase include [1]

- improved survival among children with congenital heart disease at risk for IE, including increased numbers of operations
- increased use of prosthetic materials and indwelling devices
- changing neonatal and pediatric intensive care unit practices
- intravenous drug abuse in specific age groups (adolescents).

In contrast, whereas almost 50% of cases of IE in developed countries occurred in children with rheumatic heart disease (RHD) before the 1970s, the decline of RHD prevalence in those areas means that it is now relatively unusual for IE to be associated with RHD. In still developing countries, however, RHD remains an important underlying substrate for IE. Pooled data from 20 published series concerning specific congenital cardiac abnormalities associated with IE are shown in Table 60.1.

All ages can be affected, although it has been estimated that 50% of occurrences are in children ≥10 years of age. In particular, IE occurrence appears to be increasing at both ends of the age spectrum of childhood. Premature neonates are increasingly reported with right-sided IE, for example, and this is often associated with central catheters and longer-term indwelling arterial lines [1,3,4,6]. Older teens and young adults with postoperative congenital heart disease represent an additional emerging population for the development of IE, as treatment advances have increased life expectancy and vigor of lifestyle for patients with even the most complex cardiovascular abnormalities.

Pathogenesis

For IE to develop, two independent events are normally required: damage to an area of endothelium, and bacteremia caused by organisms with adherence capacity. Normal intact

Table 60.1 Underlying heart disease in children with infective endocarditis.

Disease	No. of patients[a]	Percentage of total
Congenital heart disease		
Acyanotic heart lesions		
Ventricular septal defect	194	21.8
Ventricular septal defect and other	18	2.0
Patent ductus arteriosus	25	2.8
Aortic stenosis	89	10.0
Subvalvar aortic stenosis	9	1.0
Coarctation of aorta	25	2.8
Pulmonary stenosis	21	2.4
Atrioventricular defect	16	1.8
Atrial septal defect	11	1.2
Mitral valve abnormality	16	1.8
Mitral valve prolapse	8	0.9
Cyanotic heart lesions		
Tetralogy of Fallot	143	16.0
Transposition of great vessels	35	3.9
Truncus arteriosus	8	0.9
Tricuspid atresia	9	1.0
Pulmonary atresia	8	0.9
Single ventricle	9	1.0
Other	79	8.9
Rheumatic heart disease	86	9.7
No heart disease	75	8.4

endothelium is not conducive to bacterial colonization. Endothelium is typically damaged by an abnormally high velocity jet stream that results in turbulent blood flow. A classic model developed by Rodbard [7] to delineate the hemodynamic mechanisms responsible for the development of endocarditis showed that endothelial damage and bacterial deposition can occur in a low-pressure area immediately distal to an obstruction. Examples of such physiology include coarctation of the aorta, regurgitant mitral or aortic valve, or ventricular septal defect. Thus, endothelium on the ventricular side of a regurgitant aortic valve would be damaged, and the right ventricular free wall (or right-sided heart valves) would be damaged from the jet created by a ventricular septal defect. Endothelium can also be damaged by direct trauma from intracardiac devices, such as an indwelling catheter, or from an intracardiac operation.

Trauma to the endothelium can induce thrombogenesis (deposition of fibrin and platelets), which leads to a sterile lesion known as *nonbacterial thrombotic endocarditis (NBTE)*.

This lesion is more receptive than normal undamaged endothelium to colonization by bacteria and serves as a nidus for subsequent infection. After bacteremia with an organism that can adhere to the NBTE, a vegetation forms. Certain bacteria are more likely than others to adhere and are also more able to avoid eradication by the host's defenses [8]. The adherence of streptococci may be related in part to the extracellular production of the polysaccharide dextran, which facilitates adherence [9]. The vegetation itself is composed of fibrin, platelets, red blood cells, white blood cells, and the microorganisms, which can grow to a concentration that is achievable in pure culture in a Petri dish.

Microbiology

Most instances of endocarditis are caused by a limited number of microorganisms. The most logical explanation relates to bacterial adherence. An *in vitro* study demonstrated that bacteria frequently responsible for endocarditis, such as viridans streptococci, readily adhere to canine or human cardiac valves, whereas Gram-negative organisms, which infrequently cause endocarditis, adhere poorly to valves [8].

In most series of endocarditis in children, Gram-positive cocci account for at least two-thirds of recoverable bacteria. Table 60.2 summarizes data from representative series outlining the organisms associated with IE in children [1]. Viridans streptococci were the largest group responsible for endocarditis in these specifically pediatric series. Staphylococci (*Staphylococcus aureus* and coagulase-negative staphylococci) were the second largest group. Gram-negative organisms less frequently cause endocarditis in children. Neonates, immunocompromised patients, and intravenous drug abusers, however, are at an increased risk for Gram-negative bacterial endocarditis. The slow-growing fastidious Gram-negative bacilli in the HACEK group (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella*) can also cause endocarditis in children. They frequently affect damaged cardiac valves and often cause emboli. Other Gram-negative bacilli, such as *Neisseria gonorrhoeae*, can cause endocarditis presenting as an acute illness, affecting previously normal valves, and commonly resulting in valvar destruction. In intravenous drug abusers, the most commonly isolated organism is *S. aureus*. Other organisms include *Pseudomonas* and other Gram-negative bacilli and fungi (predominantly *Candida* species) [10].

In prosthetic valve endocarditis (PVE), the organisms differ according to whether endocarditis occurs within the first year after operation or later. Infection during the first year is primarily due to coagulase-negative staphylococci acquired during the operative procedure or nosocomially acquired [14]. *S. aureus*, Gram-negative bacilli, diphtheroids, and *Candida* species are also common causes of PVE during this period. The coagulase-negative staphylococci recovered

within the first year of operation are frequently resistant to methicillin and all other β-lactams. In contrast, infection occurring more than 1 year after operation is caused by organisms similar to those present in native valve endocarditis [14].

Fungal endocarditis is relatively unusual in children and has a high morbidity and mortality even with intensive treatment [15–17]. It is difficult to diagnose and treat, and complications, especially embolization, are frequent [18]. The most frequently recovered fungal organism is *Candida albicans*; other organisms include *Aspergillus* species, *Torulopsis glabrata*, other *Candida* species, and other fungi [17,18]. Fungal endocarditis occurs in intravenous drug abusers and patients undergoing cardiac valve replacement, and also in immunocompromised patients and in neonates. In neonates, fungal endocarditis may be a complication of prolonged use of indwelling venous catheters, prolonged hyperalimentation, and broad-spectrum antibiotic use [19–21].

In the series in Table 60.2, ~5–7% of instances of endocarditis were culture-negative. There are many possible reasons for failure to recover organisms in apparent IE, particularly previous treatment with antibiotics [22]. However, when cultures are negative, physicians should carefully evaluate such patients for the possibility of other diseases (see the section on culture-negative endocarditis below).

Diagnosis

Criteria for the clinical diagnosis of IE have been developed over the years. In 1994, criteria were developed by Durack *et al.* [23] at Duke University. These so-called "Duke criteria" are listed in Table 60.3 and defined in Table 60.4. There are

Table 60.3 Duke criteria for diagnosis of infective endocarditis.

Definite infective endocarditis

Pathologic criteria

Microorganisms: demonstrated by culture or histology in a vegetation, or in a vegetation that has embolized, or in an intracardiac abscess, *or*

Pathologic lesions: vegetation or intracardiac abscess present, confirmed by histology showing active endocarditis

Clinical criteria, using specific definitions listed in Table 60.4

2 major criteria, *or*

1 major and 3 minor criteria, *or*

5 minor criteria

Possible infective endocarditis

Findings consistent with infective endocarditis that fall short of "definite" but not "rejected"

Rejected

Firm alternative diagnosis for manifestations of endocarditis, *or*

Resolution of manifestations of endocarditis, with antibiotic therapy for 4 days or less, *or*

No pathologic evidence of infective endocarditis at surgery or autopsy, after antibiotic therapy for 4 days or less

Reproduced with permission from Durack *et al. Am J Med* 1994;**96**:200–9.

two major criteria and six minor criteria. There are three diagnostic categories: definite, possible, and rejected. The clinical criteria can be used to establish a definitive diagnosis of IE when two major criteria, one major plus three minor criteria, or five minor criteria are met. The Duke criteria are effective in establishing a diagnosis of IE in both adults [24] and children [13].

Table 60.4 Definitions of terms used in the Duke criteria for the diagnosis of infective endocarditis[a].

Major criteria

1. Positive blood culture for IE
   - A. Typical microorganism consistent with IE from two separate blood cultures as noted below:
     - i. viridans streptococci[b], *Streptococcus bovis,* or HACEK group *or*
     - ii. community-acquired *Staphylococcus aureus* or enterococci, in the absence of a primary focus
   - B. Microorganisms consistent with IE from persistently positive blood cultures defined as
     - i. at least two positive cultures of blood samples drawn ≥12 h apart *or*
     - ii. all of three or a majority of four or more separate cultures of blood (with first and last sample drawn at least 1 h apart)
2. Evidence of endocardial involvement
   - A. Positive echocardiogram for IE defined as
     - i. oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation, *or*
     - ii. myocardial abscess, *or*
     - iii. new partial dehiscence of prosthetic valve
   - B. New valvar regurgitation (worsening or changing of pre-existing murmur not sufficient)

Minor criteria

1. Predisposition: predisposing heart condition or intravenous drug use
2. Fever: temperature ≥38.0 °C
3. Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway's lesions
4. Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor
5. Microbiologic evidence: positive blood culture but does not meet a major criterion as noted in Table 60.3[c] or serologic evidence of active infection with organism consistent with IE
6. Echocardiographic findings: consistent with IE but do not meet a major criterion above

[a]HACEK: *Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* species, and *Kingella kingae*. IE, infective endocarditis.
[b]Includes nutritional variant strains.
[c]Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.
Reproduced with permission from Durack *et al. Am J Med* 1994;**96**:200–9.

Clinical features

Symptoms of endocarditis usually arise within 2 weeks of the initiating bacteremia [25]. They are usually related to cardiac complications caused by the infection, persistent bacteremia, systemic embolization, or immunopathologic reactions by the patient. Endocarditis can mimic many disorders, including other infectious diseases, lymphoma, leukemia, and connective tissue diseases. Endocarditis should be part of the differential diagnosis in any patient with an underlying cardiac abnormality who has unexplained fever or who has another unusual illness that could be related to endocarditis.

Clinical findings in IE stem from the underlying principle disorders: microbial blood-borne infections, valvitis, immunologic responses, and peripheral embolic events.

Fever is the most common finding in patients with endocarditis, with the exception of neonates. Fever is frequently low grade, reaching a maximum temperature of 39 °C. In endocarditis caused by virulent bacteria such as *S. aureus*, however, there can be a spiking high fever. Other nonspecific symptoms include myalgia, arthralgia, anorexia, night sweats, headache, and malaise. Because initial symptoms are usually mild, the diagnosis of IE is often not made until 2–4 weeks after the infection starts. By this time, vegetations are well established and may be difficult to eradicate.

New or changing cardiac murmurs are usually heard in patients with valvar involvement but auscultatory findings in general depend on the specifics of the underlying heart disease and the location of the infection. Murmurs may not be heard at the initial examination. Frequent auscultation is essential because it may be difficult to recognize a new or changing murmur in a patient with a pre-existing cardiac abnormality and because vegetation pathology can be dynamic. Careful and frequent auscultation is necessary to assist not only with the diagnosis but also with the patient's medical or operative management. In some patients, notably those with complex cyanotic congenital heart disease post-systemic–pulmonary shunt creation, no change in murmur may be detected. A declining systemic saturation reflecting graft infection and/or pulmonary emboli may be the first apparent clinical sign.

The classic peripheral manifestations of endocarditis may be less frequent today than reported in the past and are often absent in endocarditis involving the tricuspid valve. *Petechiae* are the most common but least specific manifestations and are found on the palpebral conjunctiva, the buccal and palatal mucosa, and the extremities. *Splinter hemorrhages*, which resemble a splinter caught in the nail bed, are also a nonspecific finding in endocarditis. They are more helpful diagnostically if they are present in the proximal rather than the distal nail bed. *Osler's nodes* are small, tender, purple, subcutaneous nodules that develop in the digits and persist for hours or days. They are not pathognomonic and may be seen in other disorders, such as systemic lupus erythematosus and disseminated gonococcal infections. *Janeway's lesions* are small, erythematous or hemorrhagic, macular lesions on the palms and soles; unlike Osler's nodes, they are not tender. *Roth's spots* (also known as Litten's sign) are oval retinal hemorrhages with pale centers and are relatively rare.

Neurologic manifestations are found in ~20% of children with endocarditis [5]. They are associated with increased mortality and are more frequent in patients with *S. aureus* endocarditis. Neurologic complications include cerebral emboli, mycotic aneurysms, cerebritis, brain abscess, cerebral hemorrhage, and, less commonly, meningitis.

Embolic manifestations occur in some children with endocarditis, usually in association with infections that produce large, bulky vegetations. Clinically recognized emboli are found most commonly in the pulmonary or cerebral circulations. Endocarditis involving the left side of the heart often results in peripheral embolization, leading to ischemia, infarction, or mycotic aneurysms (aneurysms caused by growth of the organism in a vessel wall). Specific clinical findings depend on the localization of the emboli. Mycotic aneurysms may be silent but can rupture or thrombose weeks or months after IE has been cured. Embolization from the right side may be no less frequent, but such emboli are less easily appreciated clinically because of filtration by the lungs. Sometimes they cause an erroneous diagnosis of pneumonitis. Large, infected emboli may complicate endocarditis of the tricuspid valve, primarily in infants with IE secondary to indwelling catheters and in intravenous drug users. Embolic events are often an indication for surgical intervention. Table 60.5 reviews complications associated with the need for surgery.

Renal involvement occurs in some patients with endocarditis. Although overt renal dysfunction is usually secondary to hemodynamic changes, renal emboli may be asymptomatic or cause flank pain, may result in gross or microscopic hematuria, but rarely cause significant renal dysfunction. Renal insufficiency may also occur from immune complex glomerulonephritis, particularly in patients with endocarditis caused by less virulent bacteria, such as coagulase-negative staphylococci. Azotemia may result from immune complex nephritis, but it usually improves after appropriate antimicrobial therapy.

Table 60.5 Complications of IE indicating possible surgical therapy.

Related to vegetation
- Recurrent embolization despite antibiotics.
- Persistence of vegetation despite treatment.
- Anterior mitral leaflet lesion >10 mm in size.
- Increasing vegetation size on appropriate antibiotics.

Related to cardiac function.
- Acute severe mitral and/or aortic insufficiency with ventricular failure.
- Heart failure despite appropriate therapy.
- Valve rupture/perforation with chamber enlargement.

Extension of infection
- New heart block.
- Myocardial abscess proliferation on appropriate antibiotics.
- Valvar annulus abscess development.

Splenomegaly has been reported in 15–50% of patients with IE, but appears to be a less common finding in recent reports compared with earlier era case series.

In neonates, the clinical findings of IE may completely mimic other common syndromes such as septicemia or congestive heart failure from other etiologies [3,6]. Respiratory distress, hypothermia, tachycardia, hypotension, and new feeding difficulty may be the initial manifestations. A new murmur may, of course, follow; but often no murmur is present at all, especially in IE associated with indwelling central line infection. Peripheral emboli resulting in meningitis or osteomyelitis are not uncommon and neonates seem particularly prone to neurologic complications, including apnea and seizures.

Laboratory features

Blood cultures

A positive blood culture is a valuable aid in making the diagnosis of endocarditis. Although a positive blood culture in a child with an underlying or predisposing cardiac lesion does not necessarily indicate endocarditis, one must consider such a diagnosis. Blood cultures should be obtained in a child with a predisposition for endocarditis and persistent, unexplained fever.

It is impossible to specify the exact number of cultures that should be obtained in each situation. The collection of three sets of blood cultures during a 24 h period detects virtually all the usual organisms [26]. Once the etiologic agent has been identified, appropriate antimicrobial therapy can be begun. Sometimes making careful observations and obtaining more blood cultures before initiating antibiotic therapy are appropriate measures. In severely ill patients, three blood cultures should be obtained during a 1–2 h period and antibiotic therapy instituted. The counting of

days of recommended duration of therapy should begin on the first day on which blood cultures were negative when blood cultures were initially positive. At least two sets of blood cultures should be obtained every 24–48 h until bloodstream infection is cleared.

The bacteremia of endocarditis is often low grade and continuous [27]. Therefore, it is of no advantage to obtain blood cultures at any particular body temperature. Furthermore, the more blood that is collected, the better is the chance of growing the bacteria. At least 20 ml of blood is usually collected from an adult patient, but this may not possible in a small child, from whom as large a volume as is reasonable (preferably 3–5 ml) should be obtained. Either arterial or venous blood can be used, and samples should be drawn through venipuncture, not through an indwelling catheter. These samples should be taken after carefully sterilizing the venipuncture sites, as if for minor surgery. It is important to take blood from more than one site to reduce the risk of confusion by a skin contaminant. The microbiology laboratory should be consulted about the optimal volumes of blood and culture medium.

Culture-negative endocarditis

Culture-negative endocarditis refers to an individual with IE whose blood cultures are persistently negative. Blood cultures can be negative for a variety of reasons [28]. Previous antimicrobial therapy is a major cause of a negative blood culture [29]. Blood cultures should become positive after cessation of the antimicrobial therapy; they remain negative for a longer time after prolonged prior antibiotic treatment [27]. The antibiotic can be removed from the blood with the use of a resin device [26], if the laboratory is notified, in order to enhance microbial growth.

On occasion, a patient clinically suspected of having endocarditis may not have received antibiotics, yet still has a negative blood culture. True culture-negative endocarditis is uncommon. The data in Table 60.2 show that only 5–7% in three series had negative cultures. Many of these individuals eventually demonstrate subsequent proof of infection, either from culture of an infected embolus or from vegetations removed in the operating room or at necropsy. Some microorganisms capable of causing endocarditis are difficult to grow in culture with the use of standard laboratory techniques, and prolonged incubation, special media, or other special techniques are needed [22,26]. Consultation with a clinical microbiologist is invaluable in seeking unusual and fastidious organisms. Microorganisms reported to cause apparent culture-negative endocarditis include fastidious bacteria such as the nutritionally deficient streptococcus, fungi, HACEK organisms, *Coxiella burnetii*, and *Chlamydia* [22,30].

Other laboratory tests

A variety of other laboratory tests, although nonspecific, can help support the diagnosis of endocarditis. Acute-phase reactants (C-reactive protein and the erythrocyte sedimentation rate) are commonly elevated. Anemia is also common but may be missed if there was preceding polycythemia. It may be absent acutely but usually appears or worsens in long-standing infection. Leukocytosis is usually present, although it is not a prominent feature of fungal endocarditis. Rheumatoid factor is present in as many as half of individuals with endocarditis, especially if it is of long duration [27]. Circulating immune complexes (CICs), formed by an antibody–antigen interaction, are found in the sera of most patients with IE, especially in those whose illness is of longer duration [31,32]. CICs are associated with arthritis and acute or chronic glomerulonephritis. Levels of CICs usually fall with successful antibiotic treatment of IE and hence may be used to monitor therapy. Urinalysis may show proteinuria and macroscopic or microscopic hematuria.

Echocardiography

Many studies have confirmed the standard role of echocardiography in the diagnosis and management of endocarditis in adults [28,33] and children [5,34–48] with suspected IE. Two-dimensional echocardiography has a sensitivity in children of up to 80% [4,37–40]. Neither the sensitivity nor specificity of echocardiography is 100%, so that a normal echocardiogram does not exclude endocarditis. In fact, echocardiography may be more helpful in children with normal cardiac anatomy or with isolated valvar abnormalities than in children with very complex congenital anomalies [1]. The application of the Duke criteria for the diagnosis of IE in children has further demonstrated that in addition to a positive blood culture, echocardiography plays a major role in the diagnosis [13].

Transesophageal echocardiography (TEE) has been increasingly used in diagnosing endocarditis in adults, showing superior sensitivity for detecting vegetations compared with transthoracic echocardiography (TTE) [38,39]. In adult studies, TEE is able to detect smaller vegetations (1–1.5 mm) than is TTE (2 mm). Definitive studies of the usefulness of TEE in children with endocarditis have not been published, but standard practice now incorporates the use of TEE in children in whom TTE windows may be limited or in whom the diagnosis cannot be made using TTE but clinical suspicion remains high.

In addition to detecting vegetations (Videoclip 60.1), echocardiography is also useful for evaluating valvar and extravalvar complications of IE and for aiding in decision-making concerning the necessity for and timing of cardiac

operation (Table 60.5) (Videoclip 60.2). For more complete guidelines on the use of echocardiography in the diagnosis of IE, the reader is referred to the 1997 American College of Cardiology/American Heart Association Guidelines for the clinical use of echocardiography and its 2003 update [39,40].

Antimicrobial treatment

Eradicating infecting organisms in patients with endocarditis is the target of antibiotic therapy. A prolonged period of therapy (at least 2 weeks, often 4–6 weeks) is necessary for several reasons. Organisms are embedded within the fibrin–platelet matrix, which impedes the entry of host phagocytic cells into the vegetation, and they exist in high concentrations with relatively low rates of bacterial metabolism and cell division, which result in decreased susceptibility to antibiotics [41,42].

It is important to establish the microbiologic diagnosis before therapy is begun. This allows susceptibility testing and determination of minimal inhibitory concentration (MIC), the minimal concentration of antibiotic that inhibits growth *in vitro*. MIC determination helps in choosing the most appropriate antibiotic regimen. Treatment regimens outlined for viridans group streptococci, *Streptococcus bovis*, *Abiotrophia defectiva*, *Granulicatella* species, and *Gemella* species are subdivided into categories based on penicillin MIC data. Peak and trough serum levels should be monitored when potentially toxic antibiotics, such as vancomycin and aminoglycoside, are used. This ensures that levels are adequate and below the toxic range.

Bactericidal, rather than bacteriostatic, antibiotics should be chosen whenever possible to lessen the possibility of treatment failures or relapses. In treatment regimens where a combination of antibiotics is employed, it is important to administer the medications at or close to the same time in order to maximize the synergistic killing effect on the microbe [11,12,28–33,35–66]. Parenteral administration is recommended because of the need to achieve high serum levels of the antibiotics. In infants and small children, intravenous antibiotics are preferred over intramuscular agents because of small muscle mass. In addition, intramuscular injections can be painful. The use of heparin lock devices for intravenous therapy in older children allows them more mobility and activity. Outpatient treatment of endocarditis can be considered in selected patients after initial treatment in the hospital and after hemodynamic stability and the patient's (or parent's) compliance are confirmed. Outpatient therapy is now frequently used in adults [46], but it has been more sparingly recommended in children.

Blood cultures should be repeated often to assess the adequacy of the antibiotic regimen and to document the cessation of bacteremia. Bacteremia generally resolves within several days of beginning appropriate therapy. Patients with endocarditis require close follow-up. Obtaining follow-up blood cultures at 1 and 2 months after completing treatment is important, because most relapses occur during this period [28,47].

Cardiovascular surgery may be lifesaving in some patients with IE, but decisions for operative intervention must be individualized. Indications for operation include progressive cardiac failure, valvar obstruction, suppurative complications around or near an infected valve, fungal endocarditis, persistent bacteremia, and significant embolic events [28,66], especially when the aortic or mitral valve is involved. Medical management of progressive valvar damage and resulting cardiac failure can be deleterious. Operation should not be delayed solely because a full course of antibiotic therapy has not been completed or because a patient is seriously ill from complications of IE.

A detailed set of recommendations for antibiotic treatment of infective endocarditis has been produced by the American Heart Association [35] and the European Society of Cardiology [12]. Tables 60.6–60.8 are modeled after these guidelines. Antimicrobial treatment of endocarditis caused by the various Gram-positive organisms is detailed in the following sections.

Streptococcal and enterococcal endocarditis on native or prosthetic cardiac valves (Tables 60.6–60.8)

Streptococci are among the most common organisms causing IE in children [1,2]. Most of these organisms are viridans streptococci; the rest are *S. bovis* (nonenterococcal group D streptococci) or *Streptococcus pyogenes* (group A streptococci). Penicillin-susceptible streptococci have MIC to penicillin of ≤0.12 µg ml^{-1}. Treatment for native valve endocarditis caused by streptococci is given in Table 60.6. For patients who are able to take penicillin, 4-week therapeutic regimens with aqueous crystalline penicillin G or ceftriaxone have high cure rates.

A 2-week combined penicillin (or ceftriaxone) and aminoglycoside regimen has become increasingly popular for use in uncomplicated native valve IE, but is not recommended for patients who have had endocarditis for >3 months or for those who have extracardiac foci of infection, intracardiac abscesses, or mycotic aneurysm. It is also inappropriate for children at risk for adverse events caused by gentamicin therapy.

For patients allergic to β-lactam antibiotics, vancomycin therapy is recommended (Table 60.6). Each dose of this antibiotic should be infused during 1–2 h to reduce the risk of the histamine-release "red man" syndrome. Children "allergic" to penicillins, but without a clear-cut history of an anaphylactic reaction, may be candidates for penicillin desensitization.

Table 60.6 Therapy of native valve endocarditis caused by viridans group streptococci and *Streptococcus bovis*.

Regimen	Dosage[a] and route	Duration (weeks)	Comments
For patients with highly penicillin-susceptible strains (minimum inhibitory concentration ≤0.12 µg ml⁻¹)			
Aqueous crystalline penicillin G sodium *or*	Penicillin 200 000 U kg⁻¹ per 24 h i.v. in 4–6 equally divided doses (not to exceed 18 million U per 24 h)	4	Preferred in patients with impairment of 8th cranial nerve function or renal function
Ceftriaxone sodium	Ceftriaxone 100 mg kg⁻¹ per 24 h i.v./i.m. in 1 dose (not to exceed 2 g per 24 h)	4	
Aqueous crystalline penicillin G sodium *or*	Penicillin 200 000 U kg⁻¹ per 24 h i.v. in 4–6 equally divided doses (not to exceed 18 million U per 24 h)	2	2-week regimen not intended for patients with known cardiac or extracardiac abscess or for those with creatinine clearance of <20 ml min⁻¹, impaired 8th
Ceftriaxone sodium *plus*	2 ceftriaxone 100 mg kg⁻¹ per 24 h i.v./i.m. in 1 dose (not to exceed g per 24 h)	2	cranial nerve function, or *Abiotrophia*, *Granulicatella*, or *Gemella* spp. infection; gentamicin dosage should be adjusted to achieve peak serum concentration of 3–4 µg ml⁻¹ and trough serum concentration of <1 µg ml⁻¹ when 3 divided doses are used
Gentamicin sulfate[b]	3 mg kg⁻¹ per 24 h i.v./i.m. in 1 dose or 3 equally divided doses[c]	2	
Vancomycin hydrochloride[d]	40 mg kg⁻¹ per 24 h i.v. in 2–3 equally divided doses (not to exceed 2 g per 24 h unless concentrations in serum are inappropriately low)	4	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone; vancomycin dosage should be adjusted to obtain peak (1 h after infusion completed) serum concentration of 30–45 µg ml⁻¹ and a trough concentration range of 10–15 µg ml⁻¹
For patients with strains relatively resistant to penicillin (minimum inhibitory concentration >0.12 to ≤0.5 µg ml⁻¹)			
Aqueous crystalline penicillin G sodium *or*	Penicillin 300 000 U per 24 h i.v. in 4–6 equally divided doses (not to exceed 24 million U per 24 h)	4	Patients with endocarditis caused by penicillin-resistant (MIC >0.5 µg ml⁻¹) strains should be treated with regimen recommended for enterococcal endocarditis
Ceftriaxone sodium *plus*	100 mg kg⁻¹ per 24 h i.v./i.m. in 1 dose (not to exceed 2 g per 24 h)	4	(see Table 60.4). Gentamicin dosage should be adjusted to achieve peak serum concentration of 3–4 µg ml⁻¹ and trough serum concentration of <1 µg ml⁻¹ when 3 divided doses are used
Gentamicin sulfate[b]	3 mg kg⁻¹ per 24 h i.v./i.m. in 1 dose or 3 equally divided doses[c]	2	
Vancomycin hydrochloride[d]	40 mg kg⁻¹ per 24 h i.v. in 2 or 3 equally divided doses (not to exceed 2 g per 24 h, unless serum concentrations are inappropriately low)	4	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone therapy; vancomycin dosage should be adjusted to obtain peak (1 h after infusion completed) serum concentration of 30–45 µg ml⁻¹ and a trough concentration range of 10–15 µg ml⁻¹

[a]Dosages recommended are for patients with normal renal function.
[b]Other potentially nephrotoxic drugs (e.g., nonsteroidal anti-inflammatory drugs) should be used with caution in patients receiving gentamicin therapy.
[c]Data for once-daily dosing of aminoglycosides for children exist, but no data for treatment of IE exist.
[d]Vancomycin dosages should be infused during the course of at least 1 h to reduce risk of histamine-release "red man" syndrome.

On occasion, IE may be due to streptococci that are relatively resistant to penicillin (MIC >0.12 but ≤0.5 µg ml⁻¹). For these patients, the recommended treatment regimen is 4 weeks of penicillin or ceftriaxone combined with gentamicin for the first 2 weeks. For children who are allergic to β-lactams, vancomycin should be used.

Therapy for prosthetic valve/prosthetic material streptococcal endocarditis is given in Table 60.7. For penicillin-susceptible strains, 6 weeks of aqueous crystalline penicillin G or ceftriaxone with or without gentamicin for the first 2 weeks is recommended. The clinical benefit of gentamicin has not been formally shown, however (see the comments

Table 60.7 Therapy for endocarditis of prosthetic valves or other prosthetic material caused by viridans group streptococci and *Streptococcus bovis*.

Regimen	Dosage[a] and route	Duration (weeks)	Comments
Penicillin-susceptible strain (minimum inhibitory concentration ≤0.12 µg ml⁻¹)			
Aqueous crystalline penicillin G sodium *or*	300 000 U kg⁻¹ per 24 h i.v. in 4–6 equally divided doses (not to exceed 24 million U per 24 h)	6	Penicillin or ceftriaxone together with gentamicin has not demonstrated superior cure rates compared with monotherapy with penicillin or ceftriaxone for patients with highly susceptible strain.
Ceftriaxone *with or without*	100 mg kg⁻¹ i.v./i.m. once daily (not to exceed 2 g per 24 h)	6	Gentamicin dosage should be adjusted to achieve peak serum concentration of 3–4 µg ml⁻¹ and trough serum concentration of
Gentamicin sulfate[b]	3 mg kg⁻¹ per 24 h i.v./i.m. in 1 dose or 3 equally divided doses[c]	2	<1 µg ml⁻¹ when 3 divided doses are used; gentamicin therapy should not be administered to patients with creatinine clearance of <30 ml min⁻¹
Vancomycin hydrochloride[d]	40 mg kg⁻¹ per 24 h i.v. or in 2 or 3 equally divided doses (not to exceed 2 g per 24 h unless concentrations in serum are inappropriately low)	6	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone; vancomycin dosage should be adjusted to obtain peak (1 h after infusion completed) serum concentration of 30–45 µg ml⁻¹ and a trough concentration range of 10–15 µg ml⁻¹
Penicillin relatively or fully resistant strain (minimum inhibitory concentration >0.12 µg ml⁻¹)			
Aqueous crystalline penicillin sodium *or*	300 000 U kg⁻¹ per 24 h i.v. in 4–6 equally divided doses (not to exceed 24 million U per 24 h)	6	See comments for penicillin, ceftriaxone and gentamicin above
Ceftriaxone *plus*	100 mg kg⁻¹ i.v./i.m. once daily (not to exceed 2 g per 24 h)	6	
Gentamicin sulfate[b]	3 mg kg⁻¹ per 24 h i.v./i.m. in 1 dose or 3 equally divided doses[c]	6	
Vancomycin hydrochloride[d]	40 mg kg⁻¹ per 24 h i.v. in 2 or 3 equally divided doses (not to exceed 2 g per 24 h unless concentrations in serum are inappropriately low)	6	See comments for vancomycin above

[a]Dosages recommended are for patients with normal renal function.
[b]Other potentially nephrotoxic drugs (e.g., nonsteroidal anti-inflammatory drugs) should be used with caution in patients receiving gentamicin therapy.
[c]Data for once-daily dosing of aminoglycosides for children exist, but no data for treatment of IE exist.
[d]Vancomycin dosages should be infused during the course of at least 1 h to reduce risk of histamine-release "red man" syndrome.

in the table). Vancomycin is recommended for patients unable to tolerate penicillin or ceftriaxone. For children with penicillin relatively or fully resistant strains, 6 weeks of gentamicin should be added to the 6 weeks of penicillin or ceftriaxone.

Enterococcal endocarditis is uncommon in children. Treatment (Table 60.8) is difficult because of the relative resistance of enterococci to penicillin, expanded-spectrum penicillins, and vancomycin and in view of their variable resistance to aminoglycosides [56,57]. The treatment regimen requires combination therapy of penicillin G or ampicillin with gentamicin for at least 4 and preferably 6 weeks [51,56]. For patients allergic to penicillins (but without a history of anaphylactic-type reaction), penicillin desensitization can be considered. If desensitization is not considered feasible, vancomycin plus gentamicin for 4–6 weeks is recommended. Nutritionally variant streptococci or streptococci with MIC >0.5 µg ml⁻¹ should be treated with the regimens listed for enterococci.

The above recommendations are for native valve enterococcal endocarditis. If the infection involves a *prosthetic* cardiac valve, 6 weeks of penicillin combined with gentamicin for at least the first 2 weeks is recommended [58]. If the infection is caused by "relatively penicillin-resistant" enterococci, penicillin treatment may be required for 8 weeks. A vancomycin plus gentamicin regimen is recommended for penicillin-allergic individuals who are not desensitized to penicillins.

Table 60.8 Therapy for native valve or prosthetic valve enterococcal endocarditis caused by strains susceptible to penicillin, gentamicin, and vancomycin.

Regimen	Dosage[a] and route	Duration (weeks)	Comments
Ampicillin sodium *or*	300 mg kg⁻¹ per 24 h i.v. in 4–6 equally divided doses (not to exceed 12 g per 24 h)	4–6	Native valve: 4-week therapy recommended for patients with symptoms of illness ≤3 months; 6-week therapy recommended for patients with symptoms >3 months
Aqueous crystalline penicillin G sodium *plus*	300 000 U kg⁻¹ per 24 h i.v. in 4–6 equally divided doses (not to exceed 30 × 10⁶ U per 24 h)	4–6	Prosthetic valve or other prosthetic cardiac material: minimum of 6 weeks of therapy recommended
Gentamicin sulfate[b]	3 mg kg⁻¹ per 24 h i.v./i.m. in 3 equally divided doses	4–6	
Vancomycin hydrochloride[c] *plus*	40 mg kg⁻¹ per 24 h i.v. in 2 or 3 equally divided doses	6	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ampicillin. Adjust vancomycin to achieve 1 h serum concentration of 30–45 µg ml⁻¹ and trough concentration of 10–15 µg ml⁻¹
Gentamicin sulfate[b]	3 mg kg⁻¹ per 24 h i.v./i.m. in 3 equally divided doses	6	6 weeks of vancomycin therapy recommended because of decreased activity against enterococci

[a]Dosages recommended are for patients with normal renal function.
[b]Dosage of gentamicin should be adjusted to achieve peak serum concentration of 3–4 µg ml⁻¹ and a trough concentration of <1 µg ml⁻¹. Patients with a creatinine clearance of <50 ml min⁻¹ should be treated in consultation with an infectious diseases specialist.
[c]Vancomycin dosages should be infused during the course of at least 1 h to reduce risk of histamine-release "red man" syndrome.

Staphylococcal endocarditis on native or prosthetic valves or other prosthetic material (Table 60.9)

Staphylococcal endocarditis in children has become more prevalent in recent years [2,59] and *S. aureus* is the most common cause of IE in the developed world [67]. Staphylococci are coagulase positive (*S. aureus)* or coagulase negative (*S. epidermidis* and various other species). Most staphylococci are highly resistant to penicillin G and ampicillin because of production of of β-lactamases [59], one form of which is termed penicillinase. Staphylococci sensitive to penicillinase-resistant penicillins are termed oxacillin (or methicillin) susceptible. For oxacillin-susceptible strains of staphylococcal IE, in the absence of prosthetic materials antibiotic therapy must include a semisynthetic, penicillinase-resistant penicillin (nafcillin or oxacillin). The antibiotic should be administered intravenously for 6 weeks for complicated right-sided IE and for left-sided IE. A 2-week regimen can be used for uncomplicated right-sided IE and for left-sided IE. Gentamicin may be added for the first 3–5 days, although the clinical benefit of aminoglycosides has not been established. For patients who are penicillin allergic, cephalosporins are recommended as an alternative. Cephalosporins should not be used in patients with a history of an anaphylactic-type reaction to penicillin; rather, vancomycin should be used in these individuals.

Some coagulase-negative staphylococci and *S. aureus* strains are oxacillin resistant. Therefore, patients with IE associated with these organisms should not receive nafcillin, oxacillin, or a cephalosporin but should instead be treated for 6 weeks with vancomycin.

Staphylococcal endocarditis involving a prosthetic cardiac valve or other cardiac prosthetic material is most often, but not always, nosocomially acquired. Most infections involve methicillin-resistant organisms, especially if the endocarditis develops within 1 year of a cardiac operation [58]. Treatment requires a minimum of 6 weeks of vancomycin plus rifampin, with gentamicin for the first 2 weeks. If the bacteria are oxacillin susceptible, nafcillin or oxacillin can replace vancomycin. For further recommendations on the treatment of staphylococcal endocarditis involving intracardiac prosthetic material, the reader is referred to the American Heart Association guidelines [28,52].

Staphylococcal bacteremia in patients with indwelling venous catheters or lines may be treated for 10–14 days with appropriate antibiotics after removal of the catheter, provided that the patient is not severely ill and has no signs of organ involvement.

Gram-negative bacterial endocarditis

Gram-negative bacteria are an infrequent cause of endocarditis in children (see Table 60.2). The Gram-negative bacteria most commonly causing endocarditis in children are the HACEK group of fastidious coccobacilli (*Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Actinobacillus actino-*

Table 60.9 Therapy for endocarditis caused by staphylococci.

Regimen	Dosage[a] and route	Duration (weeks)	Comments
In the absence of prosthetic materials			
Oxacillin-susceptible strains			
Nafcillin or oxacillin[b]	200 mg kg^{-1} per 24 h i.v. in 4–6 equally divided doses (not to exceed 12 g per 24 h)	6	For complicated right-sided IE and for left-sided IE; for uncomplicated right-sided IE, 2 weeks. It is optional to add gentamicin sulfate[†], 3 mg kg^{-1} per 24 h i.v./i.m. in 3 equally divided doses for 3–5 days; however, the clinical benefit of aminoglycosides has not been established. For penicillin-allergic (nonanaphylactoid type) patients, consider skin testing for oxacillin-susceptible staphylococci and questionable history of immediate-type hypersensitivity to penicillin
Cefazolin	100 mg kg^{-1} per 24 h i.v. in 3 equally divided doses (not to exceed 6 g per 24 h)	6	Cephalosporins should be avoided in patients with anaphylactoid-type hypersensitivity to β-lactams; vancomycin should be used in these cases. It is optional to add gentamicin sulfate[†], 3 mg kg^{-1} per 24 h i.v./i.m. in 3 equally divided doses for 3–5 days; however, the clinical benefit of aminoglycosides has not been established
Oxacillin-resistant strains			
Vancomycin[c]	40 mg kg^{-1} per 24 h i.v. in 2 or 3 equally divided doses	6	Adjust vancomycin dosage to achieve 1 h serum concentration of 30–45 μg ml^{-1} and trough concentration of 10–15 μg ml^{-1}.
In the presence of prosthetic valve or other prosthetic material			
Oxacillin-susceptible strains			
Nafcillin or oxacillin[b] plus	Nafcillin or oxacillin 200 mg kg^{-1} per 24 h i.v. in 4–6 equally divided doses (not to exceed 12 g per 24 h)	≥6	Vancomycin should be used in patients with immediate-type hypersensitivity reactions to β-lactam antibiotics; cefazolin may be substituted for nafcillin or oxacillin in patients with non-immediate-type hypersensitivity reactions to penicillins. Gentamicin dosage should be adjusted to achieve peak serum concentration of 3–4 μg ml^{-1} and trough serum concentration of <1 μg ml^{-1} when 3 divided doses are used; gentamicin therapy should not be administered to patients with creatinine clearance of <30 ml min^{-1}
Rifampin plus	20 mg kg^{-1} per 24 h i.v./p.o. in 3 equally divided doses (not to exceed 900 mg per 24 h)	≥6	
Gentamicin[d]	3 mg kg^{-1} per 24 h i.v./i.m. in 3 equally divided doses	2	
Oxacillin-resistant strains			
Vancomycin[c] plus	40 mg kg^{-1} per 24 h in 2 or 3 equally divided doses	≥6	Adjust vancomycin to achieve 1 h serum concentration of 30–45 μg ml^{-1} and trough concentration of 10–15 μg ml^{-1}. Gentamicin dosage should be adjusted to achieve peak serum concentration of 3–4 μg ml^{-1} and trough serum concentration of <1 μg ml^{-1} when 3 divided doses are used; gentamicin therapy should not be administered to patients with creatinine clearance of <30 ml min^{-1}
Rifampin plus	20 mg kg^{-1} per 24 h i.v./p.o. in 3 equally divided doses (not to exceed 900 mg per 24 h	≥6	
Gentamicin[d]	3 mg kg^{-1} per 24 h i.v./i.m. in 3 equally divided doses	2	

[a]Dosages recommended are for patients with normal renal function.
[b]Penicillin G 300 000 U kg^{-1} per 24 h i.v. in 4–6 equally divided doses (not to exceed 24 × 10^6 U per 24 h) may be used in place of nafcillin or oxacillin if strain is penicillin susceptible (minimum inhibitory concentration ≤0.1 μg ml^{-1}) and does not produce β-lactamase.
[c]Vancomycin dosages should be infused during course of at least 1 h to reduce risk of histamine-release "red man" syndrome.
[d]Gentamicin should be administered in close temporal proximity to vancomycin, nafcillin, or oxacillin dosing.

mycetemcomitans, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*). Recommended therapy for the HACEK group for both native valve and prosthetic valve (or other prosthetic material) IE is a 4-week course of ceftriaxone or ampicillin–sulbactam. In adults ciprofloxacin is an alternative for patients unable to tolerate ampicillin or cephalosporins but is generally not recommended for patients <18 years of age.

Other Gram-negative organisms, such as *Escherichia coli*, *Pseudomonas aeruginosa*, or *Serratia marcescens*, are occasionally noted. Most patients with these organisms are adolescent or

adult intravenous drug abusers, although a postoperative cardiac patient, an immunocompromised individual, or a neonate may occasionally have endocarditis with one of these organisms. Therapy must be individualized, guided by identification of the organism and antimicrobial susceptibility testing. Most experience has been with a broad-spectrum penicillin, such as ticarcillin, or a cephalosporin, such as cefotaxime or ceftazidime, combined with an aminoglycoside, such as gentamicin or amikacin [60]. At least 6 weeks of therapy is recommended. For specific treatment options, information is reviewed in the AHA guidelines [28] and those published by the ESC [66].

Gonococcal endocarditis can be treated successfully with high-dose penicillin, provided that the organism is penicillin susceptible. For penicillin-resistant organisms, an appropriate third-generation cephalosporin is recommended.

Fungal endocarditis

The prognosis in fungal endocarditis is poor and associated with high mortality and morbidity. Few patients survive when the entire treatment is only with antifungal agents. Valve replacement operation in conjunction with antifungal agents is usually required [16]. Operation is best performed after 10 days of medical therapy, but earlier if there are embolic phenomena or a deteriorating clinical picture.

Amphotericin B remains the first-line antifungal agent for medical therapy. A "test" dose of $0.1\,\text{mg}\,\text{kg}^{-1}$ of amphotericin B (maximum, 1 mg) is administered initially. If it is well tolerated, it is followed by a dose of $0.5\,\text{mg}\,\text{kg}^{-1}$ for 1 day and then 1 $\text{mg}\,\text{kg}^{-1}$ per day as the maintenance dose. The minimal duration of therapy should be 6–8 weeks. Renal function and serum potassium concentration should be carefully monitored.

Prosthetic valve endocarditis

Infection of a prosthetic cardiac valve occurs in 1–6% of all patients at some time during the lifespan of the prosthesis [66]. Antibiotic therapy for patients with an infected prosthetic cardiac valve or other prosthetic material must be appropriate for the specific infecting agent. Therapy is given for 6 weeks or longer. Treatment regimens for a prosthetic valve infected with streptococci, staphylococci, enterococci, or HACEK organisms are discussed in the preceding sections.

Prosthetic valve endocarditis caused by diphtheroids is best treated with penicillin and gentamicin, or with vancomycin for penicillin-allergic patients [61]. Duration of therapy should be 6 weeks.

Therapy for prosthetic valve endocarditis caused by Gram-negative bacilli must be based on the results of *in vitro* MIC tests and *in vitro* evaluation of antimicrobial synergy. Common regimens include a third-generation cephalosporin or a broad-spectrum penicillin with gentamicin for at least 6–8 weeks.

Experience with prosthetic valve endocarditis, derived mainly in adults, has emphasized that early replacement of the infected valve may lower the high mortality rate associated with such infections [14]. The timing of replacement of an infected prosthesis must be individualized. Some authorities recommend that most patients with staphylococcal or early-onset prosthetic valve endocarditis should undergo replacement of the infected prosthetic valve. Indications for cardiac operation during active infection of a prosthetic valve include moderate to severe heart failure, significant valvar obstruction, fungal endocarditis, persistent bacteremia despite appropriate antibiotics for 10–14 days, an unstable prosthesis, ruptured sinus of Valsalva or ventricular septum, and recurrent major emboli [14]. Less definite indications for surgery include a single major embolus, bacteriologic relapse after an appropriate course of therapy, echocardiographic demonstration of a large vegetation, and extension of infection to an annular abscess or myocardial abscess [14].

Culture-negative endocarditis

Blood culture-negative IE most commonly occurs as a result of prior administration of antibiotics before blood cultures were obtained. It can also occur because of infection with fastidious organisms or nonbacterial pathogens. Treatment of culture-negative IE is difficult. A variety of possible treatment regimens for native valve and early and late prosthetic valve IE are given by the AHA and ESC [28,66]. If blood cultures remain negative after careful workup and specialized laboratory techniques, patients with native valve endocarditis should be treated with a penicillinase-resistant penicillin (nafcillin or oxacillin) and gentamicin. Some experts recommend adding penicillin to this regimen [5]. If the infection involves a prosthetic cardiac valve, vancomycin should be added to the regimen [58]. For penicillin-allergic individuals, vancomycin and gentamicin should be used. Discontinuing the aminoglycoside after 2 weeks may be considered if there has been a substantial response to therapy. Treatment should be continued for 6 full weeks [66].

Prevention

Preventing endocarditis is desirable whenever possible. However, there has never been a prospective, controlled study in patients with underlying structural cardiac disease to determine definitively whether prophylactic antibiotics provide protection against the development of endocarditis during bacteremia-inducing procedures. Further, only a minority of instances of endocarditis (≤20%) have been attributable to an invasive procedure, and only about half of individuals who develop endocarditis have an underlying cardiac anomaly for which prophylaxis would have been given. Durack estimated that <500 instances of endocarditis per year in the United States could be prevented by use of a fully effective prophylactic regimen [62]. Nevertheless, for over 50 years antimicrobial prophylaxis regimens developed

Table 60.10 Comparison of recommendations from various groups.

AHA	ESC	NICE [65]
Patient groups for whom IE prophylaxis is recommended		

Cardiac conditions associated with the highest risk of adverse outcome from IE. This includes:
1. Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
2. Previous infective endocarditis
3. Congenital heart disease (CHD), specifically:
  a. unrepaired cyanotic congenital heart disease, including those with palliative shunts and conduits
 	
  b. completely repaired CHD with prosthetic material or device either by surgery or catheter intervention during the first 6 months after the procedure
 	
  c. repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
4. Cardiac transplantation recipients who develop cardiac valvulopathy
	Cardiac conditions at highest risk of IE. This includes:
	1. Patients with a prosthetic valve or a prosthetic material used for cardiac valve repair
	2. Patients with previous IE
	3. Patients with congenital heart disease:
	  a. cyanotic congenital heart disease, without surgical repair, or with residual defects, palliative shunts, or conduits
	  b. congenital heart disease with complete repair with prosthetic material whether placed by surgery or by percutaneous technique, up to 6 months after the procedure
	  c. when a residual defect persists at the site of implantation of a prosthetic material or device by cardiac surgery or percutaneous technique
		No patient groups are recommended to receive routine IE prophylaxis

Types of medical/dental procedures for which prophylaxis is recommended for patient groups above		
All dental procedures and events that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. Does *not* include the following: 1. Routine anesthetic injections through uninfected tissue 2. Taking dental radiographs 3. Placement of removable prosthodontic or orthodontic appliances 4. Adjustment of orthodontic appliances 5. Placement of orthodontic brackets 6. Shedding of deciduous teeth and bleeding from trauma to the lips or oral mucosa	All dental procedures requiring manipulation of the gingival or periapical region of the teeth or perforation of the oral mucosa. Does *not* include the following: 1. Local anesthetic injections in uninfected tissue 2. Removal of sutures 3. Dental X-rays 4. Placement or adjustment of removable prosthodontic or orthodontic appliances or braces 5. Shedding of deciduous teeth or trauma to the lips and oral mucosa	Prophylaxis is not recommended for any procedure

by the American Heart Association were the accepted standard of practice in most countries. Recently, however, the world-wide view of the concept of prophylactic antibiotics has been dramatically changing. The absence of definitive data supporting their use, increasing reports of failure to prevent IE even when prophylactic regimens were scrupulously adhered to, and concerns about antibiotic overuse and anaphylactic reactions have driven revisions of the practice. Furthermore, not all situations in which bacteremia may occur are readily identifiable. Also, bacteremias occur spontaneously on a daily basis (chewing of food, teeth brushing) and cannot logically be prevented. In view of these issues, the British Society for Antimicrobial Chemotherapy issued markedly restrictive guidelines in 2006 which sharply limited the use of prophylactic antibiotics to prevent IE [63]. Amplifying this more restrictive approach, the AHA issued revised guidelines in 2007 which recommend limiting the use of prophylactic antibiotics to those in whom the risk of developing endocarditis was not only high but in whom, if infected, the morbidity and/or mortality likelihood would be

Table 60.11 Regimens for a dental procedure.

Situation	Agent	Regimen[a]
Oral	Amoxicillin	50 mg kg^{-1} (not to exceed 2 g)
Unable to take oral medication	Ampicillin	50 mg kg^{-1} i.m. or i.v. (not to exceed 2 g)
	or	
	Cefazolin or ceftriaxone	50 mg kg^{-1} i.m. or i.v. (not to exceed 1 g)
Allergic to penicillins	Cephalexin[b,c]	50 mg kg^{-1} (not to exceed 2 g)
or	or	
Ampicillin – oral	Clindamycin	20 mg kg^{-1} (not to exceed 600 mg)
	or	
	Azithromycin or clarithromycin	15 mg kg^{-1} (not to exceed 500 mg)
Allergic to penicillins	Cefazolin or ceftriaxone[b]	50 mg kg^{-1} i.m. or i.v. (not to exceed 1 g)
or	or	
Ampicillin and unable to take oral medication	Clindamycin phosphate	20 mg kg^{-1} i.m. or i.v. (not to exceed 600 mg)

[a]Single dose 30–60 min before procedure.
[b]Or other first- or second-generation oral cephalosporin in equivalent pediatric dosage.
[c]Cephalosporins should not be used in an individual with a history of anaphylaxis, antiedema, or urticaria with penicillins or ampicillin.

Table 60.12 Prophylaxis regimens for other procedures.

Procedure	Agent	Regimen[a]
Invasive respiratory tract procedure	Same as Table 60.11	Same as Table 60.11
Invasive respiratory tract procedure with known or suspected *S. aureus*	Anti-*Staph.* Penicillin	Same as above
	or	
	Cephalosporin	
	or	
	Vancomycin	20 mg kg^{-1} i.v. (not >1 g)
GI or GU procedure without known infection	No prophylaxis	–
GU tract procedure with known enterococcal urinary infection	Ampicillin	Same as above
	or	
	Amoxicillin	
	or	
	Vancomycin	20 mg kg^{-1} i.v. (not >1 g)

[a]Single dose 30–60 min before procedure.

greatest [64]. This has greatly simplified the approach as a much smaller population of patients eligible for prophylaxis was in this statement (Table 60.10). In addition, the ESC issued similar guidelines in 2009 [66]. The AHA writing group also more sharply defined the procedures for which antibiotic prophylaxis was recommended (Table 60.10). Antibiotic regimens, however, were not considerably altered from previous statements (Tables 60.11 and 60.12), with an emphasis on oral amoxicillin remaining. It should be noted

that these guidelines have engendered controversy and that both the AHA and the British statements called for close follow-up and further study to determine the impact of these fairly radical changes. At least one prominent group, however, did not feel that the new recommendations went far enough and have called for eliminating all prophylactic regimens entirely [65]. Readers are advised to follow updated statements to be issued in the future as evidence develops to ascertain which direction is most closely in line with data

development. Table 60.10 compares the recommendations issued by these three prominent organizations.

Patients at risk for IE (or their parents) should be educated about endocarditis prevention. The importance of maintaining good oral health should be explained to all patients/parents. Children at risk for IE should establish and maintain the best possible oral health to reduce potential sources of bacteremia. Individuals with cyanosis often have spongy, friable gums [11], and optimal tooth care is especially important in them. Helpful educational materials are available from the American Dental Association (www.ada.org). Those in the highest risk categories should understand the need to take the prophylactic antibiotics. Finally, they should be made aware of symptoms (such as fever of unexplained origin) that could indicate IE and the importance of contacting the patient's physician.

The risk of IE may change after operative or other reparative procedures [34]. For example, successful closure of atrial septal defect, ventricular septal defect, or patent ductus arteriosus reduces the patient's long-term risk for development of endocarditis. Other procedures, such as palliative shunts and conduits, do not alter the patient's long-term risk for endocarditis. Still other procedures, such as replacement of a native cardiac valve with a prosthetic valve, actually put the patient in a higher risk category. Patients/parents should be reminded that a child's need for antibiotic prophylaxis could change as they go through treatment. Finally, as more data become available, subsequent revisions of antibiotic prophylaxis guidelines from authorities such as the AHA may alter a given patient's need to take these routine antibiotics.

61 Rheumatic Fever

Shaji C. Menon & Lloyd Y. Tani

University of Utah, Salt Lake City, UT, USA

Acute rheumatic fever (ARF) is a systemic inflammatory autoimmune disease secondary to infection with Lancefield group A β-hemolytic streptococci (*Streptococcus pyogenes*) [1]. In its acute stage, the disease is characterized by inflammation of several organ systems, including the heart, joints, brain, and skin, with the clinical manifestations of arthritis, carditis, chorea, erythema marginatum, and subcutaneous nodules [2]. Antibiotic treatment of and prophylaxis against streptococcal pharyngitis can prevent the occurrence and recurrence of ARF [3,4]. Long-term sequelae of the inflammation are minimal, with the exception of the heart, in which inflammation during the acute phase with subsequent fibrosis and scarring of the cardiac valves may lead to rheumatic heart disease (RHD) (see Chapter 62). Starting from the middle of the twentieth century, the incidences of ARF and RHD have significantly decreased in industrialized and developed countries [5], primarily as a result of vast improvements in living conditions among the populations. With a few notable exceptions, ARF and RHD are now largely diseases of developing countries and of underprivileged and indigenous populations of developed countries [6–18].

Epidemiology

According to reports published by the World Health Organization (WHO) in 2005, the prevalence of RHD worldwide is at least 15.6 million [6]. Every year, 280 000 new cases of RHD occur and 230 000 people die secondary to RHD [6]. The reported mortality rate for RHD varies from 0.5 per 100 000 population in Denmark to 8.2 per 100 000 population in China [19]. The true incidence and prevalence of RHD are thought to be significantly higher than these conservative estimates. Epidemiologic data from underdeveloped nations are incomplete or unavailable. The prevalence of RHD in children is highest in sub-Saharan Africa (5.7 per 1000) and in the indigenous populations of Australia and New Zealand (3.5 per 1000) and south central Asia (2.2 per 1000) [2,20–24]. The prevalence of RHD increases with age and peaks between 25 and 34 years [6]. In developed countries, the prevalence of RHD is estimated to be ~0.5 per 1000 [2].

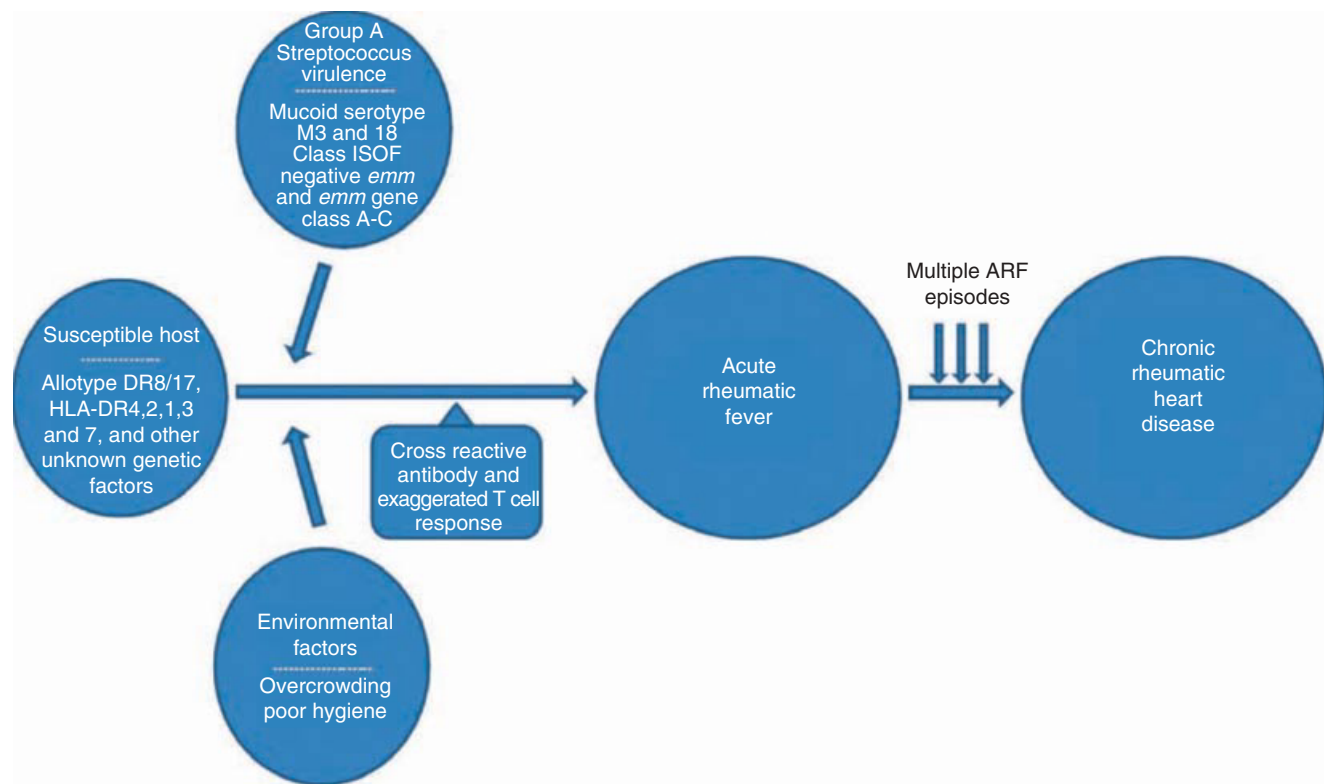
ARF develops following group A β-hemolytic streptococcal infection of the upper respiratory tract. However, only 2–3% of patients with untreated streptococcal pharyngitis develop ARF. In populations where rheumatogenic group A streptococci are endemic, the lifetime cumulative incidence of ARF in exposed individuals has been estimated at 3–6% [13]. The age distribution of ARF incidence follows the incidence of streptococcal pharyngitis. ARF occurs most commonly in children between 5 and 14 years of age and is extremely rare in children <2 years old [25,26]. Only 5% of first episodes occur in children <5 years old [27]. The first episode of ARF usually occurs before adolescence and, in the absence of secondary prophylaxis, recurrences are common during adolescent and early adulthood years. Although reported, initial attacks of ARF are uncommon in adults [6]. Ethnic and racial differences in ARF and RHD burden are well documented [6–18,20]. In some developing countries, the incidence of ARF exceeds 50 per 100 000 children [6–18]. The highest reported rates are in the indigenous populations of Australia and New Zealand. In New Zealand, the incidence of ARF in school-age Maori and Pacific Islanders is 80–100 per 100 000, compared with an incidence of 10 per 100 000 in the non-indigenous population [28]. Even more striking are the rates as high as 245–351 per 100 000 reported in Australian aboriginal children [28]. These racial and ethnic differences in ARF and RHD persist even when corrected for socioeconomic status. In addition to this ethnic and racial predilection, there is also a familial predilection [1]. The


Figure 61.1 Pathogenic pathway for ARF and RHD. (Modified from Carapetis *et al. Lancet* 2005;**366**:155–68.)

likelihood of an individual developing ARF is five times higher if a family member has had ARF [1]. In a study of children raised separately from their parents in an Israeli kibbutz, the relative risk for development of ARF was 2.93 in children with a family history of RHD compared with those without a family history [29]. Furthermore, increased concordance in monozygotic twins compared with dizygotic twins has been reported [1,30]. The inheritance pattern is multifactorial and not simple Mendelian single-gene inheritance. Although no gender predisposition has been reported in most series, a female predominance of ARF and RHD has been reported in some studies [12]. The female predilection in these studies may be attributed to reduced access to health care for females in some populations.

Pathogenesis

There is irrefutable epidemiological evidence for an association between group A β-hemolytic streptococcal infections and ARF. ARF is the result of an exaggerated immune response in a susceptible individual to the cross-reactive group A streptococcal epitope [6]. The three key factors that determine the pathogenesis of ARF are (1) rheumatogenicity of group A streptococcus, (2) genetic susceptibility, and (3) host immune response [6] (Figure 61.1).

The organism

Streptococcus pyogenes (group A streptococcus) is a Gram-positive, β-hemolytic, non-motile, non-spore-forming coccus that occurs in chains or in pairs (Figure 61.2a) and is commonly found in the throat and on the skin. The prevalence of group A streptococcus carriage in an unselected, office-based adult population has been estimated at 5–12% [19,31,32]. Group A streptococcus may cause scarlet fever, impetigo, otitis media, sinusitis, or cellulitis, and is the most common cause of bacterial pharyngitis among children and adults [33]. Streptococcal pharyngitis occurs primarily among children 5–15 years of age [34].

The typical clinical and epidemiological features of group A streptococcal pharyngitis are shown in Table 61.1 [35]. Other more serious infections caused by group A streptococcus include necrotizing fasciitis, myositis, meningitis, and streptococcal toxic shock syndrome [36]. ARF and acute glomerulonephritis occur as immune-mediated post-streptococcal sequelae [36]. Group A streptococci produce a multitude of virulence factors and toxins, including M protein (impedes phagocytosis, binds immunoglobulins), adherence and colonization factors such as streptococcal fibronectin-binding protein 1 and lipoteichoic acid, hyaluronic acid capsule (inhibits phagocytosis by polymorphonuclear leukocytes and macrophages), and factors facilitating liquefaction of pus and spreading of infections
Figure 61.2 A 10-year-old boy presented with a 2-week history of fever, arthritis, breathlessness on exertion, and signs of heart failure. Throat swab culture was positive for group A streptococcus. (a) Grams stain of throat swab culture shows group A streptococcus in chains and pairs. (b) 2D echocardiogram, parasternal long-axis view shows posteriorly directed mitral valve regurgitation. The patient developed worsening heart failure secondary to mitral valvulitis requiring surgical intervention and mitral valve replacement. (c) Gross pathology specimen of resected mitral valve anterior leaflet shows thickened and edematous leaflet suggestive of acute rheumatic fever-associated valvulitis. (d) Microscopic images show signs of acute inflammation and foci of fibrinoid necrosis (arrow) with surrounding lymphohistiocytic infiltrate consistent with the patient's clinical history of acute rheumatic carditis. Following surgical replacement of the mitral valve, the patient's clinical condition improved and left ventricular function normalized. Ao, aorta; LA, left atrium; LV, left ventricle.

Table 61.1 Clinical and epidemiological features suggestive of group A streptococcal tonsillopharyngitis[a].

5–15 years of age
Presentation in winter or early spring (in temperate climates)
History of sick contact
Sudden-onset sore throat
Pain on swallowing
Fever
Scarlet fever rash
Headache
Nausea, vomiting, and abdominal pain
Tonsillopharyngeal erythema or exudate
Soft palate petechiae ("doughnut" lesions)
Red and swollen uvula
Tender, enlarged anterior cervical nodes

[a]Features suggestive of viral origin are coryza, cough, conjunctivitis, hoarseness, diarrhea, and characteristic exanthems or enanthems.

such as streptokinase, streptodornase (DNases A, B, C, and D), hyaluronidase, streptolysins, and streptococcal pyrogenic exotoxin B [37]. In addition to these factors, *S. pyogenes* possesses additional virulence factors. C5a peptidase (SCPA) inhibits the chemotactic signals by cleaving the complement component of C5a [37]. A protein antigen very closely associated with the M protein molecule of group A streptococci is called serum opacity factor (OF). OF opacifies mammalian serum by interacting with high-density lipoproteins and is antigenic and type specific [34]. OF is a potential vaccine candidate because it can evoke antibodies that protect against infections by OF-positive group A streptococci [38].

Rebecca Lancefield classified β hemolytic streptococci into 20 different groups (Lancefield groups) (A–H and K–V) based on the serologic reactivity of cell wall polysaccharide antigens [34]. The M protein is considered a major somatic virulence factor that binds the host fibrinogen and blocks the binding of complement to the underlying

peptidoglycan and inhibits phagocytosis [34]. M protein is a filamentous α-helical coiled macromolecule that is part of the cell membrane [34]. M protein is the major cause of antigenic shift and antigenic drift among group A streptococcus [39]. Based on M protein, about 120 different serotypes or genotypes of *S. pyogenes* have been identified [36]. Following an acute infection, type-specific antibodies against M protein confer immunity. Several epitopes of M protein cross-react with human myocardial and brain tissue. M serotypes 1, 3, 5, 6, 18, 19, and 24 may form mucoid colonies heavily encapsulated with antiphagocytic properties which have been associated with ARF, and are considered rheumatogenic [19,40–42]. In contrast, M serotypes 2, 49, 57, 59, 60, and 61 have been associated with pyoderma and glomerulonephritis, but not ARF [19]. Other reports have challenged this notion of higher rheumatogenic potential of specific M serotypes [19,43–45]. In many regions of the world with a high prevalence of ARF and RHD, rheumatogenic M serotypes are infrequently seen [44]. Furthermore, serotypes associated with skin infections have been associated with ARF [45]. In the Maori population of New Zealand, the classic rheumatogenic M-serotypes associated with pharyngitis are absent [44]. In the native Australian population with a high incidence of ARF, there is a low incidence of streptococcal pharyngitis and pharyngeal carriage, but a high incidence of pyoderma [46,47]. Although this suggests that other serotypes, possibly associated with streptococcal impetigo, may play a role in the pathogenesis of ARF in some patients, there is lack of conclusive evidence of streptococcal skin lesions leading to ARF.

Based on production of OF, the group A streptococcus can be classified into two antigenic groups, class I and II [48]. Class I strains are predominantly serum OF-negative and are associated with ARF, whereas class II strains are serum OF-positive and are associated with post-streptococcal glomerulonephritis [49]. Another means of classifying group A streptococcus is by M genotype; *emm* and *emm*-like genes on the group A streptococcus chromosome can be used to classify them into five groups, A–E [50]. Groups A–C are associated with pharyngitis and ARF, group D is associated with skin infections, and group E is known to cause infection at either site [50]. In highly endemic regions of the world, the streptococci identified from patients with ARF show evidence of significant genetic recombination, cross-trophism between skin and pharyngeal strains, and blurring of a distinction between rheumatogenic and non-rheumatogenic strains [51]. Another possible mechanism for pathogenicity of skin streptococcal strains in ARF includes immune priming of a host by repeated impetigo or pharyngeal colonization resulting in a subsequent exaggerated immune response. Horizontal transfer of genetic information between skin and throat strains of streptococci has also been documented [6].

Host factors

Only 2–3% of individuals with acute streptococcal pharyngitis develop RF, indicating the role of host susceptibility in the development of ARF [19]. Familial clustering and autosomal recessive inheritance of ARF have been reported [52,53]. The incidence of post-streptococcal pharyngitis associated recurrent ARF in individuals with a past history of ARF is as high as 65% compared with 2–3% in the general population [54]. Specific human leukocyte antigens (HLA-DR) class II alleles are associated with ARF [55]. The role of HLA-DR antigens in ARF susceptibility may be explained by their modulating role in the immune response [19,55]. HLA-DR alleles DR4, DR2, DR3, and DRw6 have been implicated as possible disease susceptibility alleles [56–60]. The presence of multiple predisposing HLA-DR alleles suggests that HLA predilection is not linked to one specific allele but is likely influenced by a gene near the HLA-DR locus. HLA-DR4 is present more frequently in Caucasians, DR2 in African-American populations, DR1 and DRw6 in South African populations, and HLA-DR3 in Indian populations [19,61]. Furthermore, there are HLA-specific predilections for different organ system involvement: HLA-A10 and HLA-DR11 with cardiac involvement and HLA-C2 in ARF without cardiac involvement. However, these susceptibility alleles vary in different populations [56–60]. Another susceptibility marker of ARF disease is a specific B-cell alloantigen,(D8/17) [62]. In one study, 95% of patients with a history of ARF carried the D8/17 antigen. In contrast, this antigen was found in 50% of first-degree relatives and only 4% of controls. This association between D8/17 and ARF has been found in different patient groups, including Australian aboriginal, North American, Caribbean, Israeli, Russian, Mexican, and Chilean populations [63]. The D8/17 antigen is thought to be a binding site for group A streptococcus on B cells. Although the D8/17 antibody may bind to the antigen on the B cells and cross-reacts with human cardiac, skeletal, and smooth muscle, and with streptococcal M protein, the precise role of the D8/17 antigen in ARF pathogenesis remains uncertain [64]. The D8/17 antigen was not highly prevalent in an Indian RHD population, which showed a higher incidence of monoclonal antibodies PG-12A, PG-13A, and PG-20A raised against B cells [65–67]. High concentrations of circulating mannose-binding lectin 72 and polymorphisms of transforming growth factor-β 173 and immunoglobulin genes have been associated with ARF [68,69].

Host immune response

Molecular mimicry between group A streptococcus antigens and human host tissue is believed to be the basis of an autoimmune response leading to the manifestations of ARF [70,71]. Structural and immunological similarities between α-helical cardiac proteins such as cardiac myosin, laminin,

and vimentin and group A streptococcus M protein, which is also α-helical, has been postulated as responsible for this molecular mimicry [72,73]. Laminin is an extracellular matrix protein present in the basement membrane of valves and around endothelium. This may explain the valvitis of ARF. T cells from rats immunized with group A streptococcus M protein and from RHD patients proliferate in response to both group A streptococcus M protein and cardiac myosin, but not to skeletal muscle myosin [57]. Human valve tissue also cross-reacts with streptococcus *N*-acetylglucosamine in the group A streptococcus carbohydrate. Normal cardiac cell turnover might expose self cardiac antigens, such as intracardiac myosin, to T cells. Subsequent exposure to group A streptococcus M protein that cross-reacts with cardiac myosin results in an exaggerated immune response from these T cells. The immune response is further emboldened by the high levels of cytokines in the human body resulting from streptococcal superantigens [74,75]. Apart from the initial antibody-mediated damage, T cell-mediated cellular immunity and macrophage infiltration are thought to result in long-term valvar fibrosis and dysfunction (chronic RHD).

Environmental factors

Disparity in the incidences of ARF and RHD between developing and developed nations indicates the key role that environmental factors play in the pathogenesis of disease. Poor living conditions, overcrowding, and limited access to health care are the most significant determinants of disease distribution [19]. In temperate climates, the incidence of streptococcal infections and ARF is higher in early fall, late winter, and early spring [19].

Pathology

Rheumatic fever is characterized by inflammation of the heart, skin, joints, and brain. Cardiac inflammation and its sequelae are responsible for the majority of immediate and long-term morbidity and mortality [19]. Acute RHD is a pancarditis, involving all three layers of the heart [19]. However, valvitis, rather than myocarditis or pericarditis, is the dominant factor responsible for the cardiac clinical manifestations, morbidity, and mortality associated with ARF [76–79]. Rheumatic carditis is almost always associated with mitral valvitis [19]. Unlike other myocarditides, significant myocyte necrosis and troponin elevation are rare. Cardiac manifestations are secondary to significant mitral and/or aortic valvar regurgitation and the resultant acute left heart volume overload (Figure 61.2b). The mitral valve is the primary target of endocardial involvement in ARF [80] (Figure 61.2c). Mitral annular dilatation and chordal elongation of the anterior leaflet of the mitral valve cause mitral regurgitation and, in the extreme, prolapse of the anterior leaflet with resultant mitral regurgitation directed posterolaterally

[80,81]. Dilatation of the left ventricle and restriction of posterior mitral leaflet mobility contribute to chronic MR in patients with RHD [82]. Mitral valvar involvement also includes valve edema and aggregation of fibrin and platelets forming small (1–3 mm) vegetations sometimes called "verrucae" along the closure lines of the leaflets [83,84]. The pathology of chronic RHD is described in Chapter 62.

The distribution of valvar involvement is variable. The mitral valve is most commonly involved, followed by aortic, tricuspid, and rarely pulmonary valve. Laminin in the valvar basement membrane and endothelium cross-reacts with sensitized T cells which may be responsible for initial valvitis [85]. However, cell-mediated immunity resulting in infiltration by macrophages and T cells is responsible for chronic valve injury [86,87]. Isolated pericarditis in the absence of valvitis is rare. Myocarditis may result in conduction system abnormalities. Endomyocardial biopsy studies in ARF have shown the absence of focal or diffuse myocytic necrosis and cellular infiltration of mononuclear lymphocytes, classic features of myocarditis as defined by Dallas Criteria [19]. There is usually focal perivascular mononuclear cell infiltration resulting in formation of the Aschoff body that is considered virtually pathognomonic of ARF [19]. An Aschoff body consists of a central area of fibrinoid collection surrounded by lymphocytes, histiocytes, and large basophilic cells (Figure 61.2d). Many of these cells have elongated nuclei with a distinctive chromatin pattern, sometimes called caterpillar or owl-eye nuclei. Cells containing these nuclei are called Anichkov's myocytes. These foci may be found in the pericardium, the myocardium, or the valves. Coronary arteritis has been described. As healing starts, Aschoff nodules and inflammatory cells disappear and fibroblastic proliferation occurs [88].

ARF-associated arthritis is characterized by a fibrinous and sterile effusion without erosion of the joint surfaces or pannus formation. Erythema marginatum is secondary to vasculitis and the subcutaneous nodules have histological features similar to Aschoff's nodules. Inflammation of the basal ganglia and caudate nuclei is responsible for Sydenham's chorea. The changes in the brain, joints, and skin usually resolve with time and do not result in long-term sequelae.

Clinical features and diagnosis

ARF shares many clinical features with other collagen vascular disorders. There is no single diagnostic test for ARF. The diagnosis is based on the Jones criteria, established in 1944 [89]. The criteria are divided into major and minor manifestations and in most patients the diagnosis requires evidence of a preceding group A streptococcal infection. The criteria have been revised and updated multiple times (Table 61.2) [90–93] with the aim of increasing the specificity of diagnosis following decreasing incidence of ARF in industrialized

Table 61.2 Updated Jones criteria (1992) for the diagnosis of a first episode of ARF [19][a].

Major manifestations	Minor manifestations	Supporting evidence of antecedent group A streptococcal infection
1. Carditis 2. Polyarthritis 3. Chorea 4. Erythema marginatum 5. Subcutaneous nodules	*Clinical* 1. Arthralgia 2. Fever *Laboratory* 1. Elevated acute-phase reactants: erythrocyte sedimentation rate or C-reactive protein 2. Prolonged P–R interval on electrocardiogram	1. Elevated or rising streptococcal antibody titer 2. Positive group A streptococcal throat culture or rapid streptococcal antigen test

[a]Two major or one major and two minor manifestations must be present, plus evidence of antecedent group A streptococcal infection are required for diagnosis of ARF. In patients with established RHD, recurrence of ARF requires two minor manifestations plus evidence of antecedent group A streptococcus infection. Chorea and indolent carditis do not require evidence of antecedent group A streptococcal infection.

nations [94]. In underdeveloped countries and indigenous populations of the developed countries, strict application of the updated Jones criteria may result in underdiagnosis of ARF. The WHO criteria (2002–2003) made the diagnostic criteria for recurrent ARF less stringent [19] to increase the sensitivity of diagnosis of recurrent ARF in regions of the world where the incidence is higher.

Based on the Jones criteria, two major or one major and two minor manifestations, plus evidence of antecedent group A streptococcus infection, are required for diagnosis of ARF [19]. Chorea and indolent carditis do not require evidence of antecedent group A streptococcus infection. It is important to remember that ARF is not ruled out if the Jones criteria are not met. This is similar to the atypical Kawasaki patient who subsequently develops coronary aneurysms. The WHO includes criteria (2002–2003) for diagnosing a recurrent episode of ARF:

1 In patients without established RHD: diagnose as if the first episode with Jones criteria.

2 In patients with established RHD: diagnosis requires two minor manifestations, plus evidence of antecedent group A streptococcus infection. Evidence of antecedent group A streptococcus infection as per Jones criteria, but with addition of recent scarlet fever [19].

Revision of some of criteria is being considered. In high-risk populations, the major features considered for revision to increase the sensitivity include joint manifestations, the diagnosis of carditis, and the definition of recurrent ARF. Monoarthritis or a polyarthralgia rather than the classic migratory polyarthritis are a presenting features in the indigenous New Zealand population. Furthermore, echocardiography is more sensitive than auscultation in detecting rheumatic valvitis, allowing detection of subclinical carditis.. The role of echocardiography in the diagnosis of ARF is still in question. Published guidelines from Australia (2005) and New Zealand (2006) accept subclinical carditis, monoarthritis, and polyarthralgia as major criteria [2,95].

Major manifestations

Arthritis

Arthritis is present in >75% of patients with ARF and is both the most common and earliest major manifestation [19]. It usually affects the large joints (knees and ankles followed by wrists and elbows) [19]. Joint involvement is more common in adolescents than adults [19]. An inverse correlation between the severity of arthritis and carditis has been reported [54]. Joint involvement ranges from arthralgia alone to severe arthritis characterized by pain, swelling, warmth, erythema, severe limitation of motion, and exquisite tenderness to pressure or motion. Patients with severe lower limb arthritis may be unable to walk ("pseudo-paralysis"). The hips and small joints of the hands and feet are occasionally affected. Involvement of shoulders and lumbosacral, cervical, sternoclavicular, and temporomandibular joints is rare. This is an asymmetric and migratory polyarthritis [19]. The arthritis in one joint can last for a few hours and then appear in another joint. A number of joints can be affected in succession, and the periods of involvement may overlap. In endemic areas, such as India and Australia, joint involvement may be less severe [96,97], perhaps from early self-treatment with anti-inflammatory agents. The arthritis of ARF is highly responsive to salicylates. If the arthritis persists for more than 48–72 h following

Table 61.3 Common differential diagnoses [19,157,166].

Diagnosis	Confirmatory test
Polyarthritis and fever	
Infectious	Synovial fluid and blood culture
Bacterial septic arthritis	Serology
Viral arthritis	Serology
Lyme disease	Blood culture
Bacterial endocarditis	Culture and serology
Reactive	
Enteric infection, Reiter syndrome	Culture
Inflammatory bowel disease	Clinical findings
Rheumatoid arthritis	Clinical findings and serology
Systemic lupus erythematosus	Clinical findings and serology
Chorea	
Seizures	Electroencephalogram (EEG) and altered consciousness
Familial chorea	Family history, MRI or CT scan
Cerebrovascular accidents	MRI and CT scan
Drug intoxication	Drug screen (phenytoin, metoclopramide, amitriptyline, fluphenazine)
Oral contraceptive-induced chorea	History
Pregnancy-induced chorea	History and pregnancy test
Wilson disease	Serum ceruloplasmin and urine copper
Hyperthyroidism	Thyroid function test
Hyperparathyroidism	Low serum calcium and high phosphorus
Erythema marginatum	
Sepsis	Blood culture
Drug reaction	History and drug screen
Glomerulonephritis	Urine microscopy and analysis
Juvenile rheumatoid arthritis	Clinical findings and serology
Lyme disease	Serology

initiation of salicylate therapy, the diagnosis of ARF should be reconsidered. Untreated, the arthritis of typically lasts for 2–3 weeks. If the joint is aspirated on suspicion of septic arthritis, the synovial fluid usually contains thousands of white blood cells, with a preponderance of polymorphonuclear leukocytes. Bacterial cultures are sterile [19]. The differential diagnosis for arthritis and other major criteria are shown in Table 61.3.

The term "post-streptococcal reactive arthritis" (PSRA) was first introduced in 1959 to describe arthritis occurring after an episode of group A streptococcal pharyngitis in the absence of other major criteria of ARF [98]. PSRA typically affects the small joints and is less responsive to anti-inflammatory agents [99]. There is no clear distinction between PSRA and ARF associated arthritis and some of these patients have developed full-blown ARF [99–101].

Although these patients have a lower risk of carditis, they should be observed for several months for evidence of cardiac involvement [101]. PSRA should be diagnosed with caution in populations with high risk of ARF. Antibiotic prophylaxis is recommended for 5 years in high-risk populations and for 1 year in low-risk populations [100,101]. If clinical evidence of carditis is not observed, the prophylaxis can be discontinued. If valvar disease is detected, the patient should be classified as ARF and continue secondary prophylaxis (discussed below).

Carditis

Although ARF is a systemic disease, the only manifestation leading to permanent damage is carditis. Carditis is the single most important prognostic factor in ARF [19]. RHD, a sequela of ARF, is the most common cause of acquired heart disease worldwide [19]. It accounts for 35–40% of cardiovascular disease-related hospital admissions, and is the predominant reason for cardiac surgery in developing countries. About 50% of patients with ARF have cardiac involvement [102]. The interval between arthritis and carditis rarely exceeds 7–10 days. The severity of cardiac involvement is variable, and the clinical diagnosis of carditis is based on the appearance of murmurs of mitral and/or aortic regurgitation, a pericardial friction rub, sometimes with radiographic cardiomegaly, and/or signs of heart failure [19]. Recurrent ARF with carditis is diagnosed by a new murmur, a change in a previous murmur [19], a new pericardial friction rub, or a radiographic increase in heart size [19]. Myocarditis without valvitis is unlikely to be of rheumatic origin [19].

Symptoms of carditis are related to the degree of valvar dysfunction and pericardial inflammation, and include shortness of breath, dyspnea on exertion, cough, paroxysmal nocturnal dyspnea, chest pain, and orthopnea. Myocarditis may result in disproportionate sinus tachycardia in a resting patient. Pericarditis is evident as distant heart sounds, a friction rub, and chest pain [19]. Low-voltage QRS complexes on ECG and cardiac enlargement on chest X-ray suggest a significant pericardial effusion. Pericarditis invariably occurs with concomitant left-sided valvar involvement. Both tamponade and subsequent constrictive pericarditis are very uncommon. A diagnosis of ARF should be reconsidered when pericarditis is present in the absence of valvar involvement. Uncommon presentations are arrhythmias and conduction system abnormalities. A prolonged PR interval (first-degree AV block) is a manifestation of myocarditis and a minor Jones criterion.

Inflammation of valve support structures along with changes in leaflets results in mitral valve dysfunction and regurgitation [81]. Isolated mitral valve involvement is seen in ~65% of patients, isolated aortic valve involvement in ~5%, and combined mitral and aortic valve involvement in ~30% of patients with carditis. The tricuspid and pulmonary valves are rarely involved. Characteristic murmurs of acute

mitral valvitis include the high-pitched, blowing, holosystolic, apical murmur of mitral regurgitation. In some patients, the murmur may be audible after positioning the patient in a left lateral decubitus position and auscultating over the apex with the patient at held expiration. With significant mitral regurgitation, a low-pitched, apical, mid-diastolic, flow murmur (Carey Coombs murmur) resulting from relative mitral stenosis can be heard. This murmur never occurs in isolation. Some authorities describe another mid-diastolic murmur that is isolated, not associated with cardiomegaly or mitral regurgitation, that is believed to be due to turbulence as blood flows over the mitral vegetations. Aortic regurgitation results in a high-pitched, decrescendo, diastolic murmur heard best at the mid-left sternal border. More subtle aortic regurgitant murmurs may be audible with the patient sitting up, leaning forward, with held expiration. Severe aortic regurgitation leads to bounding pulses due to aortic runoff. In chronic RHD, murmurs of mitral and aortic stenosis may be heard.

Echocardiography and ARF

Valvitis is the characteristic finding of the endocardial involvement in acute rheumatic carditis, with mitral regurgitation the most common abnormality. Echocardiographic findings of acute rheumatic mitral regurgitation include (1) annular dilatation, (2) chordal elongation/rupture, (3) leaflet prolapse, (4) coaptation defect, (5) nodules on valve tips with mild thickening of leaflets, and (6) left ventricular dilatation and subsequent dysfunction with significant valvar regurgitation [19,81,82]. Small nodules on the mitral valve leaflet found in >25% of patients with ARF disappear on follow-up [82]. Ventricular dilatation is usually not from myocardial dysfunction and systolic function indices are preserved. The ventricular function normalizes rapidly after surgical correction of significant valvar regurgitation [19].

Very mild valvar involvement may be subclinical and diagnosed solely by echocardiography in patients without a murmur [103–107]. Compared with the pre-echocardiography era, the auscultatory skills of medical professionals have declined. The clinical diagnosis of rheumatic carditis may not be made with confidence [106–108]. Mild valvar regurgitation is not always detected by routine clinical auscultation and may be missed even by expert clinicians [102,109]. In the Utah ARF outbreak, Doppler evidence of mitral regurgitation was demonstrated in 19% of ARF patients who were clinically considered to have either isolated arthritis or pure chorea [110]. Using WHO echocardiographic criteria, the prevalence of subclinical carditis is about 18% in patients with ARF without a murmur [111]. Although echocardiography has greater sensitivity than auscultation for assessing cardiac and valvar function, the role of echocardiography in identifying acute rheumatic carditis remains controversial [112]. Echocardiographic evidence of trivial amounts of valvar regurgitation is common in the normal population [113].

Physiological mitral regurgitation is present in 2.4–45% of individuals, aortic regurgitation in 0–33%, tricuspid regurgitation in 6.3–95%, and pulmonary regurgitation in 21.9–92% [19,114–116]. Echocardiographically detected physiologic mitral regurgitation is seen in 38–45% of healthy children with a normal heart, and may be even higher in febrile patients [113,117]. Physiologic valvar regurgitation must be distinguished from pathologic regurgitation by specific criteria. On echocardiography, mitral valvar regurgitation is considered pathologic if a mosaic color jet is visible in two imaging planes, is holosystolic by spectral Doppler, has a peak velocity >2.5 m s, and extends >1 cm beyond the plane of valve leaflets [19,105,118]. Similarly, aortic regurgitation is considered pathologic if it is visible in two planes, is holodiastolic, and extends >1 cm beyond the aortic valve leaflets [19,106]. "Physiologic" tricuspid and pulmonary regurgitation are much more common in the general population and in isolation cannot be considered a sign of rheumatic carditis. At present, the Jones criteria do not include subclinical carditis. The barriers for including echocardiographic criteria for diagnosis of ARF include (1) the long-term outcome of subclinical carditis is not well known, (2) difficulty in differentiating subclinical pathologic from physiological regurgitation, (3) limited availability of echocardiography in regions with a high incidence of ARF, and (4) risk of overdiagnosis of ARF in low-risk populations. Recent studies of RHD prevalence using echocardiography in India and Africa showed unexpectedly high rates of subclinical RHD (21–51 per 1000 school children) [119,120], perhaps from unrecognized subclinical carditis. Judicious use of echocardiography in high-risk populations may improve the sensitivity of ARF diagnosis and avoid misdiagnosis of ARF [19].

The recent Australian and New Zealand guidelines include echocardiographic subclinical carditis as a major criterion for ARF. All patients with suspected or definite ARF should have echocardiography to evaluate carditis [121–123]. The WHO recommends that silent indolent rheumatic carditis diagnosed by echocardiography should be managed as RHD until proven otherwise [19].

Sydenham's chorea (chorea minor, "St. Vitus Dance")

Sydenham's chorea, the third most common manifestation of ARF, occurs in 5–36% of patients [19,124] but rarely after 20 years of age. Chorea is a manifestation of involvement of the basal ganglia. The disease was first named by Thomas Sydenham in 1686 as "St. Vitus Dance" to differentiate it from then prevalent exorcism-associated dancing. The latent period between ARF and chorea is usually between 1 and 7 months and can be as long as 12 months [19]. Because of this long latency period, polyarthritis and chorea do not occur simultaneously and evidence of an antecedent streptococcal infection is often absent [19]. The clinical features of

chorea include emotional lability, personality change, muscular weakness, and uncoordinated, involuntary, abrupt, and purposeless movements. Other features of chorea include dysarthric speech, gait problems, and poor fine motor skills. The onset of chorea may be subtle and characterized by fretfulness, irritability, inattentiveness to schoolwork, and fidgety behavior. Chorea can be either unilateral or bilateral [125]. The manifestations are exacerbated by stress and they disappear or become less pronounced during sleep and with sedation. Hypotonia and abnormal movements result in lack of coordination, gait disturbances, and speech impairment, sometimes severely disturbing activities of daily living. Patients with chorea may manifest psychological and psychiatric issues such as depression, anxiety, personality changes, emotional lability, obsessive–compulsive disorder (OCD), tics, and attention deficit disorder. Clinical maneuvers to elicit features of chorea include (1) milkmaid's grip (contraction and relaxation of the hand muscles while squeezing the examiner's fingers), (2) wormian darting movements of the protruded tongue (bag of worms), (3) staccato and jerky speech, (4) "spoon" or "dish" appearance of the extended arms due to flexion of the wrist and hyperextension of the metacarpophalangeal joints, (5) pronation of one or both hands when raised above the head ("pronator sign"), and (6) worsening of handwriting or difficulty in buttoning and unbuttoning while testing for fine motor skills [19]. Patients with chorea gravidarum or chorea occurring with oral contraceptives may have a past history of Sydenham's chorea, suggesting enhanced susceptibility to chorea in some individuals [19]. Sydenham's chorea is usually self-limiting and resolves after a median duration of 15 weeks [19], ranging from 1 week to more than 2 years; it may recur [19]. The spectrum of post-streptococcal disease has expanded with the recognition of pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS), which is characterized by OCD or a tic disorder with abrupt onset in childhood or exacerbations of symptoms temporally related to a preceding streptococcal infection [126,127]. Despite growing evidence of association between preceding streptococcal infection and OCD, its pathophysiologic implications remain controversial [127].

Erythema marginatum

Erythema marginatum is rare in ARF, occurring in 3–5% of patients [128], but some reports find it in >15% of ARF patients [19]. The variable incidence is possibly related to its transient nature. The rash is characterized by erythematous, serpiginous, macular, or papular lesions with a pale center (normal skin). The rash has been referred to as "smoke rings" [19]. The lesions are multiple, non-pruritic, non-painful, blanching, change in size and shape, and are often evanescent. They occur primarily on the trunk and proximal extremities but rarely on the face. They can be accentuated by warming the skin or friction. Erythema marginatum almost never occurs as the sole major manifestation, and is almost always associated with clinical, but not necessarily severe, carditis. Erythema marginatum occurs early in the ARF disease process and usually resolves quickly. It can persist or recur for months or even years after ARF has subsided [19].

Subcutaneous nodules

Subcutaneous nodules are uncommon, occurring in 2–3% of patients with ARF, but the incidence varies significantly in different populations and has been reported as >20% in some series [19,129]. These lesions are characterized by firm nodules approximately 0.5–2 cm in diameter along the extensor surfaces of tendons and on bony prominences. Sites of predilection include the extensor surfaces of the elbows, knees, and the wrists, the occiput, and the spinous processes of the thoracic and lumbar vertebrae. These nodules are non-tender and mobile with normal-appearing overlying skin and can be easily missed. They are not evanescent, usually persisting for a few days, ranging up to 1–2 weeks, rarely more than 1 month. Subcutaneous nodules almost never occur as the sole major manifestation, and most commonly occur with significant carditis [130].

Minor criteria and other manifestations

Fever and arthralgia are "minor" Jones criteria for the diagnosis of ARF. Although these two findings are the most common features of ARF, they lack specificity and are therefore classified as minor criteria. Fever is an almost universal manifestation of ARF and ranges from 101 to 104 °F (38.4 to 40.0 °C). The fever lacks a characteristic pattern. The fever may be low grade in children with mild carditis or patients may be afebrile at the time of presentation, especially in febrile patients who have received anti-inflammatory medication before a temperature is documented. Patients with chorea are usually afebrile. Arthralgia without objective signs of arthritis is common. Arthralgia usually involves larger joints, is often migratory in nature, and can range from mild discomfort to debilitating and severe pain. Arthralgia cannot be used as a minor criterion if arthritis is used as a major criterion.

An ECG should be performed in patients with suspected ARF. First-degree atrioventricular (AV) block is a minor Jones criterion [131]. First-degree AV block indicates more severe carditis, but is not associated with a greater likelihood of progression to RHD, and can be seen in more than one-third of patients with acute group A streptococcal infection in the absence of ARF [130,132]. With carditis, other ECG findings include sinus tachycardia, other conduction abnormalities, and arrhythmias. More severe conduction abnormalities can be seen [133,134].

Abdominal pain (typically periumbilical or epigastric) and epistaxis occur in ~5% of patients with ARF and may precede other manifestations [19,131]. They lack specificity and are not included in the Jones criteria.

Laboratory testing

No single laboratory test is diagnostic. Elevation of acute-phase reactants, such as C-reactive protein and erythrocyte sedimentation rate (ESR), is a minor Jones diagnostic criterion and is always present in the early phase of ARF. ESR is normal in patients with heart failure and increases as heart failure resolves [135]. Elevated acute-phase reactants can help distinguish between ARF and chronic and indolent RHD and also guide the duration of therapy.

A complete blood count (CBC) and peripheral smear may reveal leukocytosis with a predominance of polymorphonuclear leukocytes. Mild to moderate normocytic, normochromic anemia may be seen. The urine may contain protein, white cells, and red cells.

Radiographic studies may reveal cardiomegaly secondary to pericardial effusion or chamber enlargement in significant valvar regurgitation. Pulmonary edema may be evident in severe carditis and valvar regurgitation. Cardiac catheterization is rarely required in the management of ARF. Cardiac catheterization may be recommended in patients with chronic RHD who might benefit from balloon valvoplasty of a stenotic mitral valve or for coronary vascular evaluation prior to surgery in adults [136,137].

Documentation of a recent group A streptococcal infection is key. A throat culture or rapid streptococcal antigen test should be performed, but these tests are positive in only a minority of patients because of the latency period between pharyngitis and ARF. The gold standard for detecting *S. pyogenes* remains a throat swab culture, but 24–48 h are needed for growth of the bacteria and this may delay the initiation of antibiotics [19]. Rapid streptococcal tests based on carbohydrate cell-wall antigen detection have high specificity but the sensitivity varies with the type of test kit [19]. Furthermore, some patients are chronic carriers of streptococci. Measurement of streptococcal antibody titers is recommended to diagnose an antecedent infection [34]. An elevated or rising streptococcal antibody titer on a repeat test performed 3–4 weeks apart is considered evidence of an antecedent infection [19]. The serum titer of antistreptolysin O (ASO) is elevated in 80% or more of patients with ARF [138]. If the ASO titer is normal, an anti-DNase B titer can be measured. An elevated titer of at least one of these two tests is found in 90% of patients with a recent preceding group A streptococcal infection. ASO titers begin to rise at approximately 1 week and peak 3–6 weeks after the infection. Anti-DNase B titers begin to rise 1–2 weeks and peak 6–8 weeks after the infection. If both tests are initially normal, serial sampling may show a rising titer, providing evidence of an antecedent streptococcal infection. The cutoff for elevated streptococcal antibody titers varies with the test, patient's age, and geographic region. The titers are higher among school-age children than adults.

Treatment

All manifestations of ARF except carditis resolve spontaneously. Treatment of ARF can shorten the duration of inflammation. None of the treatment strategies, except for those preventing recurrences, alters the outcome of acute carditis and its sequelae. Many treatment strategies are not based on strong clinical evidence, but are driven by anecdotal experiences and institutional practices.

Treatment of group A streptococci

Antibiotics do not modify the acute course or long-term outcome of carditis, [138,139], but penicillin is given to eradicate any rheumatogenic group A streptococci remaining in the pharynx and to prevent its spread to close contacts [140,141]. Antibiotic therapy is warranted even if the throat cultures are negative (Table 61.4).

Treatment of arthritis

Fever, arthritis and arthralgia rapidly resolve with salicylate administration [142] which should be avoided until the diagnosis of ARF is confirmed [19]. The most widely used anti-inflammatory drugs are salicylates and corticosteroids. The usual dosage of salicylates is 80–100 mg kg^{-1} per day in children and 6–8 g per day in adults given in divided doses every 4–6 h. Salicylate levels should be measured, targeting a level of 20–30 mg dl^{-1} [19,143]. If gastrointestinal side effects are bothersome, a smaller dose can be given and gradually increased. Gastrointestinal prophylaxis may prevent salicylate-induced gastric mucosal damage and bleeding. Patients may develop gastrointestinal bleeding and signs of salicylism (e.g., headache, hyperpnea, tinnitus). After 2 weeks, the dosage may be gradually tapered and continued for an additional 4 weeks. In milder disease, 2 weeks of therapy may be sufficient and then aspirin can be stopped without tapering. The patient should be observed for "rebound" symptoms in the following 2 weeks. On cessation of anti-inflammatory therapy, the clinical and laboratory markers of acute inflammation may recur but usually resolve spontaneously. When the clinical rebound is significant, extending the course of salicylate therapy to 9–12 weeks may be effective. Influenza vaccine should be given to children receiving aspirin during the influenza season (autumn/winter). Other nonsteroidal anti-inflammatory agents, such as naproxen, have been used successfully in patients with arthritis, but have not been evaluated for carditis [19,143–145].

Treatment of carditis

In patients with symptomatic carditis, bed rest is recommended during the acute phase. This reduces the myocardial work load. Once the acute symptoms resolve, gradual mobilization is recommended [138]. Many patients with asymptomatic carditis are treated as outpatients with

Table 61.4 Primary prevention of acute rheumatic fever (ARF). Treatment of group A streptococcal tonsillopharyngitis.

Agent	Dosage	Mode	Duration
Benzathine penicillin G	600 000 units for ≤27 kg (60 lb) 1.2 million units for >27 kg or	Intramuscular	Single dose
Penicillin V (phenoxymethylpenicillin)	Children: 250 mg 2–3 times daily for ≤27 kg (60 lb); children >27 kg (60 lb). Adolescents and adults: 500 mg 2–3 times daily or	Orally	10 days
Amoxicillin	50 mg kg⁻¹ once daily (maximum 1 g)	Orally	10 days
For individuals allergic to penicillin			
Narrow-spectrum cephalosporin (cephalexin, cefadroxil)[a]	Variable or	Orally	10 days
Clindamycin	20 mg kg⁻¹ per day divided into three doses (maximum 1.8 g per day) or	Orally	10 days
Azithromycin	12 mg kg⁻¹ once daily (maximum 500 mg) or	Orally	5 days
Clarithromycin	15 mg kg⁻¹ per day divided into two doses (maximum 250 mg per dose)	Orally	10 days

recommendations for rest during the acute phase and gradual mobilization as symptoms and acute inflammation resolve. There is no evidence that prolonged bed rest accelerates recovery. Anti-inflammatory doses of salicylates are recommended for patients with mild to moderate carditis. Some experts believe that corticosteroids should be used in treating severe carditis with associated cardiac failure because of their more potent anti-inflammatory effect [19,146,147]. Although neither salicylates nor corticosteroids change the long-term outcome of carditis, they are important in reducing inflammation [146–148]. Compared with aspirin, steroids result in more prompt resolution of inflammation, fever, and more rapid disappearance of existing murmurs and prevent the development of new murmurs [149–152].

Prednisone (or equivalent) at a dose of 2 mg kg⁻¹ in children or 40–60 mg per day in adults, may be used initially. After 2–3 weeks, steroids should be tapered slowly during an additional 3-week period [19]. If a rebound phenomenon (more common with corticosteroid use) is observed with tapering of corticosteroids, salicylates can be added for 4–6 weeks. Patients receiving corticosteroids should be monitored for side effects of gastrointestinal upset and bleeding, sodium and water retention, impaired glucose tolerance, and suppression of pituitary–adrenal axis. With fulminating carditis and profound heart failure, intravenous corticosteroids may be used. The duration of anti-inflammatory therapy is based upon the clinical response to therapy and acute-phase reactants becoming normal [19,143]. Progressive

heart failure is predominantly a result of acute valvar dysfunction. In severe, intractable heart failure, emergency valve replacement may be life-saving.

Treatment of Sydenham's chorea

Sydenham's chorea is self-resolving. Patients with mild manifestations can be managed with reassurance, rest, and avoidance of stressful environments. With severe symptoms affecting daily activities, treatments include phenobarbital, carbamazepine, diazepam, steroids, haloperidol, valproic acid, plasma exchange, and intravenous γ-globulin [153–155]. In a randomized double-blind study, adjunctive treatment with prednisone reduced the intensity and duration of acute Sydenham's chorea, but the effect on late recurrence is unknown [156]. Another study showed a reduction in severity of chorea with intravenous immunoglobulin (IVIG) therapy [19,157].

Prevention

Primary prevention

Improvement in living conditions and access to healthcare are keys to reducing the overall rate of ARF. Primary prophylaxis with antibiotics following tonsillopharyngitis caused by group A streptococcus started within 9 days of the onset of a sore throat prevents most subsequent ARF [19,158–160]. However, in more than two-thirds of patients with ARF,

Table 61.5 Treatment of acute rheumatic fever.

All patients
Treatment of group A streptococcal tonsillopharyngitis

Polyarthritis and fever
Acetaminophen and codeine until the diagnosis is established
Aspirin once diagnosis is confirmed
Naproxen can be used in patients without carditis
Influenza vaccine for children receiving aspirin during influenza season

Carditis
Anti-inflammatory treatment with aspirin for mild to moderate carditis
and corticosteroids for severe carditis

Table 61.6 Secondary prevention of rheumatic fever (prevention of recurrent attack) [19,101].

Agent	Dosage	Mode
Benzathine penicillin G	600 000 units for ≤ 27 kg (60 lb), 1.2 million units for >27 kg every 4 weeks[a] or	Intramuscular
Penicillin V (phenoxymethylpenicillin)	Children: 250 mg twice daily or	Orally
Sulfadiazine	0.5 g once daily for patients ≤ 27 kg (60 lb), 1.0 g once daily for patients >27 kg (60 lb)	Orally
For individuals allergic to penicillin and sulfadiazine		
Erythromycin ethylsuccinate	250 mg twice daily	Orally
	or	
Azalides	Variable	Orally

[a]In high-risk situations, administration every 3 weeks is justified and recommended.

Table 61.7 Duration of secondary prophylaxis [19,101].

Category	Duration after last attack
United States [101]	
Rheumatic fever with carditis and residual heart disease (persistent valvar disease[a])	10 years or until 40 years of age (whichever is longer), sometimes lifelong prophylaxis
Rheumatic fever with carditis but no residual heart disease (no valvular disease[a])	10 years or until 21 years of age (whichever is longer)
Rheumatic fever without carditis	5 years or until 21 years of age (whichever is longer)
World Health Organization [19]	
Patients without proven carditis	For 5 years after the last attack, or until 18 years of age (whichever is longer)
Patients with carditis (mild mitral regurgitation or healed carditis)	For 10 years after the last attack, or at least until 25 years of age (whichever is longer)
More severe valvar disease	Lifelong
After valve surgery	Lifelong

[a]Clinical or echocardiographic evidence.

---

there is no prior history of a sore throat, making primary prevention impossible [128]. The recommended antibiotic regimens for primary prevention or treatment of tonsillopharyngitis caused by group A streptococcus are listed in Table 61.4. No clinical isolate of group A β-hemolytic streptococcus (*S. pyogenes*) has been resistant to penicillin [19]. In a 1965 study of Navajo schoolchildren, patients with a culture-positive sore throat and carriers of group A streptococcus were treated with antibiotics The ARF incidence was reduced by 21%. This reduction was achieved at a cost of US$12 per child per year, or $65 000 per ARF patient prevented [161]. In contrast, a randomized study of school children in Auckland, New Zealand, found no reduction in ARF between treatment and no treatment groups. In addition to the lack of symptoms with pharyngitis, poor access to healthcare, inadequate microbiological testing facilities, poor availability of antibiotics, and the reluctance of some populations to seek medical services all limit the role of primary antibiotic prophylaxis in many high-risk populations.

Group A streptococcus vaccines are under development. A multivalent, M-serotype-specific vaccine is in phase II trials in North America. The lack of specific M serotype prevalence in high-risk regions and changing serotypes will limit its use [162]. Alternative vaccine production strategies using non M-type group A streptococcus protein or conserved regions of the M protein are under development.

Treatment of ARF is summarized in Table 61.5.

Secondary prevention

In patients with past history of ARF or RHD, long-term administration of antibiotics for the prevention of streptococcal pharyngitis and recurrent ARF is the only proven and cost-effective treatment. The greater the number of ARF recurrences, the higher is the likelihood of valvar damage and chronic RHD. Secondary prevention is the key to reducing RHD-associated morbidity and mortality worldwide, especially in ARF endemic regions. The recommended antibiotic regimens for secondary prophylaxis are listed in Table 61.6 [36]. Intramuscular benzathine penicillin G administered once every 3 weeks (every 4 weeks in low-risk areas or low-risk patients) is more effective than oral penicillin or sulfadiazine [19,163,164]. The serum levels of penicillin are less predictable with oral administration, even

in patients with good compliance [19]. The duration of secondary prophylaxis varies based on previous history and underlying heart disease and is listed in Table 61.7 [36]. Patient and family education, emphasizing the importance of adherence to secondary prophylaxis, is paramount to successful programs. Good follow-up, health education, central registries for case documentation and gathering epidemiological data, and continued research are important in worldwide reduction of ARF- and RHD-associated morbidity and mortality.

Long-term administration of antibiotics for the prevention of streptococcal pharyngitis and ARF in patients with a past history of ARF or RHD is the only proven strategy to prevent recurrence. Details of secondary prevention are presented in Chapter 62 and discussed in the literature [19,36,163,164].

Bacterial endocarditis prophylaxis

The American Heart Association (AHA) no longer recommends endocarditis prophylaxis for all patients with RHD [165]. Prophylaxis is recommended, however, for high-risk patients, including those with prosthetic valves, residual defects adjacent to prosthetic materials, and previous infective endocarditis (see Chapter 60). For patients in high-risk populations with RHD receiving chronic penicillin prophylaxis, the recommendations advise the use of a prophylactic agent other than penicillin because oral flora may have developed penicillin resistance [165].

62 Rheumatic Heart Disease

Raman Krishna Kumar

Amrita Institute of Medical Sciences and Research Center, Kerala, India

Introduction

Rheumatic heart disease (RHD) is the only long-term sequel of rheumatic fever (RF). Children with a scarred heart valve as a consequence of RHD are seldom seen in developed nations, but RF and RHD are significant public health problems in developing nations, where it selectively targets the underprivileged [1,2].

Before penicillin was introduced, the natural history of RF was characterized by initial episodes occurring in the very young, frequently associated with carditis, often severe [3,4], and recurrences were common. Advanced heart valve scarring with severe hemodynamic and clinical consequences, such as congestive heart failure, were common in the very young [2,5,6], often occurring several years after the first episode. After penicillin was introduced, the incidence and severity of acute RF declined sharply, as did recurrent episodes and RHD. The interval between acute RF and RHD increased progressively [3,4], as did the age of onset of clinically manifest RHD [2].

Where the disease is still rampant, the natural history of RF resembles that of the pre-penicillin era [1,2,5,6]. Juvenile rheumatic mitral valve stenosis is seen almost exclusively in regions with a high incidence of RF [2,6,7].

Epidemiology

Global trends

A few decades before penicillin was introduced, a sharp decline in acute RF and RHD occurred in all industrialized nations. Improving living standards, reduced overcrowding, better access to healthcare and more widespread use of antibiotics allowed prompt treatment of streptococcal infections and helped abort epidemics [1,2]. Industrialized nations now have an average annual RF incidence of <0.5 per 100 000 and RHD prevalence of <0.05 per 1000. The resurgence of RF in the United States during the mid-1980s and its persistence, however, suggest that additional factors also contribute to its occurrence [8]. Selected populations, such as Pacific Islanders, Maoris, and Australian Aborigines, continue to have an extremely high prevalence of RHD [9] that may not be altogether explained by living conditions and access to health care. (See Chapter 61).

In the developing world, RF and RHD continue unabated, reflecting the relatively poor living standards and availability of health care [1,2,7]. The prevalence of RHD in school-age children varies from 0.4 to 21 per 1000 children in developing countries [2,7,10–14], where 10–35% of cardiac admissions are for patients with RF and RHD. One in every 150 deaths in developing nations is estimated to be from RHD, with a total of >200 000 deaths per year [2]. RHD remains an obvious public health burden across the developing world.

Estimates of RHD prevalence

School surveys are often used [2]. In the worst affected regions, however, school enrollment rates are low and many affected children may not attend school [7]. Population-based registries can capture all age groups, but depend heavily on referral mechanisms. Hospital-based statistics have serious limitations because only the most seriously affected are represented.

Older surveys used cardiac auscultation to obtain estimates. More recent surveys used echocardiography to confirm the diagnosis when cardiac auscultation was abnormal (mostly audible murmurs) [15,16]. Congenital and nonrheumatic

heart valve disease can be incorrectly labeled as RHD in studies that use auscultation alone. Both strategies likely missed subclinical RHD [2].

Recent large population-based surveys used portable echocardiography. Marijon *et al.*, screening with echocardiography, suggested a very high prevalence of RHD in children from Cambodia and Mozambique. Most patients were clinically silent and no children with mitral stenosis were identified [17]. The natural history of clinically silent heart valve disease detected through echocardiography is unknown. It is unclear whether penicillin prophylaxis is warranted for these children, although most investigators recommend it.

Pathogenesis of rheumatic heart valve disease

Only heart valves are permanently damaged during an episode of RF. All other affected tissues typically heal without residua: pericarditis, chorea, and arthritis all resolve completely without constriction, long-term neurologic consequences, or joint disability, respectively. One of the mysteries of RF is the remarkable tendency for the disease to heal rather than to scar the tissues it affects, with the exception of cardiac valves. The following hypothesis appears most plausible.

Histopathologic findings indicate widespread diffuse collagen–vascular involvement during an acute episode of RF [18]. The immunologic findings suggest that RF predominantly damages the vascular endothelium and mesothelium. The adjacent subendothelial and submesothelial tissues are affected to a very limited depth [18]. The damaged endothelium is replaced by new endothelium within days after injury without significant scarring. The valves are structurally unfortunate in having a small core of connective tissue covered by two layers of endothelium.

The endothelium is initially damaged from a humoral immune response, resulting in VCAM-1 being expressed on the endothelium, followed by activation of cellular immune responses. As a result, CD4+ and CD8+ T lymphocytes and macrophages attach to the valvar endothelium and migrate to the connective tissue core, establishing an inflammatory response accompanied by neovascularization of the valve substance. The endothelium of the newly formed vessels may serve as a substrate for additional inflammation and perhaps set up a vicious cycle of inflammation, neovascularization, and further damage, resulting eventually in a permanently scarred valve [2,18].

Pathology of rheumatic heart valve disease

In autopsies of patients dying of RHD, the mitral valve was most commonly afflicted, either alone or together with the aortic (31.6%) and tricuspid valves (52.8%). Involvement of the tricuspid valve occurred in 38.4%. The extent and severity of the pathology was most marked in the mitral valve, followed by the aortic and tricuspid valves, respectively [19]. Pulmonary valve involvement is exceptional and almost always associated with the involvement of all the other valves. Mitral regurgitation is the commonest lesion encountered in adolescents and children [20].

Most of the gross pathologic features are well demonstrated by cross-sectional [two dimensional (2D)] and more recently, by three-dimensional (3D) echocardiography. Real-time 3D imaging allows an excellent understanding of mechanisms of most hemodynamic consequences of valvar pathology. Figures 62.1–62.5 serve to illustrate the pathology of the mitral valve defined by both 2D and 3D echocardiography (Table 62.1). Table 62.2 shows the echocardiographic correlations with the pathologic features of the aortic valve.

Clinical features of RHD

History and physical examination

A history of acute RF may be difficult to obtain in many patients with RHD [21]. Episodes of RF may be indistinguishable from other common childhood febrile conditions, especially in the absence of arthritis. Not all episodes of RF are severe enough to warrant medical attention [21]. A diagnosis of rheumatic carditis requires careful auscultation because murmurs can be subtle during the first episode of RF. Subcutaneous nodules are relatively uncommon and seldom clinically obvious, and must be searched for carefully at specific locations [22]. Erythema marginatum is also uncommon, often transient, and cannot be easily seen in dark-skinned individuals [23]. Rheumatic chorea often occurs late after the inciting streptococcal sore throat and is sometimes subtle [21].

The ability of family members to recall a history of RF depends on their socioeconomic and cultural background. In general, however, families of children with established RHD at a young age often recall the episode. In the worst affected, acute episodes of RF may evolve rapidly into established RHD with severe affliction of the cardiac valves after a very short quiescent interval [24].

The symptoms and physical signs (Table 62.3) of established RHD are related to the severity of the valve affliction and the individual lesions.

Mitral regurgitation

Mitral regurgitation (MR) is by far the commonest lesion seen in RHD. The inability to increase cardiac output during activity results in fatigue, the commonest symptom of significant MR. MR also causes palpitations because of a volume-loaded hyperdynamic left ventricle and tachycardia. Dyspnea is uncommon unless MR is severe, acute, or the left ventricular myocardium is failing. With a

(a)   (b)

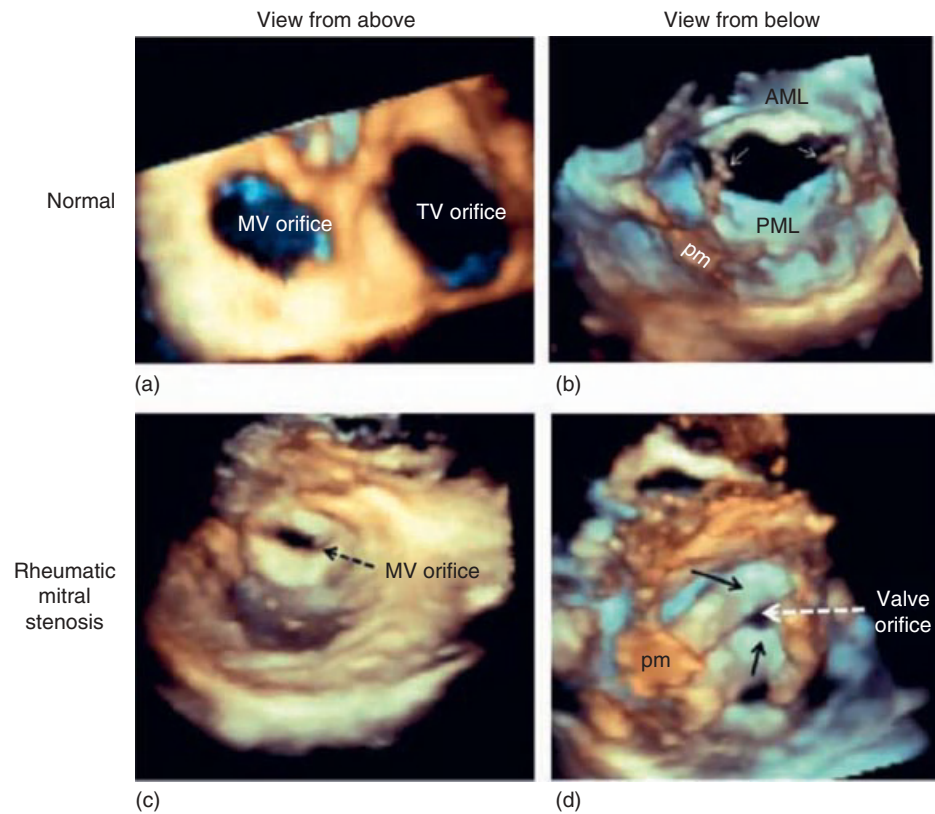
(c)   (d)


Figure 62.1 3D echocardiographic imaging in rheumatic mitral stenosis. All images were obtained through transthoracic echocardiography. Panels (a) and (c) show views from the atrial aspect, and (b) and (d) show views from the ventricular aspect. Diastolic frames from a normal mitral valve are shown in (a) and (b). Note that the mitral valve orifice is completely open in diastole and valve tissue is barely seen from the atrial aspect (b). Panels (c) and (d) show diastolic frames of the mitral valve from a 20-year-old patient with rheumatic mitral stenosis. Unlike in the normal valve, the mitral valve leaflet substance is seen from the atrial aspect during diastole. The solid arrows point towards the chordae tendinae of the tensor apparatus of the valve. Note the extensive thickening of the chordae that can no longer be distinguished from the papillary muscle (pm) unlike in the normal valve in (b). AML, anterior mitral leaflet; PML, posterior mitral leaflet; pm, papillary muscle; MV, mitral valve; TV, tricuspid valve.
Figure 62.2 These 3D images were obtained from a patient with pure rheumatic mitral valve stenosis (a, c) before and after (b, d) balloon mitral valvotomy (BMV) with the Inoue balloon. Panels (a) and (b) show views from the atrial aspect and (c) and (d) show views from the ventricular aspect. All images were obtained during diastole. Note the thickened chordopapillary apparatus. These images demonstrate that the mechanism of benefit in BMV is through splitting along the commissures of the leaflets (white arrows). Leaflet movements continue to be restricted by the fibrosis in the chordopapillary apparatus (black arrows).

907
Figure 62.3 Rheumatic mitral valve disease with mitral stenosis and regurgitation. These frames are from a 10 year old child with rheumatic heart disease with severe affliction of the mitral valve. Although the predominant lesion is mitral regurgitation, there is also some mitral stenosis. 3D echocardiograms are shown in (a) and (b) and equivalent 2D frames obtained from apical four-chamber views in (c) and (d). The diastolic frame in the 3D image (a) shows the mitral valve from its left atrial aspect. Note that the leaflet substance is seen in diastole. The equivalent diastolic frame in 2D (c) shows several features of rheumatic affliction. The anterior mitral leaflet (AML) is thickened. The tip of the AML is oriented horizontally and does not point downwards, suggesting restriction of mobility of diastolic motion. The posterior mitral leaflet (PML) is also thickened and mobility is restricted to even a greater degree. The chordae tendinae beneath the PML are visibly thickened. During systole, the PML stays in a relatively fixed position. The free edge of the AML moves to a position above the optimal zone of coaptation between the two leaflets. The resultant regurgitation orifice is shown by white arrows in both the 3D and 2D frames. This orifice is typically crescentic and extends along the length of the AML. The resultant color Doppler jet is directed posteriorly and laterally. AML, anterior mitral leaflet; LA, left atrium; LV, left ventricle; PML, posterior mitral leaflet.

failing left ventricle, left ventricular diastolic pressure increases, left atrial and pulmonary venous pressures increase, and pulmonary congestion appears. Pulmonary arterial hypertension follows significant pulmonary venous hypertension. Some children with chronic severe MR can have disproportionately severe pulmonary arterial hypertension (PAH) from exaggerated vasoconstriction of the pulmonary arterioles [25]. Physical examination is considered in Table 62.3.

Acute marked MR causes severe symptoms in the initial stages, due to pulmonary venous hypertension causing pulmonary congestion. Over time, the left atrium dilates and becomes more compliant. The LV dilates, accommodates the extra volume, and the LV end diastolic pressure declines. A substantial reduction in dyspnea follows. This sequence is seen fairly frequently following an initial episode of RF with carditis and severe MR. Over time, symptomatic improvement occurs without a significant reduction in the degree of MR.

Mitral stenosis

In children, rheumatic mitral stenosis (MS) is less frequent than MR. The very early onset of juvenile MS, sometimes as early as 6 years [26], is largely confined to selected parts of the world where RHD is endemic with a very high prevalence [6,7].
Figure 62.4 Pathology of the chordopapillary apparatus in juvenile RHD. Frames (a)–(c) were obtained from a 10-year-old child with a combination of mitral stenosis and regurgitation and (d) was obtained from a 20-year-old female with severe mitral stenosis documented at 12 years age with recurrence of symptoms after a "successful" balloon valvotomy 8 years previously. Note the diffuse fibrosis with fusion and shortening of the tendinous cords that can no longer be easily distinguished from the adjacent papillary muscle below and the valve leaflets above. Frame (d) was obtained through "virtual dissection" of the 3D image after removing the anterior wall of LV. This represents an extreme example of juvenile mitral valve stenosis that is not uncommon in regions where RHD is very prevalent.

Pulmonary venous hypertension and pulmonary congestion develop from elevated mean left atrial pressure. Dyspnea is, therefore, much commoner than in isolated MR. The severity of PAH varies, depending on the degree of "adaptive" pulmonary vasoconstriction. Thus, it is not unusual for children with severe (juvenile) MS and severe pulmonary venous and arterial hypertension to have no discomfort at rest in spite of extremely high pulmonary arterial and left atrial pressures. The severity of symptoms in MS is determined by the duration of diastolic filling. With tachycardia, diastole shortens to a greater extent than systole. Therefore, these children are exquisitely sensitive to tachycardia, whether from exercise, anxiety, or fever, and can deteriorate suddenly with these precipitating events. Physical examination is considered in Table 62.3.

Aortic regurgitation (AR)

The symptoms of AR are similar to those of MR. However, severe chronic AR may be tolerated very well for several years with no apparent limitation in exercise tolerance. Physical examination (Table 62.3) is characteristic and usually allows fairly accurate assessment of severity. The manifestations of aortic "run-off" are excellent indicators of severity of AR.

Tricuspid regurgitation

Tricuspid regurgitation (TR) typically results from elevated right ventricular pressure. There are no specific symptoms of TR. With the onset of TR, the dyspnea may be relieved to some extent in patients with MS. The patients may have a

(a)   (b)   (c)

(d)   Predominant AS, Systole   (e)   Predominant AS, Diastole   (f)   Predominant AR, Diastole
Figure 62.5 Aortic valve involvement in RHD. 2D echo frames of the aortic valve are shown in (a)–(c) and equivalent 3D frames in (d)–(f). Frames (a), (b), (d) and (e) are from a patient with predominant aortic stenosis (AS) and (c) and (f) from a patient with predominant aortic regurgitation (AR). The individual cusps are marked as R for right, L for left and N for noncoronary cusps. Note the thickening of the leaflet edges particularly in the central region where the three cusps come together. Aortic stenosis in this example (a, d) results from fusion of right–left and right non-coronary commissures; The resultant systolic orifice area is considerably reduced. The valve is largely competent in diastole (b, e). In the patient with AR (c, f), the valve closure is incomplete and the regurgitation orifice is seen during diastole. This results from shrinkage of the leaflet substance from extensive fibrosis. The thick leaflet margin is particularly evident along the free edge of the right coronary cusp.

Table 62.1 Pathology of rheumatic mitral valve disease and echocardiographic correlates.

Mitral valve	Pathology	Echocardiographic correlate
Anterior mitral leaflet (AML)	Thickening and restriction of leaflet mobility, especially at the edges, causing characteristic diastolic doming of the valve	Thickening (>3–4 mm) is identified on echocardiograms; diastolic doming is easily identified on 2D echocardiography
Posterior mitral leaflet (PML)	Fixed to a greater extent by the fibrotic and shortened tendinous chords	Fixed PML is very characteristic and a readily identifiable feature of chronic RHD irrespective of whether the dominant lesion is MS or MR
Commissures	Symmetric fusion of commissures of the mitral valve contributes substantially to mitral valve stenosis in most patients. This results in the characteristic "fish mouth" appearance	Commissural fusion is identified in the parasternal short-axis view during 2D echocardiography. The valve area of the stenotic valve is often calculated in this view along the free and fused margins of the leaflets
Tensor apparatus	Thickening and shortening of chords; extensive fibrosis involving the chords, papillary muscles, and the adjacent leaflets also contributes to mitral valve stenosis and accounts for residual stenosis after balloon dilation of the valve. Rupture of chords can occur during an episode of rheumatic fever, causing severe MR. Lengthening of the chords has also been described	The tensor apparatus of the mitral valve can be seen very well with both 2D and 3D echocardiography. Much of the reduced leaflet mobility is due to fibrosis and shortening of the tensor apparatus. Rupture of chords is identified by examining the free edge of the leaflets. Often the AML is involved

Table 62.2 Pathology of rheumatic aortic valve disease and echocardiographic correlates.

Aortic valve	Pathology	Echocardiographic correlate
Leaflet	Thickening especially at the edge, fibrosis, and shortening of the leaflet substance. Irregular thickening or nodularity is typical of RHD	Rolled up margins are identified on 2D echocardiography in the parasternal short-axis views. The reduction in valve substance reduces the zone of coaptation, causing incomplete closure and regurgitation
Commissures	Fusion can involve one or more commissures and causes reduced mobility	Doming of the aortic valve with aortic stenosis is due to commissural fusion

Table 62.3 Physical examination of the cardiovascular system in rheumatic heart disease.

Valve lesion	Mild	Moderate	Severe
Mitral stenosis	Normal S2, opening snap (OS) with wide A2–OS interval, relatively soft and late-onset mid-diastolic murmur often heard with the bell of the stethoscope. Murmur may be unmasked by exercise	S2 split normal but P2 is loud, A2–OS interval shortens, prominent mid-diastolic murmur with presystolic accentuation	Evidence of significant pulmonary hypertension, close splitting of S2, loud P2, short A2–OS interval, prominent mid-diastolic murmur with presystolic accentuation[a]
Mitral regurgitation	Normal apex, normal S2, no S3, blowing apical pan-systolic murmur, usually without a thrill, no flow murmurs. S1 merges with the murmur but may be loud and distinct with accompanying MS	Hyperdynamic apex, widely split S2, S3 may be present, prominent pan-systolic murmur	Cardiac enlargement, downward and outward displaced apex, hyperdynamic precordium, widely split S2 (early A2), P2 may be loud if pulmonary hypertension develops, S3 and frequently a mid-diastolic flow murmur without presystolic accentuation (unless associated with MS)
Aortic stenosis[b]	Normal carotid pulsations, no clinical evidence of left ventricular hypertrophy, relatively short ejection systolic murmur that peaks in early systole	Some delay in carotid upstroke may be appreciable, clinical evidence of LVH in the form of a sustained heave in the apical impulse. Prominent ejection systolic murmur, relatively longer duration peaking in mid-systole	Delayed carotid upstroke, clinical evidence of LVH, long ejection systolic murmur with delayed peaking
Aortic regurgitation	No peripheral signs of increased aortic run-off, normal pulse pressure, early diastolic murmur (EDM)	Wide pulse pressure (>50 mmHg), diastolic pressure usually >50 mmHg, hyperdynamic apical impulse, prominent EDM	Wide pulse pressure (>80 mmHg), diastolic pressure <50 mmHg, often as low as 0 mmHg (free AR), signs of increased aortic run-off are easily demonstrable, cardiac enlargement, hyperdynamic apical impulse, prominent EDM
Tricuspid regurgitation	Pan-systolic murmur of TR audible in the left lower parasternal region (may be heard only during inspiration)	Prominent TR murmur	Liver enlarged with systolic pulsations, elevated jugular venous pulsations (JVP) with prominent V waves, prominent murmur
Tricuspid stenosis (TS)	Mild and moderate TS are usually clinically silent	Elevated JVP with prominent a waves, prominent presystolic pulsations; the mid-diastolic murmur of TS may also be heard in the left lower sternal area	

[a]Rarely severe mitral stenosis may not be associated with a identifiable mid-diastolic murmur (silent MS); usually this is accompanied by severe pulmonary hypertension and gross right ventricular enlargement.
[b]Aortic stenosis (AS) is rarely seen in children with RHD. Isolated AS is exceptional. Some aortic regurgitation invariably accompanies AS and, typically, signs of AR are masked by AS.

history of pain in the right hypochondrium due to a congested liver, and fatigue due to a decrease in systemic output.

Aortic and tricuspid stenosis are rare in children with RHD. Isolated aortic valve involvement with dominant aortic stenosis is more likely to have a congenital basis.

Combined valve lesions

Combined lesions are frequent in RHD. Typically, MS and MR coexist, and their clinical features can be readily identified in most patients. Combinations of mitral, aortic, and tricuspid valve disease are common. The severity of each valve's involvement must be quantified to allow correct management decisions. For example, in a child with MS, if MR is moderate or severe and commissural in origin, balloon mitral valvoplasty is precluded. Similarly, in a patient undergoing mitral valve repair or replacement, the decision to replace the aortic valve is dictated by the severity of associated AR [27].

Chest X-ray

Left atrial and atrial appendage enlargement almost invariably accompany significant mitral valve disease. Right atrial enlargement is seen with PAH and tricuspid valve involvement. Left ventricular enlargement occurs with AR and MR. The lung fields show varying degrees of pulmonary venous congestion depending on the severity and duration of pulmonary venous hypertension (Figure 62.6).

Electrocardiogram

Left atrial enlargement and right ventricular hypertrophy are seen in pure or dominant MS (Figure 62.7). Left ventricular enlargement with volume overload from MR or AR is evident by Q waves in lateral chest leads. Atrial fibrillation is very unusual in children even with severe left atrial enlargement.

Echocardiography

Echocardiography is the most important investigation, and correlates well with pathology (Tables 62.1 and 62.2 and Figures 62.3, 62.8, and 62.9). Other specific features of RHD include simultaneous involvement of multiple valves, because the association of mitral and aortic valve pathology is infrequent in other conditions. The echocardiographic diagnosis may not be straightforward. Hence it helps to correlate the echocardiographic findings with the clinical context. The threshold for diagnosis of RHD is understandably lower in regions where RHD is very prevalent.

The severity of individual lesions can be defined with precision. Gradients across the affected valves can be determined and the severity of regurgitant lesions quantified (Figures 62.3, 62.8, and 62.9). The hemodynamic

Figure 62.6 Chest X-ray (posterior–anterior view) from an 8-year-old patient with juvenile mitral stenosis as a result of RHD. There is evidence of severe pulmonary venous hypertension in the form of prominent upper lobe pulmonary veins (cephalization), interstitial haze, and prominent inter-lobar fissures (arrow). Additionally, there is evidence of an enlarged left atrium (lifting up of the left bronchus) and left atrial appendage (straightening of the left heart border).

consequences of various lesions can be studied, including chamber enlargement, PAH, and ventricular function. Serial echocardiography often guides decisions regarding timing of operation. Important complications, such as infective endocarditis, can be recognized echocardiographically.

Echocardiographic criteria for rheumatic heart valve disease

A number of conditions must be distinguished from rheumatic valve disease. Specific criteria for rheumatic heart disease have been developed by an NIH working group (http://www3.niaid.nih.gov/topics/streptococcal/protocols.htm), and are listed below. Validation of these criteria by international long-term follow-up studies, particularly for patients with subtle or borderline findings, is in progress.

Echocardiographic evidence of *definite RHD* is *any* of:

1 A mitral regurgitant jet at least 2 cm from the coaptation point of the valve leaflets, seen in two planes and persisting throughout systole, *plus* thickened mitral valve leaflets and/or elbow or dog-leg deformity of the anterior mitral valve leaflet.

2 An aortic regurgitant jet at least 1 cm from the coaptation point of the valve leaflets, seen in two planes, *plus* thickened mitral valve leaflets and/or elbow or dog-leg deformity of the anterior mitral valve leaflet.
Figure 62.7 Electrocardiogram from an 8-year-old child with RHD and severe mitral stenosis. There is evidence of right ventricular hypertrophy in the form of rightward deviation of the QRS axis, prominent R waves in V1 and persistent S waves in V5 and V6. Additionally, there is evidence of left atrial enlargement in the form of prominent broad P waves in lead II.
Figure 62.8 2D echocardiography for RHD and mitral stenosis. (a) A diastolic frame from the parasternal long axis view. The characteristic "dog-leg" or "elbow' deformity is shown in the anterior mitral valve leaflet (AML). The tips of the AML are thickened. The thick and shortened chordae attached to the posterior mitral leaflet are also shown in this frame. Frame (b) is a picture obtained from the parasternal short-axis view. This view captures the mitral valve orifice in mid-diastole and allows accurate estimation of the mitral valve area. This view is also very useful in planning balloon mitral valvotomy (BMV). In this patient, for instance, we can expect that the commissures would split favorably after BMV. Panel (c) is a Doppler tracing from the same patient showing the characteristic M-shaped flow acceleration across the stenotic valve that is seen in patients with MS and sinus rhythm. The second peak results from atrial contraction and is responsible for the presystolic accentuation of the mid-diastolic murmur.
Figure 62.9 2D echocardiograms and color Doppler from a patient with RHD involving the aortic valve. The dominant lesion here is aortic regurgitation that is the result of fibrosis and shortening of the individual leaflet cusps. The jet is characteristically central (a, b). The thickened cusps are seen in the lower systolic frame (c) obtained in the parasternal short-axis view.

3 Any significant mitral stenosis (defined as flow acceleration across the mitral valve with a mean pressure gradient greater than 4 mmHg).

Echocardiographic evidence of *probable RHD* is *any* of:

1 Thickened mitral valve leaflets and/or elbow or dog-leg deformity of the anterior mitral valve leaflet regardless of the degree of mitral or aortic regurgitation.

2 A mitral regurgitant jet at least 2 cm from the coaptation point of the valve leaflets, seen in two planes and persisting throughout systole *without* thickened mitral valve leaflets and/or elbow or dog-leg deformity of the anterior mitral valve leaflet (in the setting of possible ARF, this may represent acute carditis, before valve leaflets have developed structural abnormalities).

3 An aortic regurgitant jet at least 1 cm from the coaptation point of the valve leaflets, seen in two planes *without* thickened mitral valve leaflets and/or elbow or dog-leg deformity of the anterior mitral valve leaflet.

Specific diagnostic challenges

Recurrence of RF in RHD

Detection of RF recurrence in a patient with pre-existing RHD is challenging. A diagnosis of carditis is difficult to establish unless by serial auscultation or echocardiography a new valve lesion is carefully documented. Other major diagnostic criteria may not be present in a recurrent episode. According to 2002–2003 WHO criteria, a diagnosis of recurrence of RF in RHD requires at least two minor manifestation of RF plus evidence of preceding group A streptococcal infection (in the form of elevated ASO titers or a positive throat swab for group A beta hemolytic streptococcus) [2].

Infective endocarditis

Infective endocarditis can complicate regurgitant lesions of the mitral or aortic valve resulting from RHD [28], but is

very uncommon in patients with pure mitral stenosis. In a large study of 1763 patients with RHD, the incidence of endocarditis was 2.3% over an average follow-up of 5.3 years [28]. The consequences of infective endocarditis are often devastating, and early diagnosis is vital before major valve damage occurs. Infective endocarditis must be considered in a patient with established RHD who has had a fever lasting more than 4–5 days. Distinguishing endocarditis from rheumatic fever recurrence is often challenging. Three or more blood cultures before giving antibiotics are mandatory. Other indicators of endocarditis, such as microscopic hematuria, leukocytosis, thrombocytopenia, and elevations in acute phase reactants have limited sensitivity and specificity. Echocardiography can identify vegetations on valves previously affected by RHD. Transesophageal echocardiography improves sensitivity substantially, especially in older children.

Complications and natural history

Pulmonary arterial Hypertension

PAH frequently complicates RHD and is a significant prognostic variable [29]. It is frequently associated both with severe MS and MR in children [26,29,30]. The PAH is due to passive transmission of left atrial and pulmonary venous hypertension, interstitial edema. and reactive pulmonary arteriolar vasoconstriction [31]. Following balloon mitral valvotomy, the component of the PAH attributable to passive transmission resolves immediately [30,31], while the reactive component resolves slowly over weeks to months.

Ventricular dysfunction

Left ventricular dysfunction is usually due to long-standing and severe mitral or aortic regurgitation. Combined severe MR and AR accentuate left ventricular enlargement and dysfunction that contribute to poor long-term outcomes following double valve replacement in children with RHD. Much of the dysfunction appears to result from chronic volume overload; available evidence does not support a substantial role for myocardial injury during episodes of rheumatic carditis [32]. The natural history of severe MR and AR is not well characterized in children and may differ from that in adults. Right ventricular dysfunction develops secondary to severe and long-standing PAH.

Infective endocarditis

Endocarditis must be suspected in the presence of persistent fever or sudden worsening of heart failure [25,28].

Dysrhythmias

Unlike in adults, atrial fibrillation is uncommon in children with RHD even with severe left atrial enlargement. Uncontrolled ventricular responses typically herald the onset of atrial fibrillation. The resultant tachycardia markedly worsens symptoms in patients with mitral stenosis.

Thromboembolism

Severe atrial dilation with resultant stasis of blood in the left atrium (often visible as spontaneous contrast in echocardiograms) promotes clot formation. Atrial fibrillation greatly increases the propensity for thrombosis. The left atrial appendage (LAA) is the most frequent site for clots that are often silent. However, there is a risk of dislodgement of an LAA clot if balloon mitral valvotomy is attempted. Therefore, transthoracic and, if needed, transesophageal echocardiography must be used to examine the LAA before balloon mitral valvotomy is contemplated.

Recurrence of rheumatic fever

Patients with established RHD are at a particularly high risk of recurrence of RF following an episode of streptococcal sore throat [33]. Recurrences are almost invariably associated with carditis. Many episodes of RF recurrences are not clinically obvious and this is reflected in the relatively liberal WHO criteria for diagnosis of recurrent RF in RHD [2].

Treatment of established rheumatic heart valve disease

Secondary prophylaxis to prevent recurrences of rheumatic fever

All patients with established RHD or one or more previous episodes of RF must receive regular penicillin. The success with secondary prophylaxis depends critically on patient education [2]. Benzathine penicillin injection (1.2 million units every 3–4 weeks, and 0.6 million units for children under 25 kg) is the most effective method. For high-prevalence regions, 3-weekly penicillin is recommended [2,34]. Compliance with benzathine penicillin injections has varied from 40 to 86% in reports from India [23,35]. Daily oral penicillin (250 mg penicillin V every 12 h) is an alternative. Compliance with oral penicillin is difficult to ensure because many doses may be missed inadvertently. Secondary prophylaxis is especially important in those who have not yet developed established RHD or those with mild disease. Patients with penicillin allergy may receive erythromycin (250 mg twice daily) or sulfonamides (1 g once daily; 0.5 g once daily for patients weighing 27 kg or under) [2,36].

Prophylaxis against infective endocarditis

Prophylaxis is no longer necessary unless there is a likelihood of a breach of oral mucosa, manipulation of either gingival tissue or the periapical region of teeth in presence of valve lesions that are at the highest risk of endocarditis [37]. Hence routine endocarditis prophylaxis is largely unnecessary for

pure mitral valve stenosis. High-risk lesions include prosthetic valve(s), AR, and MR [36,37]. Details of antibiotic prophylaxis are given in Chapter 60.

Drug therapy for heart failure: mitral stenosis

Diuretics, typically furosemide (frusemide), relieve symptoms of pulmonary congestion. Additionally, they often help to reduce the heart rate at rest and after exercise, and heart rate reduction translates into an increased diastolic filling period that helps reduce left atrial pressure. Digoxin, traditionally administered for this purpose, has been replaced by β-blockers because of their better efficacy and safety profile. β-Blockers may prevent acute worsening of symptoms and occurrence of pulmonary edema [38,39]. However, they do not appear consistently to improve exercise capacity in patients with MS who are in sinus rhythm [40]. β-Blocker alone or with a small dose of diuretic can be used in moderate MS while awaiting balloon mitral valvotomy or with a suboptimal result following the procedure [41]. Also see Chapter 27.

Regurgitant lesions

Diuretics are the mainstay when symptoms of pulmonary congestion accompany severe MR or AR. The role of systemic vasodilators, most commonly ACE inhibitors and calcium channel blockers, to reduce systemic afterload in isolated MR and AR is controversial [36]. Available data from adults do not support the role for systemic afterload reducing agents to delay development of LV dysfunction in MR. An important additional consideration in RHD is the presence of varying degrees of the mitral stenosis that accompanies MR. Also see Chapter 28.

For isolated severe AR, vasodilators are perhaps indicated for short-term therapy (until aortic valve surgery can be performed) in symptomatic patients, particularly with ventricular dysfunction [36]. In asymptomatic children with severe AR, there is no evidence that vasodilators can delay surgery. Also see Chapter 31.

Catheter-based management of mitral stenosis: balloon mitral valvotomy

Balloon mitral valvotomy (BMV), also known as percutaneous trans-septal mitral commissurotomy (PTMC), has largely replaced closed or open mitral commissurotomy for MS in children [41–43]. Improvement in mitral valve area following BMV or PTMC largely results from splitting of the fused commissures (Figure 62.2). The sub-valvar pathologic abnormalities of MS remain after BMV, so the mitral valve area does not normalize after BMV.

Among all available methods for BMV, the most popular is the Inoue balloon assembly that is specifically designed for the mitral valve. Catheter hardware and balloon assembly kits designed for adults are often adapted for pediatric use. Key adaptations include using the pediatric trans-septal needle and smaller balloons (24 mm) The initial step involves puncture of the inter-atrial septum with a Brockenbrough needle.

It is important to pay careful attention to the diameter of the balloon to avoid producing MR. The Inoue balloon can be inflated to a range of diameters based on the amount of fluid used for inflation. The average balloon diameter is determined by the height of the patient (the formula is 10 + height in cm/10); a child of 140 cm will typically require a 25 mm balloon). The mitral valve may not always yield at prescribed balloon diameters and oversizing by 1–2 mm may be needed to "split" the commissures. It is important to proceed carefully in a stepwise fashion with echocardiographic evaluation after each dilation to help minimize MR.

The pathologic features of the valve are important determinants of immediate and long-term outcome. Echocardiography can assess the variables that predict the results of BMV both in reduction in valve area and gradient and occurrence of significant MR (see Figure 62.8). These variables include the nature of commissural fusion, severity of subvalvar deformity, leaflet mobility, and calcification. Trivial MR via the central valve orifice does not worsen and may disappear following BMV. However, MR at the commissures may progress following BMV [43].

The immediate results of BMV in children are comparable to those in adults. In a series of 81 children with juvenile MS, Bahl *et al.* demonstrated an increase in valve area by $172 \pm 62\%$ (from a mean of 0.8 ± 0.4 to $2.2 \pm 0.5\,\text{cm}^2$) [44].

Long-term follow-up after BMV is mandatory because of the significant risk of restenosis with time. Restenosis is typically associated with significant residual MS (typically because of subvalvar pathology) following BMV. Repeat BMV is an option for restenosis and helps postpone mitral valve surgery.

Surgery for RHD

For significant MR, valve repair should be considered.. Excellent immediate and acceptable intermediate term outcomes follow valve repair of MR in RHD [45,46]. These reports could be subject to publication bias. The results of mitral valve repair in RHD are not as consistently reproducible as for MR associated with a myxomatous valve [47]. For the combination of MR and MS, it is particularly difficult to make management decisions.

There are major long-term concerns about operations in RHD. The inflammation in chronic RHD may continue well beyond the initial episode of RF and result in continuing injury to the mitral valve and tensor apparatus after "successful" repair [19]. There are several other challenges. Repeated operations are unrealistic in most environments where RHD is prevalent because of the expense involved with open-heart surgery. Furthermore, there are limitations to mitral valve replacement with a mechanical prosthetic valve in younger patients. Monitoring anticoagulation is particularly challenging in most parts of the developing world. Pregnancy imposes a substantial additional risk in

females. In the developing world, a number of factors, such as valve pathology, gender, age, resources, surgical expertise, and patient and family preferences, must be considered for mitral valve replacement in RHD.

There are no clear guidelines for the timing of mitral valve surgery (particularly replacement) in children. Standard guidelines for mitral valve surgery in adults do not apply to children. The natural history of chronic valve regurgitation appears to be very different in children and adults. Persistent symptoms, in spite of maximally tolerated medications, warrant consideration of surgery especially in the presence of pulmonary artery hypertension. For an asymptomatic child, evidence of ventricular dysfunction merits consideration for surgery. Rheumatic aortic valve disease is less suited for repair. Fortunately, it is not always necessary to operate on AR unless it is severe. There are isolated reports of good results following aortic valve repair for RHD [48,49]. The Ross operation is a poor option for RHD and the long-term durability of the pulmonary autograft is very limited in children with RHD [50]. Small children pose a significant challenge for aortic valve replacement. The aortic root often needs to be enlarged to fit the smallest available mechanical prosthesis and this requires technical expertise.

For patients with RHD with combined mitral and aortic valve disease, the threshold for replacing both valves is fairly high. because of expense, morbidity, and concerns regarding long-term anticoagulation. Many surgeons, therefore, choose to replace the more severely affected valve (typically the mitral valve) and to leave the less severely affected valve alone. Mild or moderate aortic valve disease does not progress rapidly over several years after mitral valve replacement for RHD [27].

Associated tricuspid valve disease can be repaired in most instances. Typically, annuloplasty of the dilated tricuspid valve annulus restores competence [51].

Prevention of RF and RHD – A public health perspective

RF and RHD continue to be important public health problems in the developing world [1,2,7,35]. The magnitude of the problem remains unrecognized in these regions and this obstructs planning public health strategies for disease prevention. Very few systematic surveys are available from rural populations which have a poor health care infrastructure, urban slums, or tribal colonies [35].

Penicillin prophylaxis, particularly secondary prophylaxis, remains the mainstay for prevention of RF and RHD [2]. Its importance should be stressed at institutional and governmental levels. Education about the disease is needed for health professionals and the public in these regions. Patients with established RHD and those who have had an episode of RF should receive targeted education on the importance of penicillin prophylaxis.

An effective vaccine against group A streptococcus (GAS) has the potential to reduce the RF–RHD disease burden, but many difficulties need to be overcome before an effective vaccine is available [35]. A number of questions remain about the usefulness of vaccines for streptococcal strains found in the developing world. There is also the practical issue of identifying the population at risk in the developing world, given the changing disease epidemiology. An effective vaccine cannot be seen as a magic bullet to control RHD, while disregarding the various interactive forces that contribute to disease occurrence. Any public health effort to control RF–RHD should adopt a comprehensive approach that includes all facets of disease prevention to achieve an enduring impact on the reduction of disease burden.

63   Kawasaki Disease

Hirohisa Kato & Kenji Suda
Kurume University School of Medicine, Kurume, Japan

Kawasaki disease (KD) occurs in infants and children as an acute systemic vasculitis syndrome of unknown etiology; it mainly affects small- and medium-sized arteries, particularly the coronary arteries [1]. The cardiovascular problems in KD are related to coronary arterial lesions: aneurysm formation, thrombotic occlusion, progression to coronary artery disease, and premature atherosclerosis [2]. This disease was first described more than 40 years ago by Tomisaku Kawasaki in Japan [3,4]. Subsequently, it has been recognized throughout the world, and it is now a leading cause of acquired heart disease in children in North America and Japan.

History and background

When this disease was first described, it was considered benign and the prognosis good, because all acute symptoms disappeared within 2–3 weeks and the patient became well. Yamamoto and Kimura reported a patient with myocarditis [5], but coronary artery involvement went unrecognized. In 1970, the first nationwide survey in Japan demonstrated that 1.7% of the patients died from acute myocardial infarction (MI), and all four autopsies showed coronary arteritis accompanied by aneurysms and thrombotic occlusion. At that time, most pediatricians considered that KD was complicated by vasculitis only in small number of fatalities, because of the great contrast in prognosis between these rare fatalities and the large number of survivors who were asymptomatic.

In 1975, Kato *et al*. performed coronary angiography in 20 infants and children when their acute symptoms had disappeared. Of these, 12 showed multiple coronary aneurysms in both right and left coronary arteries, the first recognition that coronary aneurysms are present not only in fatalities

but also in asymptomatic survivors [1]. From the pathologic and coronary angiographic findings, KD was recognized as a systemic vasculitis syndrome of small- and medium-sized arteries in infants and young children.

In the past, KD may have been misdiagnosed as other diseases [6], such as scarlet fever [7], Izumi fever, measles, rheumatic fever [8], juvenile rheumatoid arthritis, drug hypersensitivity, Stevens–Johnson syndrome [9], and infantile polyarteritis [10], all now listed in the differential diagnosis of KD [11]. Landing and Larson reported identical pathologic findings in fatal KD and infantile polyarteritis, which was described only by autopsies [12]. Recent views are that infantile polyarteritis is the same as fatal KD, and that KD is a systemic vasculitis syndrome in infants and young children with a wide spectrum of clinical symptoms and disease severity.

Synonyms for Kawasaki disease include Kawasaki syndrome and (acute infantile) mucocutaneous lymph node syndrome (MCLS), now rarely used. The International Classification of Diseases (ICD-9) designates KD and mucocutaneous lymph node syndrome under rubric 446.1.

Epidemiology

The epidemiology in Japan, where KD is most prevalent, has been well documented [13]. The incidence has increased since 1968, and the number of patients affected now totals about 250 000. KD affects >10 000 children each year in Japan, and the incidence increased steadily to 216.9 per 100 000 children younger than 4 years by 2007–2008 [14]. The age distribution is from 1 month with a peak at 1 year; 50% of patients are younger than 2 years, and occurrence after 10 years of age is rare. Boys are affected more often than girls, with a ratio of 1.5:1.

KD is now widely prevalent in Asia, North America, South America, Europe, and Australia. Asians are more susceptible (5–10 times) than are white persons [15]. In countries with predominantly white populations, the incidence is ~15 per 100 000 children under 5 years of age [16]. There is a wide distribution, with no geographic difference between urban and rural areas or south and north. Seasonal variations are not distinct, but there are small peaks in winter–spring. The recurrence rate is about 3.3%, and 1–2% of siblings are affected, which is approximately 10 times the incidence in the general child population [17]. The increased incidence of KD among siblings and parents of patients, and racial differences, support a genetic predisposition. Time–space clustering and outbreaks in a community are recognized, but there is no evidence of person-to-person transmission. In 1979, 1982, and 1986, there were large nationwide outbreaks of KD in Japan, and occasional local clusters were recognized [18].

Pathology

On the basis of Hamashima's analyses of 37 KD autopsies, the Japanese Kawasaki Disease Research Committee reported the following pathomorphologic findings [19,20]. KD is an acute inflammatory disease with systemic vasculitis distinguishable from classic periarteritis nodosa of the Kussmaul–Maier type, a progressive and recurrent angiitis with marked fibrinoid necrosis but with rare pulmonary vasculitis. In contrast, KD is an acute inflammatory disease lasting about 7 weeks with rare and mild fibrinoid necrosis. Infantile polyarteritis nodosa (IPN) is indistinguishable from KD in many pathologic aspects [12,21], and clinical details of IPN are highly suggestive of KD.

The course of vasculitis can be classified into four stages according to the duration of illness:

1 *Stage 1 (1–2 weeks of illness):* Perivasculitis and vasculitis of the microvessels (arterioles, capillaries, and venules), small arteries, and veins; inflammation of intima, externa, and perivascular areas in the medium- and large-sized arteries; edema and inflammation with leukocytic and lymphocytic infiltration.

2 *Stage 2 (2–4 weeks of illness):* Less inflammation in the microvessels, small arteries, and veins than in stage 1; inflammatory changes of intima, media, externa, and perivascular areas in the medium-sized arteries with focal panvasculitis; aneurysms with thrombi and stenosis in the medium-sized arteries, especially in the coronary arteries. Panvasculitis is rarely seen in the large arteries. Edema (exudative stage), infiltration with monocytes or necrosis (infiltrative stage), and cellular granulation with increase of capillaries occur.

3 *Stage 3 (4–7 weeks of illness):* Subsidence of inflammation in the microvessels, small arteries, and veins and granulation in the medium-sized arteries.

4 *Stage 4 (>7 weeks of illness):* Scar formation and intimal thickening with aneurysms, thrombi, and stenosis in the medium-sized arteries (generally no acute inflammation in the vessels). These findings may persist until adult age and were observed in some autopsied patients who died more than 10 years after the illness.

KD is a systemic vasculitis syndrome which may involve many organs, such as myocardium (interstitial myocarditis with mild necrosis) [22] and the conduction system, and in other organs may cause pericarditis, endocarditis, cholecystitis, cholangitis, pancreatic ductitis, sialadenitis, meningitis, and lymphadenitis.

Etiology and pathogenesis

The etiology of KD remains unknown, despite extensive investigation. On the basis of clinical features and epidemiologic data, KD is now considered to be either of infectious origin with an unknown agent or an infection-triggered immune disorder. A variety of possible causative agents, such as bacteria, fungi, mycoplasma, rickettsiae, and viruses, have been proposed without confirmation. So far, two major hypotheses have been discussed in the past decade: the viral etiology and the superantigen or bacterial toxin theories.

KD has clinical similarities to scarlet fever and toxic shock syndrome, both of which are caused by toxin-producing bacteria. These toxins are superantigens capable of stimulating T cells carrying particular variable regions of the T cell receptor β-chain. A recent study on peripheral blood T cells in KD has shown that T cells expressing T cell receptor variable regions Vβ2 and Vβ8 were selectively expanded [23]. These observations suggest that KD may be caused by a toxin (superantigen)-producing microorganism, including viruses. Leung *et al.* suggested that the expansion of Vβ2+ T cells in most patients with KD may be caused by a new clone of toxic shock syndrome toxin-secreting *Staphylococcus aureus* or SPEB- or SPEC-producing group A streptococci by study of bacterial culture from patients with KD [24]. However, several other studies did not support this theory [25]. Yoshioka *et al.* reported that streptococcal pyogenic exotoxin (SPEC) induces activation and polyclonal expansion of Vβ2- and Vβ6.5-positive T cells, and that SPEC-induced activation of T cells may lead to the pathogenesis of KD [26]. Recently, Nagata *et al.* reported that several gut bacteria isolated from the jejunal mucosa produce superantigen and heat shock proteins that may have some role in the pathogenesis of KD [27].

Yersinia pseudotuberculosis appears to be one of the etiologic agents of KD [28], although only a small group of KD patients can be explained by this organism. *Propionibacterium acnes* isolated from the cervical lymph node of patients produced a cytotoxic protein-like bacterial exotoxin [29,30], but its etiologic role remains to be determined.

Epstein–Barr virus (EBV) induced clinical pictures mimicking those of KD on rare occasions [31] and 3/37

patients with chronic active EBV infection developed coronary lesions. However, epidemiologic, serologic, and virologic studies do not support EBV as a causative agent of KD. Rowley *et al.* reported that IgA plasma cells infiltrate the vascular wall and also other tissues such as myocardium, respiratory tract. kidney, and pancreas in acute KD. They suggested a mucosal portal of entry of a conventional antigen; however, no specific microbe has been proposed as the etiologic agent [32]. The possible association between a novel human corona virus (HcoV-NH) and KD has been reported, but further studies are necessary [33].

The acute phase of KD is associated with markedly increased production of inflammatory cytokines. tumor necrosis factor-alpha (TNFα), IL-1β and γ-IF induce activation antigens and adhesion molecules such as endothelial leukocyte adhesion molecule 1 and intercellular adhesion molecule 1 (ICAM-1) on endothelial cells, and TNFα and γ-IF caused endothelial injury in *in vitro* studies [34]. Leung *et al.* proposed a hypothesis that anti-endothelial antibodies cause endothelial injury in KD, based on the findings that circulating autoantibodies in KD were cytotoxic against human umbilical vein endothelial cells treated with TNFα, IL-1β or γ-IF [35]. Coronary artery endothelial cells in KD actually expressed activation antigens in a necropsy study [36]. Vascular endothelial growth factor (VEGF), monocyte chemotactic and activating factor (MCAF or MCP-1), and TNFα may have important roles in the pathogenesis of vasculitis [37–39].

The epidemiologic studies suggest a genetic predisposition for this disease. No single human leukocyte antigen (HLA) is common to most patients with KD. Recently, Onouchi *et al.* reported the important genetic role of the functional polymorphisms in the inosotol 1,4,5-triphosphate 3-kinase C gene in a network of gene single nucleotide polymorphisms [40].

Many hypotheses on the etiology and pathogenesis of KD have been proposed, but a host–microbial relationship specific to KD has not been identified. KD is widely scattered in the community, is self-limited, has multiorgan involvement, can recur, and has a tendency for epidemics every 3–4 years. These findings suggest that this disease may be caused in some susceptible children by a common infectious agent(s).

Clinical manifestations and diagnosis

The diagnosis of KD is made according to the diagnostic guidelines prepared by the Japan Kawasaki Disease Research Committee listed in Table 63.1 because of the absence of a specific laboratory test. These guidelines describe well the major symptoms and other significant clinical manifestations and laboratory findings. The principal diagnostic criteria of KD are persistent fever, conjunctival injection, changes in the mucosa of the oropharynx, changes in the peripheral extremities, erythematous rash, and cervical lymphadenop-

athy. At least five of the six principal features should be satisfied for a diagnosis of KD. However, some patients do not fulfill the classic criteria, and are diagnosed as having incomplete KD.

Fewer than four of the six principal symptoms indicate incomplete KD. Fever duration may be <5 days, particularly in those treated with γ-globulin within the first five febrile days. However, patients with four of these symptoms can be diagnosed when coronary abnormality is recognized by two-dimensional echocardiographic findings such as dilatation or non-uniformity of arterial lumen and brightness of the arterial wall. Incomplete KD is recognized in ~10% of all KD patients who have a higher incidence of coronary aneurysms (25%). Children <6 months or >7 years of age sometimes demonstrate atypical symptoms. Incomplete KD should be considered in children with unexplained fever for >4 days with three other principal symptoms. High CRP (>3 mg dl⁻¹), elevated ESR (>40 h⁻¹), thrombocytosis (>400 000), white blood cell count (>15 000), and erythema and induration at the site of previous vaccination of BCG (Bacillus Calmette–Guérin) are helpful findings for diagnosing incomplete KD. In children >7 years old, sometimes high fever and neck lymphadenopathy are initial symptoms for several days from the onset. Echocardiography should be considered in patients with suspected incomplete KD to check the coronary arterial wall brightness, ectasia, and lack of uniform diameter of the coronary artery. The American Heart Association Committee published guidelines for the management of patients with incomplete KD [41].

Cardiovascular spectrum and cardiac evaluation

Cardiovascular spectrum

The cardiovascular spectrum of 2450 patients with acute KD seen over the last 35 years in our Hospital is indicated in Table 63.2. Coronary aneurysms were diagnosed in 14%. Since γ-globulin treatment was introduced, the incidence of coronary aneurysms has declined to 8.3%. Coronary artery involvement is the most important lesion in KD; however, aneurysms in other arteries such as the axillary, iliac or renal arteries were observed in 1.0% of the patients. Valvar heart disease appeared in about 1.4% of the patients. MI occurred in 36 patients, with 12 deaths. Half of the fatalities did not demonstrate ischemic findings before the onset of MI [42].

In the earlier period most patients received aspirin only, but we introduced γ-globulin treatment from 1992, leading to a significant decline in the incidence of transient dilatation and aneurysm formation of coronary artery, systemic artery aneurysms, pericarditis, and myocarditis.

Although there are several scoring systems to identify high risk for coronary artery abnormalities or patients resistant to γ-globulin treatment who have a higher risk of coronary

Table 63.1 Diagnostic guidelines for Kawasaki disease.

Principal symptoms

1. Fever persisting for at least 5 days
2. Changes in peripheral extremities
   Initial stage: reddening of palms and soles, indurative edema
   Convalescent stage: membranous desquamation from fingertips
3. Polymorphous exanthema
4. Bilateral conjunctival congestion
5. Changes in lips and oral cavity: reddening of lips, strawberry tongue, diffuse injection of oral and pharyngeal mucosa
6. Acute nonpurulent cervical lymphadenopathy
   At least five of the principal symptoms should be satisfied for the diagnosis of Kawasaki disease to be made. However, patients with four of the principal symptoms can be diagnosed as having Kawasaki disease when coronary aneurysm is recognized by two-dimensional echocardiography or coronary angiography

Other significant symptoms or findings

The following symptoms and findings should be clinically considered:

1. Cardiovascular auscultation (heart murmur, gallop rhythm, distant heart sounds), electrocardiographic changes (prolonged PR-QT intervals, abnormal Q wave, low-voltage ST-T changes, arrhythmias), chest radiograph findings (cardiomegaly), two-dimensional echocardiographic findings (pericardial effusion, coronary aneurysms), aneurysm of peripheral arteries other than coronary (e.g., axillary), angina pectoris or MI
2. Gastrointestinal tract: diarrhea, vomiting, abdominal pain, hydrops of gallbladder, paralytic ileus, mild jaundice, slight increase in serum transaminase
3. Blood: leukocytosis with shift to the left, thrombocytosis, increased erythrocyte sedimentation rates, positive C-reactive protein, hypoalbuminemia, increased α_2-globulin, slight decrease in erythrocyte count and hemoglobin levels
4. Urine: proteinuria, increase in leukocytes in urine sediment
5. Skin: redness and crust at the site of Bacille Calmette–Guérin inoculation, small pustules, transverse furrows of the fingernails
6. Respiratory: cough, rhinorrhea, abnormal shadow on chest radiograph
7. Joint: pain, swelling
8. Neurologic: pleocytosis of mononuclear cells in cerebrospinal fluid, convulsion, unconsciousness, facial palsy, paralysis of the extremities

Remarks

1. For changes in peripheral extremities, the convalescent stage is considered important
2. Male-to-female ratio, 1.3–1.5; patients younger than 5 years of age, 80–85%; fatality rate, 0.3–0.5%
3. Recurrence rate, 2–3%; proportion of siblings, 1–2%

From *Diagnostic Guidelines of Kawasaki Disease*, 4th edn, Japan Kawasaki Disease Research Committee, Tokyo, 1984.

aneurysms [43,44], the Harada score, which was initially used to determine selection for IVIG treatment, is now often used to select patients with greater risk for coronary artery disease [45]. The patients who fulfill four of the following items may develop the coronary artery lesions: (1) white blood count >12 000 mm^{-3}, (2) platelet count <350 000 mm^{-3}, (3) CRP >3 mg dl^{-1}, (4) hematocrit <35%, (5) albumin <3.5 g dl^{-1}, (6) age ≤12 months, and (7) male gender.

Myocardial infarction and death

The main cause of death in KD is acute MI. A study of 104 fatalities in KD in Japan suggests that 56.7% of the patients died of acute MI and 18% died of congestive heart failure caused by ischemia. Five deaths were due to rupture of coronary aneurysms. In the 1970s the fatality rate in Japan was ~2%; however, by 2007–2008 it had declined markedly to 0.03%. We analyzed 195 KD patients with MI from the nation-wide survey in Japan [46]. MI usually occurred within 1 year

of illness, but late deaths several years after acute KD have increased recently. Death might occur at any time with obstructive lesions. Attacks of MI are relatively more frequent at night when the patient is sleeping or resting, with primary manifestations of shock symptoms, pallor, restlessness, vomiting, and abdominal pain. Chest pain was more frequently recognized in the survivors and in children >4 years of age. Asymptomatic MI was seen in 37%. Of the patients with MI, 22% died at the first attack; 16% of the survivors from the first attack had a second attack. The fatality rate was 63% in the second attack and 83% in the third attack. From coronary angiographic studies in the patients with MI, most of those who died had obstructions in the left main coronary artery or in both the right main coronary artery and the left anterior descending artery. In survivors, one-vessel obstruction, particularly in the right coronary artery, was frequently recognized.

Early recognition and treatment for acute MI are critical. Recurrence of MI is observed in ~20% of the patients who

Table 63.2 Cardiovascular spectrum: chronological changes (Kurume University: 1973–2007).

Lesion	1973–1990	1991–2007	Total
	Aspirin era $n = 1355$	γ-Globulin + aspirin era $n = 1095$	$n = 2450$

[a] $p < 0.005$.

have had a previous MI. Because the mortality of recurrent MI is high, careful management is needed for such patients. Patients with complications after MI, such as ventricular aneurysm, papillary muscle dysfunction, heart failure, severe arrhythmias, and post-infarction angina, are managed by medical and/or surgical approaches.

Systemic artery involvement

Coronary artery involvement is the most important lesion in KD, but aneurysms in other arteries were observed in 0.9% of patients [42].Our angiographic study of 22 patients with systemic artery aneurysms demonstrated aneurysms in axillary arteries (18), common iliac arteries (16), internal iliac arteries (12), renal artery (6), mesenteric arteries (2), and internal thoracic arteries (2). One patient had large common iliac artery aneurysms associated with dilatation of aorta. Although the prognosis of systemic artery aneurysms is generally favorable, renovascular hypertension may develop in a patient having a renal artery lesion, and intrathoracic arterial lesions may cause difficulty during coronary bypass surgery. There are some reports of digital gangrenous changes [47].

Valvar heart disease, myocarditis, and pericarditis

Valvar heart disease appears in ~1% of the patients, mostly mitral valve and rarely aortic. We demonstrated acute mitral regurgitation in 29/2450 patients (1.2%), half of which eventually disappeared after a few months to several years. The etiology of this condition may be valvitis or papillary muscle dysfunction caused by ischemia [48]. We had six

patients with aortic regurgitation (0.2%). Aortic regurgitation appeared after the acute or subacute stage of illness and progressed to severe regurgitation in several years in some patients [49]. Pericarditis or pericardial effusion appeared in 11.8% of the patients in the acute phase, was mostly subclinical, and disappeared within 1–2 weeks. Massive pericardial effusion or cardiac tamponade was rare. There have been no reports on progression of acute to chronic or constrictive pericarditis. Relatively mild myocarditis was observed in 25.2% of patients in the acute phase, especially in the first and second weeks of illness, regardless of coronary aneurysms. Gallop rhythm, distant heart sound, ST-T segment changes, and decreased voltage of R waves on ECG may suggest myocarditis. In many instances, cardiac enzyme levels such as creatine kinase did not change significantly. Cardiomegaly or decreased ejection fraction of the left ventricle caused by myocarditis was noted in some patients. It generally resolved, seldom developing into a chronic dysfunction or cardiomyopathy.

Echocardiography

The evaluation of the coronary artery lesions in KD in the acute stage of illness is important, even essential, and is usually done by two-dimensional echocardiography (2DE) for all patients and coronary angiography (CAG) for selected patients.

Serial 2DE studies are the most important and essential method to evaluate coronary aneurysms. The approach for 2DE in KD is well described in the Japan Kawasaki Disease Research Committee Report on Standardization of Diagnostic

Criteria and Reporting of Coronary Artery Lesions [50] and the Committee Report of the American Heart Association [51]. Coronary aneurysms are classified as small (<4 mm internal diameter in children <5 years old or >4 mm in children ≥5 years old), medium (5–8 mm) and giant or large (>8 mm) by the Japanese Research Committee. Recently, some reports have suggested that these criteria may underestimate the true incidence of coronary artery dilatation [52–54]. Mild dilatation or ectasia may be underestimated by these criteria, so the body surface area-adjusted coronary dimensions (Z-score) may evaluate the minimal changes of the coronary artery diameter more accurately [55]. If the serial 2DE studies reveal abnormal findings in a patient, coronary angiography may be indicated [56].

The evaluation of coronary artery morphology is particularly important in KD. The precordial short-axis segment is the standard approach for evaluating the left main coronary artery, the left anterior descending artery, and the right main coronary artery. The posterior descending artery can be evaluated by the apical four-chamber view. The middle segment of the right coronary artery is seen in the apical four-chamber view. From echocardiographic studies, it is evident that coronary artery dilatation appears at around 10 days of illness, and ~40% of patients reveal transient coronary artery dilatation in this period. However, two-thirds of these demonstrate transient dilatation and regression within 3–5 weeks from the onset of illness. This means that Kawasaki vasculitis may demonstrate various degrees of coronary artery dilatation from mild transient dilatation, small- or moderate-sized aneurysms, or giant aneurysms in more than half of the patients in the acute phase [57]. Aneurysms are classified as saccular if the axial and lateral diameters are nearly equal or as fusiform if symmetric dilatation with gradual proximal and distal tapering is seen. If the coronary artery diameter looks larger than normal without segmental dilatation, the coronary artery is considered ectatic. False-negative diagnoses were mainly due to isolated small peripheral coronary artery aneurysms, which appeared rarely. Follow-up echocardiography is essential to evaluate such findings to assess whether the ectatic changes are pathologic or normal. We routinely perform 2D echocardiography at the time of diagnosis, at around 8–10 days of illness when coronary dilatation may appear, at 2 weeks, and at 8 weeks after the onset of the disease.

Acute coronary thrombosis is also diagnosed by serial 2DE at the cardiac clinic. At that time, thrombolytic treatment by urokinase or t-PA is indicated [58]. Evaluating stenotic lesions of the coronary artery by 2DE is sometimes difficult, although by using a high-frequency transducer and careful examination it may be possible. The features of abnormal examinations are the loss of the uniformity of the lumen of arteries, irregularity of the arterial wall, and a dense echo in the coronary arterial wall.

Coronary angiography and heart catheterization

Selective coronary artery angiography (CAG) is the most accurate method for defining the severity of coronary arterial abnormalities in KD. We have used specially designed catheters (three types) for selective coronary angiography for infants, toddlers, and school children, with which coronary angiography can be performed safely and successfully [56]. The indications for CAG include abnormal 2DE findings, symptoms or signs of ischemia, audible valve regurgitation during auscultation, evidence of cardiac dysfunction, and the use of intracoronary thrombolytic treatment. If patients have severe coronary lesions, other systemic vascular involvement, such as the axillary, iliac, renal, or intrathoracic artery aneurysms, should be evaluated. Because the regression of coronary artery aneurysms and progression to stenotic lesions mostly occurred within 2 years from the onset of illness, repeat follow-up CAG is essential, especially in patients having coronary aneurysms [42]. The definition of regression of coronary aneurysms is that the follow-up CAG demonstrates completely normal findings with disappearance of aneurysms and even no irregular arterial wall in the whole coronary artery system. Regression can be diagnosed by CAG, but 2DE may miss some mild abnormal findings that subsequently progress to coronary artery disease. CAG is most important and essential for evaluating stenotic or obstructive lesions of the coronary artery or assessment of the collateral circulation (Figure 63.1).

The clinical feasibility of intravascular ultrasound imaging for coronary arteries has been reported in patients who had suffered from KD to assess the long-term pathology *in vivo* [59]. At the site of regressed aneurysms, there is marked thickening of the intima, as mentioned previously. The portion of the coronary artery with normal angiographic findings showed normal ultrasound findings except in the region near the regressed aneurysm, which showed mild intimal thickening. Positive remodeling (or compensatory remodeling) may contribute to maintaining the normal lumen although with mild intimal thickening [60].

Other noninvasive techniques

Magnetic resonance imaging (MRI) may evaluate aneurysms in the proximal coronary artery and the coronary flow profile [61–63]. MDCT (multi-detector-row computed tomography) is also available to evaluate coronary aneurysms, the wall morphology, and the tissue characterization of the coronary artery [64], but needs breath holding for several seconds; it may be useful for older children or adults.

Evaluating myocardial ischemia

Because the morbidity and mortality of this disease mostly depend on the extent of associated coronary artery disease, it is particularly important to assess accurately any myocardial ischemia during the follow-up. However, the available methods have some limitations for young children. 2DE can detect

Figure 63.1 Serial echocardiography and coronary angiography of giant coronary aneurysm and thrombus formation. (a, b) Two-dimensional echocardiography and coronary angiography at 1 month of illness demonstrated giant aneurysms in the left main trunk, the left anterior descending artery (LAD), and the circumflex artery (LCX). Ao, aorta; PA, pulmonary artery. (c, d) Ten months later, two-dimensional echocardiography demonstrated massive, dense abnormal echo in the left main trunk (arrows), which suggested massive thrombotic formation (T) in the coronary aneurysm. At that time, coronary angiography showed the decreased size and a severe obstruction of the coronary aneurysm. (Reproduced with kind permission from Springer Science+Business Media:Cardiovascular Medicine , Echocardiography of patient with myocardial infarction by thrombosis, 3rd ed, 2007, p 979–994, Willerson JT, Cohm JN, Wellens JJ, Holmes DR, Figure 41.3.)
coronary aneurysms, but evaluating stenosis is not satisfactory. Similarly, the sensitivity of electrocardiography for detecting myocardial ischemia is inadequate. Coronary angiography is an accurate method to assess coronary artery involvement, but repeated evaluation is often difficult because of the invasive technique. Although an exercise stress test can detect myocardial ischemia and being noninvasive is easy to repeat, its sensitivity is not sufficient even in patients with significant coronary stenosis, and it is difficult to perform in young children. Myocardial single-photon emission computed tomography (SPECT) using pharmacologic stress (i.e., dipyridamole infusion) is considered the most accurate diagnostic method for identifying myocardial ischemia, especially in children in whom an exercise test cannot be performed [65]. Because pharmacologic stress SPECT provides quantitative analysis, the changes in severity of myocardial ischemia are detectable when serial studies are performed. Kamiya reported the sensitivity of detecting myocardial ischemia using various methods in patients having significant coronary stenosis (>75%) [66]. The most sensitive method was dipyridamole stress SPECT (85% sensitivity), whereas the sensitivity of a treadmill exercise test was <50%. Recently, many types of stress tests have been reported in children with KD, including nuclear perfusion scans with exercise [67], exercise echocardiography [68], stress echocardiography

using dobutamine [69], and contrast echocardiography with dipyridamole stress [70].

Long-term cardiovascular sequelae and natural history

Long-term consequences of coronary aneurysms and follow-up

The natural history or fate of coronary aneurysms is an important issue in KD [83]. We followed 594 consecutive patients with acute KD between 1973 and 1983 for 10–21 years [42]. In all patients, we evaluated the coronary lesions by coronary angiography just after the acute stage. A total of 146 patients (24.6%) were diagnosed as having coronary aneurysms. A second angiography, performed 1–2 years later in all 146 patients who previously had coronary aneurysms, demonstrated that 72(49.3%) had regression of the coronary aneurysms, suggesting that coronary aneurysm in KD shows a strong tendency for regression. None of the patients with regression of coronary aneurysms had cardiac symptoms in the long-term follow-up periods, and results of their ECGs, exercise stress test, thallium myocardial scintigraphy, and left ventricular function were all within normal limits. In contrast, by 10–21 years after the onset of
Figure 63.2 Regression of coronary aneurysms. (a) Eight-month-old boy with four coronary aneurysms in both right and left coronary arteries. (b) Two years later. Follow-up coronary angiography demonstrated regression of aneurysms, which included the disappearance of aneurysms and no irregular arterial wall in the entire coronary artery system.

the illness, stenosis in the coronary aneurysms had developed in 28 patients. Myocardial infarction occurred in 11 patients, with five deaths. From this study, we estimated that about 4% of patients with KD may develop ischemic heart disease.

When does this complication occur? We studied the time and incidence of regression or progression to obstructive lesions from the onset of KD using the Kaplan–Meier life table method. Regression of coronary aneurysms mostly occurred within 2 years from the onset of illness, whereas the obstructive lesions developed at 2 years and gradually increased over several years.

We investigated various factors that could affect the prognosis of coronary aneurysms [71]. The risk factors for coronary aneurysms developing into ischemic heart disease are aneurysmal diameter >8 mm, shape of large diffuse or saccular type, prolonged fever for >21 days, and age at onset >2 years. In the 26 patients with giant coronary aneurysms, stenotic lesions developed in 12, and no regression occurred in our follow-up study. Hence giant coronary aneurysms have a critical problem because they have a strong potential to develop ischemic heart disease. The incidence of giant coronary aneurysms was 17.8% in the patients with coronary aneurysms and 4.4% among all KD patients in our series (Figure 63.2).

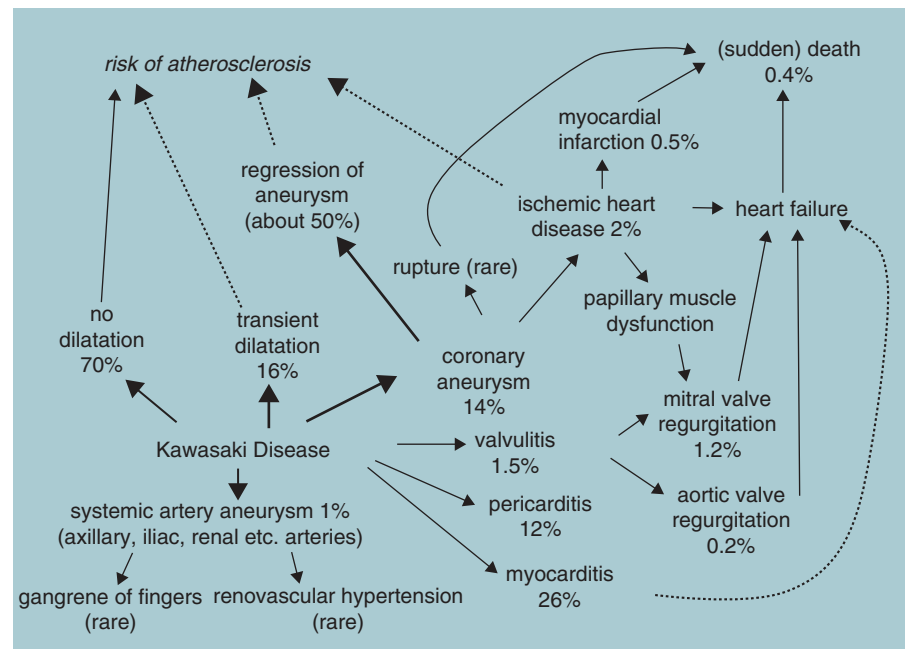
The pathologic mechanism of regression of aneurysms is marked proliferation of intima with rich smooth muscle cells and well-regenerated endothelium without massive thrombus formation [72]. Hemodynamic forces may

regulate such arteries to maintain adequate lumina. It is uncertain whether intimal thickening eventually develops into obstructive lesions. However, from our 10–21 years' follow-up study, none of the patients who had regressed aneurysms developed ischemic heart disease. However, the regressed coronary aneurysms have intimal thickening and impaired endothelial function, so they should be carefully followed during adulthood to determine if they develop secondary atherosclerotic changes (Figure 63.3).

Kawasaki vasculitis may be an atherosclerotic risk factor

Pathology of the coronary artery in KD several years after onset demonstrates marked intimal proliferation and, in some patients, calcification, deposits of protein-like material and hyalinized degeneration in the thickened intima. An intravascular ultrasound study of the coronary artery after KD demonstrated marked thickening of the intima and calcification in the coronary aneurysms [59]. These findings are similar to arteriosclerotic lesions. Suzuki *et al.* reported the active expression of various growth factors in the coronary artery in the late phase of KD, suggesting that active vascular remodeling continues even several years after onset [73,74].

Concerning vascular function after KD, we studied the distensibility of the coronary arterial wall by intracoronary infusion of isosorbide dinitrate [75] and endothelial function by intracoronary infusion of acetylcholine [76,77]. Both vascular distensibility and endothelial function long after KD

Figure 63.3 Cardiovascular spectrum and natural history.


were impaired in the patients with coronary artery aneurysms, stenosis, and regressed aneurysms. Dhillon *et al.* [78] and Mitani *et al.* [79] also reported that endothelial dysfunction was observed even in the normal artery in KD. Pathology of the coronary artery in adults after KD demonstrated premature atherosclerotic changes [80]. Mitani *et al.* suggested that the high-sensitivity C-reactive protein was elevated in the late coronary sequelae in KD, and found dense calcium and necrotic core areas in the coronary arterial wall by a virtual histology-intravascular ultrasound study, which suggests the potential role of atherogenesis in the coronary artery in the long term after KD [81,82].

Adult coronary artery disease due to childhood kawasaki disease

It is now more than 40 years since the first description of KD as a new clinical entity, and many of the early KD children are now adults [83]. We surveyed major cardiovascular centers in Japan for such adults to investigate any coronary sequelae that might be due to their earlier KD, and reported 21 such patients and their cardiac conditions [84]. Most of these 21 patients were diagnosed as having fever of unknown origin, sepsis, or pneumonia, because they suffered from suspected KD before its first description in 1968. Most of the patients had ischemic symptoms, such as acute or old MI or angina pectoris, two or three decades after the onset of suspected KD. Some of the patients had mitral regurgitation or arrhythmias. Almost all had multiple coronary aneurysms with obstruction or stenosis and with severe calcification of the arteries. Coronary aneurysms of unknown etiology were also reported in 109 patients who had no suspected history

of KD. These patients were mostly free from ischemic symptoms but had abnormal Q waves on ECG or calcification of the coronary artery on chest X-ray. We suspect that some of these patients might have had childhood KD.

Our study suggested that some patients with coronary artery sequelae of KD have already developed young adult ischemic heart disease. A past history of KD in infancy or childhood is important, but this is sometimes unrecognized or was diagnosed as another disease. Abnormal Q waves or mitral regurgitation of unknown origin in younger adults is also important. Coronary angiographic findings are essential for diagnosis; there are multiple aneurysms frequently associated with calcification. Familial hypercholesteremia or collagen vascular disease should be excluded. After our publication [84], many reports of adult coronary artery disease probably due to childhood KD appeared and were reviewed by Burns and co-workers [85,86].

The issues concerning KD in adults include (1) the patients with coronary artery disease or valvar heart disease not diagnosed as having KD during childhood, (2) adults diagnosed as having KD during childhood without evaluating the coronary lesions during KD, (3) adults having persistent coronary artery lesions, and (4) adults who develop premature atherosclerosis after KD with various coronary risk factors. Those patients should be evaluated and followed by adult cardiologists. The coronary artery sequelae of KD may be an important cause of ischemic heart disease in young adults, particularly those under 40 years of age. Adult cardiologists should recognize this condition and include the sequelae of KD in the differential diagnosis of early-onset coronary artery disease in adults.

Treatment and management

Treatment in acute phase

After it became apparent that KD is not a benign self-limited disease, but can be fatal and result in significant long-term sequelae, especially coronary aneurysms, the target of the treatment of KD is to control inflammation as quickly as possible, especially within 10 days of illness, to prevent the development of coronary aneurysms.

Initial treatment

In 1979, Kato *et al.* [87] first compared the effectiveness of five different types of treatment protocols, (1) 30 mg kg^{-1} of aspirin, (2) aspirin and 2–3 mg kg^{-1} of prednisolone, (3) prednisolone alone, (4) prednisolone plus warfarin, and (5) antibiotics in the acute phase of KD, and found that aspirin was the most effective treatment (32/36, 89%) and steroid therapy was the least effective, with patients treated with prednisolone alone showing an incidence of coronary artery aneurysm of 65% (11/17). Based on this observation, oral aspirin has been one of the standard treatments in the acute phase of KD. In combination with intravenous γ-globulin infusion (IVGG), in Japan 30 mg kg^{-1} of aspirin in three doses is given and in the United States 80–100 mg kg^{-1} of aspirin in four doses is given during the febrile period. After being afebrile for 48–72 h, the dose of aspirin is reduced to 3–5 mg kg^{-1} and the aspirin is continued for 6–8 weeks after the onset of illness. Aspirin is thought to exert anti-inflammatory effects in high doses and anti-platelet effects in low doses. In patients with coronary aneurysms, aspirin should be continued indefinitely unless the patients show regression of coronary aneurysms.

Subsequently, Furusho *et al.* [88,89] reported that high-dose IVGG as a treatment for acute KD dramatically decreased the incidence of coronary aneurysms from 42 to 15%. Initially IVGG was given as 200 or 400 mg kg^{-1} for 4–5 consecutive days. However, several multi-institutional randomized controlled trials conducted in Japan [90–92] and the United States [93] revealed that the most effective regimen of this treatment includes a total of 1 or 2 g kg^{-1} of IVGG over 12–24 h together with medium- to high-dose aspirin. Interestingly, meta-analyses of these studies demonstrated a dose–response effect of IVGG [94,95], with higher doses given in a single infusion having a greater effect. The precise mechanisms by which IVGG produce such a striking anti-inflammatory effect and a marked reduction in the development of coronary abnormalities is still not clear.

Because most coronary artery dilation starts to occur at around 10 days of illness, initial treatment should be started within 7 days of illness to control inflammation and prevent the progression to coronary aneurysm.

Although current standard treatment using high-dose IVGG and oral aspirin is fairly effective, with an 80–90%

success rate, some patients are still resistant to initial treatment. To improve the effectiveness of initial treatment, additional steroid either as an intravenous prednisolone infusion or methylprednisolone pulse therapy was examined. Inoue *et al.* [96] reported the effectiveness of 2 mg kg^{-1} of intravenous prednisolone infusion in addition to 1 mg kg^{-1} of IVGG over 2 days plus aspirin, with tapering of oral prednisolone over 15 days. In their randomized controlled study, this regimen showed significantly fewer coronary artery aneurysms than with control treatment, 1 g kg^{-1} of IVGG over 2 days plus aspirin (2.2 versus 11.4%). However, drawbacks of this protocol included universal use of steroid and a rather long treatment period. Another trial with a dose of 30 mg kg^{-1} intravenous methylprednisolone infusion in addition to 2 g kg^{-1} of IVGG plus high-dose aspirin conducted in North America showed only a minimal beneficial effect [97].

Additional treatment

In patients resistant to initial treatment, many different types of treatment [98] are offered, such as another dose of IVGG alone or with addition of urinastatin, erastase inhibitor, steroid pulse therapy of 30 mg kg^{-1} of intravenous methylprednisolone infusion, inhibitor of TNFα [99–101], cyclosporine A [102], methotrexate [103], and plasma exchange [104].

Although failing as the initial treatment, pulse steroid therapy using methylprednisolone was revisited as the second or third treatment to reduce the cost of treatment in place of another dose of IVGG. As the second treatment, Furukawa *et al.* [105] reported comparable effectiveness (77 versus 63%) of pulse steroid therapy with the same incidence of coronary aneurysms (11 versus 11%) to the second dose of IVGG, although they were concerned about a tendency for fever to recur later in patients resistant to pulse steroid therapy, which could potentially delay the therapeutic decision-making process. As the third treatment, Hashino *et al.* [106] reported comparable effectiveness of pulse steroid therapy to the third dose of IVGG with shorter duration of fever. However, transient coronary dilation during pulse steroid therapy was observed, hence careful echocardiographic monitoring of the coronary artery is mandatory in this treatment. In addition, several adverse effects, such as hypertension, bradycardia, and hypothermia during this treatment, have to be checked [105,107].

To eradicate all the active cytokines, plasma exchange can be a definitive treatment in these diseases with cytokine storms. Indeed, plasma exchange is reported to be significantly effective treatment for patients resistant to IVGG [104]. However, the choice of the treatment depends on institutional accessibility and experience with this treatment.

Because serum levels of TNFα, a pro-inflammatory cytokine, increase markedly in patients with acute KD, with the highest levels observed in patients who developed coronary artery aneurysms [108,109], blockade of TNFα

might be effective in controlling inflammation. Recently, infliximab, a chimeric murine/human IgG1 monoclonal antibody that binds specifically to human TNFα, was given to patients with KD resistant to IVGG [100–102]. In the initial descriptive study, 13 of 16 patients who were resistant to initial IVGG responded to this drug, and a randomized controlled study is under way [102].

High-risk patients

Because we know that 15–20% of patients do not respond to the initial IVGG, it is reasonable to offer strengthened treatment for selected high-risk patients. Several risk scoring systems [43,44,110] have been developed in addition to Harada's scoring system [45]. Egami *et al.* reported a scoring system assigning 1 point for (1) infants less than 6 months old, (2) treatment ≤4 days of illness, (3) platelet count ≤30 × 10⁴ μl⁻¹, and (4) CRP ≥80 mg l⁻¹, and 2 points for (5) ALT ≥80 IU l⁻¹. A cut-off point of ≥3 with this prediction score identified patients with KD resistant to the initial IVGG with 78% sensitivity and 76% specificity [43]. Kobayashi *et al.* also reported a scoring system assigning 1 point for (1) age ≤12 months and (2) platelet count ≤30 × 10⁴ μl⁻¹, and 2 points for (3) sodium ≤133 mmol l⁻¹, (4) treatment ≤4 days of illness, (5) AST ≥100 IU l⁻¹, (6) % neutrophils ≥80%, and (7) CRP ≥100 mg l⁻¹. A cut-off point of ≥4 with this prediction score identified patients with KD resistant to the initial IVGG with 86% sensitivity and 67% specificity [44]. In addition, Sano *et al.* reported a simplified scoring system, in which patients with two of the three predictors (1) CRP ≥70 mg l⁻¹, (2) total bilirubin ≥0.9 mg dl⁻¹, and (3) AST ≥200 IU l⁻¹ could be resistant to the initial IVGG with 77% sensitivity and 86% specificity [110]. Although each of these risk-scoring systems may work well in selected institutions, multiple scoring or determination of percentage neutrophils can be cumbersome and the value of AST can be falsely elevated because of hemolysis frequently seen in small infants.

Based on these scoring systems to identify patients who would be resistant to the initial IVGG and carry a higher risk of coronary aneurysms, a combination of IVGG and pulse steroid therapy was offered to the selected patients as the initial treatment [111,112], although these studies could not prove effectiveness because of their retrospective nature [111] or small sample size [112]. Based on another scoring system [43], a randomized controlled trial of combination therapy consisting of 2 mg kg⁻¹ of intravenous prednisolone infusion, 2 g kg⁻¹ of IVGG, and 30 mg kg⁻¹ of aspirin in the acute phase with tapering of oral steroid is under way.

Treatment for patients with coronary aneurysms

In patients with coronary artery aneurysms, especially giant coronary aneurysms, anti-thrombotic treatment to prevent MI using continuous infusion of heparin should be considered in addition to aspirin, once the physician has recognized the development of coronary aneurysms. Care

must be taken to prevent insufficient anti-thrombosis because generally infants require a larger dose of heparin than do adults, namely 20–25 IU kg⁻¹ h⁻¹, to achieve the target level of anti-thrombotic effect, 60–85 s in activated pro-thrombin time. This anti-thrombotic treatment should be replaced by oral warfarin treatment and continued until the size of aneurysm decreases to medium or small without any sign of stenosis.

Even with the anti-thrombotic therapy, some patients may suffer from MI. In MI or impending MI in which thrombus is seen in coronary artery aneurysms, intracoronary thrombolysis using infusion of urokinase [58] or tissue plasminogen inhibitor [113] with or without coronary catheter intervention has been applied successfully.

Interestingly, a study suggested that abciximab, a platelet glycoprotein IIb/IIIa receptor inhibitor, may enhance regression of coronary artery aneurysms [114].

Management in late phase (Tables 63.3 and 63.4)

Long-term medical treatment for coronary aneurysms

Anti-thrombosis

In patients with small- to medium-sized coronary artery aneurysm, 3–5 mg kg⁻¹ of aspirin is given until regression of coronary artery aneurysm is confirmed. In patients with a giant coronary artery aneurysm, complete regression of the aneurysm cannot be expected, but rather development of thrombotic occlusion or stenosis adjacent to the aneurysm must be anticipated. Historically, warfarin plus aspirin was used to prevent acute MI with a high success rate. Sugahara *et al.* [115–117] reported a significantly lower incidence of MI in patients treated with warfarin plus aspirin compared with aspirin alone (5.2 versus 32.7%), with an MI-free rate of 95% at a mean follow-up of 7.7 years. The target strength of anti-thrombotic treatment using warfarin is set at 1.6–2.5 times the international normalized ratio of prothrombin time according to the revised guidelines of the Japanese Circulation Society. Warfarin is given even to infants with a giant coronary aneurysm despite the potential risk of developing bleeding complications, because there is a greater risk of thrombotic occlusion early after onset. In a multi-institutional study that enrolled 83 patients with giant coronary aneurysm treated with warfarin plus aspirin, Suda *et al.* [116] reported a 91% cardiac event-free rate at 10 years and an acceptably low hemorrhagic complication rate of 2.2% per patient-year.

Although other anti-platelet medications such as dipyridamole, flurbiprofen, and ticlopidine have been given in isolated regimens or in combination with aspirin or warfarin, there are few data concerning the effectiveness of these drugs. A recently approved anti-thrombotic agent, dabigatran etexilate (Pradaxa), that is safer and easier to control than warfarin may become available for children.

Table 63.3 Indications of treatment by classification of severity of coronary artery lesions.

Treatment[a]	Severity level[b]	Evidence level[c]
Anti-thrombotic drugs (aspirin, dipyridamole, ticropidine)	IV, V III I, II	Class I Class II Class III
Anticoagulant drugs (warfarin)	IV, V III I, II	Class I Class II Class III
Coronary vasodilators (Ca channel blockers, β-blockers, nitrates, etc.)	V IV I, II, III	Class I Class II Class III
Drug for heart failure (ACE inhibitors, angiotensin II receptor blockers, β-blockers)	V IV I, II, III	Class I Class II Class III
PCI	V (b) V (a) I, II, III, IV	Class I Class II Class III
CABG	V (b) V (a) I, II, III, IV	Class I Class II Class III

[a]ACE, angiotensin-converting enzyme; PCI, percutaneous coronary intervention; CABG, coronary artery bypass grafting.
[b]See Table 63.4.
[c]Evidence level:
Class I   Conditions for which there is general agreement that the treatment is useful and effective.
Class II   Conditions for which there is a divergence of opinion regarding the usefulness/efficacy of a treatment.
Class III   Conditions for which there is general agreement that the treatment is not useful/effective and may in some cases be harmful.

Revascularization therapy

Because increasing numbers of patients develop coronary stenosis adjacent to coronary aneurysms, catheter and surgical interventions to alleviate myocardial ischemia must be offered in a timely fashion [118,119]. There are three indications: patients presenting with clinical ischemic symptoms, patients presenting without clinical ischemic symptoms but having ischemic findings detected by several stress tests, and patients having no ischemic findings detected by any stress tests but with ≥75% of stenosis in the left anterior descending artery that can cause sudden cardiac death by its obstruction [118,119]. The selection of catheter or surgical intervention is determined by the same indications

as in adult coronary artery disease, where catheter intervention is not indicated in multiple coronary lesions, long segmental lesion, and coronary ostial lesions.

Based on the above indications, almost all types of catheter interventions for coronary artery disease have been offered in KD, such as balloon angioplasty [120,121], stent implantation [122,123], and rotational ablation [124–126]. Within 6 years after the onset of KD when coronary artery calcification is usually mild, coronary angioplasty is indicated. Special care must be taken to keep low inflation pressures of <8–10 atm to avoid the risk of new aneurysm formation [119].

Late after the onset of KD, catheter interventions must be chosen based on the degree of calcification and intimal growth, and intravascular ultrasound plays a pivotal role in evaluating vascular wall pathology [59]. With heavy circumferential calcification of the coronary wall, coronary rotational ablation, with as large a burr size as possible, is the choice of intervention to ensure long-term patency [125,126]. In addition to bare stents, covered [127] or drug-eluting stents [128] have been implanted in patients with KD, but the application of this procedure is limited because of the relatively larger equipment size and a risk of new coronary aneurysm formation and re-stenosis.

In patients who were unsuitable for catheter interventions, coronary artery bypass graft surgery has been offered with great success [129–131]. As a conduit vessel for bypass, an internal mammary artery is preferred to a saphenous vein graft because of its excellent patency and growth potential [132]. Age <12 years was once the limiting factor of patency of grafts, but this limitation has been overcome with technical innovation in addition to appropriate indications and timely catheter intervention [133–135].

Because re-stenosis at the site of catheter intervention or stenosis of anastomosis of the bypass graft has been reported, meticulous follow-up is mandatory [135]. In addition, although both catheter and surgical interventions are offered to relatively young patients with ischemic heart disease, sometimes it is still challenging and even risky for a small infant to undergo these interventions. Further development of equipment and techniques for these procedures is awaited.

In addition to catheter and surgical interventions, medical treatment to facilitate revascularization or neo-vascularization has been explored. Tateno *et al.* [136] reported the effectiveness of heparin–exercise therapy composed of twice-daily exercise with a bicycle ergometer plus heparin infusion in patients with totally occluded coronary arteries and stress-induced myocardial ischemia. After 10 days of this treatment, patients showed significant alleviation of myocardial ischemia as evaluated by dypyridamole-loading single photon emission computed tomography. Suda *et al.* [137] also reported the effectiveness of intermittent heparin infusion to alleviate myocardial ischemia in a small infant with multiple occluded coronary arteries.

Table **63.4** Summarized guidelines.

Severity level	Description	Pathophysiology	Diagnosis/clinical course	Treatment	Daily life/exercise management[a]
I	No dilatation	There is no evidence whether or not a history of Kawasaki disease is a factor associated with arteriosclerotic lesion	Follow up patients for 5 years. Evaluate at 30 days, 60 days, 6 months, 1 year, and 5 years after onset with ECG, echocardiography, and, if necessary, chest X-ray. It is desirable that patients be evaluated with exercise ECG at the final examination	Basically, no treatment is required during the remote phase.	No restriction is placed on daily life or exercise. Consult with parents (or patients) to determine further management. Lifetime prevention of lifestyle-related diseases is important. Junior and senior high school students should be educated on lifestyle-related diseases (blood lipid measurement, education on smoking cessation, and prevention of obesity)
II	Transient dilatation during the acute phase	During the acute phase, histopathologically vasculitis develops in the outer layer of the tunica media and then expands to the intima in coronary arteries. Echocardiography reveals diffuse dilatation of coronary arteries, but these changes subside within 30 days after onset		Patients with no coronary aneurysms after the acute phase may discontinue anti-platelet drugs such as aspirin	
III	Regression	In many patients regression may occur 1–2 years after onset, particularly in small- or medium-sized aneurysms. In the segment with regression, decrease in coronary diastolic function, abnormal function of vascular endothelium, and substantial intimal hyperplasia have been reported	Basically, follow patients annually with ECG, echocardiography, and chest X-ray up to entry into elementary school (age 6–7 years), and then with the same methods and exercise ECG in 4th grade (age 9–10 years), at entry into junior high school (age 12–13 years), and entry into senior high school (age 15–16 years). Follow patients who had coronary aneurysms with a large internal diameter during the acute phase with an appropriate combination of imaging techniques[b]		No restriction is placed on daily life or exercise. Follow the recommendations for Categories I and II
IV	Remaining coronary aneurysms	Aneurysms remaining during the convalescence phase or later are considered sequelae. Histopathologically, progression of inflammation leads to rupture of the internal elastic band, causing panangiitis. The internal and external elastic bands are broken into fragments and ruptured by arterial pressure to form aneurysms. Patients with giant aneurysms must be observed carefully for myocardial ischemia, since in such patients myocardial ischemia may develop even if no significant stenotic lesions are present	Patients must be followed with exercise ECG and an appropriate combination of imaging techniques[b]. It is desirable that patients who had coronary aneurysms with a large internal diameter during the acute phase be evaluated with stress myocardial scintigraphy every 2–5 years to monitor for progression to stenotic lesions	Continue treatment with anti-platelet agents such as aspirin. Anticoagulant therapy may be needed in patients with giant coronary aneurysms or thrombi in coronary aneurysms. CABG may be indicated for patients with giant coronary aneurysms not accompanied by significant stenotic lesions when myocardial ischemia has occurred	No restriction is placed on daily life or exercise except for those with giant aneurysms.

(continued)

Table 63.4 (cont'd).

Severity level	Description	Pathophysiology	Diagnosis/clinical course	Treatment	Daily life/exercise management[a]
V (a)	Coronary stenotic lesions (no findings of ischemia)	Thrombotic occlusion of medium-sizes or giant aneurysms may develop during the relatively early stage after onset. Sudden death may occur, although two-thirds of patients with occlusion are asymptomatic. Patients often show improvement of myocardial ischemia due to the development of recanalized vessels and collateral flow after occlusion. Development/progression of regional stenosis during the remote phase is more prevalent in the left than the right coronary artery. The segments with greatest prevalence are the proximal segment or the main trunk of the left anterior descending artery. The risk of progression to stenosis/ occlusion is higher in larger aneurysms.	Patients must be followed for life, and physicians must design the tailor-made management plan for individual patients. Follow-up examination must include exercise ECG and an appropriate combination of imaging techniques[b]. Although the schedule may differ among individuals, patients are generally evaluated every 3–6 months	Continue treatment with anti-platelet drugs such as aspirin. Use Ca channel blockers, nitrates, β-blockers, ACE inhibitors, and angiotensin receptor II blockers to prevent ischemic attacks and heart failure	No restriction is placed on daily life or exercise. For patients other than those with giant aneurysms. Explain the importance of drug treatment and ensure adherence, and also symptoms which may occur and actions to be taken when ischemia develops. Patients must be followed at least annually until regression of aneurysms is documented
V (b)	Coronary stenotic lesions (with findings of ischemia)	Stenosis may develop during long-term follow up		Follow the instructions for drug treatment in Category V (a). Consider CABG or appropriate PCI technique when exercise ECG or stress myocardial scintigraphy reveals ischemia	Exercise should be restricted. Categorize in "D" or higher category based on patient condition. School sports club activities should be "prohibited." Select the most appropriate category from "A" to "D" on the basis of findings of exercise testing and evaluation of severity of myocardial ischemia. Educate patients well about the importance of drug treatment

Anti-atherosclerosis

In addition to impaired vascular distensibility and endothelial function, dyslipidemia was reported in a cluster of patients with coronary artery aneurysms long after KD [138]. In fact, accelerated atherosclerosis expressed by thickened intima–media complex of the carotid artery and also increased stiffness was observed in patients with coronary artery aneurysms caused by KD [139,140]. Therefore, anti-atherosclerosis using statin or angiotensin receptor antagonists may be applied, as in adult patients with atherosclerosis. There is only one short-term study that showed the effectiveness of oral atorvastatin in patients with coronary aneurysms caused by KD as judged by improved endothelial function and decreased serum level of CRP in addition to a decrease in total and LDL-cholesterol [141]. Strategies to stop, delay, or even reverse early atherosclerosis seen in patients with a history of KD must be explored.

Prognosis

Since it is more than 40 years after the first description of this disease, the long-term prognosis of patients with a history of KD has been available for over 20 years. Based on a cohort of 6576 patients, Nakamura *et al.* [142] reported that the mortality rate among males with cardiac sequelae because of KD was significantly higher than in the general population, with a standardized mortality ratio of 2.55 (95% confidence interval 1.23–4.70). On the other hand, the mortality of females with cardiac sequelae and of both males and females without cardiac sequelae was not significantly elevated.

In terms of patients with giant coronary aneurysms who might have the worst prognosis, we have followed a cohort of 76 patients with giant coronary aneurysms caused by KD since 1972 [143]. The survival rate of these patients was acceptably high, being 88% at 30 years after onset. On the other hand, the cumulative cardiac intervention rate was also high, being 59% at 25 years, reflecting ongoing development of coronary stenosis that required appropriate cardiac interventions.

Hypertension in Children and Adolescents

Bonita Falkner

Thomas Jefferson University, Philadelphia, PA, USA

Introduction

Hypertension may occur in any phase of childhood, from the newborn period through adolescence. There is a normal upward trend in blood pressure (BP) level throughout childhood that corresponds to normal growth and development. In children and adolescents, hypertension is defined as the BP level at the extreme of the normal distribution in healthy children. The diagnosis of hypertension requires BP measurements, systolic and/or diastolic, that are consistently ≥95th percentile for age, sex, and height [1]. With this statistical definition, the prevalence of hypertension is theoretically from 1 to 5%. More recent data, drawn from asymptomatic children and adolescents in primary care clinics [2] and in school screenings [3], indicate that the prevalence of hypertension is ~3.5%, with higher rates among obese adolescents. Therefore, hypertension is a very common chronic health issue in childhood. As measurement of BP in children during routine health care visits has become common practice, and as a result of the rising rates of childhood obesity, more children with hypertension are being identified. Because secondary causes of hypertension can be detected more frequently in hypertensive children, relative to adults, the approach to evaluating hypertension in the young differs from that of adults. High BP in the young is evaluated to determine whether the elevated BP is an early expression of primary hypertension or due to secondary hypertension. As in adults, severe untreated hypertension in children can have a poor outcome [4]. Children with primary (essential) hypertension commonly have the same risk factors for cardiovascular disease as adults, and can benefit from interventions to control the BP.

Definition of hypertension in childhood

Hypertension in adults is defined by the level of BP that predicts a heightened risk for subsequent cardiovascular or renal events. The risk for cardiovascular events increases as systolic BP rises above 120 mmHg [5], but hypertension continues to be defined as BP ≥140/90 mmHg, regardless of adult age or gender. In children, with the exception of extreme hypertension, long-term data which link a particular level of BP in childhood with subsequent cardiovascular events, such as stroke, heart failure, or kidney failure, are unavailable. In the absence of such data, hypertension is defined statistically. The combined results of several large epidemiologic studies that measured BP in healthy children [1,6] provide data from which the normal distribution of BP in children and adolescents in the United States has been established. An analysis of BP data from healthy children in Europe describes a very similar BP distribution pattern in childhood [7–9].

There is a consistent relationship of BP with body size in childhood. The BP level rises progressively with increasing age throughout childhood, and parallels the age-related increase in height. A gender difference in BP distribution emerges in adolescence and is concurrent with a gender difference in height. The definition of hypertension in children and adolescents is systolic and/or diastolic BP that, on repeated measurement, is ≥95th percentile for age, gender, and height [1]. The severity of hypertension is now staged: Stage 1 is systolic or diastolic BP that is between the 95th percentile and 5 mmHg above the 99th percentile, and Stage 2 is average systolic or diastolic BP that is >5 mmHg above the 99th percentile for age, gender, and height. In adults, a BP level between 120/80 and 139/89 mmHg is

designated prehypertension. Prehypertension in children is defined as systolic or diastolic BP between the 90th and 95th percentile for age, sex, and height. Because the BP level at the 90th percentile is >120/80 mmHg in some taller adolescents, a BP level >120/80 mmHg but <95th percentile is considered prehypertension in adolescents. Normal BP is systolic and diastolic BP <90th percentile for age, sex, and height. Table 64.1 provides the level of BP for the 50th, 90th, 95th, and 99th percentile for age and height percentile for boys, and Table 64.2 provides the same percentile levels for girls [1]. The 50th percentile for systolic and diastolic BP is provided to denote the midpoint of the BP distribution.

There are some limited data on normal levels of BP in newborns and very young infants [10–12]. In a large study on newborn infants that included a broad range of birth weights and gestational ages [12], at birth BP was directly related to both weight and gestational age. Daily BP measurements in healthy newborns, regardless of weight or gestational age at birth, demonstrate a rapid and consistent increase in BP during the first 5 days of life [11], reflecting the normal hemodynamic transition from intrauterine to extrauterine life. Subsequently, BP is directly related to body weight and age, in terms of gestation or post-conception age. The upper 95% confidence limit (CL) for a term infant (40 weeks post-conceptional age) is 90 mmHg for systolic blood pressure. Systolic BP levels >90 mmHg are considered hypertensive in a term infant, and by 4–6 weeks of age (44–46 weeks post-conception age) a systolic BP >100 mmHg represents hypertension.

Measurement of blood pressure in the young

Measurement of BP in children and adolescents should be performed in a standard method. In an office or clinic setting, the preferred method for BP measurement in children is auscultation with a cuff sphygmomanometer.

Correct BP measurement in children requires an appropriately sized BP cuff for the size of the child's upper arm [1]; the bladder width should be ~40% of the arm circumference midway between the olecranon and the acromion. This size of cuff bladder will usually cover 80–100% of the arm circumference. Most manufacturers of BP cuffs provide lines on the cuff that are useful in choosing the correct cuff size. The equipment necessary to measure BP in children 3 years of age through adolescence includes three pediatric cuffs of different sizes, and also a standard adult cuff, an oversized cuff, and a thigh cuff for leg BP measurements. The last two cuffs may be needed for obese adolescents.

Measurement of BP in children should be performed in a quiet and comfortable room after 3–5 min of rest. With the exception of acute illness, the BP should be measured with the child seated. The arm with the BP cuff should be supported at heart level. The child's feet should be on the floor while the BP is measured, rather than dangling from an examination table. Over-inflation of the cuff should be avoided because of discomfort, particularly in younger children. The BP should be measured and recorded at least twice.

Systolic BP is determined by the onset of the auscultated pulsation or first Korotkoff sound. The disappearance of Korotkoff sounds or fifth Korotkoff sound (K5) is the definition of diastolic pressure in adults. In children, particularly preadolescents, a difference of several millimeters of mercury is frequently present between the fourth Korotkoff sound, the muffling of Korotkoff sounds (K4), and K5 [13]. Normative BP data in children indicate that K5 can be used as the measure of diastolic BP in both children and adults [1].

The measured BP level in a child is interpreted by determining if the BP level is within the normal level (<90th percentile) or elevated for age (≥90th percentile). Precise interpretation requires plotting the BP on the pediatric BP tables according to the child's height percentile, age, and gender. Table 64.1 provides the systolic and diastolic BP levels for the 50th, 90th, 95th, and 99th percentile according to age (rows) and height percentile (columns) in boys. Table 64.2 provides the BP levels at each percentiles for age and height in girls. These tables can also be accessed at www.nhlbi.nih.gov/guidelines/hypertension/child_tbl.htm.

The child's height is measured and plotted on a standard growth curve. The height percentile is used in the tables, and the child's BP is compared with the BP level for the 90th, 95th, and 99th percentile at the child's age, gender, and height percentile. This process is cumbersome in a busy clinical setting. For practical purposes, BP measurements of 120/80 mmHg in adolescents and of 110/70 mmHg in children are considered "high-risk" BP in the young, and require a closer look at the BP tables.

An elevated BP level in a child or adolescent must be confirmed on repeated visits before confirming a diagnosis of hypertension or prehypertension. A more accurate characterization of an individual's BP level is an average of multiple BP measurements taken for weeks or months. A notable exception to this general guideline is if the child is symptomatic or has profoundly elevated BP. With their availability and convenience, automated devices for BP measurement are being used more frequently. Automated devices are acceptable for BP measurement in newborn and young infants in whom auscultation is difficult, and in intensive care units where frequent BP measurement is necessary. The reliability of these instruments in an ambulatory clinical setting is less clear because they need frequent calibration and established reference standards are lacking. When an elevated BP measurement is obtained using an automated device, the BP measurement should be repeated by auscultation to verify the measurements.

Table 64.1 Blood pressure (BP) levels for boys by age and height percentile.

Age (years)	BP percentile	Systolic BP (mmHg)							Diastolic BP (mmHg)

Reproduced from the National Guidelines on High Blood Pressure in Children and Adolescents NIH website www.nhlbi.nih.gov?guidelines/hypertension/child_tbl.htm

Ambulatory BP monitoring (ABPM) for 24h has become increasingly used in evaluating adults with hypertension, and is being applied to older children and adolescents. Some population standards for ambulatory BP values in children and adolescents are available [14] and this information can be helpful [15]. For example, ABPM can be used to identify white coat hypertension and masked hypertension. White coat hypertension is defined as average BP (systolic and diastolic BP) <95th percentile on ABPM despite BP measurements >95th percentile in a physician's office or other clinical setting. Masked hypertension is the reverse, with average systolic or diastolic BP >95th percentile on ABPM but with office or clinic BP measurements <95th percentile. ABPM is also useful in determining the need for and effectiveness of pharmacologic therapy. When ABPM is used in children or adolescents, the appropriate cuff size should be used.

Causes of hypertension in the young

Secondary hypertension
Secondary hypertension from underlying renal or endocrine disorders is found more frequently during childhood than in adults. Secondary hypertension is generally characterized by marked elevations in BP. Before the development of normative data on BP levels in children, BP was measured infrequently. When elevated BP was detected in children, the hypertension was, by current standards, fairly severe, and led to the belief that hypertension in children was *always* secondary. This concept has now changed, largely from a better understanding of normal levels of BP in the young and the practice of regularly measuring the BP in children as part of health assessment and maintenance.

The prevalence of secondary hypertension in the young varies according to the age and severity of hypertension. In a series of children, an identifiable secondary cause for hypertension was found in 90% of children <10 years of age, and only 10% were considered to have primary hypertension [16]. In another series including both children and adolescents with hypertension, an underlying cause of the hypertension was identified in 65% of the adolescents, with 35% thought to have primary hypertension [17].

The age of the child and severity of BP elevation are helpful in distinguishing secondary from primary hypertension. Children <12 years of age with sustained hypertension are more likely to have a secondary cause. The degree of hyperten-

Reproduced from the National Guidelines on High Blood Pressure in Children and Adolescents NIH website www.nhlbi.nih.gov?guidelines/hypertension/child_tbl.htm

sion is an important clue, as severe BP elevation in a young child is most likely due to an underlying abnormality. Children and adolescents with Stage 2 hypertension should be carefully evaluated for both possible cause of the hypertension and evidence of target organ damage. Although the list of conditions that can cause hypertension in the young is fairly long, the majority of the identifiable causes of hypertension in the young are related to renal disorders. Table 64.3 provides a list of underlying causes for chronic hypertension in the young, and the conditions associated with acute hypertension in the young.

Hypertension is uncommon in healthy newborn infants; however, certain conditions increase the risk for hypertension. Neonates with an umbilical artery catheter have heightened risk for thromboembolic events [18]. Low birth weight infants, with respiratory distress syndrome, who later develop bronchopulmonary dysplasia are at risk for hypertension. These infants frequently require chronic corticosteroid therapy with resulting sodium retention [19]. The most commonly identified causes of hypertension in newborn infants are renal artery thrombosis, renal artery stenosis, congenital renal malformations, patent ductus arteriosus, coarctation of the aorta, and bronchopulmonary dysplasia [20]. Infants who have been treated with the extracorporeal membrane oxygenation

procedure have also been observed to develop hypertension. In some critically ill newborn infants with hypertension, an underlying cause may not be identified. Regardless of whether a cause for the hypertension is determined, BP control and monitoring in these infants are important.

For children <10 years of age, the leading causes of secondary hypertension are renal parenchymal diseases, coarctation of the aorta, and renal artery stenosis. Coarctation of the aorta can be missed in infants and toddlers, and should be considered in an asymptomatic hypertensive child [21]. In later childhood, essential hypertension can also be detected. Causes of acute hypertension include post-infectious glomerulonephritis and hemolytic uremic syndrome. Some disorders, such as hemolytic uremic syndrome, may lead to permanent renal scarring that causes chronic hypertension.

Among hypertensive adolescents, primary (essential) hypertension occurs more frequently than secondary hypertension. The most frequent secondary causes of hypertension are renal parenchymal diseases, such as chronic pyelonephritis, and various types of chronic glomerulonephritis, such as focal segmental glomerulosclerosis, and IgA nephropathy. Adolescent behaviors that may contribute to high BP are illicit substance use, especially cocaine and amphetamine-related

Table 64.3 Secondary causes of hypertension.

Chronic hypertension

Renal	*Drugs*
Chronic glomerulonephritis	Corticosteroids
Interstitial nephritis	Alcohol
Collagen vascular diseases	Appetite suppressants
Reflux nephropathy	Anabolic steroids
Polycystic kidney disease	Oral contraceptives
Medullary cystic disease	Nicotine
Hydronephrosis	
Hypoplastic/dysplastic kidney	*Syndromes*
	Alport syndrome
Cardiac and vascular	Williams (renovascular lesions)
Coarctation of aorta	Turner (coarctation or renovascular)
Renal artery stenosis	Tuberous sclerosis (cystic renal)
Takayasu arteritis	Neurofibromatosis (renovascular)
	Adrenogenital syndromes
Endocrine	Liddle syndrome
Hyperthyroidism	
Pheochromocytoma	
Primary aldosteronism	

Acute hypertension

Renal	*Drugs*
Post infectious glomerulonephritis	Cocaine
Schönlein–Henoch purpura	Phencyclidine
Hemolytic uremic syndrome	Amphetamines
Acute tubular necrosis	Jimson weed
Vascular	*Miscellaneous*
Renal or renal vascular trauma	Burns
	Orthopedic surgery
Neurogenic	Urologic surgery
Increased intracranial pressure	
Guillain–Barré syndrome	

compounds. Other substances associated with high BP in adolescents include appetite suppressants (both prescription and over-the-counter remedies), oral contraceptives, excessive alcohol intake, and the use of anabolic steroids for body building [22].

Primary hypertension

Primary, or essential, hypertension classically has been considered a disorder of older adults. The concept that essential hypertension has its roots in childhood can be inferred from BP tracking data, which demonstrate that children with elevated BP continue to have elevated BPs as adults [1]. Risk factors associated with hypertension in adults, such as overweight and a positive family history of hypertension or cardiovascular disease, may be present in children with high BP. Although the combination of higher BP level for age and typical risk factors was thought to indicate risk for future hypertension, more recent reports indicate that this condition is more than just a risk for future problems. Using echocardiographic measures of cardiac mass adjusted for body size and appropriate childhood reference values for cardiac structure, left ventricular hypertrophy (LVH) has been reported in 30–40% of children and adolescents with hypertension [23,24]. Longitudinal data demonstrate a direct link between risk factors in childhood, including BP levels, with intermediate measures of target organ injury including greater intima–media thickness of carotid arteries [25] and vascular stiffness [26]. With this emerging evidence on the consequences of elevated BP in the young, primary hypertension in childhood can be considered the early phase of a chronic disease.

Primary hypertension in children and adolescents is associated with several clinical characteristics or associated risk factors. The degree of BP elevation is generally mild, ~95th percentile, and there is often considerable variability in BP over time. A consistent observation in children exhibiting mild essential hypertension is a positive history of hypertension in parents and/or grandparents [27,28].

Excess body weight has an effect on BP in both children and adults, and BP is higher in both overweight and obese children and adolescents [29,30]. Primary hypertension in childhood is frequently associated with obesity, which appears to be a contributory factor as even a modest reduction in excess adiposity is associated with a reduction in BP [31,32]. The cluster of mild BP elevation, a positive family history of hypertension, and obesity is a typical pattern in children and adolescents with essential hypertension [33].

The prevalence of childhood obesity has markedly increased both in the United States [34] and worldwide [35]. Data from the National Health and Nutrition Examination Survey (NHANES) indicate that as of 2004 the prevalence of obesity had increased to 17.4% among boys and to 17.8% among girls [36]. An analysis of two separate sets of data from NHANES demonstrates a statistically significant increase in childhood BP levels. The increase in BPs is largely due to the concurrent increase in obesity [37].

Among adult patients with cardiovascular disease, there is an overlap of hypertension, non-insulin-dependent diabetes mellitus, atherosclerosis, and obesity, a constellation described as the insulin-resistance syndrome or the metabolic syndrome [38]. The metabolic syndrome is clinically defined by a cluster of risk factors including abdominal obesity, abnormal glucose tolerance, dyslipidemia, and high BP. Adults with the metabolic syndrome are at increased risk for developing diabetes and cardiovascular events. Children also can exhibit characteristics of the metabolic syndrome [39]. The rates of metabolic syndrome among adolescents have increased in the past two decades, concurrent with the increases in rates of obesity and hypertension [40,41]. The characteristics of the metabolic syndrome are also congruent with the overweight child having a strong family history of hypertension or early heart disease. These children often have high BP [42]. Although these children are not at risk for immediate adverse effects of the higher than normal BP, they are at increased risk for premature cardiovascular disease.

Multiple factors, including both genetic and environmental factors, contribute to the origin, onset, and progression of primary hypertension. Barker *et al*. [43] proposed an alternative causative factor for primary hypertension based on historical data indicating an association of hypertension and ischemic heart disease in adult men who had low birth weights. They proposed that lower birth weight is a consequence of an altered or impaired intrauterine nutritional environment. Impaired fetal growth is indicative of alterations in organ growth which may affect organ function later in life [43,44]. Higher BP is the putative link between compromised intrauterine growth and the long-term risk for cardiovascular disease [43]. The low birth weight hypothesis is supported to some extent by experimental laboratory studies and population data [45]. However, the concept conflicts with the body of data in both childhood and adulthood, which consistently demonstrate a direct relationship between body weight and BP, and with data demonstrating BP tracking from childhood to young adulthood [46–48]. When reports on the association of birth weight with future BP are examined in a meta-analysis, the effect of birth weight on future BP is in the range of a 1–3 mmHg BP reduction for each 1 kg increase in birth weight [49]. Low birth weight appears to be linked with later overweight or obesity, and when the adolescent or adult weight is considered in analyses of population data, the birth weight effect is damped [50]. Although the population effect of low birth weight appears small, low birth weight can be another factor that increases risk for later obesity and high BP [51].

Evaluating hypertension in children and adolescents

A medical evaluation is needed for a child or adolescent with sustained hypertension, verified by repeated BP measurements ≥95th percentile. The extent of the diagnostic evaluation is determined by the suspected type of hypertension. When a secondary cause is considered, as in a young patient or one with severe hypertension, a more extensive evaluation may be necessary. On the other hand, if the elevated BP is more likely an early expression of primary hypertension, a few diagnostic screening studies may be sufficient. Currently, the recommendations for assessment of hypertension in children include evaluation for (1) an identifiable cause, (2) co-morbidity, and (3) target organ damage [1].

The medical history and physical examination are keys in determining whether the patient's presentation indicates primary hypertension or reflects a secondary, and potentially correctable, cause. Secondary causes should be suspected in any child who is hypertensive and is not growing normally, has a sudden onset of elevated BP, and has no positive family history of hypertension.

Another set of findings characterizes children and adolescents with essential (primary) hypertension: slight to mild elevations in BP, a strong family history of essential hypertension, elevated resting heart rate, variable BP readings upon repeated measurement, and obesity. If no other abnormalities are found on history or physical examination, these children require less extensive evaluation for an underlying disorder than those in whom secondary causes are suspected. Alternatively, the children with early expression of essential hypertension, particularly if obese, may have associated co-morbidities that include dyslipidemia, sleep apnea, and impaired fasting glucose.

Medical history
The family history of cardiovascular disease is very important. In both first- and second-degree relatives, the family history of hypertension, myocardial infarction, stroke, renal disease, diabetes, and obesity should be obtained. It can be relevant to the diagnosis in a hypertensive child if relatives had an onset at an early age of any of these conditions. A family history of genetically determined conditions that have hypertension as a component such as polycystic kidney disease and neurofibromatosis should be sought. Another familial disorder with hypertension is glucocorticoid-remediable aldosteronism, an autosomal dominant condition, which should be considered when multiple family members have early-onset hypertension associated with hypokalemia or stroke [52].

Past medical history can be pertinent. For example, with a history of urinary tract infections, there may be associated reflux nephropathy, renal scarring, and resultant hypertension. A history should be obtained of medications and over-the-counter products, including oral contraceptives and decongestants. Information should be obtained about health-related behaviors such as usual diet, amount of physical activity, and athletic participation. Other adverse adolescent lifestyles to consider are use of "street" drugs, smokeless tobacco, cigarettes, diet aids, ethanol, and anabolic steroids.

Physical examination
The child's general growth rate and growth pattern should be assessed, including weight gain or weight loss. Weight, height, and body mass index (BMI) should be plotted according to age and gender on the child growth charts. Growth abnormalities associated with hypertension can be seen with chronic renal disease, hyperthyroidism (causing primarily systolic hypertension), pheochromocytoma, adrenal disorders, or certain genetic abnormalities such as Turner syndrome.

To rule out coarctation of the aorta, the evaluation should include upper- and lower-extremity BP measurements taken with appropriately sized cuffs. Normally the leg BP levels are slightly higher than the arm BP levels. A child with coarctation will have systolic hypertension in an upper extremity, sometimes absent or decreased femoral pulses, and a BP

differential of >10 mmHg between the upper and lower extremities [21].

Other physical clues may suggest a secondary etiology for hypertension. Abnormal facies or dysmorphic features may suggest a syndrome associated with specific lesions causing hypertension. Examples are Turner and Williams syndromes, which have renovascular or cardiac lesions that cause hypertension. Renal vascular lesions may sometimes have an audible abdominal bruit detectable by auscultation of the abdomen. Skin lesions are sometimes the first manifestations of disorders such as tuberous sclerosis and systemic lupus erythematosus. Acanthosis nigricans in overweight children may be a sign of abnormal glucose tolerance, and can occur in children or adolescents with metabolic syndrome.

Diagnostic testing

When the history and physical examination provide clues for a specific underlying cause for the hypertension, testing should be directed to the area of clinical suspicion. In the absence of clues, however, underlying renal disease should be considered because chronic kidney disease is the most frequent cause of secondary hypertension in the pediatric population. The initial studies to screen for renal abnormalities include a urinalysis, electrolytes, creatinine, complete blood count, urine culture, and renal ultrasound. An evaluation for "co-morbidity" or other associated risk factors includes measurement of fasting plasma lipids for dyslipidemia, a sleep history to screen for sleep apnea, and if there is a positive family history of diabetes or acanthrosis nigricans on physical examination, additional testing of glucose tolerance may be indicated.

The other component of the evaluation includes assessing target organ injury. Target-organ injury provides a measure of chronicity and severity (characteristics sometimes difficult to ascertain from the history) and aid in deciding whether pharmacologic therapy should be instituted. Left ventricular hypertrophy (LVH) is an independent risk factor for cardiovascular morbidity and mortality in adults, and is considered to be the most prominent clinical evidence of target organ damage resulting from hypertension during childhood and adolescence [1]. Echocardiography is a sensitive means to detect and determine whether the child is developing LVH. Chest X-ray and electrocardiogram (ECG) are much less sensitive measures of LVH in children. In children, the echocardiographic measurements of left ventricular mass (LVM) should be indexed to height (in meters) to the power of 2.7 ($m^{2.7}$). Left ventricular mass index (LVMI, $LVM/m^{2.7}$) >51 g is a criterion for LVH in older children, adolescents and adults [1]. The proportion of hypertensive children and adolescents with this definition of LVH is small (<10%). However, when LVH is based on the LVM distribution in normal children, the prevalence of LVH in hypertensive children is higher. A cross-sectional study of 130 patients, ranging in age from 6 to 23 years, with persistent BP elevation >90th percentile for an average of 2 years reported that only 45% of the patients had a LVMI <90th percentile. Nineteen patients (14%) had an LVMI >99th percentile. Among those with LVMI >95th percentile, 17% had concentric hypertrophy and 30% had eccentric hypertrophy. When LVH was defined as LVMI ≥95th percentile, LVH was most frequent among overweight males [23]. Male gender and BMI also predicted LVMI in a recent report on children with high BP and chronic kidney disease[53].

Obesity may also contribute to the development of LVH in children with high BP. An analysis of longitudinal data from the Bogalusa Heart Study has shown that higher LVM in young adulthood is predicted by higher BP and adiposity in childhood [54].

Evidence for other sites of target organ damage in children with high BP is beginning to emerge. Data from a population study on healthy children show a significant association of higher BP with a reduced retinal diameter [55], so that an ophthalmologic examination can be helpful. Subtle changes in cognitive function among children with hypertension have been reported. These findings have been in measures of executive function such as problem solving and decision making [56,57]. There is also some evidence of increasing urinary albumin excretion, suggestive of possible renal injury, in children with high BP and other risk factors [58,59]. The clinical usefulness of other measures of target organ damage in evaluating individual pediatric patients requires additional investigation.

The remainder of the evaluation should be directed by specific findings on history, physical examination, and results of initial screening studies. An algorithm for evaluating hypertension in the young is provided in Figure 64.1. The algorithm indicates steps in evaluating and managing hypertension in children according to the severity of the hypertension, and the presence or absence of obesity.

Treatment of hypertension in children and adolescents

Health-related behavior changes in diet, physical activity, and weight control improve BP control in adults. Children may also benefit from these lifestyle changes. Children and adolescents with Stage 1 or mild elevation of BP, and without target organ damage, should begin treatment with non-pharmacologic interventions, including weight reduction or control (if overweight), exercise, and diet modifications. Children with secondary hypertension commonly require more intensive management, including treatment with antihypertensive medication [60].

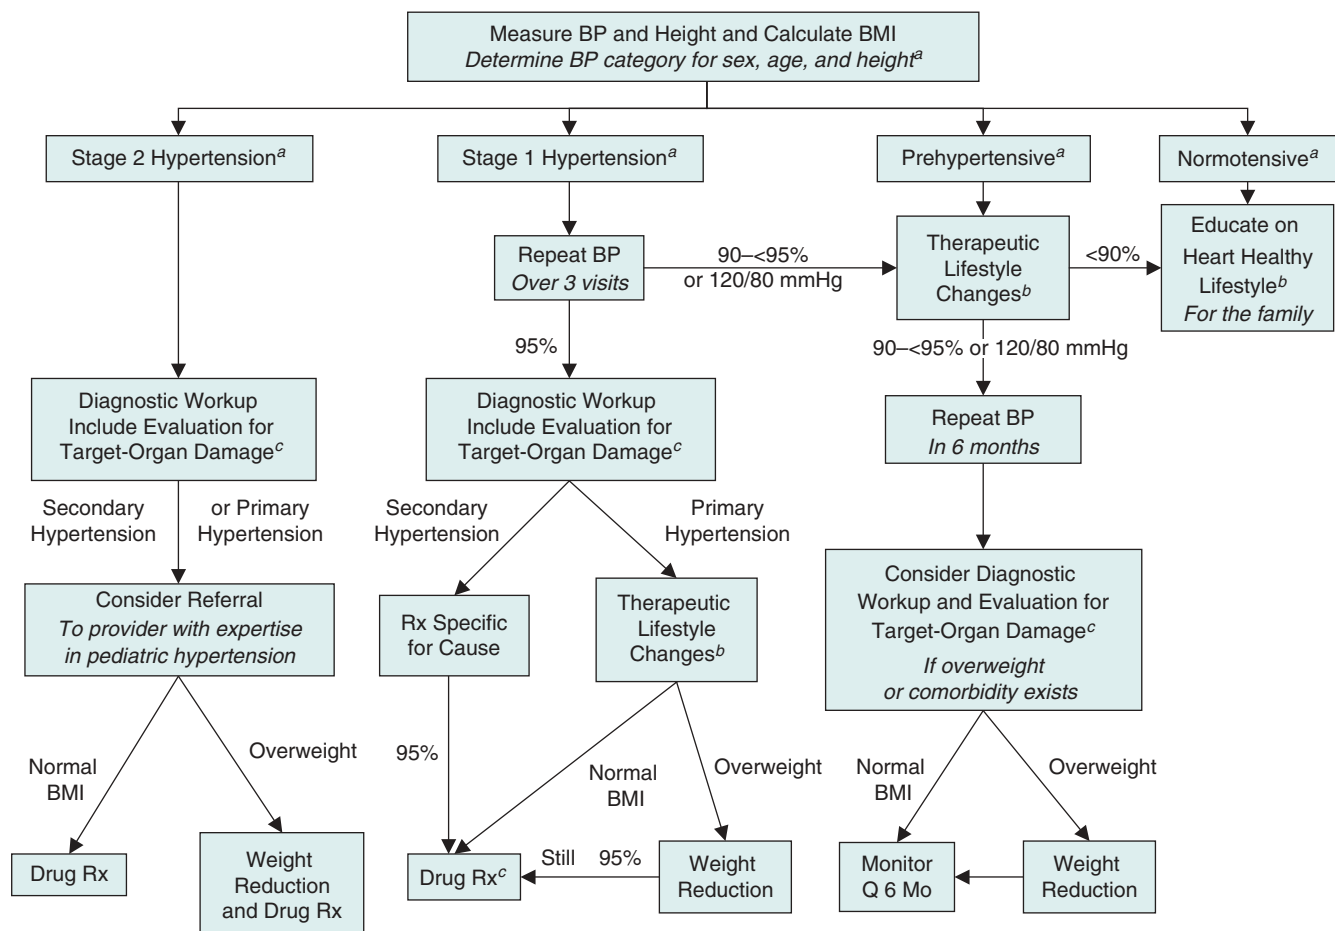
Obesity is often associated with mild hypertension in childhood and weight reduction has benefit. Exercise training lowers BP in older children and adolescents [61] but,


Figure 64.1 An algorithm is provided to guide the evaluation and management of prehypertension, Stage 1 hypertension, and Stage 2 hypertension. [a]See Tables 64.1 and 64.2 for blood pressure classification. [b]Diet modification and physical activity. [c]Children and adolescents with Stage 1 and Stage 2 hypertension should receive an echocardiogram to evaluate for target organ damage. Also consider in children with diabetes or other risk factors.

unless highly motivated, is difficult to sustain in both children and adults. Weight reduction can be extremely difficult to achieve and generally requires multiple strategies, including nutritional counseling, dietary education, emotional support, information about exercise, and family involvement. Power weight-lifting should be discouraged in hypertensive adolescents due to its potential to induce marked BP elevation. Participation in sports should be encouraged provided that BP is under reasonable control, regular monitoring of BP occurs, and a thorough examination has excluded cardiac abnormalities [22].

The guidelines for dietary modifications in the pediatric population are less clear than in adults. Information on the effects of salt on BP in children is not as definitive as in adults. A meta-analysis of 10 separate studies that investigated the effect of a change in sodium intake on BP in children found that a 54% reduction in sodium intake was associated with a 2.47 mmHg reduction in systolic BP [62,63]. Although the individual effect of lowering sodium intake on BP in children

appeared modest, the lifelong effect could be more substantial. Another effect of high dietary salt is thirst. In a study that compared sodium intake with the amount and type of beverage consumption in children, a high intake of sugary beverages was associated with high sodium intake [64]. There seems to be a subset of adolescents, particularly if obese, who demonstrate BP sensitivity to salt and also other risk factors for hypertension [65]. Because the usual dietary intake of sodium for most children and adolescents in the United States far exceeds nutrient requirements, it is reasonable to restrict sodium intake to <4 g day^{-1} by decreasing fast-food consumption and refraining from adding salt to cooked foods [1].

Current information on the effects of potassium, magnesium, and calcium intake on BP in children is even less definitive. The dietary intervention clinical trial Dietary Approaches to Stop Hypertension (DASH), conducted in adults with high BP, reported results that could be relevant to dietary management of children with high BP. In adults

Table 64.4 Antihypertensive drugs for outpatient management of hypertension in children 1–17 years old[a].

Class	Drug	Dose[b]	Dosing interval	Evidence[c]	FDA labeling[d]	Comments[e]
Angiotensin-converting enzyme (ACE) inhibitor	Benazepril	Initial: 0.2 mg kg⁻¹ day⁻¹ up to 10 mg day⁻¹ Maximum: 0.6 mg kg⁻¹ day⁻¹ up to 40 mg day⁻¹	q.d.	RCT	Yes	1. All ACE inhibitors are contraindicated in pregnancy – females of childbearing age should use reliable contraception
	Captopril	Initial: 0.3–0.5 mg kg⁻¹ per dose Maximum: 6 mg kg⁻¹ day⁻¹	t.i.d.	RCT, CS	No	2. Check serum potassium and creatinine periodically to monitor for hyperkalemia and azotemia
	Enalapril	Initial: 0.08 mg kg⁻¹ day⁻¹ up to 5 mg day⁻¹ Maximum: 0.6 mg kg⁻¹ day⁻¹ up to 40 mg day⁻¹	q.d.–b.i.d.	RCT	Yes	3. Cough and angioedema are reportedly less common with newer members of this class than with captopril
	Fosinopril	Children: >50 kg Initial: 5–10 mg day⁻¹ Maximum: 40 mg day⁻¹	q.d.	RCT	Yes	4. Benazepril, enalapril, and lisinopril labels contain information on the preparation of a suspension; captopril may also be compounded into a suspension
	Lisinopril	Initial: 0.07 mg kg⁻¹ day⁻¹ up to 5 mg day⁻¹ Maximum: 0.6 mg kg⁻¹ day⁻¹ up to 40 mg day⁻¹	q.d.	RCT	Yes	5. FDA approval for ACE inhibitors with pediatric labeling is limited to children ≥6 years of age and to children with creatinine clearance ≥30 ml min⁻¹ per 1.73 m²
	Quinapril	Initial: 5–10 mg day⁻¹ Maximum: 80 mg day⁻¹	q.d.	RCT, EO	No	
Angiotensin-receptor blocker	Irbesartan	6–12 years: 75–150 mg day⁻¹ ≥13 years: 150–300 mg day⁻¹	q.d.	CS	Yes	1. All ARBs are contraindicated in pregnancy – females of childbearing age should use reliable contraception
	Losartan	Initial: 0.7 mg kg⁻¹ day⁻¹ up to 50 mg day⁻¹ Maximum: 1.4 mg kg⁻¹ day⁻¹ up to 100 mg day⁻¹	q.d.	RCT	Yes	2. Check serum potassium, creatinine periodically to monitor for hyperkalemia and azotemia 3. Losartan label contains information on the preparation of a suspension 4. FDA approval for ARBs is limited to children ≥6 years of age and to children with creatinine clearance ≥30 ml min⁻¹ per 1.73 m²
α- and β-blocker	Labetalol	Initial: 1–3 mg kg⁻¹ day⁻¹ Maximum: 10–12 mg kg⁻¹ day⁻¹ up to 1200 mg day⁻¹	b.i.d.	CS, EO	No	1. Asthma and overt heart failure are contraindications 2. Heart rate is dose limiting 3. May impair athletic performance 4. Should not be used in insulin-dependent diabetics
β-Blocker	Atenolol	Initial: 0.5–1 mg kg⁻¹ day⁻¹ Maximum: 2 mg kg⁻¹ day⁻¹ up to 100 mg day⁻¹	q.d.–b.i.d.	CS	No	1. Non-cardioselective agents (propranolol) are contraindicated in asthma and heart failure
	Bisoprolol/HCTZ	Initial: 2.5/6.25 mg day⁻¹ Maximum: 10/6.25 mg day⁻¹	q.d.	RCT	No	2. Heart rate is dose limiting 3. May impair athletic performance
	Metoprolol	Initial: 1–2 mg kg⁻¹ day⁻¹ Maximum: 6 mg kg⁻¹ day⁻¹ up to 200 mg day⁻¹	b.i.d.	CS	No	4. Should not be used in insulin-dependent diabetics
	Propranolol	Initial: 1–2 mg kg⁻¹ day⁻¹ Maximum: 4 mg kg⁻¹ day⁻¹ up to 640 mg day⁻¹	b.i.d.–t.i.d.	RCT, EO	Yes	5. A sustained-release formulation of propranolol is available that is dosed once daily
Calcium channel blocker	Amlodipine	Children: 6–17 years 2.5–5 mg q.d.	q.d.	RCT	Yes	1. Amlodipine and isradipine can be compounded into stable extemporaneous suspensions
	Felodipine	Initial: 2.5 mg day⁻¹ Maximum: 10 mg day⁻¹	q.d.	RCT, EO	No	2. Felodipine and extended-release nifedipine tablets must be swallowed whole
	Isradipine	Initial: 0.15–0.2 mg kg⁻¹ day⁻¹ Maximum: 0.8 mg kg⁻¹ day⁻¹ up to 20 mg day⁻¹	t.i.d.–q.i.d.	CS, EO	No	3. Isradipine is available in both immediate-release and sustained-release formulations; the sustained release form is dosed q.d. or b.i.d.
	Extended-release nifedipine	Initial: 0.25–0.5 mg kg⁻¹ day⁻¹ Maximum: 3 mg kg⁻¹ day⁻¹ up to 120 mg day⁻¹	q.d.–b.i.d.	CS, EO	No	4. May cause tachycardia

Class	Drug	Dose	Frequency	Evidence[c]	FDA-approved pediatric labeling[d]	Comments[e]
Central α-agonist	Clonidine	Children: ≥12 years Initial: 0.2 mg day^{-1} Maximum: 2.4 mg day^{-1}	b.i.d.	EO	Yes	1. May cause dry mouth and/or sedation 2. Transdermal preparation also available 3. Sudden cessation of therapy can lead to severe rebound hypertension
Diuretic	HCTZ	Initial: 1 mg kg^{-1} day^{-1} Maximum: 3 mg kg^{-1} day^{-1} up to 50 mg day^{-1}	q.d.	EO	Yes	1. All patients treated with diuretics should have electrolytes monitored shortly after initiating therapy and periodically thereafter 2. Useful as add-on therapy in patients being treated with drugs from other drug classes 3. Potassium-sparing diuretics (spironolactone, triamterene, amiloride) may cause severe hyperkalemia, especially if given with ACE inhibitors or ARBs. 4. Furosemide is labeled only for treatment of edema but may be useful as add-on therapy in children with resistant hypertension, particularly in children with renal disease. 5. Chlorthalidone may precipitate azotemia in patients with renal diseases and should be used with caution in those with severe renal impairment
	Chlorthalidone	Initial: 0.3 mg kg^{-1} day^{-1} Maximum: 2 mg kg^{-1} day^{-1} up to 50 mg day^{-1}	q.d.	EO	No	
	Furosemide	Initial: 0.5–2.0 mg kg^{-1} per dose Maximum: 6 mg kg^{-1} day^{-1}	q.d.–b.i.d.	EO	No	
	Spironolactone	Initial: 1 mg kg^{-1} day^{-1} Maximum: 3.3 mg kg^{-1} day^{-1} up to 100 mg day^{-1}	q.d.–b.i.d.	EO	No	
	Triamterene	Initial: 1–2 mg kg^{-1} day^{-1} Maximum: 3–4 mg kg^{-1} day^{-1} up to 300 mg day^{-1}	b.i.d.	EO	No	
	Amiloride	Initial: 0.4–0.625 mg kg^{-1} day^{-1} Maximum: 20 mg day^{-1}	q.d.	EO	No	
Peripheral α-antagonist	Doxazosin	Initial: 1 mg day^{-1} Maximum: 4 mg day^{-1}	q.d.	EO	No	May cause hypotension and syncope, especially after first dose
	Prazosin	Initial: 0.05–0.1 mg kg^{-1} day^{-1} Maximum: 0.5 mg kg^{-1} day^{-1}	t.i.d.	EO	No	
	Terazosin	Initial: 1 mg day^{-1} Maximum: 20 mg day^{-1}	q.d.	EO	No	
Vasodilator	Hydralazine	Initial: 0.75 mg kg^{-1} day^{-1} Maximum: 7.5 mg kg^{-1} day^{-1} up to 200 mg day^{-1}	q.i.d.	EO	Yes	1. Tachycardia and fluid retention are common side effects 2. Hydralazine can cause a lupus-like syndrome in slow acetylators 3. Prolonged use of minoxidil can cause hypertrichosis 4. Minoxidil is usually reserved for patients with hypertension resistant to multiple drugs
	Minoxidil	Children: <12 years Initial: 0.2 mg kg^{-1} day^{-1} Maximum: 50 mg day^{-1} Children: ≥12 years Initial: 5 mg day^{-1} Maximum: 100 mg day^{-1}	q.d.–t.i.d.	CS, EO	Yes	

ACE, angiotensin-converting enzyme; ARB, angiotensin-receptor blocker; HCTZ, hydrochlorothiazide; q.d., once daily; b.i.d., twice daily; t.i.d., three times daily; q.i.d., four times daily.

[a]Includes drugs with prior pediatric experience or recently completed clinical trials.

[b]The maximum recommended adult dose should not be exceeded in routine clinical practice.

[c]Level of evidence upon which dosing recommendations are based (CS, case series; EO, expert opinion; RCT, randomized controlled trial).

[d]FDA-approved pediatric labeling information is available. Recommended doses for agents with FDA-approved pediatric labels are the doses contained in the approved labels. Even when pediatric labeling information is not available, the FDA-approved label should be consulted for additional safety information.

[e]Comments apply to all members of each drug class except where stated otherwise.

Table 64.5 Antihypertensive drugs for management of severe hypertension in children 1–17 years old.

Drug	Class	Dose[a]	Route	Comments
Most useful[b]				
Esmolol	β-Blocker	100–500 µg kg⁻¹ min⁻¹	i.v. infusion	Very short-acting – constant infusion preferred. May cause profound bradycardia. Produced modest reductions in BP in a pediatric clinical trial
Hydralazine	Vasodilator	0.2–0.6 mg kg⁻¹ per dose	i.v., i.m.	Should be given every 4 h when given i.v. bolus. Recommended dose is lower than FDA label
Labetalol	α- and β-blocker	Bolus: 0.2–1.0 mg kg⁻¹ per dose up to 40 mg per dose Infusion: 0.25–3.0 mg kg⁻¹ h⁻¹	i.v. bolus or infusion	Asthma and overt heart failure are relative contraindications
Nicardipine	Calcium channel blocker	1–3 µg kg⁻¹ min⁻¹	i.v. infusion	May cause reflex tachycardia
Sodium nitroprusside	Vasodilator	0.53–10 µg kg⁻¹ min⁻¹	i.v. infusion	Monitor cyanide levels with prolonged (>72 h) use or in renal failure; or co-administer with sodium thiosulfate
Occasionally useful[c]				
Clonidine	Central α-agonist	0.05–0.1 mg per dose, may be repeated up to 0.8 mg total dose	p.o.	Side effects include dry mouth and sedation
Enalaprilat	ACE inhibitor	0.05–0.1 mg kg⁻¹ per dose up to 1.25 mg per dose	i.v. bolus	May cause prolonged hypotension and acute renal failure, especially in neonates
Fenoldopam	Dopamine receptor agonist	0.2–0.8 µg kg⁻¹ min⁻¹	i.v. infusion	Produced modest reductions in BP in a pediatric clinical trial in patients aged up to 12 years
Isradipine	Calcium channel blocker	0.05–0.1 mg kg⁻¹ per dose	p.o.	Stable suspension can be compounded
Minoxidil	Vasodilator	0.1–0.2 mg kg⁻¹ per dose	p.o.	Most potent oral vasodilator; long-acting

ACE, angiotensin-converting enzyme; i.m., intramuscular; i.v., intravenous; p.o., oral.

[a]All dosing recommendations are based upon expert opinion or case series data except where noted otherwise.

[b]Useful for hypertensive emergencies and some hypertensive urgencies.

[c]Useful for hypertensive urgencies and some hypertensive emergencies.

with mild BP elevation (<160 mmHg systolic, 80–95 mmHg diastolic), a significant reduction in both systolic and diastolic BP occurred in subjects consuming a diet high in fruits, vegetables, and low-fat dairy products, compared with the subjects consuming the usual diet [66]. These results indicate a benefit for BP from diets that are high in multiple nutrients, including potassium, calcium, magnesium, and other vitamins. A similar approach may benefit children. A small study by Couch *et al.* [67] compared a DASH diet for children with standard nutrition counseling in 57 children with hypertension and prehypertension. A greater reduction in systolic BP occurred in the children assigned to the DASH diet compared with standard diet counseling. The results support recommendations for children that encourage optimal intakes of fruits, vegetables, fiber, and dairy products, with reductions in processed foods.

Pharmacologic therapy is indicated if non-pharmacologic approaches are unsuccessful, or when a child is symptomatic, has severe hypertension, or target organ damage. Children with diabetes mellitus or chronic kidney disease may benefit from additional renal protection with BP reduction.

For these children, it is reasonable to use pharmacologic therapy to lower BP to a level <90th percentile for age, sex, and height.

Most medications used for hypertension in adults can be used for children. Efficacy and long-term safety data are limited in children. The choice of antihypertensive medication should be individualized and depends upon the child's age, the etiology of the hypertension, the degree of BP elevation, adverse effects, and concomitant medical conditions. In most patients, therapy is begun with a single agent. The dose is titrated upwards slowly until the BP is controlled. usually defined as maintaining systolic and diastolic pressure <90th percentile. If BP control cannot be achieved using the maximum dose of a single agent, a second medication can be added or, alternatively, another agent from a different class selected. The more commonly used medications for chronic antihypertensive therapy in children are listed in Table 64.4 and those for use in acute, hypertensive emergencies in Table 64.5 [1].These tables can be accessed at www.nhlbi.nih.gov/guidelines/hypertension/child_tbl.htm. The dosing recommendations for children have been based mainly upon

practitioners' experience, not on large, multicenter trials. Some clinical trial work has been conducted on the medications that are already approved and prescribed for hypertension in adults. The results of these clinical trials, although still limited, provide some information on efficacy, safety, and dosing to guide pharmacologic therapy in children.

Beta-adrenergic blockers, such as propranolol, metoprolol, and atenolol, are good choices in some nonasthmatic children, but may not be well tolerated by athletes in whom exercise capacity could decrease. More frequently, first-line medications are either angiotensin-converting enzyme (ACE) inhibitors or calcium antagonists. ACE inhibitors rarely cause side effects (e.g., cough, rash, neutropenia) in children, are usually well tolerated, and many formulations have the advantage of once-a-day dosing. Not only are they effective in controlling BP, but they may also have beneficial effects on renal function, peripheral vasculature, and cardiac function. Importantly, children with diabetes and those with chronic kidney disease may be at special risk for progressive renal deterioration and may benefit from ACE inhibitors [68]. Because of their vasodilator effects on the efferent arteriole, ACE inhibitors can severely reduce glomerular filtration and should therefore be used with caution in patients with renal artery stenosis, a solitary kidney, or a transplanted kidney [69]. ACE inhibitors are contraindicated during pregnancy because of possible teratogenic effects upon the lungs, kidneys, and brain of the fetus [70], and so should be used with special caution in adolescent females who are or may become sexually active. Angiotensin receptor blockers (ARBs) also interact with the renin–angiotensin system and have benefits similar to ACE inhibitors. Experience is being developed in treating children with these agents.

Several calcium antagonists (or calcium channel blockers, CCBs) are being used in children. In children, CCBs can be either an initial therapy or the second or third medication when more than one drug is needed to control BP. As with most oral antihypertensive preparations, the appropriate dose for small children is often lower than the strength of available tablets. This makes determining the initial dose determinations challenging. When CCBs are needed for BP control in chronic hypertension, long-acting preparations are preferred, provided that the correct dosage preparation can be used.

Diuretics are generally recommended as initial drug therapy for uncomplicated hypertension in adults, based on a vast amount of clinical trial data. No such information is available to guide recommendations for the pharmacologic management of hypertension in children and adolescents. Unless there is clinical evidence of fluid retention in a hypertensive child, such as may occur when the elevated BP is related to chronic steroid use, diuretics are usually not preferred as the first step in drug treatment. Some hypertensive children, however, may achieve adequate BP control with a thiazide diuretic alone. Children receiving thiazide

diuretics may develop hypokalemia and require potassium supplements, which, for children, is extremely unpleasant and can lead to problems with adherence to the regimen. Although not favored as an initial drug to treat hypertension in children, low-dose diuretics can be very useful as a second or third drug in those children who require multiple drugs to achieve BP control.

65 Cardiovascular Risk Factors: Obesity, Diabetes, and Lipids

William A. Neal, Collin John & Alia Rai

Robert C. Byrd Health Science Center, West Virginia University School of Medicine, Morgantown, WV, USA

Hyperlipidemia in children and adolescents remains a significant risk factor for cardiovascular disease (CVD) later in life, yet <2% of children have evidence of severe genetic dyslipidemia associated with premature coronary artery or cerebrovascular disease. These typically autosomal dominant familial hyperlipidemias are not preventable and may result in death in early to mid-adulthood if not diagnosed and treated appropriately. In this chapter, we briefly review the pathophysiology of the various lipid disorders, and discuss screening and individualized treatment guidelines applicable to children and adolescents.

It is the worldwide obesity epidemic, however, which confers the greatest risk to public health. Obesity was identified as a major risk factor for cardiovascular disease by the American Heart Association in 1998 [1]. The projection that one in four children alive today may develop type 2 diabetes secondary to chronic obesity is alarming [2]. In contrast to genetic dyslipidemia, obesity is preventable and must be addressed by a broad-based population approach involving all sectors of society. Although around one billion people are affected by malnutrition worldwide, and perhaps 1.5 million children die annually from severe undernutrition, many others are at risk because of qualitatively poor but energy-rich diets. The decrease in physical activity in many parts of the world further contributes to the obesity epidemic.

Healthcare providers have traditionally had a minimal impact on preventing and treating youth obesity. There are many reasons for this, but the unsustainable cost of disability related to obesity, £2 billion per year in the United Kingdom alone, calls for much greater emphasis on prevention as a major component of medical practice [3].

Epidemiology of childhood obesity

According to the National Health and Nutrition Examination Survey (NHANES) in 2007–2008, currently 16.9% of children and adolescents aged 2–19 years are obese, defined as a body mass index (BMI) >95th percentile for age and gender [4]. That obesity has reached epidemic proportions is evident by its marked increase in prevalence over the past several decades. Since 1976–1980, obesity has doubled from 5 to 10% among preschool children, tripled from 6.5 to 19.6% in children 6–11 years old, and increased nearly fourfold among adolescents, from 5 to 18.1% [4].

The rate of obesity in the United States varies significantly among regions. The prevalence is greatest in the southeastern United States, especially in rural Appalachia. The Coronary Artery Risk Detection in Appalachian Communities (CARDIAC) Project has documented an obesity rate of 17.7% among kindergarten students, 22.2% among 2nd graders, and 28.4% among 5th graders. Cultural attitudes, low population density, and poverty each contribute in disparate ways to obesity in this mostly white population [5].

Some racial/ethnic groups are affected more than others both in the United States and throughout the world. NHANES data from 2003–2004 showed a 24% prevalence of obesity among black girls and 22% among Mexican American boys [6]. Selected Pacific Islanders, such as Samoans, have obesity rates approaching 75% [7]. Childhood overweight and obesity in India rose from 16% in 2002 to 24% in 2006, and it is postulated that East Asians are more susceptible to the metabolic syndrome and diabetes than US Caucasians [8].

The recently established European Childhood Obesity Surveillance Initiative reports that 24% of 6–9-year-olds are overweight (>85th –94.9th percentile) or obese [9].

Weight status in China has increased significantly as a result of urbanization and globalization. Whereas only 5% of people living in the countryside are obese, in some cities the prevalence exceeds 20%. Access to fast-food restaurants and processed foods readily available in cities is considered a major contributing factor [10].

Genetic and prenatal determinants of body composition

The Barker hypothesis states that the greatest threat to adult health is a child of low birth weight who remains small during infancy, then rapidly gains weight thereafter [11]. The proposed mechanism, referred to as the "thrifty phenotype," is that less than optimal exposure to nutrients during intrauterine life causes the fetus to set its metabolic "thermostat" adversely so it is ill suited for the nutritional prosperity of postnatal life; this leads to excessive fat production rather than lean muscle mass [12]. In contrast to intrauterine nutritional deprivation, excessive maternal weight gain during pregnancy leads to large babies and higher BMI during adolescence and adulthood [13].

Barker's *early origins hypothesis* has evoked considerable controversy among epidemiologists. Critics argue that his theory detracts from the importance of behavioral issues as risk factors for premature heart disease. However, there is little doubt that genetic factors play an etiologic role in obesity [14]. Genes affecting leptin receptors have been identified in mouse models, and a number of candidate genes in humans have been associated with body fat and its distribution. The effect of nutrition on gene expression, epigenetics, is only now emerging as a mechanism by which our children and grandchildren's body composition is determined.

Smoking among pregnant women is increasing in developing countries and is associated with obesity among their offspring, presenting an opportunity for public health intervention [15].

Effect of obesity on cardiovascular disease

The strong relationship between obesity and hypertension is well established [16]. Long-standing hypertension may lead to renal failure and chronic congestive heart failure. Sympathetic nervous system activation secondary to obesity affects renal structure and function that in turn increase sodium adsorption and adversely affect renin–angiotensin regulation.

Childhood obesity confers a selective effect on lipoprotein and insulin metabolism. Its impact on low-density lipoprotein (LDL) cholesterol is modest whereas there is a strong inverse relationship with high-density lipoprotein (HDL) cholesterol levels. Compared with children of normal weight, obesity confers a twofold likelihood of increase in LDL cholesterol levels but a sevenfold likelihood of low HDL cholesterol levels. In obese individuals, low HDL cholesterol is often accompanied by elevated triglycerides and serum insulin. The constellation of obesity, hypertension, dyslipoproteinemia, hypercoaguability, and elevated insulin is characteristic of the metabolic syndrome, or *insulin resistance syndrome*. Whether insulin resistance is an independent risk factor for accelerated atherosclerosis is unknown, but its relationship to type 2 diabetes is established. The rise in childhood obesity has resulted in a concurrent rise in type 2 diabetes [17].

Approximately one-third of obese children and half of morbidly obese children are at great risk of developing type 2 diabetes. Body fat distribution is related to insulin resistance in that visceral fat is a greater metabolic determinant than skeletal fat [18].

Prevention, assessment, and treatment of childhood overweight and obesity

Body mass index (BMI), the ratio of weight in kilograms to the square of height in meters, is the most practical means of describing gender- and age-specific weight status. Obesity is defined as BMI >95th percentile, and overweight is defined as BMI between the 85th and 94.9th percentiles. BMI <5th percentile is considered "underweight" and BMI >99th percentile defines "morbid obesity." Because BMI normative values are unavailable for children <2 years of age, a weight for height value >95th percentile is used to categorize overweight in this age group (see addendum).

BMI levels correlate with body fat [19] and cardiovascular risk [20]. Because BMI percentiles are continuous, any given cut point is imperfect in distinguishing absolute risk. Muscular athletes, for example, often fall within the obese category because of tissue-dense lean muscle mass. More precise measures of body composition, such as dual-energy X-ray absorption (DEXA), are used in selected research studies. Waist circumference in children correlates with visceral adiposity and is a clinically useful adjunct to BMI as it is more likely reflects modest weight changes and lifestyle modification.

The Expert Committee Regarding the Prevention, Assessment, and Treatment of Child and Adolescent Overweight and Obesity recommends that clinicians avoid harsh use of the term "obese" during provider–patient encounters so as to minimize embarrassment or an inference of judgment. "Overweight" and "obese," however, are appropriately used in documentation of weight status and risk assessment in the patient's health record [21].

Figure 65.1 details recommended steps to prevent and treat overweight and obesity developed by the Expert

Panel [21]. BMI should be calculated at every well child visit. Assessment includes medical risk, including growth, child and family history, parental obesity, and laboratory evaluation (glucose, insulin, hemoglobin A1-C, CRP, and fasting lipid profile) when BMI >95th percentile.

Behavior risk includes assessment of energy balance determined by quality of diet and the relative amounts of sedentary and physical activity. Family and patient concern about weight status and attendant risk, and also motivation to change, is of paramount importance. Effective behaviors for change include (1) limiting consumption of sweetened beverages; (2) limiting daily television and screen time to <2 h per day; (3) daily breakfast; (4) limited patronage of fast-food restaurants; (5) eating family meals together; and (6) food portion control. The child should undertake 60 min of moderate to vigorous physical activity daily [22]. Because smoking is a known cause of atherosclerosis (and also many other disorders), preventing smoking is an important part of treatment.

The technique of *motivational interviewing* includes reflective listening in a non-judgmental manner to elicit patient and parental concern and readiness to change [23]. Providing an opportunity for child–parent decisions about the actions for lifestyle changes is likely to be rewarding.

The chronic care model

Preventing childhood overweight and obesity requires a population approach. It is ideally suited to the theoretical and conceptual concepts of the *chronic care model* [24]. This model conceptualizes prevention and treatment in the context of health systems, including delivery system design, decision support, and clinical information systems; with self-management and support of the community. It connects a well-prepared practice team (the *medical home*) with an informed participatory patient. The application of this clinical model to preventing and treating obesity, regardless of the age of the patient, represents an ecological framework recommended by the Institute of Medicine [25]. It incorporates assets within the local community, such as dietetic, behavioral, and physical activity support, into the treatment paradigm. It relies on public policy to enhance the built environment, foster coordinated school wellness, conduct social marketing, and optimize public transportation.

Publicly available guides for practitioners and patients alike, such as the *We Can* program, are effective in promoting healthy weight management [26]. Quality improvement initiatives

implemented in school-based health centers have likewise improved the treatment of pediatric overweight [27].

Diabetes mellitus

Diabetes mellitus (DM) has long been recognized as a major risk factor for the development of coronary artery disease. The two major subgroups of DM are characterized by the ability to synthesize insulin. Type I DM is characterized by an absolute inability to synthesize insulin whereas Type II DM is characterized by insulin resistance. Although they result from contrasting mechanisms, both lead to elevated blood glucose, which in turn accelerates the development of various disorders, including coronary artery disease.

Type II diabetes mellitus

Type II DM is characterized by hyperglycemia resulting from a relative insulin resistance. Because insulin is produced, type II DM is referred to as non-insulin-dependent diabetes mellitus (NIDDM). Compared with type I DM, type II DM is a much greater public health problem because it is associated with obesity. This association theoretically gives a basis for prevention. Although typically thought of as adult onset DM, this term is antiquated and grossly inaccurate. As the worldwide pediatric obesity epidemic escalates, so does the incidence of type II DM among older children. Given the sporadic nature of screening children for type II DM worldwide, the true incidence and prevalence of type II DM Is difficult to estimate. In the United States, a retrospective study showed that the incidence of type II DM in children aged 10–19 years increased from 0.7/100 000 in 1982 to 7.2/100 000 in 1994 [28]. Similar trends have been found in studies in Japan, Argentina, and Thailand [29–31]. The prevalence of type II DM in the United States is estimated to be 18/100 000 individuals among non-Hispanic white youth 10–19 years old, with rates of 106/100 000 and 145/100 000 individuals in African-American and Navajo youth, respectively [32–34].

The diagnosis of type II DM can be made when a child meets one of the following four criteria [35]:
- a hemoglobin A1C >6.5%
- a fasting plasma glucose >126 mg dl^{-1}
- a 2 h plasma glucose >200 mg dl^{-1} following an oral glucose tolerance test
- a random plasma glucose >200 mg dl^{-1} in a child exhibiting classic signs and symptoms of hyperglycemia.

The American Diabetes Association also has developed criteria for individuals at risk for developing type II DM. These individuals are often referred to as having "impaired glucose tolerance" or "borderline diabetes." The criteria are:
- a fasting plasma glucose 100–125 mg dl^{-1}
- a 2 h plasma glucose 140–199 mg dl^{-1} following an oral glucose tolerance test
- a hemoglobin A1C 5.7–6.4%.

Treatment of type II DM focuses on lifestyle modification, with emphasis on healthy weight loss and monitoring of carbohydrate intake. In children, metformin is the only agent shown in a treatment study to reduce fasting plasma glucose levels compared with placebo without significant side effects [36]. Furthermore, in a recent study of obese adolescents with fasting hyperinsulinemia who did not meet criteria for type II DM, the addition of metformin to lifestyle modifications helped lower insulin levels and BMI, which could potentially prevent progression to type II DM [37].

Complications in type II DM are generally divided into two groups, microvascular and macrovascular. Microvascular complications occur in smaller arteries and the most commonly affected organs are the eyes, kidneys, and peripheral nerves. Macrovascular complications occur in larger arteries, notably the coronary arteries and peripheral arteries. In fact, the link between adult coronary artery disease and type II DM is so well established that both the American Diabetes Association and American Heart Association classify type II DM as a "coronary heart disease risk equivalent."

Type I diabetes mellitus

Type I DM (IDDM) is characterized by a lack of insulin production. It is commonly called childhood-onset or juvenile diabetes because the typical age of onset is childhood. There are various hypotheses about the etiology of this disease, including autoimmune, viral infection, and dietary. The incidence of type I DM in the United States is ~23.6/100 000 annually and the prevalence is about 200/100 000 [32]. The incidence of type I DM continues to increase worldwide for unknown reasons. In type I DM, treatment is focused on replacing insulin exogenously, with varying regimens and preparations of insulin available. Complications from type I DM are identical with those from type II DM.

Metabolic syndrome

"Metabolic syndrome," also termed "syndrome X" or "the deadly quartet," refers to adults with a constellation of specific cardiovascular disease risk factors. The World Health Organization first published criteria for this syndrome in 1998 [38], and subsequently other health organizations [39] have developed their own criteria to "diagnose" this condition. Although the criteria vary by the defining organization, the major unifying theme is that this syndrome is well recognized and established within the adult population. The major components include hypertension, central obesity, elevated fasting glucose, elevated triglycerides, and reduced HDL cholesterol.

There is no official definition of the metabolic syndrome in children and adolescents, despite the increasing prevalence of the specific components within this population. The use of a single set of cut points throughout all ages of childhood,

despite changing physiology, the lack of an accepted normal range for insulin across childhood, and the physiological insulin resistance in puberty, are just a few of the problems making it difficult to define metabolic syndrome in the pediatric population. The American Heart Association recently published a scientific statement about the metabolic syndrome in children [39].

Hyperlipidemia in children and adolescents

As demonstrated in the Bogalusa Heart Study and the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) Study [40,41], the pathological changes of atherosclerosis begin in childhood, although clinical manifestations do not appear until middle age. In the Bogalusa study, autopsy findings on young people registered in the study showed early atherosclerotic lesions in the aorta and the coronary arteries that correlated with elevated LDL cholesterol, elevated blood pressure, and obesity, and were inversely related to HDL cholesterol levels [40].

The PDAY study also showed atherosclerotic changes in teenagers, and that the progression of the atherosclerotic changes can be delayed by reducing risk factors through lifestyle changes and medication [41]. Ideally, interventions should occur before clinical manifestations of CVD develop, hence the need to intervene in childhood.

Many years will be needed to establish scientifically a decreased CVD mortality in adults from risk factor modification in children. However, pathologic change in young people coupled with the evidence that modifying risk factors improves the atherosclerotic lesions persuades us that every effort should be made to identify and treat children at risk. Familial aggregation of premature CVD, generally defined as atherosclerotic disease before 55 years of age, suggests the likelihood of an abnormality of lipoprotein metabolism.

Lipoprotein metabolism

Because they are insoluble in water, lipids are transported by lipoprotein. Lipoprotein consists of a core of triglycerides and cholesteryl esters surrounded by phospholipids, cholesterol, and proteins, called apoproteins, which have multiple metabolic functions. The density of lipoproteins is inversely proportional to the ratio of lipid to protein. The lipoproteins found in serum include:
- low-density lipoprotein (LDL)
- high-density lipoprotein (HDL)
- very-low-density lipoprotein (VLDL)
- intermediate-density lipoprotein (IDL)
- chylomicrons.

Lipoproteins effect transport of fat either absorbed from the diet (exogenous pathway) or synthesized by the liver and adipose tissue (endogenous pathway). HDL metabolism is responsible for transport of excess cholesterol from peripheral tissues back to the liver for excretion as bile acids, a process called "reverse cholesterol transport."

Nongenetic, secondary causes of lipoprotein abnormality include endocrine disorders such as hypothyroidism and diabetes, nephrotic syndrome, obesity, alcoholism, and selected medications, such as thiazides, anabolic steroids, and beta-blockers.

Genetic dyslipidemias are categorized according to aberrations in specific lipoproteins: hypercholesterolemia, hypercholesterolemia with hypertriglyceridemia, hypertriglyceridemias, and disorders of HDL metabolism. Rare disorders of cholesterol metabolism are not discussed in this chapter [42].

Hypercholesterolemias

Polygenic
The most common cause of hypercholesterolemia is referred to as "polygenic" which affects about one in 30 individuals. It represents the interaction of multiple genes and environmental influences, such as a high-fat diet and sedentary activity. Elevation in LDL cholesterol is modest and generally controllable by adopting a healthy lifestyle.

Familial hypercholesterolemias (FH)
These monogenic autosomal co-dominant disorders are characterized by LDL receptor defects that lead to abnormal LDL uptake and metabolism. Nearly 800 mutations have been described, with patterns varying according to ethnic and racial groups. Severe mutations are associated with failure of synthesis of LDL receptors, whereas in others receptors are present but defective.

The homozygous form is rare, with a prevalence of 1/1 000 000. In affected individuals, the LDL cholesterol level ranges between 450 and 850 mg dl^{-1} and may exceed 1000 mg dl^{-1}. Multiple tendon and cutaneous xanthomas can be seen from a young age, and corneal arcus is also present. Atherosclerotic changes in the aortic root and the coronary arteries develop early, and can result in CVD by age 10 years. These individuals rarely survive to adulthood. Their response to cholesterol-lowering medication is not optimal. Hence LDL apheresis and liver transplantation have been used as therapeutic options.

Of greater importance is the heterozygous form of FH, with a prevalence of 1/500 worldwide, that can be treated effectively with cholesterol-lowering medications. Selected populations, such as Afrikaners, a group of French Canadians, and some Lebanese Christians, have been identified with "founder effect" mutations that result in frequencies >1/250.

The phenotypic expression of the disease is influenced modestly by environmental factors. CVD typically manifests between the ages of 30 and 50 years. Premenopausal women usually present later than men because of the protective effect of circulating estrogen.

A strong family history of premature heart disease affecting a parent, grandparent, and other first- and second-degree family members, in association with LDL cholesterol levels exceeding 190 mg dl^{-1}, should alert one to the probability of phenotypic expression of heterozygous FH. Genetic studies may confirm the diagnosis but are generally not performed clinically. When FH is suspected, other family members should be screened so that primary prevention can begin in those affected. As an autosomal dominant condition with nearly full penetrance, 50% of first-degree relatives and 25% of second-degree relatives would be expected to have the disease.

Familial defective ApoB-100 (FDB)

This autosomal dominant condition results in inefficient binding of LDL by the LDL receptor. Phenotypically, individuals resemble those with heterozygous FH. The prevalence is 1/700. Specialized laboratory testing can distinguish FDB from FH, but as treatment is identical, this is unnecessary.

Hypercholesterolemia with hypertriglyceridemia

Familial combined hyperlipidemia (FCH)

This autosomal dominant defect causes moderate elevation in both LDL cholesterol and triglycerides. Serum HDL may be decreased. The prevalence is ~1/150, and it is found in 10% of survivors of premature coronary artery disease. Premature atherosclerosis is not as prevalent in FCH as with FH. Typically, the LDL level is not as elevated as in heterozygous FH. Xanthomas are not present. Elevated apoB levels and increased small, dense LDL particles support the diagnosis.

Not infrequently, children and adults who fulfill criteria for a diagnosis of FCH also have visceral adiposity, hypertension, and hyperinsulinemia suggestive of the metabolic syndrome. Although criteria for the diagnosis of metabolic syndrome in children have not been developed, this constellation of findings indicates risk for type II DM.

Hypertriglyceridemias

Familial hypertriglyceridemia (FHTG)

This autosomal dominant condition is also called type IV hyperlipidemia according to the Frederickson classification system. It occurs in 1/500 of the population. It is caused by the production of abnormal VLDL due to a deficiency of lipoprotein lipase or apoprotein C-II. The triglyceride levels typically range from 200 to 1000 mg dl^{-1}, associated with a

Table 65.1 AHA recommended cut-off points for serum cholesterol levels in children aged 2–19 years.

Serum cholesterol	Acceptable	Borderline	High
Total cholesterol (mg dl^{-1})	<170	170–199	>200
LDL cholesterol (mg dl^{-1})	<110	110–129	>130

normal LDL and possibly low HDL. Although not highly associated with premature coronary vascular disease, it can result in pancreatitis. It generally does not become manifest until adulthood. To make the diagnosis, at least one other family member should have hypertriglyceridemia.

Disorders of HDL cholesterol

Primary hypoalphalipoproteinemia

Isolated low HDL may follow an autosomal dominant pattern, although often the family history is negative. HDL cholesterol levels are <10th percentile for gender and age. It is caused by increased catabolism of HDL and often a reduction in apoA-1 synthesis. The degree to which it may contribute to atherosclerosis is uncertain.

Hyperalphalipoproteinemia

This interesting but unusual condition is characterized by HDL levels >80 mg dl^{-1}. It appears to have a cardioprotective effect.

Lipoprotein patterns in children and adolescents

The AHA recommends the use of cut-off points for serum cholesterol levels in children between 2 and 19 years of age as shown in Table 65.1.

HDL cholesterol levels <40 mg dl^{-1} are a risk factor for heart disease. Triglyceride levels >150 mg dl^{-1} are abnormal and probably contribute to the development of atheromatous plaques, although not to the same extent as elevated LDL cholesterol.

Although the total cholesterol slowly rises until puberty, it transiently falls at that point from lowering of the HDL in males and of the LDL in females.

Screening and treatment for dyslipidemias

In 2008, the American Academy of Pediatrics (AAP) published recommendations for cholesterol screening and treatment in childhood [43]. They recommend a targeted

approach similar to that originally proposed by the National Cholesterol Education Program [44]. The recommendations are to screen selectively the following children:

1 children with a family history of dyslipidemia or premature coronary artery disease (which is defined as <55 years in men and 65 years in women)

2 children with an unknown family history, especially those with other risk factors such as obesity, hypertension, DM, or smoking.

Screening should occur between 2 and 10 years of age.

There is some rationale for universal blood cholesterol screening, especially in regions where the prevalence of heart disease and diabetes is well above average. A recent study of over 20 000 5th grade children who participated in a school-based blood cholesterol screening program found that one-third of the children who qualified for consideration of pharmacologic intervention (LDL >160 mg dl^{-1} plus other risk factors) would have been missed had selective screening criteria based on a positive family history been used [45].

Treatment guidelines

The AAP recommends a "two-pronged approach," which consists of a population focus and an individualized approach [43]. The population approach refers to the general recommendations for a healthy lifestyle appropriate for all children. The individualized approach targets children identified as being at increased risk for CVD because of a genetic dyslipidemia, obesity, hypertension, or DM.

Dietary modifications

Elevated LDL cholesterol is controlled best by a diet low in saturated fat and cholesterol. The AAP guidelines recommend that saturated fat should supply no more than 7% of the total caloric intake, and that no more than 200 mg of cholesterol should be consumed per day. Lifestyle modification alone is unlikely to lower blood cholesterol levels sufficiently to a safe range in children with severe genetic dyslipidemias.

An important dietary approach for both primary and secondary prevention of CVD considers the *type* of fats consumed. A diet with increased mono- and polyunsaturated fats and limited carbohydrate intake can decrease LDL and modestly increase HDL cholesterol.

Elevated triglycerides are controlled best by a diet with restricted carbohydrate and sugar intake.

Other nonpharmacologic approaches

Increased soluble fiber intake lowers LDL cholesterol levels. The AAP recommends a supplemental fiber dose of the child's age in years + 5 g per day, up to a maximum of 20 g [43].

Increased intake of plant sterols and stanols can decrease LDL cholesterol slightly, and may be found in some yogurt drinks and spreads.

Increased physical activity increases HDL and reduces LDL cholesterol and triglycerides. The AAP "5–2–1–0" plan recommends five fruits and vegetables daily, <2 h of "screen" time per day, at least 1 h of physical activity per day, and no sweetened drinks.

Omega-3 fatty acids can decrease triglycerides, and are well tolerated by children as a supplement. These fatty acids are present in oily cold-water fish (including salmon, sardines, mackerel, and tuna), eggs, milk, and some berries.

Pharmacologic intervention

The AAP guidelines have specific recommendations for children who should receive medication [43]. A child must be at least 8 years of age, and have failed to lower their cholesterol sufficiently after a suitable period of dietary restrictions. Pharmacologic treatment of children <8 years of age should be reserved for the rare child with homozygous FH and LDL cholesterol levels exceeding 500 mg dl^{-1}. For children with moderately severe heterozygous dyslipidemias, medication is recommended if:

- LDL cholesterol remains >190 mg dl^{-1}.
- LDL cholesterol remains >160 mg dl^{-1} and other risk factors are present, including positive family history of premature CVD, obesity, and/or hypertension.
- LDL cholesterol is >130 mg dl^{-1} in children with DM.

The goal of therapy is to decrease the LDL cholesterol to <130 mg dl^{-1}, or more ideally <110 mg dl^{-1}. There is no reason to lower LDL levels more as is recommended in high-risk adults.

Medications available include the following:

- *Bile acid-binding resins:* May lower the cholesterol by 10–20% below baseline and have the advantage of no systemic effects. However, the associated gastrointestinal discomfort and the fact that dosage forms are neither practical nor palatable for children limited their use.
- *Niacin:* Decreases both LDL cholesterol and triglycerides and also increases HDL cholesterol. The associated flushing, headaches, and elevations in hepatic enzymes prohibit its routine use in children. Niacin has been used selectively in children with marked hypertriglyceridemia at risk for acute pancreatitis, although dietary restriction of complex sugars and carbohydrates usually significantly lowers triglyceride levels.
- *HMG-CoA reductase inhibitors (statins):* These are extremely effective, cause a 20–50% decrease in LDL cholesterol, and reduce plaque inflammation. The rare side effects include liver enzyme elevation and rhabdomyolysis. Hepatic transaminases must be monitored regularly but they can be allowed to increase 2–3-fold before the medication needs to be discontinued. Children rarely report the muscle aches and cramps that adults note.
- *Cholesterol-absorption inhibitors (ezetimibe):* This relatively new class of medication is often useful in children with moderate elevation of LDL cholesterol not severe enough to

justify statins, or in combination with statins when there is severe hypercholesterolemia. They can decrease LDL by 20%. Side effects are few.

• *Fibric acid derivatives:* These are used in adults with for severe hypertriglyceridemia. This class of medication has very limited utility in children and may cause liver toxicity.

66 Cardiac Tumors

Saroja Bharati

Advocate Hope Children's Hospital, Advocate Christ Medical Center, Oak Lawn, IL; Rush University
Medical Center; Rosalind Franklin University of Medicine and Science, Chicago Medical School and
University of Illinois at Chicago, Chicago, IL, USA

Although cardiac tumors are rare in children, recent advances in various types of imaging techniques have made it possible to diagnose them fairly accurately. Today, most benign tumors are surgically removed with reasonable success [1–30].

The tumors usually seen in childhood are rhabdomyoma, fibroma, mesothelioma of the atrioventricular (AV) node, and sarcoma. Other types of tumors in children are myxoma, lipoma, papillary fibroelastoma, tumor of heterotopic tissue (teratoma), leiomyoma, granular cell tumor, mesothelioma, hemangioma, lymphangioma, melanoma, paraganglioma (pheochromocytoma), neurofibroma, neuroblastoma, neurinoma, lymphoma, and carcinoids.

Incidence

Primary cardiac tumors are extremely rare, with an incidence of 0.0017–0.28% in autopsy series. Approximately 75–80% of tumors of the heart and pericardium are benign. Among the benign tumors, atrial myxomas constitute 75%.

Genetics

Little is known about the cause of pediatric cardiac tumors. In the past two decades, however, a genetic etiology has been recognized for some tumors. Clinical genetic analysis has shown that Carney complex is transmitted as an autosomal dominant disorder and can manifest in a variety of tumors such as psammomatous melanotic schwannoma, pituitary adenoma, and testicular Sertoli cell tumors [31]. Molecular genetic studies have demonstrated that mutations in a subunit of protein kinase A and mutations in the MYH 8 gene that encodes prenatal myosin could be primary causes of the disorders that predisposes to cardiac tumorogenesis [31].

Likewise, tuberous sclerosis complex (TSC) is an autosomal dominant disorder that results from mutations in TSC1 or TSC2 genes and is associated with hamartoma formation in multiple organ systems [32].

Clinical manifestations

The clinical manifestations of cardiac tumors depend on the site, size, and characteristic pathological and histochemical features [3–30]. The tumor may remain asymptomatic and sudden death may be the first manifestation [24–26].

Tumors of the heart may produce hemodynamic effects, dysrhythmias, pericarditis, intracavity obstruction, embolism, mechanical hemolysis, and constitutional symptoms. Some tumors, such as carcinoids, may have biologic effects and with malignant tumors metastasis elsewhere in the body may be seen.

The hemodynamic effects include obstruction to the inflow or outflow tract of any chamber on the right or left side of the heart or intracavity obstruction at the level of the AV valves. Pulmonary hypertension may occur due to pulmonary emboli from the right heart, or due to pulmonary venous obstruction produced by left atrial or left ventricular outflow tract obstruction. Ascites may occur from right atrial obstruction. Various types of arrhythmias occur, such as atrial fibrillation, flutter, supraventricular tachycardia, pre-excitation, AV block, and repetitive ventricular tachycardia. The tumor may produce pericardial effusion and tamponade or may cause constrictive pericarditis. Emboli may pass to the brain or elsewhere in the systemic circulation. Depending on the site of the tumor, there may be left or right heart failure. The symptoms then include cardiac failure, general malaise, loss of weight, syncopal episodes, and pulmonary edema. Mechanical hemolysis and hemolytic

anemia may be produced by the tumor mass. In some patients the symptoms may resemble those of infective endocarditis with fever, signs of peripheral embolization, increase in sedimentation rate, and hyperglobulinemia. If the tumor is malignant, metastasis may occur in lungs, lymph nodes, mediastinum, liver, pancreas, spleen, kidneys, adrenals, bone, and brain.

Tumors of the pericardium

Pericardial tumors are less frequently seen than those within the heart and are very rare in children. The benign tumors are benign mesothelioma, miscellaneous pericardial celomic cysts, angiomas (hemangioma and lymphangioma), lipoma, leiomyoma, fibroma, neurofibroma, neuroblastoma, and neurinoma. The malignant tumors are rare and include various types of sarcomas and malignant mesothelioma [1,2,4,10–14].

Tumors of the heart

Rhabdomyoma

Rhabdomyoma is the most common primary cardiac tumor in infancy and childhood. It is rarely seen after the age of 15 years. It is usually associated with TSC complex, an autosomal dominant disorder resulting from mutations of TSC1 or TSC2 genes. It occurs with hamartoma formation in multiple organ systems. About 80% of the tumors present before the age of 1 year. The tumor is usually multiple but may be single. It is often in the walls of the right and left ventricle or the interventricular septum (Figure 66.1), but is rare in the atrial septum [1,5,7,10–15,32].

Microscopically, the tumor consists of vacuolated cells that look like spider cells and contain glycogen. On electron microscopy, glycogen is seen in the cytoplasm and in the mitochondria. The intercellular junctions resemble intercalated discs, desmosomes, and nexus.

The tumor may obstruct a coronary artery or affect the conduction system. It can also obstruct the tricuspid, pulmonary, mitral, or aortic valve, or the outflow tract of the right and left ventricle. Rarely, the tumor presents as fetal hydrops with AV block.

Although the obstructive phenomena may predominate in patients with outflow tract obstruction, they may also have varying types of arrhythmias, such as atrial fibrillation, flutter, supraventricular tachycardia, pre-excitation, AV block, and ventricular tachycardia. In general, the arrhythmias are abolished after surgical removal of the tumor. Rhabdomyomas are completely benign, with no metastasis, and most of them spontaneously regress either partially or completely.
Figure 66.1 Multiple rhabdomyomas of the heart, left ventricular (LV) view. Arrows point to rhabdomyomas. (Reproduced from Bharati, S, Lev M. Cardiac tumors. In: Adams FH, Emmanouilides GC, Riemanschneider TA, eds. *Moss' Heart Disease in Infants, Children and Adolescents*, 4th edn. Baltimore, MD: Williams and Wilkins, 1989: 886–90, with permission from Wolters Kluwer.)

Fibroma

Fibroma is the second most common tumor in infancy. It is almost always solitary. The tumor occupies the septal or parietal wall of the left ventricle. Because it is not encapsulated, it intermingles with the myocardial cells of the wall of the ventricular mass. Despite this, it can often be shelled out at surgery and usually does not recur. The fibroma may compress the anterior descending coronary artery or affect the conduction system to varying degrees and cause AV block. The tumor may produce subaortic or subpulmonary obstruction or arrhythmias and may lead to sudden death [1–15].

Microscopically the tumor contains fibrous tissue, fibroblasts, fat cells, endothelial-lined spaces, and smooth muscle cells. It has also been called fibrous hamartoma [1,2,10,11].

Teratoma

Teratomas are extremely rare cardiac tumors. They contain derivatives of all three germ layers and may be associated with congenital heart disease [1–5,10–14]. They are usually extracardiac but intrapericardial. They may be attached to the right ventricular outflow tract and compress the heart and cause tamponade. Like all teratomas, intrapericardial teratoma has a malignant potential.

Myxoma

Although myxomas are rarely seen before the age of 15 years, they do occur in adolescence [10,11,17–24]. The

(a)   (b)
Figure 66.2 (a) Myxoma gross appearance. Arrows point to the region of attachment of tumor to atrial septum. (b) Myxoma. Hematoxylin–eosin stain, original magnification ×150. (Reproduced from Bharati, S, Lev M. Cardiac tumors. In: Adams FH, Emmanouilides GC, Riemanschneider TA, eds. *Moss' Heart Disease in Infants, Children and Adolescents*, 4th edn. Baltimore, MD: Williams and Wilkins, 1989: 886–90, with permission from Wolters Kluwer.)

tumor is usually in the left atrium and frequently in the right atrium. It is uncommon in the ventricles. Occasionally the tumor may be bilateral. When it occurs in the left atrium, it is usually near the fossa ovalis, but can occur in the parietal wall. In general, the tumor is attached to the atrial septum by a pedicle but it may be attached directly to the atrium. In one type the myxoma is transparent and in another it is a round or oval firm mass (Figure 66.2a).

Microscopically, it consists of plump endothelial cells associated with thin-walled capillaries and a large amount of amorphous matrix (Figure 66.2b). The myxoma cells are elongated and spindle shaped, with round or oval nuclei and a prominent nucleolus. Some cells are binucleated. The cells are arranged in syncytial groups and intimately associated with cleft-like, thin-walled capillaries. They have the combined features of smooth muscle cells and fibroblasts. On electron microscopy, a distinctive feature of myxoma cells is the presence of numerous cytoplasmic filaments. Calcification may occur. Large, thick-walled blood vessels are present in the pedicle. The predominant substance in the matrix is an acid mucopolysaccharide related to chondroitin C. The tumor also presents a variety of cell types: fibroblastic cells, macrophages, lymphocytes, plasma cells, mast cells, and mature and immature muscle cells. Gamma-Gandy bodies consisting of hemosiderin-laden macrocytes and degenerated collagen fibers encrusted with iron and calcium are also seen.

Most authors believe that the tumor originates from multipotential mesenchymal cells. Some believe that the myxoma is a true neoplasm and not an altered thrombus. A minority opinion still regards it is an organized mural thrombus, modified by mechanical forces.

Myxoma may embolize systemically or less commonly to one or both lungs. Occasionally, myxoma of the heart is associated with similar tumors in the choroid plexus, the left lateral ventricle of the brain, and the scapula. It is not known whether these constitute metastases or are related to embolization.

Clinically, the symptoms vary from obstruction of a valve to tumor embolus or systemic symptoms, or the patient may be asymptomatic. Myxomas often masquerade as mitral valve disease, connective tissue disorder, or infective endocarditis. Fever is common, and there may be weight loss, Reynaud's syndrome, polymyositis, hyperglobulinemia, and an elevated erythrocyte sedimentation rate. Some have attributed these findings to an increase in circulating interleukin-6 [24].

The mortality rate for surgical removal of cardiac myxoma is <5%. Recurrence may occur but is uncommon. Various types of arrhythmias, such as atrial flutter, fibrillation, junctional rhythm, sinus arrest, or complete AV block, may occur following surgical removal of the myxoma.

Cardiac myxomas are associated with various complexes [10,11,20–24,31]. One such complex consists of cardiac myxoma, multiple pigmented skin lesions (lentiginosis), myxoid fibroadenoma of the breast, skin myxomas, and primary pigmented nodular adrenocortical disease of the adrenal. A second, LAMB complex, consists of lentiginosis, atrial myxoma, mucocutaneous myxoma, and blue nevi. Another, NAME complex, consists of nevi, atrial myxoma, neurofibromatosis, and ephelides. Finally, Carney complex is a familial multiple neoplasia disorder consisting of cardiac myxoma, lentiginosis, primary pigmented nodular adrenocortical disease, bilateral myxoid fibroadenoma of the breast in the female, and testicular tumors in the male [(large cell calcifying Sertoli cell tumor and steroid-type tumor (Leydig cell)], with pituitary adenoma associated with acromegaly and giantism.

Arch Intern Med* 1976;**135**:224–8, with permission from the American Medical Association. Copyright © 1976 American Medical Association. All rights reserved.)

Papillary fibroelastoma

Although this is the second most common type of cardiac tumor, and the most common to affect endocardium and cardiac valves, it is rare in childhood. Any valve can be involved, most often aortic or mitral, then tricuspid, and least often the pulmonary valve. The fibroelastoma has a flower-like appearance with multiple elongated branching papillary fronds attached to the endocardium by a short pedicle [33]. Usually asymptomatic, it is a cause of systemic or pulmonary embolism; those on the aortic valve may cause myocardial infarction or sudden death. They are diagnosed by echocardiography, and can be removed surgically.

Other benign tumors

Several other benign tumors in the heart have been reported, including lipoma, hemangioma, granular cell tumor, and myoblastoma [1,2,10–14].

Mesothelioma of the AV node

This is a benign localized tumor of the AV node (Figure 66.3a) [10,25,26]. Although the tumor is rare, it may become evident clinically in adolescents. It usually produces complete heart block that may result in sudden death. The tumor affects the distal part of the atrial septum and the approaches to the AV node, and the AV node may be completely replaced by the tumor mass. It rarely extends to the AV bundle. Histologically it consists of cells arranged in masses or tubular form with no evidence of anaplasia (Figure 66.3b). In ultrastructure studies, it appears to be derived from mesothelial cells. About 50% of the reported patients are in younger age groups and more often in women.

Sarcoma

Primary cardiac sarcomas are rare in children but have been described in adolescence [1,2,5,10–14,28–30]. They are usually found in the atria, especially the right. Angiosarcoma is the most common type. The origin of these tumors in order of frequency is right atrium, left atrium, right ventricle, and left ventricle. These tumors are often associated with metastases to the lung, lymph nodes, mediastinum, liver, kidneys, adrenals, spleen, pancreas, brain, and bone. There are a number of types of sarcoma: angiosarcoma, rhabdomyosarcoma, leiomyosarcoma, spindle cell sarcoma, neurogenic sarcoma, osteosarcoma, undifferentiated sarcoma (Figure 66.4), fibrosarcoma, liposarcoma, fibromyxosarcoma, myxosarcoma, malignant melanoma,
Figure 66.4 Sarcoma of atrial septum undifferentiated. Hematoxylin–eosin stain, original magnification ×120. T, tumor. (Reproduced from Bharati, S, Lev M. Cardiac tumors. In: Adams FH, Emmanouilides GC, Riemanschneider TA, eds. *Moss' Heart Disease in Infants, Children and Adolescents*, 4th edn. Baltimore, MD: Williams and Wilkins, 1989: 886–90, with permission from Wolters Kluwer.)
Figure 66.5 Metastases of an osteogenic sarcoma to the tricuspid valve in a 16-year-old girl. RV, right ventricle. Arrows point to the tumor on the tricuspid valve. (Reproduced from Bharati, S, Lev M. Cardiac tumors. In: Adams FH, Emmanouilides GC, Riemanschneider TA, eds. *Moss' Heart Disease in Infants, Children and Adolescents*, 4th edn. Baltimore, MD: Williams and Wilkins, 1989: 886–90, with permission from Wolters Kluwer.)

and mesenchymoma Among the lymphomas are reticulum sarcoma and lymphosarcoma.

Metastatases to the heart

In older people, metastatic tumors to the heart are twice as common as primary tumors. Carcinomas arising from breast, bronchi, kidneys, malignant melanoma, chondrosarcoma, malignant lymphoma, and leukemia may metastasize or spread to the heart. On the other hand, in children or adolescents, osteogenic sarcoma (Figure 66.5) [10,11] and chondrosarcoma are the most common causes of metastases to the heart.

67 Connective Tissue Disorders

Lut Van Laer & Bart Loeys
Center for Medical Genetics, Antwerp University Hospital,
University of Antwerp, Antwerp, Belgium

Introduction

"Connective tissue" refers to a complex structure composed of a cellular component (fibroblasts, smooth muscle cells) and the extracellular matrix. The extracellular matrix includes both structural proteins such as collagen, fibrillin, and fibronectin and ground substance such as proteoglycans. This matrix provides specific environmental signals to control cell morphology, migration, differentiation, proliferation, and metabolism. Together they form a network that provides resistance to mechanical forces while allowing diffusion of small molecules.

In the cardiovascular system, connective tissue is mostly present in the valves and vessel walls. The valves themselves (both atrioventricular valves and semilunar valves) are composed of different layers of connective tissue, covered with endothelial cells. As an example, the adult human aortic valve cusps are composed of about 10–15% of elastin and 45–55% of collagen. The composition of the extracellular matrix in blood vessels depends on the type and subtype of vessel, for example, elastic or muscular arteries, small, medium, or large veins. The larger arteries have proportionately more fibrillin and elastin, whereas the middle-sized arteries have more collagen in the medial layers.

Connective tissue disorders comprise a heterogeneous group of diseases, mostly affecting the ocular, skeletal, integument, and cardiovascular system. Common ocular findings include ectopia lentis, myopia, and corneal fragility. Frequent skeletal features include overgrowth leading to pectus deformities, scoliosis, disproportionate body measurements, joint laxity and contractures, osteoporosis, and fractures. The skin can be characterized by skin hyperlaxity, cutis laxa, easy bruising, smooth and velvety skin, and atrophic scarring. Cardiovascular findings include aortic and arterial aneurysms with tortuosity, valve insufficiency, patent ductus arteriosus, and atrial/ventricular septal defects.

In contrast to the skeletal dysplasias and osteogenesis imperfecta, which mainly affect the hard connective tissues, three groups of heritable disorders primarily affecting the soft connective tissues are discussed in this chapter, namely the heterogeneous group of Ehlers–Danlos syndromes, the aneurysm syndromes including Marfan and Loeys–Dietz syndrome, and the rare group of cutis laxa syndromes.

Ehlers–Danlos syndromes

Classification

The Ehlers–Danlos syndromes (EDS) comprise a clinically and genetically heterogeneous group of heritable disorders of which the principal clinical features are the result of varying degrees of tissue fragility of the skin, ligaments, blood vessels, and internal organs. The prevalence of EDS is estimated as ~1/5000 births, with no racial predisposition. However, this may be an underestimate as this group of diseases is not well known among clinicians. The first attempts to classify the EDS resulted in the Berlin Nosology in 1986, in which 10 subtypes were recognized [1]. Elucidating the molecular basis of several types of EDS resulted in refinement of this classification, which led to the 1997 Villefranche Nosology [2]. This classification recognizes six subtypes, based on clinical characteristics, mode of inheritance, and biochemical and molecular findings. The most frequent types of Ehlers–Danlos syndrome include the classic, hypermobility and vascular type, whereas the kyphoscoliosis, arthrochalasis, and dermatosparaxis types are very rare. During the past few years, it has become clear that this classification remains insufficient and that many patients present with overlapping

forms of EDS, which cannot unambiguously be classified into one of the six recognized subtypes. Recent insights into the molecular and biochemical basis of some EDS variants call for a refinement of the Villefranche classification, which will likely further improve appropriate diagnosis and counseling of affected families.

Clinical diagnosis

The main clinical characteristics of EDS present to varying degrees in each subtype of the syndrome, include joint hypermobility, skin hyperextensibility, delayed wound healing with atrophic scarring, easy bruising, and generalized fragility of the soft connective tissues.

Joint hyperlaxity is usually generalized but can vary tremendously in severity. Joint hypermobility is generally assessed using the Beighton scale. A score above five (out of nine) indicates joint hyperlaxity. However, joint hyperlaxity is present in ~10–20% of the normal population. Other common features in EDS include uni- or bilateral dislocation of the hip, club feet, and pes planum. During childhood, complications are usually limited to delayed motor development due to muscular hypotonia. From young adulthood on, subluxations and dislocations may occur, either spontaneously or after minimal trauma. All joints can be involved, but the most frequent ones include the costo-vertebral and costo-sternal joints, clavicles, shoulders, knee with patellar joint, and temporomandibular joints. Other problems related to joint hypermobility are joint effusions and premature osteoarthritis. Often adolescents start to suffer from chronic musculoskeletal pain, which is distinct from the acute pain associated with dislocations. The severity of the complaints is typically greater than expected based on physical and radiological examination, and the impact can be devastating, with disruption of sleep, work, physical activities, and social relations.

Skin hyperextensibility is characteristic for all EDS subtypes, except in the vascular type. In contrast to the skin in cutis laxa syndromes, the skin of EDS patients is hyperelastic, which means that it extends easily and snaps back after release. The skin is often very smooth and velvety to the touch. Wound healing is delayed, resulting in the formation of widened atrophic scars, so-called "cigarette-paper scars." These atrophic scars are typically located over knees, elbows, shins, forehead, and chin. In the vascular type, the skin is not hyperextensible, but rather thin and transparent, typically showing the venous pattern over the chest, abdomen, and extremities. Easy bruising is a common finding in patients with EDS and in small children it may even be the presenting symptom to the pediatrician. It manifests as spontaneous ecchymoses, frequently recurring in the same areas and causing a characteristic brownish discoloration of the skin, especially in exposed areas such as shins and knees. There is a tendency towards prolonged bleeding, for example, following brushing of the teeth, in spite of a normal coagulation status.

Other manifestations of generalized tissue fragility are observed in multiple organs and include cervical insufficiency, inguinal, umbilical, or other hernias, recurrent rectal prolapse in early childhood, and dehiscence of sutured incisions in skin or mucosa. Structural cardiac malformations are uncommon in most EDS types, but mitral valve prolapse and, less frequently, tricuspid valve prolapse may occur. The vascular type of EDS deserves special attention because this condition is associated with an increased risk of life-threatening complications and a decreased life expectancy.

Vascular Ehlers-Danlos syndrome

Vascular EDS (or the former type IV Ehlers–Danlos syndrome) is an autosomal dominant disorder caused by mutations in the gene encoding for type III collagen (COL3A1) (see Table 67.3). Clinical diagnosis can be confirmed biochemically by reduced type III collagen or identifying the causal COL3A1 gene after mutational analysis. In addition to the joint and skin problems, vascular EDS is clinically characterized by fragility of intestinal and genitourinary organs and vascular fragility leading to dissection or rupture of medium to large muscular arteries. Typically in vascular EDS, dissections often occur without preceding dilatation/aneurysm formation. In vascular EDS patients, complications in early childhood are rare. In the largest series reported so far, the average age at the time of a first complication was 23.5 years, with rupture of the gastrointestinal tract likely to occur at an earlier age than arterial rupture [3]. About half of the arterial complications in vascular EDS involved the thoracic or abdominal arteries and the rest were divided equally between the head, neck, and limbs. In vascular EDS, the reported incidence of fatal complications during or immediately after vascular surgery is around 45% [3]. It is very difficult to establish useful guidelines for cardiovascular imaging in vascular EDS because complications may occur unannounced and no specific treatment is available at present. Some authors advise not pursuing any additional investigation or surveillance, because a conservative approach will be adopted irrespectively and undue anxiety would be created. Others recommend noninvasive cardiovascular imaging with echocardiography and vascular computed tomography/magnetic resonance imaging (CT/MRI) [4].

Other rare variants of EDS

Although vascular ruptures are most typical for the vascular type of EDS, they can also occur in the rare kyphoscoliosis type of EDS. Features of classic EDS may be found in patients with other rare variants of EDS. For example, a subgroup of patients with the classic EDS phenotype has been observed who developed severe cardiac valvar problems, and in whom a complete deficiency of the proα2-chain of type I collagen has been identified. This autosomal recessive condition has been termed the "cardiac valvar subtype of

EDS" [5–7]. Classic EDS features were also observed in a number of children with non-glycine substitutions in the type I collagen triple helical domain [8]. Recent observations showed that this phenotype evolves to a vascular EDS-like phenotype in adult life, with increased risk for spontaneous arterial rupture [9].

Genetics/Inheritance

Most forms of EDS are autosomal dominant, although some more rare autosomal recessive forms occur. In the vascular form of EDS, every family has its own private mutation in the COL3A1 gene. Mutations most often affect the highly conserved glycine residues present at every third amino acid position in the helical domain of the type III collagen. About 50% of the COL3A1 mutations occur *de novo*, so the absence of a family history does not preclude this diagnosis.

Pathophysiology

Mutations of the COL3A1 gene typically result in a structural alteration of type III collagen that leads to intracellular storage and impaired secretion of collagen chains. A possible regulatory role for the type III collagen molecule has been suggested, although formal studies are still ongoing.

Marfan syndrome

Introduction

Over 100 years ago, the French pediatrician Antoine-Bernard Marfan described a 5-year-old girl, Gabrielle, with long slender digits, long bone overgrowth, and muscle hypoplasia [10]. Since then, clinical research has further delineated this condition and identified it as a systemic disorder of the connective tissue with severe manifestations in the cardio-vascular, ocular, and skeletal system demanding a multi-disciplinary approach for both diagnosis and management. Marfan syndrome (MFS) occurs worldwide with an incidence estimated up to 1/5000, affecting both sexes equally [11]. The disease demonstrates autosomal dominant inheritance with high penetrance and marked inter- and intrafamilial variability. MFS is caused by mutations in the FBN1 gene, encoding an important extracellular matrix protein, fibrillin-1.

Clinical characteristics

Long bone overgrowth contributes to the most striking observations in MFS, leading to disproportionately long limbs and anterior chest deformities due to rib overgrowth. Other major manifestations include arachnodactyly, elbow contractures, scoliosis or spondylolisthesis, protrusio acetabulae (detected by X-ray), and calcaneal displacement resulting in pes planus with hindfoot valgus. Arachnodactyly is often a subjective finding but requires the thumb sign (when the fully adducted thumb extends beyond the ulnar border of the palm) and wrist sign (when the distal phalanges of the thumb and fifth finger fully overlap when grasping the contralateral wrist). Patients may present with typical facial characteristics including downslanting palpebral fissures, enophthalmia, retrognathia, and a high arched palate with tooth crowding. Joint hypermobility may predispose to ligamentous injury, dislocations, chronic joint pain and premature arthrosis. Other troublesome locomotor symptoms include muscle hypoplasia and myalgia resulting in fatigue and spinal pain. These symptoms increase with age and affect up to 98% of adult patients [12]. MFS patients have been considered to have an increased number of fractures due to osteopenia, but this remains to be confirmed.

Ocular lens dislocation of any degree should promptly trigger further assessment for MFS. It occurs in about 50–67% of all patients. Final diagnosis of ectopia lentis can only be made by slit lamp examination. High myopia, retinal detachment, cataract, or glaucoma occur and may cause significant visual impairment or even blindness [13].

Although other systems may be severely impaired in MFS, cardiovascular pathology remains the leading cause of mortality and morbidity with aortic root dilatation, dissection, and rupture being life-threatening manifestations (see Table 67.3). The dilatation is generally greatest at the sinuses of Valsalva. Measurements should be normalized to body surface area and age [14]. Aortic root aneurysms occur in an age-dependent manner with high variability among individuals, prompting life-long follow-up. Although in severe disease the onset of dilatation occurs early in life, some individuals will never need aortic root replacement. The majority of fatal events associated with untreated MFS occur in early adult life. However, timely recognition and appropriate medical and surgical management of the disease increased the mean survival age to 72 years [15]. The improved life expectancy in MFS has revealed that patients are also prone to more distally occurring aortic manifestations, especially after aortic root replacement, requiring appropriate imaging [16]. Pulmonary artery diameters are significantly larger in MFS and may become apparent before aortic root dilatation, and so have potential diagnostic value, especially in children [17]. Two-thirds of patients have mitral valve dysfunction with most commonly valve prolapse, insufficiency and calcification often associated with myxomatous valve thickening [18]. In contrast, aortic valve insufficiency usually results from aortic root dilatation. At the extreme end of presentation, infants with neonatal MFS manifest severely impaired valve dysfunction leading to congestive heart failure, pulmonary hypertension, and even early death [19]. Primary progressive myocardial dysfunction is usually mild, but may be aggravated by β-adrenergic blockade or valve insufficiency [20].

Finally, some other organ systems are affected in Marfan patients. Dural ectasia is a frequent observation with a prevalence of up to 92% in Marfan patients, and may be detected in young children [21]. Unfortunately, many other

conditions, including neurofibromatosis and Loeys–Dietz and Ehlers–Danlos syndromes, manifest dural ectasia and its precise specificity and sensitivity are not established. Moreover, it requires specific imaging of the lumbosacral region with CT or MRI, reducing its accessibility. In some patients it causes discomfort such as low back pain, headaches, and irradiating leg pains [22].

Striae distensae independent of marked weight gain or pregnancy occur in up to two-thirds of all patients [23]. Recurrent inguinal or surgical hernias are common and need special attention. Pneumothorax and pulmonary emphysema and dysfunction, partly due to alveolar septation defects, represent rare but disabling manifestations. Restrictive lung disease may result from severe pectus deformities, but is rare in MFS. In view of the long bone overgrowth, pulmonary function should be normalized to sitting height rather than body surface area [24].

Diagnostic criteria

Diagnosis and management require a multidisciplinary approach by geneticists, cardiologists, orthopedic surgeons, and ophthalmologists with experience in this field [25]. The diagnosis of MFS has always relied on a set of international criteria, outlined by expert opinion. In 1996, the initial Berlin nosology was revised because of the risk of over-diagnosis and redefined as the Ghent nosology, a more stringent set of major and minor criteria [26]. These Ghent criteria have proven to work well because with improving molecular techniques, confirmation of the diagnosis is possible in >95% of patients [27]. However, concerns with the Ghent criteria are that some of the diagnostic manifestations have not been validated as thresholds (e.g., dural ectasia) and others necessitate cumbersome imaging studies. Moreover, in the absence of aortic dilatation, the diagnosis can be stigmatizing, hampering career aspirations and restricting life insurance opportunities. Following an international expert meeting, a revised Ghent nosology, in which aortic root aneurysm and ectopia lentis are cardinal features, is proposed [28] (Table 67.1). In the absence of any family history, the presence of these two manifestations is sufficient for the unequivocal diagnosis of MFS. In the absence of any of these two, the presence of bona fide FBN1 mutation or a combination of systemic features is required. For the latter, a new scoring system (Table 67.2) has been designed and validated. In this way, FBN1 testing is not mandatory but useful when available.

Pathophysiology

For a long time, the pathophysiology of MFS was entirely based on severely reduced and fragmented elastic fibers in affected tissues. This observation led to the hypothesis that structural deficiency of the fibrillin-1 protein was the most important player in the etiology of Marfan syndrome. Although this hypothesis offered an explanation for aortic

Table 67.1 Revised Ghent criteria for diagnosis of Marfan syndrome and related conditions[a].

With no family history:
1 Ao ($Z \geq 2$) AND EL = MFS[b]

pathology, it did not reconcile the observations of other clinical features such as long bone overgrowth, thickening of the cardiac valves, or muscle hypoplasia. The study of the fibrillin-1 mutant mouse that recapitulates the human

MFS has recently challenged this "mechanistic" view. Indeed, these mouse models have shown that structural fibrillin-1 deficiency leads to increased activation of the sequestered cytokine transforming growth factor beta (TGFβ) [29,30], which has a pivotal role in the development and maintenance of several tissues. Enhanced activation of the TGFβ pathway was shown to contribute to the development of emphysema, aortic aneurysms, and muscle hypoplasia seen in MFS. In murine models, these changes can be effectively blocked by the administration of TGFβ antibodies and an angiotensin receptor blocker, losartan [29,31,32].

Management

Cardiovascular follow-up should include serial evaluation with echocardiography or CT/MRI angiography when visibility of the aortic root and ascending aorta is limited [16]. The evaluation frequency should be tailored based upon aortic dimensions, the rate of aortic growth, and family history. β-Adrenergic blockade, titrated to physiological response, is a standard treatment to slow aortic growth mainly by virtue of its antihypertensive and negative inotropic effects [33]. If beta-blockade is contraindicated (asthma, Raynaud phenomenon, psoriasis, depression, fatigue), calcium antagonists or angiotensin-converting enzyme inhibitors may alternatively be used, although no randomized studies exist. Surgical repair of the aorta is indicated once the maximum diameter exceeds 5.0 cm in adults, when the rate of aortic growth exceeds >0.5–1.0 mm per year, or with significant aortic regurgitation. With proper aortic valve function, the preferred technique is the valve-sparing procedure, avoiding life-long anticoagulant therapy, especially in females in their fertile period. Although the superiority of this technique compared with the composite graft has not been established, the 10 year experience is very promising [34]. After surgical repair of the aortic root, imaging of the whole aorta is warranted for timely detection of aortic graft pseudo-aneurysms, more distally occurring aneurysms, and coronary artery aneurysms [25]. New therapeutic strategies, based upon the physiopathology in MFS, propose losartan as an anti-hypertensive agent attenuating TGFβ signaling. In mouse models, losartan has been shown to stop aortic growth and induces regression of emphysematous changes in the lung, even in adult life [32]. Currently ongoing randomized trials are focused on this new treatment possibility in MFS, which might also be beneficial in related conditions [31].

Orthopedic complications mainly involve anterior chest and vertebral column deformities that should be followed carefully, especially during and just after puberty. Because extreme pectus deformities have little impact on pulmonary function, surgery is considered a cosmetic issue.

Correction, preferably using the minimally invasive Nuss procedure, should not be done before the age of 11 years [35], as earlier intervention might lead to recurrent deformity due to continued rib growth. In contrast, severe (kypho)-scoliosis has major impact on quality of life, needing surgical stabilization, as bracing often remains inadequate [36]. Protrusio acetabulae is often asymptomatic in young adults, and the benefit of surgery is questioned [37]. Hormone therapy is indicated if predicted final height is unacceptable [38].

Diffraction anomalies due to lens subluxation, flat cornea, or myopia can easily be corrected by eyeglasses or contact lenses. Lens extraction for manifest ectopia lentis or cataract severely increases the pre-existing risk for retinal detachment and glaucoma with resultant significant visual impairment. Yearly examination by an experienced ophthalmologist in every Marfan patient is highly recommended.

Finally, lifestyle modifications may promote cardiovascular and psychosocial health and prevent or relieve many locomotor inconveniences, including arthrosis, fatigue, myalgia. and chronic joint pains. Patients should avoid competitive sports, straining, or isometric exercise, as these increase blood pressure and cause considerable dynamic stress on the aortic root. Additionally, contact sports should be avoided as these may precipitate aortic dissection [39]. Activity guidelines are available on the National Marfan Foundation website: http://www.marfan.org/.

Loeys–Dietz aortic aneurysm syndrome

Classification

A novel autosomal dominant aortic aneurysm syndrome characterized by the triad of hypertelorism, bifid uvula/cleft palate, and arterial tortuosity with ascending aortic aneurysm and dissection, caused by heterozygous loss-of-function mutations in the genes coding for the TGFβ receptors 1 or 2, TGFBR1 or TGFBR2, was recently described and designated "Loeys–Dietz syndrome" (LDS) [40]. Although some individuals show overlap with MFS, none satisfy diagnostic criteria. The main differences are the absence of significant long-bone overgrowth or lens dislocation, and many other discriminating findings can be present, including craniosynostosis, Chiari malformation, club feet, patent ductus arteriosus (PDA), and aneurysms/dissection throughout the arterial tree. In contrast to this typical presentation, referred to as LDS type 1, some patients show fewer craniofacial abnormalities but prominent skin and joint manifestations more reminiscent of EDS [41]. This phenotype, referred to as LDS type 2, is characterized by a velvety and translucent skin, easy bruising, widened atrophic scars, uterine rupture, severe peripartum bleedings, and arterial aneurysm/dissections throughout the arterial circulation.

Clinical characteristics

The Loeys–Dietz syndrome is characterized by four major groups of clinical findings: vascular dilatation and tortuosity, skeletal findings, facial dysmorphology, and skin symptoms.

In the cardiovascular system, dilatation of the aortic root, at the level of the sinuses of Valsalva, is the most important clinical finding (Table 67.3). At the time of diagnosis, about two-thirds of the patients already have an aneurysm of the aortic root, and virtually all LDS patients eventually develop dilatation of the aortic root [41,42]. Less frequently, and seldom isolated, aneurysms of the ascending and/or descending aorta are seen. The mean age at which aortic dilatation is established is in the teenage range. At the time of diagnosis, about one-fifth of the LDS patients already have an aortic dissection. Arterial tortuosity is seen in most individuals with a TGFBR1 or TGFBR2 mutation. Arterial tortuosity can be generalized but most commonly involves the head and neck vessels. Evaluation at baseline is best done with magnetic resonance angiography (MRA) or CT scan with 3D reconstruction. To identify all arterial aneurysms and arterial tortuosity throughout the arterial tree, it is mandatory to screen all vessels from head to pelvis. Approximately half of the individuals with LDS studied had an aneurysm distant from the aortic root that would not have been detected by echocardiography. Congenital heart diseases, such as a bicuspid aortic valve, an atrial septal defect, or a patent ductus arteriosus, are more frequently seen in LDS patients than in a normal population. Mitral valve prolapse and/or insufficiency is a recurrent finding in LDS patients, although less frequent than in MFS [43,44]. Recently, evidence was given that a TGFBR1 mutation in LDS can cause microvascular coronary artery dysplasia and subsequent cardiomyopathy [45].

Skeletal features in LDS show overlap with those of MFS: joint hyperlaxity, arachnodactyly, pectus deformity (pectus excavatum or carinatum), and scoliosis are frequently seen. In addition to the joint laxity, contractures of feet (talipes equinovarus) and fingers (camptodactyly) are common features in LDS [41,46–48]. Pes planus is often associated with inward rotation at the ankle. Dolichostenomelia (long limbs, leading to an increase in the arm span-to-height ratio and a decrease in the upper-to-lower segment ratio), as seen typically in MFS, is far less often described in LDS patients [41,46]. Other recurrent findings are cervical spine instability and spondylolisthesis [40,41,46]. The skeletal phenotype with respect to low bone mineral density and skeletal fragility is unclear. Approximately three-quarters of LDS patients have facial dysmorphologic features, and are therefore designated as patients with LDS type 1. Hypertelorism (wide-set eyes) and a cleft palate or a bifid uvula are major diagnostic characteristics of LDS [40,41]. Craniosynostosis is a recurrent feature. Most commonly the sagittal suture is prematurely closed (resulting in dolichocephaly), but the coronal suture (resulting in brachycephaly) and metopic suture (resulting in trigonocephaly) can also be involved. A bifid uvula (ranging in severity from a remarkable broad uvula, a uvula with raphe, to a clear split uvula) is the mildest form of a cleft palate. Other craniofacial findings are micro-retrognathia, blue sclerae, strabismus, and a high arched palate with dental crowding [42,49–51]. A correlation has been suggested between the severity and extent of craniofacial involvement (craniosynostosis, cleft

palate/abnormal uvula, and hypertelorism) and the age of first cardiovascular event [41]. Ectopia lentis, a cardinal clinical feature in MFS, is not seen in LDS [41]. In LDS type 2, there are no striking craniofacial features, although some patients have an isolated bifid uvula [41,52]. Some subtle facial features are observed: a tall, broad forehead, frontal bossing, a high anterior hair line, hypoplastic supraorbital margins, prominent upper central incisors in late childhood/adulthood, and an open-mouthed, myopathic face. Facies of adult LDS type 2 patients may also appear prematurely aged [52].

Skin findings include velvety, translucent skin with visible veins, and easy bruising [40,41,49]. Wound healing may be delayed, and scars appear dystrophic. Approximately 25% of LDS patients have these cutaneous features, and no craniofacial dysmorphology, and are designated as LDS type 2.

Importantly, the natural history of patients with TGFBR1/2 mutations is far more aggressive than in MFS or vascular EDS, with a mean age at death of 26.1 years. Aortic dissections occur in young childhood and/or at smaller aortic dimensions (<40 mm), and the incidence of pregnancy-related complications is high. However, these aneurysms are amenable to early and aggressive surgical intervention, a clear distinguishing feature from vascular EDS [17]. In congruence with the physiopathology in MFS, a paradoxically enhanced TGFβ signaling was demonstrated, opening perspectives on therapeutic intervention with losartan [15].

Management

Baseline evaluations are recommended to establish the extent of the disease. The aortic root must be measured by echocardiography. As approximately half of the individuals with LDS studied had an aneurysm distant from the aortic root that would have been missed by echocardiography, MRA or CT with 3D reconstruction from head to pelvis must be performed to detect arterial aneurysms throughout the arterial tree. Skeletal investigations should include an X-ray of the cervical spine to look for spine instability. Additional examinations for other manifestations of the disease (such as scoliosis or craniosynostosis) [53] can be guided based on physical examination. As there is no specific treatment for LDS, medical intervention should be focused on symptomatic treatment, prophylactic measures, and genetic counseling. Thorough follow-up of the cardiovascular situation, through echocardiography every 6 months and MRA/CT (frequency guided by initial baseline evaluation), is recommended [54]. As dissection occurs at smaller aortic diameters than observed in, for example, MFS, early and aggressive surgical intervention is a sensible approach [54]. Valve-sparing aortic root replacement using the reimplantation technique is the intervention of choice [55,56]. Because of the risk of patch pseudoaneurysm formation, the side branch technique for arch and visceral vessel reimplantation in arch and thoracoabdominal aortic repairs is advocated for patients with connective tissue disorders [57]. Open repair of descending thoracic and thoracoabdominal aneurysms should be the treatment of choice because the progressive aortic pathology is likely to result in late failures of endovascular repair as fixation zones continue to dilate [58]. Staged replacement of affected aortic segments is indicated, sometimes leading to replacement of the entire aorta [59]. Preventive, aggressive surgical reconstruction [60,61] is still controversial [62]. Beta-blocker therapy reduces hemodynamic stress. Angiotensin receptor blocker therapy may confer a long-term clinical benefit over beta-blocker therapy, similar to the beneficial role of angiotensin II blockade in patients with MFS [63]. Despite normal peripheral blood pressures, progression of aortic disease is seen in young individuals with LDS. Skeletal, craniofacial, and eye manifestations should be treated by a multidisciplinary team. Contact sports, isometric exercises, competitive sports, and activities that cause joint pain/injury should be avoided. Individuals should perform moderate physical activity.

Genetics

LDS is caused by heterozygous mutations in the TGFβ receptor 1 or 2 gene (TGFBR1 or TGFBR2), and is transmitted as an autosomal dominant trait. TGFBR1 is mapped on the long arm of chromosome 9, band 9q33–q34. The locus of TGFBR2 is situated on chromosome 3p22. No clinical difference can be made between patients with mutations in TGFBR1 and TGFBR2. About one-third of the mutations occur *de novo*.

Pathophysiology

Although the precise pathogenetic mechanism remains unclear, TGFβ signaling is enhanced in the presence of heterozygous mutations in TGFβR1 or TGFβR2 in LDS, as evidenced by increased nuclear accumulation of phosphorylated Smad2 (an intracellular mediator of TGFβ signaling) and increased output of TGFβ-responsive genes in aortic walls and aortic cell cultures derived from LDS patients. As in MFS, histology of the aortic wall in LDS patients shows disorganization of the elastic fibers in the aortic media, and increased collagen deposits, also suggestive of increased TGFβ signaling. LDS patients show predominantly medial degeneration of the diffuse type. This disturbance accounts for the propensity for arterial tears or dissections, typical for LDS syndrome.

Although until recently most studies have focused on the canonical TGFβ signaling, there is emerging evidence that non-canonical pathways such as the MAPKs (the mitogen-activated protein kinases) may have a role in aneurysm development. Recent studies observed in the aorta of fibrillin-1 deficient mice that TGFβ and angiotensin II -type 1 receptor (AT1R)-dependent activation of the extracellular-signal regulated kinases (ERK1 and ERK2) are involved in the pathogenesis of aneurysms, and further evidence for their importance was obtained from the abrogation of pathological aortic root growth after treatment with a specific ERK inhibitor [63a,63b].

Osteogenesis imperfecta

Historically, osteogenesis imperfecta (OI) has been viewed as an autosomal disorder of type I collagen, the major protein component in the extracellular matrix of bone. In the past several years, this paradigm of OI has undergone a major shift with the identification of several autosomal recessive forms. The autosomal dominant form is caused by mutations in the COL1A1 (chr 17) and COL1A2 (chr 7) coding for the alpha1 and alpha2 chain of type I collagen, respectively. Type I collagen is the major collagen in bone, which bears the brunt of the disease, but it occurs also in arterial walls and cardiac valves. [64–66]. There are four main autosomal dominant types:

I Normal stature, with bone fractures following minimal trauma, blue sclerae, and hearing loss (50% of families); tendency for decreased fractures with age. Dentinogenesis imperfecta is rare and distinguishes a subset.

II Due to *de novo* mutations, cause of intrauterine or neonatal death with gross bony and cartilaginous abnormalities. Counseling should take into account parental mosaicism.

III Very short stature and multiple fractures, leading to progressive deformity. Dentinogenesis imperfecta and hearing loss are common.

IV Milder form of type I, prominent tibial bowing.

Cardiac involvement is uncommon, and almost invariably affects the left side. Patients may have aortic root dilatation, but dissection and rupture are rare [67,68]. Aortic or mitral regurgitation may occur; mitral valve prolapse occurs, but probably not more frequently than in the normal population. Premature coronary artery disease occurs rarely.

For type V the genetic basis is unknown. In type V, the patients also have a triad of hypertrophic callus, dense metaphyseal bands, and ossification of the interosseus membranes of the forearm. Typical is the distinctive histology with irregular arrangements or a mesh-like appearance of the lamellae. Type VI is characterized by a fish-scale pattern of the lamellae and a decreased bone mineralization secondary to increased osteoid volume. Type VI is autosomal recessive and caused by mutation in the gene FKBP10, coding for FKBP65, a chaperone that participates in type I procollagen folding [69].

Types VII to IX are all severe or neonatally lethal recessive forms of OI. These forms are caused by defects of the collagen prolyl 3-hydroxylation complex [CRTAP coding for cartilage-associated protein, LEPRE-1 coding for the enzyme prolyl 3-hydroxylation (P3H1), and PPIB coding for cyclophylin B] [70–72]. Finally, two other recessive forms have recently been described with mutations in SERPINH1, which encodes the collagen chaperone HSP47 [73], and Osterix, a gene encoding a transcription factor SP7 [74].

Cutis laxa syndromes

Cutis laxa (CL) syndromes are a heterogeneous group of extremely rare connective tissue disorders characterized by an increased number of inelastic skin folds. Clinical classification is based on the mode of inheritance and systemic manifestations. Two major types of CL are important in the context of aortic aneurysm: autosomal dominant CL and type 1 autosomal recessive CL (see Table 67.3).

Autosomal dominant CL was historically considered to be a strictly dermal condition with generalized skin folds, but more recent reports mentioned pulmonary emphysema and aortic root dilatation with dissection in early adulthood [75]. The aortic pathology of these aneurysms was indistinguishable from what is seen in MFS. Mutations in the elastin (ELN) and fibulin 5 (FBLN5) genes have been associated with autosomal dominant CL.

Type 1 autosomal recessive CL is characterized by generalized cutis laxa and severe lung emphysema [76]. Arterial tortuosity with severe fragmentation of the elastic fibers is associated both in humans and mice. So far, genetic defects in patients with autosomal recessive CL are identified in the FBLN4, FBLN5, and LTBP4 genes [77–80].

Pseudoxanthoma elasticum

This rare autosomal recessive disorder of elastic tissue is associated with mutations in the ABCC6 gene on chromosome 16p3.1 [81]. The ABCC6 protein is a member of the ATP-binding transmembrane transporters but the substrate of this transporter is still unknown. There is fragmentation and calcification of elastic fibers [82,83]. The disease affects the skin that shows yellow papules and a crinkled appearance ("plucked chicken skin"). Retinal angiomatoid streaks develop and may interfere with vision. Arterial involvement is widespread and may result in gastrointestinal or other bleeding, renal vascular hypertension, intermittent claudication, or angina pectoris. Mitral valve prolapse is common [84,85]. Severe coronary arterial disease has been recorded in children as young as 8 years of age [86,87]. Restrictive cardiomyopathy has been described [88]. A few patients may have left ventricular hypertrophy, even in the absence of skin changes.

Related syndromic causes of aortic/arterial disease

Arterial Tortuosity Syndrome

Arterial tortuosity syndrome (ATS) is a rare autosomal recessive condition characterized by extensive and generalized tortuosity and aneurysms of the large and medium-sized

arteries, often resulting in death at young age (Table 67.3). Other typical features include stenosis of the pulmonary arteries, characteristic facial features including hypertelorism and bifid uvula, and several systemic connective tissue manifestations including pectus deformity, loose joints, and lax skin [89]. Loss of function of the facilitative glucose transporter GLUT10 (encoded by the SLC2A10 gene) underlies this peculiar phenotype [90]. Although it is surprising that a glucose transporter defect causes abnormal arterial patterning, additional studies indicated up-regulation of the TGFβ signaling pathway [90], consistent with the physiopathology in LDS and MFS.

Congenital contractural arachnodactyly

Congenital contractural arachnodactyly (CCA) or Beals syndrome is characterized by arachnodactyly and slender habitus in which arm span exceeds height. Most affected individuals have "crumpled" ears that present as a folded upper helix of the external ear and most have contractures of major joints (knees and ankles) at birth. The proximal interphalangeal joints also have flexion contractures, as do the toes. Hip contractures, adducted thumbs, and club foot may occur. Most affected individuals have muscular hypoplasia. Contractures usually improve with time. Kyphosis/scoliosis is present in about half of all affected individuals. Progressive enlargement of the ascending aorta at the sinuses of Valsalva has been reported, but there is no evidence that the aortic dilatation progresses to dissection or rupture [91]. FBN2, the gene encoding the extracellular matrix microfibril fibrillin-2, is the only gene known to be associated with CCA [92]. Inheritance is autosomal dominant.

Shprintzen–Goldberg syndrome (SGS)

Another differential diagnosis is Shprintzen–Goldberg syndrome (SGS), a rare craniosynostosis syndrome characterized by marfanoid skeletal features, craniofacial dysmorphism (exophthalmos, hypertelorism, downslanting palpebral fissures, maxillary and mandibular hypoplasia, high arched palate, and low-set ears), and developmental delay. Two SGS patients have been reported with TGFBR mutations; however, both patients were thought to have LDS based on aortic root aneurysm/arterial tortuosity and a bifid uvula or cleft palate [93]. Although SGS and LDS show extensive phenotypic overlap, most patients with SGS do not show vascular involvement. Other distinguishing features of LDS include bifid uvula, cleft palate, arterial tortuosity, and a low incidence of developmental delay.

Other syndromes with possible involvement of the aortic root

Turner syndrome (45,X0), Noonan syndrome (caused by PTPN11, KRAS, or SOS1 mutations), and autosomal dominant polycystic kidney disease (caused by PKD1 or PKD2 mutations) are associated with thoracic aortic aneurysm, but the precise

risk for dissection has not yet been determined. Regular evaluation of the aortic diameters is therefore recommended.

Related non-syndromic causes of aortic/arterial disease

Thoracic Aortic Aneurysm with Bicuspid Aortic Valve (TAA with BAV)

With a prevalence of 1–2%, bicuspid aortic valve (BAV) is one of the most common cardiac malformations of the general population and is found in up to 8% of patients with aortic dissection detected at postmortem examination. Importantly, the aortic dilatation often occurs above the sinuses of Valsalva, and CT or MRI is indicated if echocardiography does not allow good visualization of the ascending aorta. BAV is found in 9% of first-degree relatives of affected individuals, but accurate counseling is complicated by nonpenetrance. Increasing evidence indicates that both aberrant valve formation and aortic root dilatation are the consequences of a common underlying defect. Thus far, mutations have been identified in NOTCH1 and KCNJ2 genes in most patients with additional congenital cardiac malformations [94], but linkage analysis reveals genetic heterogeneity with loci identified on chromosomes 18q, 5q, and 13q [95].

Thoracic aortic aneurysm with patent ductus arteriosus (TAA with PDA)

Following genetic linkage analysis in two large families with a high incidence of TAA in conjunction with PDA, mutations were found in the MYH11 gene encoding the myosin heavy protein 11, a specific contractile protein of smooth muscle cells. The structural defect leads to lower aortic compliance, smooth muscle cell loss, and elastolysis, but the precise pathophysiology remains unclear [96].

Familial thoracic aortic aneurysm and dissection (FTAAD)

TAAD usually presents with no or minor systemic involvement. Importantly, aortic aneurysms in TAAD can also occur distally from the sinuses of Valsalva, warranting imaging of the entire aorta. Clinical presentation is extremely variable with regard to the age of onset and degree of progression of the dilatation. Genetic predisposition is an important etiologic factor because 20% of patients with TAAD have a positive history of familial TAAD (FTAAD) with predominantly autosomal dominant segregation with decreased penetrance.

In contrast to syndromic TAAD, the identification of genetic defects in nonsyndromic forms has only recently been started. Occasional FBN1 mutations have been identified in patients with TAAD, who often show limited skeletal marfanoid involvement and probably represent incomplete expression of the MFS. Genetic mapping studies

demonstrate large genetic heterogeneity with several loci identified so far. Some families are not linked to any of these loci so that other loci must exist. Therefore, it is not always possible to perform clinical diagnostic genetic testing for this syndrome. A first major locus mapped to 5q13–14 in 9/15 families with autosomal dominantly segregating FTAAD with reduced penetrance and 7/11 Finnish families in a subsequent study [97]. A second locus for familial aortic aneurysms, designated FAA1, mapped to 11q23–24 in a single, large family [98], characterized by a more diffuse vascular disease affecting the whole aorta in addition to middle-sized arteries. In the third locus predisposing to TAAD, TAAD2, mapped to 3p24–25 [99], TGFBR2 has been identified as the mutant gene. TGFBR2 mutations were found in 4/80 unrelated families with familial TAAD, making it a relatively rare cause of familial TAAD [100]. Although vascular disease in these families mainly involved the ascending aorta, widespread vascular involvement occurred and other connective tissue findings including pectus deformity and joint hypermobility were observed. It is unknown whether some members of these families had other features of LDS. Subsequently, TGFBR1 mutations were also identified in FTAA families [101]. Finally, mutations in the gene encoding ACTA2, another sarcomeric protein, were found responsible for up to 16% of familial aortic aneurysms. In these families, associated features included iris flocculi, livido reticularis, cerebral aneurysm, bicuspid aortic valves, and persistent ductus arteriosus [102,103].

Familial abdominal aortic dissecting aneurysm

Rupture of aortic aneurysms in adults beyond middle age, with a striking male predominance, is responsible for 1–2% of deaths in industrialized countries and has been attributed to atherosclerosis or hypertension. This attribution has had to be revised because familial aneurysms with a tendency to dissection have been described in the abdominal aorta [104,105]. Although these aortic aneurysms occur in about 1% of the population, patients with an aneurysm are 15 times more likely to have a relative with an aneurysm than is someone of the same age without an aneurysm [106,107]. The aorta shows cystic medial necrosis, sometimes with loss of elastic fibers, but microfibrillar fiber arrays have been normal. In some families, a deficiency of type III collagen was found [104,108]. Some patients have shown increases in serum and leukocyte elastolytic activity [109]. Although most of the dissection has occurred beyond middle age, deaths have occurred in children aged 10–15 years.

Should there be a family history of this disease, annual echocardiographic study of the aortic dimensions should be undertaken, as in MFS. Progressive dilatation of the aorta is a reason to consider surgical replacement of that segment.

There is an animal model of aneurysms in the blotchy mouse [110], which is known to have a deficiency of lysyl oxidase, an enzyme responsible for cross-linking elastin and collagen. Treatment with β-adrenergic blockade reduces the aneurysm formation.

Cardiac Involvement in the Mucopolysaccharide Disorders

Elizabeth A. Braunlin

University of Minnesota, Minneapolis, MN, USA

Introduction

The mucopolysaccharidoses (MPSs) are a group of lethal inherited lysosomal storage diseases that result from the functional deficiency of specific enzymes. These enzymes degrade glycosaminoglycans (GAGs), compounds which are a significant component of the extracellular matrix in all tissues [1,2]. Each type of MPS is defined by the functional absence of a type-specific enzyme causing one or two characteristic GAGs and GAG-degradation products to accumulate (Table 68.1). The GAGs accumulate, generally as proteoglycans (protein-bound GAGs), and mirror their normal somatic occurrence. They account, in general, for the phenotypic differences between the various types of MPS (Table 68.2). Within each type of MPS, numerous distinctive gene mutations have been identified [3–8], which result in variations of the amount of functional enzyme present. These unique mutations partly explain differences in disease severity. The incidence of all types of MPS varies by country or region but is thought to occur in 1/25 000–1/52 000 births [9].

Diagnosis of MPS is established by finding excessive urinary excretion of disease-specific GAGs and the concomitant absence (or marked diminution) of the associated disease-specific enzyme activity within leukocytes [10]. Mutation analysis is usually performed to assess disease severity and prognosis.

The presentation of patients with MPS is highly variable, ranging from nonimmune fetal hydrops [11,12] and cardiomyopathy in infancy [13,14] to relatively asymptomatic adults [15]. The progressive deposition of GAGs in severe forms of MPS produces a classic phenotype that may include coarsening of facial features, growth retardation and bony abnormalities (dysostosis multiplex, short stature, lumbar gibbus, "claw" hands), hepatosplenomegaly, umbilical hernia, thickening and narrowing of airways with noisy breathing, and neurological abnormalities (mental retardation, blindness, deafness, increased intracranial pressure) [10]. Not all phenotypic features are present in each type of MPS, although bony abnormalities and facial dysmorphism are the most consistent features. In attenuated forms, clinical features may be easily overlooked [15].

Cardiac findings in the MPS disorders

Cardiac involvement is common in MPS [16–21], being responsible for >50% of reported deaths in untreated individuals [22]. Progressive deposition of GAGs may result in thickened cardiac valves (regurgitant and/or stenotic) (Figures 68.1 and 68.2), myocardial hypertrophy, cardiomyopathy, diffusely narrowed epicardial coronary arteries with myointimal proliferation (Figure 68.3), dilated aortic root (Figure 68.4) and thickened arterial blood vessels sometimes mimicking coarctation of the aorta. MPS types that accumulate dermatan-sulfated GAGs are most often associated with cardiac valve involvement [16]. Conduction delay and sudden death from complete heart block have been reported [23–25] and apical ventricular aneurysms may occur [26,27]. Congenital anomalies such as ventricular and atrial septal defects have been reported rarely [28,29]. MPS cardiac studies prior to 1975 [30] should be viewed with caution as they lacked supporting biochemical data to establish the specific type of MPS. Cardiac ultrasound studies have been reported for all the mucopolysaccharidoses [16–21]. The incidence of various MPS types within these studies not only reflects those in whom a diagnosis was made (often more severe) but also their country of origin [9,31–33].

Table 68.1 Categorization of the most common types of MPS disorders by common name, enzyme deficiency and accumulated GAG.

MPS subtype	Enzyme deficiency	Accumulated GAG
I (Hurler, Hurler-Scheie, Scheie)	α-L-iduronidase	HS, DS
II (Hunter)	Iduronate-2-sulfatase	HS, DS
III (Sanfilippo)		
A	Heparan sulfamidase	HS
B	N-acetyl-α-D-gluosaminidase	
C	Acetyl-CA-α-gluosaminidase N-acetyltransferase	
D	N-acetylglucosamine-6-sulfatase	
IV (Morquio)		
A	N-acetylgalactosamine-6-sulfatase	KS
B	β-galactosidase	CS, KS
VI (Maroteaux-Lamy)	N-acetylgalactosamine-4-sulfatase	DS
VII (Sly)	β-D-glucuronidase	CS, DS, HS

CS, chondroitin sulfate; DS, dermatan sulfate; HS, heparan sulfate; KS, keratan sulfate.

Table 68.2 Distribution of GAGs.

Type of GAG	Known site of distribution
Chondroitin sulfate (CS)	Cartilage, tendon, ligament, aorta
Dermatan sulfate (DS)	Skin, blood vessels, heart valves, lung interstitium
Heparan sulfate (HS)	Ubiquitous component of extracellular matrix (ECM), basement membrane of vasculature
Keratan sulfate (KS)	Cornea, cartilage, tendons

The cardiac evaluation of individuals with MPS may be difficult because of their lack of cooperation and noisy upper airway sounds that mask the cardiac tones. The absence of cardiac murmurs does not rule out cardiac valvar disease. Measurement of right upper and lower extremity blood pressures should be performed Twelve-lead ECG and two-dimensional cardiac ultrasound with Doppler provide important information about the severity of cardiac GAG accumulation.

The ECG can identify prolonged AV conduction and (rare) acute coronary insufficiency. Cardiac ultrasound is useful in determining chamber size, wall thickness, systolic function and cardiac valve thickening. Doppler interrogation can assess the severity of hemodynamics of cardiac valve abnormalities, estimate right ventricular systolic pressure and identify obstruction within the aorta.

Baseline ECG and cardiac ultrasound should be performed when the diagnosis is established and at regular intervals thereafter regardless of treatment [34,35]. Cardiac ultrasound cannot reliably diagnose coronary artery disease, and no other routinely used test can identify this diffuse myointimal thickening. Intracoronary ultrasound has been successfully used in other types of diffuse coronary myointimal disease, such as cardiac transplant vasculopathy [36] and Fabry disease [37], but currently it remains a research tool. Coronary artery thickening should be suspected in any MPS individual, so baseline troponin and BNP should be obtained, and optimal hemodynamic stability provided if anesthesia is required. Conventional medical management, including diuretics and angiotensin-converting enzyme inhibitors or angiotensin-receptor blockers, may be useful but enzyme replacement therapy has also successfully reversed heart failure in both infants and adults with MPS I [38,39]. Cardiac valve repair or replacement has been reported in all types of MPS [40–53] except MPS VII, the youngest currently being a 6-year-old child with MPS III who underwent mitral valvoplasty for severe mitral regurgitation [46].

MPS I (Hurler, Hurler–Scheie, Scheie syndromes)

MPS I, an autosomal recessive disorder, occurs from the functional absence of α-L-iduronidase, resulting in heparan- and dermatan-sulfated GAGs accumulating

(a)

Figure 68.2 Color flow Doppler modified four-chamber image of the left ventricle of a patient with MPS IV showing aortic regurgitation (arrows).
(b)

Figure 68.1 Two-dimensional cardiac ultrasound short axis views of (a) a normal mitral valve and (b) an MPS VI mitral valve. Note the increased thickness and irregularity of the MPS VI valve (arrows).
Figure 68.3 Left anterior descending coronary artery in a 14-month-old child with MPS I shortly after HSCT. Note myointimal proliferation (arrow) and slit-like coronary lumen (*).

within virtually all organs [1,2]. There are >100 reported mutations of the α-L-iduronidase gene on chromosome 4p16.3 [3,54], explaining the marked phenotypic variability. The incidence of MPS I varies widely by country, ranging from 1/26 000 births in the Irish traveler population of Northern Ireland [31] to about 1/100 000 births in Western Australia and the UK, with 75% of the births resulting in the severe form [9,55]. Currently the preferred terminology is to identify severe (Hurler syndrome) and attenuated (Hurler–Scheie, Scheie syndromes) forms of the disorder [35]. Our understanding of the correlation between disease severity and underlying genotype is incomplete because of the large number of mutations, many of which are "private" (occurring in a single pedigree). However, homozygosity for nonsense mutations such as W402X or Q70X (both of which are common within the US) is known to produce the severe phenotype [54]. Individuals with severe untreated MPS I die within the first decade of life from either cardiac or pulmonary causes, often suddenly, whereas those with untreated attenuated MPS I may live into early adulthood or even middle age [22,55,56].
Figure 68.4 Two-dimensional cardiac ultrasound, long-axis view of the left ventricle and aorta in an adult with MPS I after HSCT, showing dilated aortic root (arrows).

Table 68.3 Systemic therapies available for the MPS disorders.

MPS type	Systemic therapy commonly offered
MPS I – severe (Hurler)	HSCT
MPS I – attenuated (Hurler–Scheie, Scheie)	ERT
MPS II – severe, attenuated (Hunter)	ERT
MPS III A–D (Sanfilippo)	(ERT)[a]
MPS IV (A, B) (Morquio)	(ERT)[a]
MPS VI (Maroteaux–Lamy)	ERT, HSCT[b]
MPS VII (Sly)	–

[a]ERTs (enzyme replacement therapies) for some subtypes of these MPS syndromes are currently under development (2011).
[b]HSCT (hematopoietic stem cell transplantation) is offered for failure of ERT.

Cardiac valve involvement (mitral and aortic) occurs in 80–100% in severe MPS I [16–20], often within the first year of life [57]. In attenuated MPS I, cardiac valve pathology may initially be less severe, but the valves become severely affected from progressive accumulation of GAGs [58]. Coronary artery stenosis or occlusion from GAG deposition within the myointima occurs within the first year of life in severe forms [59] and has been reported by late adolescence in attenuated MPS I [58]. The incidence and severity of coronary artery disease in untreated attenuated MPS I are unknown, but likely underestimated. Ventricular hypertrophy is common in MPS I; systolic ventricular function is usually normal, although a rare infant presents with dilated cardiomyopathy [38]. Progressive prolongation of atrioventricular conduction is uncommon but important.

Conventional cardiac surgical procedures have included mitral or combined mitral and aortic valve replacement [40–42] and repair of coarctation of the aorta in a 2-year-old after successful bone marrow transplantation [60].

Bone marrow or hematopoietic stem cell transplantation (HSCT) has been performed for over 30 years in infants and toddlers with severe MPS I (Table 68.3) [61]. The procedure has markedly increased the lifespan and arrested the associated neurological decline [62,63]. The HSCT procedure has a 10–15% early mortality [64], but after the peritransplant period (about 18 months), the risk of dying is exceptionally low [55]. Enzyme replacement therapy (ERT) has become available for MPS I but is generally not used as the sole therapy for severe forms of MPS I because it does not cross the blood–brain barrier [63]. With successful engraftment, cardiac hypertrophy regresses, ventricular function is preserved, and coronary artery obstruction appears arrested, or perhaps reversed [65,66]. The cardiac valves remain thickened and valve dysfunction may progress despite successful engraftment [65].

ERT has been approved for use in the USA since 2003 [67] for MPS I (laronidase, Aldurazyme). Phase III studies showed a significant improvement in pulmonary function tests and the 6 min walk for those participating in the company-sponsored trials. The cardiac effects of ERT in a small series [68] show preserved ventricular function and diminished ventricular hypertrophy, but cardiac valves remain thickened and dysfunctional. Reports detailing sudden death after 2 years of ERT with evidence of acute myocardial infarction underscore the importance of evaluating coronary artery status prior to treatment [69]. As experience with ERT has increased, studies in siblings with attenuated MPS and the same genetic mutation have shown that the clinical outcome of treatment begun soon after birth is significantly better than when treatment is delayed until 2–3 years of age [70]. A similar favorable outcome in MPS VI [71] has generated strong interest in newborn screening for the MPS disorders [72].

MPS II (Hunter syndrome – severe and attenuated)

MPS II, an X-linked disorder, occurs from the functional absence of iduronate-2-sulfatase and results in the systemic accumulation of heparan- and dermatan-sulfated GAGs [1,2]. More than 150 mutations of the iduronate-2-sulfatase gene on chromosome Xq28 have been reported [73]. MPS II is reported to occur in 1/320 000 births (1/165 000 male births) in Western Australia [9]. Hunter syndrome is divided into forms based upon the presence (severe) or absence (attenuated) of CNS involvement [73]. At present, genotype–phenotype correlation is imperfect in MPS II with the exception that the complete absence of functional enzyme

from either gene deletion or complex gene rearrangements results in the severe phenotype and the specific mutation c.1122C>T results in a mild phenotype [74]. Respiratory [73] or cardiac [75] causes account for most deaths in MPS II – within the second decade of life for severely affected and in adulthood for untreated attenuated disease [76].

Cardiac valve involvement is common in both severe and attenuated MPS II, occurring in 60–80% [16,77], with the mitral valve more often affected than the aortic. Coronary artery disease has unknown incidence but is found at postmortem examination, and likely under-reported clinically [75,27]. Ventricular hypertrophy is common and systolic ventricular function is usually normal. A large apical left ventricular aneurysm has been reported in a few patients [27]. Complete heart block and sudden death may occur from deposition of GAG within the conduction system [23].

HSCT has been performed in a small number of boys >3 years of age [78] and a 10-month-old infant [79] with MPS II. Despite successful engraftment, neurologic status continued to deteriorate in the severe form. Cardiac valve abnormalities stabilized after transplantation and neither cardiomyopathy nor myocardial infarction was reported in >17 years of follow-up [78].

Commercially available enzyme replacement for MPS II (idursulfase, Elaprase) became available in 2006 after significant improvements in pulmonary function testing and 6 min walk was demonstrated in nearly 100 individuals over a 3 year period [80]. There is sparse information on the effect of ERT upon the heart in MPS II. No change in cardiac valve findings was found in 10 adult men (>20 years of age) with clinically advanced MPS II who received ERT for 12 months [81]. Cardiac function was preserved in all but one individual with cardiomyopathy at baseline (EF of 27%) who deteriorated further (EF of 14%) during the study. As expected, LV mass was elevated at baseline and, although it decreased by 12.4% over 12 months, this was not statistically significant.

MPS III A, B, C, D (Sanfilippo syndrome)

MPS III, an autosomal recessive disorder, has four known subtypes – A, B, C and D – each resulting from the functional absence of a specific enzyme responsible for the degradation of heparan sulfate [1,2,82]. For each known subtype, the enzyme and its chromosome differ: MPS IIIA (heparan *N*-sulfatase, chromosome 17q25.3), MPS IIIB (*N*-acetylglucosaminidase, chromosome 17q21.1), MPS IIIC (acetyl-CoA glucosaminide *N*-acetyl transferase, chromosome 8p11.1), and MPS IIID (*N*-acetylglucosamine-6-sulfatase, chromosome 12q14). MPS III is the most common type of MPS, occurring in 1/58 000 births with subtypes MPS IIIA and IIIB the most frequent [9,82]. Both severe and attenuated forms of MPS III have been described from mutation analysis of

individuals with MPS IIIA, IIIB, and IIIC [83–85]. Life expectancy for severely affected individuals is between one and two decades [82], whereas those with attenuated disease may live into late adulthood [86]. Existing cardiac studies are reported without regard to subtype of MPS III.

Sanfilippo syndrome primarily affects the central nervous system and has been divided into three clinical phases [82]. The first phase is developmental delay beginning after 1–2 years of life. This is followed by progressive behavioral problems, mental deterioration, and ultimately dementia. In the third phase, neurological issues lessen while spasticity and motor difficulties, including swallowing problems, emerge and progress to death that is most often from pneumonia.

Cardiac disease has been considered uncommon in MPS III but this may be inaccurate. Cardiac ultrasound studies of large numbers of MPS III patients found morphologic and functional changes in >50–66% of mitral and 20–30% of aortic valves [16,18]. Multiple isolated reports [46,87–91] confirm that cardiac valve disease is common in MPS III. Diffuse coronary artery stenosis from myointimal proliferation has been reported from postmortem examination [89–91]. Fragmentation of collagen and the presence of GAG-laden cells have been found in the aorta and great vessels [91,92]. Ventricular hypertrophy is common and cardiomyopathy leading to cardiac transplantation may occur [16,86]. Successful mitral valvoplasty was performed in a 6-year-old child with MPS III [46].

HSCT has been performed in a few of these children, but the extent of neurologic benefit is unknown and the procedure remains investigational [63]. No cardiac follow-up after HSCT has been reported. No ERT therapy is currently available in MPS III. Genistein, a naturally occurring isoflavone that decreases synthesis of GAGs, appears to improve or stabilize neurocognitive function [93,94], but cardiac effects of genistein are unreported.

MPS IV (A, B) (Morquio syndrome)

MPS IV, an autosomal recessive disorder, has two known subtypes – A and B – each resulting from the functional absence of specific enzymes for the degradation of keratan sulfate [1,2]. The enzyme and its chromosome differ: MPS IV A (*N*-acetylgalactosamine-6-sulfate sulfatase, gene locus 16q24.3) and MPS IB B (β-galatosidase, gene locus 3p21.33) [2]. More than 150 mutations of the sulfatase gene have been identified [95], but mutation analysis of the β-galatosidase gene is more complex [96]. MPS IV is rare, ranging in incidence from 1/216 000 to 1/641 178 births [9], although it is the most common type of MPS found in Saudi Arabia [97]. MPS IV A is more common than MPS IV B. Life expectancy for severe forms of MPS IV is two to three decades whereas those with milder forms may live into the seventh

decade [95]. Individuals with MPS IV manifest skeletal abnormalities of dwarfism, pectus carinatum, and odontoid hypoplasia, the last sometimes responsible for paralysis and death. Quadriparesis has occurred as a consequence of perioperative atlanto-occipital subluxation. With rare exception, individuals with MPS IV have normal intelligence and mild facial dysmorphism.

Cardiac valvar disease is a prominent feature of MPS IV: isolated mitral valvar disease is uncommon but combined mitral and aortic valve abnormalities occur in 60–100% of those studied with MPS IV [16,98]. Coronary artery involvement with the classic features of MPS-type of myointimal proliferation occurred in a 15-year-old male [99] but not in a 48-year-old woman [100] with MPS IV. Biventricular hypertrophy and cardiomyopathy have been reported. Nonimmune fetal hydrops has been associated with MPS IV A [11,101]. Aortic valve replacement has been performed in adults with MPS IV [47,48]. Aortic valve replacement was required in an adult with MPS IV B 12 years after performance of the Ross procedure for aortic regurgitation [49].

Neither HSCT nor ERT has been reported in MPS IV and remains investigational [63].

MPS VI (Maroteaux–Lamy)

MPS VI, an autosomal recessive disorder, occurs from the functional absence of *N*-acetylgalactosamine-4-sulfatase (arylsulfatase B) and results in the systemic accumulation of dermatan-sulfated GAGs [1,2]. More than 100 mutations of the arylsulfatase gene on chromosome 5q11–q13 have been reported. [7]. The incidence of MPS VI varies widely by region from 1/43 261 births of Turkish immigrants living in Germany to 1/1 505 160 births in Sweden [102].A high prevalence of MPS VI in Brazil is attributed to an increase of one specific mutation, a finding referred to as the "founder effect." The clinical presentation of MPS VI has been divided into rapidly and slowly progressing subtypes and correlated with excretion of urinary GAG [103]. Urinary GAG levels of >200 μg mg⁻¹ creatinine are associated with a rapidly progressing phenotype manifested by small stature, impaired endurance, compromised pulmonary function, and reduced joint range of motion. The paucity of subjects over 20 years of age who excrete GAG levels >100 μg mg⁻¹ creatinine suggests that they do not commonly survive beyond age 20 years.

Cardiac valve disease occurs commonly in MPS VI [16,18,20] and generally involves both mitral and aortic valves, although the aortic valve may be less severely affected. Coronary artery disease has been reported in adults with MPS VI [50], but histopathologic evidence for MPS-type myointimal proliferation of epicardial coronary arteries is not available. In an adult with MPS VI and apical left ventricular aneurysm [26], the small coronary vessels were occluded by myointimal proliferation. Ventricular hypertrophy is common and congestive heart failure in infants has been reported [13,104]. Development of complete heart block requiring permanent pacemaker placement [24] and fibrosis of the conduction system [105] occur in MPS VI. Successful mitral [52], aortic [50], and combined aortic and mitral valve [51,53] replacement have been reported.

HSCT has improved myocardial function and relieved hypertrophy in a small series of individuals [106], but neither HSCT nor umbilical cord stem cell transplantation [107] reverse valve pathology. Cardiac findings after ERT (Naglazyme) in MPS VI have not been reported.

MPS VII (Sly syndrome)

MPS VII, an autosomal recessive disorder, occurs from the functional absence of β-glucuronidase and results in the systemic accumulation of dermatan-, heparan-, and chondroitin-sulfated GAGs [1,2]. Nearly 50 mutations of the β-glucuoronidase gene on gene locus 7q21.11 have been reported [108]. Sly syndrome is the rarest MPS disorder, calculated to be 1/345 000 births [33]. The clinical presentation is extremely variable, with dwarfism, dysostosis multiplex, and facial dysmorphology being common [109]. Nonimmune hydrops in fetuses with MPS VII occurs much more frequently than expected for such a rare disease [12,110–113].

The cardiac features are not well studied. Marked thickening and fibrosis of mitral and aortic valves with arterial stenoses from lysosomal storage material were found at autopsy from the first reported patient with MPS VII [114]. A 6-month-old child with MPS VII was found to have congestive heart failure from a thickened, prolapsing mitral valve with severe mitral regurgitation [115], and a 17-month-old child with MPS VII had dilated cardiomyopathy [116]. Sudden death has been reported in adults but without documentation for arrhythmia or atrioventricular block [117]. Diffuse hypoplasia of the thoraco-abdominal aorta occurred in a child with MPS VII and required a jump-graft for repair [118].

HSCT has been performed in a 12-year-old girl [119] with notable improvements in motor function but moderate aortic and mitral valve regurgitation remained unchanged despite successful engraftment. ERT is unavailable for MPS VII.

Conclusion

Glycosaminoglycans are ubiquitous substances that occur normally within the cardiac valves, the coronary arteries, the myocardium, and the great vessels. Cardiac valve thickening and dysfunction, coronary artery stenosis, ventricular hypertrophy, cardiomyopathy, and great vessel involvement occur from the genetic absence of lysosomal enzymes that catabolize GAGs. Awareness of potential for

progressive cardiac involvement in each MPS disorder is key to management. Conventional medical and surgical management has been useful but not curative in MPS. Systemic therapies such as HSCT and ERT preserve ventricular function, decrease ventricular hypertrophy, improve ventricular function, and arrest or reverse coronary artery disease, but do not appear to affect the cardiac valves. Systemic therapies within the first few weeks of life appear to prevent the development of cardiac pathology. The development of newborn screening for these uncommon, but devastating, diseases is an important next step.

Cardiovascular Manifestations of Pediatric Rheumatic Diseases

Bryce A. Binstadt

University of Minnesota, Minneapolis, MN, USA

Cardiovascular pathology can accompany most if not all rheumatic diseases due to pathogenic links between chronic inflammation and vascular endothelial injury. In the short term, cardiac involvement leads to greater morbidity and mortality in patients with pediatric rheumatic diseases. Perhaps more importantly, the onset of rheumatic diseases in children portends life-long exposure to vascular inflammation, a known risk factor for atherosclerotic coronary heart disease, as exemplified in adults with systemic lupus erythematosus (SLE) or rheumatoid arthritis [1,2].

This chapter discusses the cardiovascular complications of many childhood rheumatic diseases, including juvenile arthritis (including spondylitis), SLE, neonatal lupus, vasculitis, juvenile dermatomyositis, scleroderma, sarcoidosis, and Lyme disease. An additional section focuses on drug-induced lupus and also the cardiac side effects of certain immunosuppressive medications. Two key pediatric rheumatic diseases conspicuously absent from this chapter are discussed elsewhere in the book: rheumatic carditis (Chapters 61 and 62) and Kawasaki disease (Chapter 63). The diseases discussed in this chapter are depicted in Table 69.1, along with the most common sites of cardiac involvement.

Juvenile idiopathic arthritis

Juvenile idiopathic arthritis (JIA) is the current preferred term for what was known as juvenile rheumatoid arthritis (JRA) and juvenile chronic arthritis (JCA) [3]. JIA is defined as arthritis of unknown etiology that begins before the sixteenth birthday and persists for at least 6 weeks. The most recent classification scheme recognizes seven subtypes of JIA: systemic arthritis, oligoarthritis, polyarthritis (rheumatoid factor negative), polyarthritis (rheumatoid factor positive), psoriatic arthritis, enthesitis-related arthritis, and undifferentiated

arthritis (Table 69.1). Many pediatric rheumatologists continue to use the term "pauciarticular" arthritis rather than the newer "oligoarthritis." Cardiac involvement has been estimated to occur in 4.7–7.6% of patients with juvenile arthritis [4,5].

Systemic arthritis

Despite being the least common form of childhood arthritis, this is the subtype of JIA most often associated with cardiac involvement, and the only subtype for which cardiac involvement is a part of the diagnostic criteria. Systemic arthritis is characterized by arthritis in any number of joints, spiking fevers, and at least one of the following: a characteristic evanescent rash, lymph node enlargement, hepatomegaly and/or splenomegaly, or serositis (pericarditis or pleuritis).

Pericarditis, the most common cardiac manifestation in systemic arthritis, may occur at disease onset or with flares of disease. It can be asymptomatic or may cause dyspnea or chest pain. Findings can include tachycardia, a friction rub, and tachypnea. Electrocardiography or radiographs may provide clues to the diagnosis by showing T-wave abnormalities or cardiomegaly, but echocardiography is the standard diagnostic modality [6]. Pericardiectomy is sometimes required [7]. Progression to cardiac tamponade is rare but serious and may require urgent pericardiocentesis in addition to immunosuppressive therapy [8] (see Chapter 59).

Myocardial and endocardial involvement are much less common but are poor prognostic signs. Myocardial involvement may lead to cardiac dysfunction and death [4,5,9]. Aortic regurgitation has also been reported [10,11] and may require valve replacement [7].

During their initial presentation with fever, some patients have dilated coronary arteries [12], discovered typically when echocardiograms are performed to evaluate possible Kawasaki disease. The overlapping clinical features of systemic arthritis and Kawasaki disease may lead to diagnostic

Table 69.1 Pediatric rheumatic conditions affecting the heart. This table lists those diseases discussed in this chapter, with their most common anatomic sites of cardiac involvement depicted by shading. Black shading indicates common or well-recognized sites of involvement. Gray shading indicates less common sites of involvement. No shading indicates sites rarely involved.

Condition	Pericardium	Myocardium and conduction system	Valves	Coronary arteries	Other vessels
Juvenile idiopathic arthritis					
Systemic arthritis	●			○	○

Lyme disease		●			

confusion [13], and systemic arthritis should be considered in the differential diagnosis of patients who do not respond appropriately to therapy for Kawasaki disease.

Finally, patients with systemic arthritis are at risk for developing macrophage activation syndrome (MAS), a serious complication characterized by high fevers, hematologic cytopenias, and elevated liver enzymes, among other features [14]. Multi-organ failure may ensue, including, in the author's experience, profound yet reversible cardiac involvement in the form of asystole, requiring extracorporeal membrane oxygenation. Prompt recognition and aggressive treatment of MAS are essential.

The management of the cardiac manifestations of systemic arthritis depends on adequately controlling the systemic inflammatory state in close collaboration with a pediatric rheumatologist.

Polyarthritis and oligoarthritis

These forms of JIA are distinguished by the number of joints involved in the first 6 months of disease: <5 in oligoarthritis, and ≥5 in polyarthritis [3]. The rheumatoid factor positive variant of juvenile polyarthritis is indistinguishable from rheumatoid arthritis in adults. Cardiac involvement is rare among these children. Regurgitation of the aortic and/or mitral valves occurs and may require valve replacement surgery [15–17]. In addition, echocardiographic evaluation of JIA patients without cardiac symptoms can reveal systolic or diastolic dysfunction [18].

Adults with rheumatoid arthritis are at increased risk of coronary heart disease and sudden cardiac death [1]. This risk presumably extends to patients whose arthritis begins during childhood, and is hypothetically greater given their potentially longer duration of exposure to chronic inflammation. American Heart Association guidelines consider children with chronic inflammatory diseases, including JIA, at moderate risk for premature cardiovascular disease. These guidelines recommend careful identification and modification and/or treatment of traditional cardiovascular risk factors (fasting lipid profile, smoking history, family history of coronary artery disease, blood pressure, body mass index, fasting glucose, and physical activity history) and also optimal control of the arthritis [19].

Routine aerobic exercise should be encouraged for nearly all children with JIA.

Enthesitis-related arthritis

This subtype of JIA includes diseases traditionally considered under the heading "spondyloarthropathy," such as juvenile ankylosing spondylitis and HLA B27-associated juvenile arthritis. The term "enthesitis" refers to inflammation of the insertion sites of tendons or ligaments to bone. Additional features include involvement of the axial skeleton and sacroiliac joints, the HLA-B27 allele in many patients, a predominance of male patients (>6 years old), acute symptomatic anterior uveitis (red eye), and a family history of similar diseases including Reiter syndrome and inflammatory bowel disease [3].

Aortic regurgitation is the main cardiac concern in this group, but is much more common in adults than in children [20,21]. In one study of 36 patients with juvenile ankylosing spondylitis, none had cardiac symptoms, and only one had a murmur of aortic regurgitation. Three patients (8%) had mild aortic regurgitation and two had mild mitral regurgitation detected by echocardiogram [22]. In a separate study, aortic regurgitation was detected in 10% of 40 patents with HLA B27-associated juvenile arthritis [21]. Additional cardiac complications in adults with ankylosing spondylitis include conduction disturbances [23] and cardiomyopathy [20]. Baseline echocardiograms and electrocardiograms in these patients seem prudent even for asymptomatic patients [21], especially when transitioning from pediatric to adult care.

Psoriatic arthritis

Similarly to rheumatoid arthritis, adults with psoriasis or psoriatic arthritis are at increased risk for coronary heart disease and cerebrovascular accidents, thought to be related to chronic inflammation [24,25]. Therefore, children with psoriatic arthritis should be considered at moderate risk for premature cardiovascular disease and counseled accordingly (see the section Polyarthritis and Oligoarthritis above) [19].

Systemic lupus erythematosus

SLE is a multi-system autoantibody-associated disease that predominantly affects females. About 15% of SLE patients present during childhood, typically adolescence. SLE can affect nearly all tissues of the body. The numerous clinical and laboratory features of pediatric SLE are have recently been summarized [26]. In one large series of pediatric SLE, nearly half of the patients had cardiovascular involvement [27]. Raynaud's phenomenon is a common vascular manifestation of pediatric SLE, occurring in around one-fifth of patients, often at the time of diagnosis [26]. Raynaud's phenomenon may also indicate the presence of antiphospholipid antibodies, either primary or secondary to SLE [28].

Pericarditis is the only cardiac manifestation among the classification criteria for SLE, and occurs in 15–28.7% of pediatric patients [26,27,29,30]. It may occur with myocarditis, and rarely causes tamponade [30]. Anti-Ro (SS-A) and anti-La (SS-B) antibodies are detected more often in patients with cardiac involvement [30]. Pericardiectomy or creating a pericardial window might be necessary [7].

Isolated myocarditis occurs in 2–3% of pediatric SLE patients [26,30]. Cardiomegaly has been reported, however, in one-third of patients [27]. Furthermore, impaired myocardial perfusion was reported in five of 31(16%) children with SLE [31] and a similar percentage of patients have abnormalities of diastolic or systolic function [29,32]. Although myocardial involvement is often asymptomatic, congestive heart failure and arrhythmias may occur [27].

Valvar regurgitation has been reported in 20–36% of patients with pediatric SLE [29,32]. Non-infectious vegetations (Libman–Sacks endocarditis) are detected much less commonly [26], but can lead to microembolic cerebrovascular events and rarely valve regurgitation. Valve repair or replacement is the most common reason for cardiac surgery among patients with pediatric SLE [7].

Improved medical management of SLE has increased longevity, focusing attention on the long-term cardiovascular risks of SLE and its therapies [33]. Women with SLE 35–44 years of age have a 50-fold increase in incidence of myocardial infarction relative to healthy controls [34]. Younger patients are not spared; a recent literature review found 50 reports of acute myocardial infarction in SLE patients <36 years of age, including one in a 5-year-old child [35]. Patients with SLE have specific risk factors for the development of coronary artery disease, and chronic systemic inflammation alone seems to be a major driver of premature atherosclerosis [19,36,37]. The specific risk factors for premature coronary artery disease among pediatric patients with SLE include prothrombotic antiphospholipid antibodies (in 45% of patients [26]), nephritis resulting in nephrotic-range proteinuria [38] and hypertension [38,39], and dyslipidemia [40]. Corticosteroid therapy and physical inactivity (resulting from SLE disease activity) can lead to both hypertension and obesity, further increasing the risk of cardiovascular events. These concerns are detailed more extensively in a statement from the American Heart Association [19]. Children with SLE are at moderate risk for premature cardiovascular disease. As discussed in the section on juvenile arthritis, optimizing immunosuppressive and other medical management of the underlying disease and identifying and reducing traditional risk factor exposure are recommended [19]. It is reasonable for pediatric SLE patients to have echocardiograms periodically, paying particular attention to the pericardium, valves, and contractility. In addition to aggressively tailoring immunosuppressive therapy to control SLE disease activity, vigilance regarding the patient's antiphospholipid antibody status is necessary, and might include the use of

low-dose aspirin in patients without symptoms or more aggressive anticoagulation with heparin and then warfarin in patients with documented thrombotic events.

Neonatal lupus

Transplacental passage of anti-Ro (SS-A) and/or anti-La (SS-B) antibodies can cause neonatal lupus. The primary concern in affected infants is irreversible complete congenital heart block (CHB) due to antibody-mediated myocardial damage. The risk of congenital heart block among fetuses of women with anti-Ro antibodies is 2%, but this risk is increased 10-fold among women with a prior affected infant. Reversible rash occurs in 10–20% of infants, and hematologic and/or hepatic abnormalities in one-quarter; these aspects of the disease are transient. Congenital cardiac anomalies also seem more common in affected infants [41]. Mothers may be asymptomatic without evidence of SLE or a related disorder (Sjogren syndrome, mixed connective tissue disease), but up to half of them may develop symptoms subsequently [42].

The development of CHB can occur quickly during pregnancy and can lead to life-threatening cardiac dysfunction. Unfortunately, CHB, once identified, is not reversible. Efforts are therefore focused on early detection during pregnancy (via frequent echocardiograms and sonograms) and preventing the progression of heart block to cardiomyopathy by immunomodulatory agents, such as corticosteroids or intravenous immunoglobulin [43]. Involvement of a fetal–maternal medicine specialist is recommended. Prompt pacemaker implantation after delivery is often necessary [7]. Additional information regarding management is provided in Chapter 55.

Vasculitis

Vascular inflammation is the hallmark of several named diseases whose fundamental etiologies remain undefined (Table 69.2). The vasculitidies are classified according to the size and type of the vessels most often affected (Figure 69.1 and Table 69.2). Additional categorization criteria include primary vasculitis (not associated with another disease) versus vasculitis that occurs secondary to other rheumatic conditions (such as SLE, dermatomyositis, or JIA). The presence or absence of anti-neutrophil cytoplasmic antibodies (ANCAs) and the specific antigen against which those antibodies are directed also are used in classification (Table 69.2). The vasculitidies can affect virtually any organ system and, within the heart, any structure can be affected.

This section highlights the more common pediatric vasculitidies in which cardiac complications arise. Kawasaki disease, the most common childhood vasculitis associated with cardiac sequelae, is discussed in Chapter 63.

As a guiding principle, clinicians should recognize the potential for cardiac involvement in a child with any form of

Table 69.2 Major categories of noninfectious vasculitis[a].

Large-vessel vasculitis
Giant-cell arteritis
Takayasu's arteritis
Medium-sized vessel vasculitis
Polyarteritis nodosa
Kawasaki's disease
Primary granulomatous central nervous system vasculitis
Small-vessel vasculitis
ANCA-associated small-vessel vasculitis
Microscopic polyangiitis
Wegener's granulomatosis
Churg–Strauss syndrome
Drug-induced ANCA-associated vasculitis
Immune-complex small-vessel vasculitis
Henoch–Schönlein purpura
Cryoglobulinemic vasculitis
Lupus vasculitis
Rheumatoid vasculitis
Sjögren's syndrome vasculitis
Hypocomplementemic urticarial vasculitis
Behçet disease
Goodpasture syndrome
Serum-sickness vasculitis
Drug-induced immune-complex vasculitis
Infection-induced immune-complex vasculitis
Paraneoplastic small-vessel vasculitis
Lymphoproliferative neoplasm-induced vasculitis
Myeloproliferative neoplasm-induced vasculitis
Carcinoma-induced vasculitis
Inflammatory bowel disease vasculitis

[a]Vascular inflammation is categorized as either infectious vasculitis, which is caused by the direct invasion of vessel walls by pathogens (e.g., rickettsial organisms in Rocky Mountain spotted fever), or noninfectious vasculitis, which is not caused by the direct invasion of vessel walls by pathogens (although infections can indirectly induce noninfectious vasculitis, e.g., by generating pathogenic immune complexes). ANCA denotes antineutrophil cytoplasmic autoantibody.

vasculitis. Similarly, finding unexplained cardiac or vascular inflammatory disease should prompt a careful diagnostic search for systemic vasculitidies and consultation with a pediatric rheumatologist.

Wegener's granulomatosis

Wegener's granulomatosis, a necrotizing vasculitis, affects the paranasal sinuses, lungs, and kidneys and is usually associated with anti-proteinase 3 (anti-PR3) ANCA (c-ANCA). This uncommon disease in children can be severe. Cardiac complications include valvar disease, ischemic heart disease, and pericarditis [44–46]. Aggressive immunosuppression
Figure 69.1 Preferred sites of vascular involvement by selected vasculitidies. The widths of the trapezoids indicate the frequencies of involvement of various portions of the vasculature. LCA denotes leukocytoclastic angiitis. (Reproduced with permission from Jennette JC, Falk RJ, *N Engl J Med* 1997;**337**:1512–23. Copyright © Massachusetts Medical Society. All rights reserved.)

with high-dose corticosteroids and cyclophosphamide is typically required to control the disease.

Churg–Strauss Syndrome (CSS)

CSS is an eosinophilic vasculitis that usually presents as severe asthma with peripheral blood eosinophilia. ANCAs are present in some patients and may be either anti-PR3 (c-ANCA) or anti-myeloperoxidase (anti-MPO, p-ANCA). Cardiac disease is a major cause of death in this disease. In a study of 49 adult patients, 22 had evidence of cardiac involvement with impaired left ventricular function (50%), valvar regurgitation (73%), pericardial effusions (41%), and endomyocarditis (59%). Patients with endomyocarditis had a more severe outcome, and two deaths due to severe cardiomyopathy and heart failure occurred [47]. Intriguingly, cardiac involvement was associated with the *absence* of ANCAs in this series [47]. Zwerina *et al.* compared 33 children with CSS with published series of adult CSS. The incidence of pericarditis was similar in both age groups (~25%), but cardiomyopathy occurred more commonly in children than in adults (42% versus 24%, $p = 0.04$) [48]. Six of the 33 children with CSS died, three from cardiac causes [48]. Aggressive immunosuppression is required, as with Wegener's granulomatosis.

Polyarteritis nodosa (PAN)

PAN is a necrotizing vasculitis predominantly affecting medium-sized arteries, including the coronary arteries. In adults, PAN may occur in conjunction with viral hepatitis, but in children PAN is typically idiopathic. A study of 15 children with PAN reported asymptomatic diminished left ventricular systolic function and mitral and/or tricuspid regurgitation as the most common cardiac complications [49]. Additional reported complications include pericarditis and myocardial infarction. Again, aggressive immunosuppression is indicated.

Takayasu's arteritis

Takayasu's arteritis, a giant cell arteritis, affects large arteries including the aorta and its main branches, including the coronary arteries. The affected arteries may be either stenotic or aneurysmal. Involvement of the base of the aorta may lead to aortic regurgitation. It affects any age group, but mainly teenage girls.

A high degree of clinical suspicion is necessary to make the diagnosis. Presenting symptoms may relate to peripheral vascular occlusion (e.g., syncope, dizziness, claudication), coronary artery narrowing (chest pain), headache (due to renal artery stenosis and hypertension), or abdominal pain due to mesenteric artery ischemia. Absence of pulses ("pulseless disease") is a crucial diagnostic sign, along with bruits or the murmur of aortic regurgitation [50]. Life-threatening complications may occur in children, including aortic dissection [51] and sudden cardiac arrest [52], sometimes as the presenting manifestation.

When Takayasu's arteritis is suspected, echocardiography is indicated in addition to extensive angiography (magnetic

resonance and/or conventional) to determine which vessels are affected.

Cogan syndrome

This rare vasculitis causes autoimmune eye disease (keratitis most commonly), sensorineural hearing loss, and large vessel vasculitis, particularly affecting the aorta, although other arteries can be involved. Surgical repair of aortic aneurysms in an adolescent has been reported [53].

Behçet disease

Behçet disease is a primary vasculitis that can affect both arteries and veins. Symptoms include recurrent oral ulceration, genital ulceration, uveitis, and dermatologic findings (e.g., erythema nodosum). Thrombosis, the main cardiovascular complication, can occur in superficial veins, the venous sinuses, pulmonary arteries, and even within the atria or ventricles [54,55]. Aneurysms of the great vessels occur in children, and may lead to myocardial infarction [54,56]. Arrhythmias may also arise [57]. Treatment with corticosteroids, colchicine, cyclophosphamide, or azathioprine and anticoagulation can be helpful [54].

Cardiac conditions mimicking vasculitis

Patients with cardiac myxomas may present with dermatologic findings similar to those seen in patients with vasculitis (e.g., petechiae, purpura, livedo reticular, ulcerations, digital necrosis) [58]. This rare condition should therefore be considered in the patient with suspected vasculitis.

Juvenile dermatomyositis

Children with dermatomyositis have proximal muscle weakness and characteristic dermatologic findings, including a heliotrope rash and Gottron's papules. In contrast to the adult form of the disease, juvenile dermatomyositis is rarely associated with malignancies. Aggressive immunosuppressive management is indicated, and can lead to complete resolution [59]. Although not formally considered under the rubric of vasculitis, the primary pathologic process is small vessel inflammation, including capillaries. Many other organ systems can be affected, including life-threatening gastrointestinal and pulmonary disease. Renal involvement is rare. Cardiac involvement occurs rarely in children and may reflect microvascular involvement. Reported cardiac complications include myocarditis, arrhythmias, and pericarditis [60,61].

Some authors have suggested that the nailfold capillary abnormalities, such as loop formation, tufting, and drop-out, that occur in this disease and others (systemic sclerosis, SLE, and the antiphospholipid antibody syndrome) might indicate systemic microvascular involvement, including those vessels perfusing the myocardium [62].

Systemic sclerosis (scleroderma)

Although rare in children, systemic sclerosis is a life-threatening disease whose mortality is often attributable to cardiac involvement [63–66]. The disease is characterized by fibrosis of skin and other organs, including the pericardium, myocardium, and pulmonary parenchyma. Raynaud's phenomenon is common, reflecting obstruction of the digital arteries. Similar vascular occlusion underlies the pathology in the affected internal organs. Thus, the disease has multiple pathogenic pathways, including autoimmune, fibrotic, and endothelial abnormalities. Importantly, some patients initially diagnosed with mixed connective tissue disease may progress over time to a disease course indistinguishable from systemic sclerosis.

Cardiac complications are numerous, including pericarditis, decreased myocardial perfusion in association with dilated cardiomyopathy, and rhythm abnormalities [63,64,67]. Pulmonary involvement is nearly universal, and can lead to significant pulmonary hypertension. Systemic hypertension also occurs due to renal involvement, and may be severe ("scleroderma renal crisis") [68].

Systemic sclerosis is perhaps the most challenging rheumatic disease to treat. Therapies directed against the autoimmune, fibrotic, and vascular aspects of the disease have been tried [69]. Traditionally, aggressive immunosuppressive therapy is used, including cyclophosphamide and other agents. Newer biologic immunosuppressive drugs, including anti-tumor necrosis factor (TNF) agents and B lymphocyte depleting therapy, have also been studied. For patients with severe disease, autologous stem cell transplantation has been attempted. Recently, attention has been focused on blocking growth factor signaling by using the tyrosine kinase inhibitor imatinib or antibodies directed against transforming growth factor β. Bosentan, an endothelin-1 receptor antagonist, has been used in patients with interstitial lung disease. Additionally, more standard vasodilators, including calcium channel blockers and angiotensin pathway inhibitors, are used. Angiotensin pathway inhibitors are effective and indicated for scleroderma renal crisis [68].

Sarcoidosis

This multisystem disease of unknown etiology is characterized by non-caseating granulomas in any tissue. Vascular involvement, including large vessel aneurysms, has been reported in children [30]. Cardiac sarcoidosis can affect any portion of the heart, including the pericardium, myocardium, valves, and conduction system. Cardiac presentations in childhood may be severe and fatal [70,71]. Immunosuppressive therapy is indicated, typically with corticosteroids as the initial agents.

Lyme disease

Infection with the spirochete *Borrelia burgdorferi* causes Lyme disease, characterized by rash (erythema migrans), arthritis, and cranial nerve palsies or frank meningitis. Lyme carditis can cause reversible complete atrioventricular block in children [72]. Such conduction abnormalities are uncommon in children with Lyme disease, both in the United States and Europe [73,74].

Patients with suspected Lyme disease should have a careful cardiac examination and an electrocardiogram. Likewise, Lyme disease should be considered in the differential diagnosis of a patient with unexplained heart block.

Side effects of pharmacologic agents

Rheumatic side effects of cardiovascular medications

Drug-induced lupus (DIL) may accompany certain cardiac medications, notably hydralazine and procainamide, particularly with higher doses. Patients typically develop cutaneous manifestations and/or pericardial disease. Nephritis is less common than in SLE. Antinuclear antibodies (ANAs) are usually but not always detected. If present, the ANAs usually recognize histone (anti-histone antibodies). Anti-double-stranded DNA antibodies are not common in DIL. Unfortunately, DIL may not resolve after discontinuation of the triggering agent [75].

Cardiovascular side effects of anti-rheumatic medications

Drug-induced lupus may also accompany sulfasalazine and other anti-rheumatic drugs (e.g., several of the biologic therapies), and also many other medications. The potential cardiac manifestations of DIL are numerous, including heart failure and tamponade [76]. Discontinuation of the potential inciting agent is indicated.

Corticosteroids, used widely to treat pediatric rheumatic diseases, can cause several cardiac complications, including hypertension, hyperlipidemia, and premature coronary atherosclerosis [19]. Decreasing the cumulative corticosteroid exposure for a child with a rheumatic disease is now easier, with the expanding arsenal of immunomodulatory agents.

TNF inhibitors are used in many rheumatic diseases, and may cause heart failure, a complication that seems more likely in elderly than in younger patients [77]. Additionally, vasculitis develops in some patients using these agents [78]. Discontinuation of the TNF inhibitor is indicated when such complications arise.

Tocilizumab, a monoclonal antibody directed against the interleukin 6 (IL6) receptor, is approved for use in adults with rheumatoid arthritis, and is being studied for use in children with systemic JIA [79]. In adult patients, tocilizumab use has been linked to lipid abnormalities and possibly myocardial infarction and cerebrovascular accidents [80].

Conclusion

Cardiovascular complications may arise in nearly any child with a rheumatic disease. This chapter has attempted to discuss those cardiac manifestations that are more common or more severe, and also those pediatric rheumatic diseases for which lifestyle modification or medical intervention during childhood may provide long-term cardiovascular benefit.

Three elements are critical for optimizing the clinical cardiovascular management of children with rheumatic diseases:
- a high clinical index of suspicion for cardiovascular involvement, with appropriate diagnostic evaluation
- aggressive immunosuppressive control of the rheumatic disease, with attention to the potential long-term cardiac complications of the disease and also its therapies
- close communication between the pediatric rheumatologist, pediatric cardiologist, and other subspecialists.

70 Pediatric Heart Transplantation

Rebecca Ameduri[1] & Charles E. Canter[2]

[1]University of Minnesota School of Medicine, Minneapolis, MN, USA
[2]Washington University School of Medicine, St. Louis, MO, USA

Heart transplantation has become accepted in children for heart diseases associated with intractable heart failure unamenable to conventional medical or surgical therapy. Data from the registry of the International Society for Heart and Lung Transplantation (ISHLT) indicate that annually ~400 heart transplants have been performed in patients <18 years of age for the past 20 years [1]. This volume is ~10% of the total number of transplants reported to the ISHLT annually. Adults with congenital heart disease (CHD) now account for 2% of adult recipients [2]. Functional rehabilitation with no perceived activity limitations occurs in >90% of pediatric heart transplant recipients [1]. Adult survivors of pediatric heart transplantation have demonstrated a patient perception of physical and mental health similar to the general population [3].

One-quarter of pediatric heart transplants occur in infants <1 year of age, the remainder being split evenly between children 1–10 years of age and adolescents 11–18 years of age. CHD, both repaired and unrepaired, and cardiomyopathy are the most common diseases leading to heart transplantation in children (Figure 70.1) [1]. Infants are most likely transplanted for CHD. However, over the past 10 years, an increasing proportion of infant transplants have been for cardiomyopathies. Cardiomyopathies account for 50% of transplants in older children and nearly 67% of transplants in adolescents. As heart transplants have been performed for a number of years, it is not surprising that 6–7% of the heart transplants performed in older children and adolescents are for retransplantation.

Outcomes

Survival after pediatric heart transplantation has improved significantly over time and currently approaches 90% at 1 year and 77% at 5 years after transplantation (Figure 70.2)

[1]. The ISHLT registry calculates the graft half-life, the time when 50% of grafts are lost due to patient mortality or retransplantation, to be 18.4 years for infants, 14.7 years for older children, and 11.1 years for adolescents. Aside from the era effect, CHD, retransplantation, use of ventilator or dialysis at time of transplant, older recipient or donor age, sensitization to HLA antigens, higher serum creatinine, and lower heart transplant center volume are significant risk factors for 1 and 5 year mortality [1]. The increased mortality after heart transplantation associated with CHD is from an increased perioperative mortality, as outcomes are the same for patients transplanted for CHD and cardiomyopathy who survive at least 3 months after transplantation [4].

The most common causes of death after heart transplantation are rejection, transplant coronary artery disease, infection, primary graft failure (failure occurring in the first 30 days after operation) and chronic nonspecific graft failure (Figure 70.3) [1]. Primary graft failure is the most common cause of mortality in the first 30 days after transplantation, especially in infants [1,5]. Rejection, followed by infection, are the most common causes of death from 1 to 12 months after transplantation. Transplant coronary artery disease followed by nonspecific chronic graft failure are the most common causes of death >3 years after transplantation.

Mortality associated with heart transplantation really begins when the patient is listed for transplantation. Such "intent to treat" survival includes death while waiting for or after transplantation. Within the Pediatric Heart Transplant Study (PHTS) database, such "intent to treat" survival was 74% at 1 year, 66% at 5 years, and 59% at 10 years after listing for transplantation, with >50% of the 10-year mortality occurring in the first year after listing [6]. Competing risk analysis with the PHTS [7] demonstrates an overall decrease in the mortality with time while waiting in pediatric heart transplant candidates. In candidates listed for transplantation who required intravenous inotropes, mechanical ventilation,
Figure 70.1 Distribution of diagnoses in heart transplant recipients by age, from ISHLT data [1] for recent era including transplants performed from January 1996 through June 2008. (a) Infant recipients <1 year of age; (b) child recipients aged 1–10 years; (c) adolescent recipients aged 11–17 years.

or mechanical circulatory support, 19% died and 62% were transplanted within 6 months of the listing, as compared with 3% who died and 59% who were transplanted without needing such support. Within the United States Scientific Registry of Transplant Recipients (SRTR), multivariate risk factors for wait-list mortality in pediatric candidates include extracorporeal membrane oxygenator (ECMO) support, mechanical ventilation, dialysis support, CHD, and non-white race/ethnicity [8]. Patients listed on intravenous inotropic support have a 30 day wait-list mortality of 8% compared with an 18% 30 day mortality for patients listed on ventilatory support and a 38% 30 day mortality for patients listed on ECMO. Adolescent wait-list mortality has decreased by 50% over the last decade [9], likely reflecting the increased use of ventricular assist devices (VADs) as a bridge to transplant [10]. The recent availability of the Berlin Heart, which extends the ability for VAD support to children as small as 3.5 kg, may extend this benefit to younger children and infants [9,11].

Infants listed for heart transplantation face the single highest mortality waiting for heart transplantation of all children in the United States [12]. The absence of ABO isoagglutinins at birth has offered the successful [13] application of ABO-incompatible heart transplantation in infants with decreased wait-list mortality and post-transplant outcomes similar to ABO-compatible infant transplants [14]. Interestingly, ABO-incompatible heart transplant infants *do* develop antibodies to the incompatible blood group antigen in the allograft, suggesting some degree of immunologic tolerance. The proportion of infants listed for ABO-incompatible transplants has risen dramatically in recent years in the United States, especially in infants at the highest risk for wait-list mortality. This strategy has greatly increased the odds for transplantation for blood type O infant transplant candidates [15].

Indications/evaluation

A number of published consensus indications for pediatric heart transplantation have been published over the years [16,17], most recently in 2007 (Table 70.1) [7]. In general, the guidelines have included the following indications for cardiac transplantation in pediatric recipients:

- a need for ongoing intravenous inotropic, mechanical ventilatory or circulatory support
- complex CHD not amenable to conventional surgical repair or palliation or where the surgical procedure carried a higher short- and mid-term risk of mortality than transplantation
- progressive deterioration of ventricular function or functional status despite optimal medical care with digitalis, diuretics, angiotensin-converting enzyme inhibitors, and β-blockade
- postcardiac arrest malignant arrhythmia unresponsive to medical treatment, catheter ablation, or an automatic implantable defibrillator

- progressive pulmonary hypertension secondary to systemic ventricular failure or restrictive cardiomyopathy that could preclude transplantation at a later date
- growth failure secondary to severe congestive heart failure unresponsive to conventional medical treatment
- unacceptably poor quality of life secondary to heart failure
- progressive deterioration in functional status and/or presence of certain high-risk conditions following the Fontan procedure (i.e., protein-losing enteropathy, arrhythmias.

The literature about heart failure in adults supports the use of maximum oxygen consumption (VO_{2max}) to define severe heart failure and risk for 1 year mortality [18]. In general, VO_{2max} <14 ml kg^{-1} min^{-1} or <50% predicted VO_{2max} are accepted as indications for cardiac transplantation in adults [19–21]. It is difficult to apply this measurement in pediatrics because of the following: inability of young patients to perform exercise testing, baseline abnormal VO_{2max} in patients with complex CHD or cyanotic lesions even in the absence of heart failure, and the variability in VO_{2max} with different ages and sizes of patients [22–25]. For children and young adults, the use of percent predicted VO_{2max} may be a more accurate assessment of cardiac status. However, studies using exercise testing as a prognostic factor in pediatric heart disease have not been performed; therefore, exercise testing is not used as a sole criterion for defining heart failure in pediatrics.

Very few children with end-stage cardiac failure are unacceptable candidates for cardiac transplantation. The technical challenges of cardiac replacement in the presence of congenital or acquired abnormalities of body situs, pulmonary arteries, atria, and systemic and pulmonary venous return have been overcome with advanced surgical techniques. The exception is severe pulmonary arterial or venous hypoplasia [7,26]. The transplant evaluation is designed to identify the potential exclusion criteria of irreversible disease in the lungs, liver, kidney, or central nervous system, active infection, severe psychologic illness or psychosocial contraindications, or high titers of HLA antibodies that increase the risk of early rejection and graft failure (Table 70.2). Additionally, as increasing numbers of genetic etiologies for pediatric cardiomyopathy are identified [27], a genetic and/or metabolic evaluation becomes important.

There are few absolute contraindications to cardiac transplantation in children. Severe dysfunction of another organ that is not associated with low cardiac output typically excludes a patient from transplantation. HIV infection has been considered an absolute contraindication, although there are recent reports of successful cardiac transplantation in adults with HIV who are well controlled on antiretroviral therapy [28,29]. Active infection within 2 weeks before transplant also poses an increased risk of early mortality, and if possible transplant should be delayed until the infection is cleared or well controlled [1,30]. Active malignancy is a contraindication, and the cancer-free period required before cardiac transplantation depends on the type of malignancy and the opinion of the oncologist regarding likelihood

Table 70.1 American Heart Association guidelines for indications for heart transplantation for pediatric heart disease.

Cardiomyopathies and CHD in pediatric patients

Class 1:

- Heart transplantation is indicated as therapy for Stage D heart failure associated with systemic ventricular dysfunction in pediatric patients with cardiomyopathies or previous repaired or palliated CHD. Level of evidence B.
- Heart transplantation is indicated as therapy for Stage C heart failure associated with systemic ventricular dysfunction in pediatric patients with cardiomyopathies or previously repaired or palliated CHD when heart failure is associated with significant growth failure attributable to the heart disease. Level of evidence B.
- Heart transplantation is indicated as therapy for Stage C heart failure in pediatric heart disease with associated near sudden death and/or life-threatening arrhythmias untreatable with medications or and implantable defibrillator. Level of evidence C.
- Heart transplantation is indicated as therapy for Stage C heart failure in pediatric heart disease associated with reactive pulmonary hypertension and a potential risk of developing fixed, irreversible elevation of pulmonary vascular resistance which could preclude orthotopic heart transplantation in the future. Level of evidence C.
- In the presence of other indications for heart transplantation, heart transplantation is feasible in patients with pediatric heart disease and an elevated pulmonary vascular resistance index >6 Woods units m^{-2} and/or an transpulmonary pressure gradient >15 mmHg if administration of inotropic support and/or pulmonary vasodilators can decrease pulmonary vascular resistance to <6 Woods units m^{-2} and/or the transpulmonary gradient to <15 mmHg. Level of evidence B.

Class 2A:

- Heart transplantation is indicated as therapy for Stage C heart failure in pediatric heart disease associated with severe limitation of exercise and activity. If measurable, such patients would have peak maximum oxygen consumption <50% predicted for age and gender. Level of evidence C.
- Certain anatomic and physiologic conditions likely worsen the natural history of CHD in infant patients with a functional single ventricle, which can lead to use of heart transplantation as *primary* therapy. These conditions include:
    1. severe stenosis(es) or atresia in proximal coronary arteries
    2. moderate to severe stenosis and/or insufficiency of the atrioventricular and/or systemic semilunar valve(s)
    3. severe ventricular dysfunction.
    Level of evidence C
- Anatomic and physiologic conditions likely worsen the natural history of previously repaired or palliated CHD in pediatric patients which may lead to consideration for heart transplantation without severe systemic ventricular dysfunction:
    1. pulmonary hypertension and a potential risk of developing fixed, irreversible elevation of pulmonary vascular resistance which could preclude orthotopic heart transplantation in the future
    2. severe aortic or systemic A-V valve insufficiency not considered amenable to surgical correction
    3. severe arterial oxygen desaturation (cyanosis) not considered amenable to surgical correction
    4. persistent protein-losing enteropathy despite optimal medical–surgical therapy.
    Level of evidence C

Class 2B:

- The efficacy of heart transplantation as therapy for pediatric heart disease is not well established for patients with previous infection with hepatitis B, hepatitis C, or HIV infection. Level of evidence B.
- The efficacy of heart transplantation for pediatric heart disease is not well established for patients with a history of recent use of illicit drugs, tobacco, or alcohol abuse. Level of evidence B.
- The efficacy of heart transplantation for pediatric heart disease is not well established for patients with a history of psychological, behavior, or cognitive disorder; poor family support structures, or documented noncompliance with previous therapies that could interfere with successful performance of care regimens after transplantation. Level of evidence B.

Class 3:

- Heart transplantation for pediatric heart disease is not efficacious when heart disease is associated with severe, irreversible disease in other organ systems or when it is part of a severe, irreversible multi-systemic disease process. Multi-organ transplantation may be considered. Level of evidence C.
- Orthotopic heart transplantation for pediatric heart disease is not efficacious when heart disease is associated with severe, irreversible, fixed elevation of pulmonary vascular resistance. Level of evidence C.
- Heart transplantation is not feasible in the presence of severe hypoplasia of the central branch pulmonary arteries or pulmonary veins. Level of evidence C.
- The limited supply of pediatric donors, especially infant donors, makes heart transplantation not a feasible routine *primary* therapy for any specific congenital heart lesion. Level of evidence C.

Table 70.1 (cont'd).

Cardiac retransplantation in pediatric patients

Class 1:

- Retransplantation is indicated in children with abnormal ventricular function associated with Grade C or greater heart failure and at least moderate graft vasculopathy. Level of evidence B.

Class 2A:

- Retransplantation is indicated in children with normal ventricular function and at least moderate graft vasculopathy. Level of evidence B.

Class 2B:

- The efficacy of retransplantation is not well established when performed during the first 6 months following primary transplantation. Level of evidence B

Class 3:

- Retransplantation should not be performed during an episode of ongoing acute allograft rejection, even in the presence of graft vasculopathy. Level of evidence B.

Reproduced with permission from Canter CE, Shaddy RE, Bernstein D, *et al. Circulation* 2007;**115**:658–76.

Table 70.2 Basic evaluation protocol for evaluation for pediatric heart transplantation.

Cardiac catheterization

- Assess pulmonary vascular resistance and reactivity if needed
- Delineate complex anatomy (may need additional imaging with MRI/MRA or CT)

Exercise testing

- Obtain MVO_2 or 50% predicted VO_2 max

Assessment of end-organ function

- Evaluation of liver/kidney function
- Pulmonary function tests

HLA sensitization

- Panel reactive antibody

Psychosocial assessment

Financial

- Insurance and resource evaluation

Blood work

- Chemistry
  - Comprehensive panel
  - Electrolytes
  - BUN/creatinine
  - LFTs
  - Phosphorus
  - Total and direct bilirubin
  - Calcium and magnesium
  - Lipase and amylase if indicated
  - Triglycerides, cholesterol profile
  - Urinalysis (routine u/a, 24 h protein/creatinine)

Blood work (continued)

- Hematology
  - Complete blood count with differential
  - PT, PTT, INR
  - Fibrinogen
- Immunology
- HLA-tissue typing
- Panel reactive antibody
- Quantitative immunoglobulins if indicated
- Infectious disease
  - Viral testing
    - Cytomegalovirus
    - Epstein–Barr virus
    - Herpes simplex
    - HIV
    - Varicella
    - Toxoplasmosis
    - Hepatitis panel (A, B, C)
- Blood bank
  - Blood type X2
  - Blood group antibody screening

of cure or disease recurrence [31]. The post-transplant follow-up schedule is intensive, and patients must have the appropriate neuropsychiatric and social situation to allow for success [32–34].

End-stage cardiac disease is frequently associated with elevated pulmonary artery pressure and resistance. As most donor hearts have been exposed to only normal pulmonary pressures, pulmonary hypertension in the recipient may be

Table 70.3 United Network for Organ Sharing (UNOS) criteria for urgency status for pediatric heart transplant candidates in the United States [7,8].

A candidate listed as Status 1A meets at least one of the following criteria:
- Requires assistance with a ventilator
- Requires assistance with a mechanical device (i.e., ECMO, VAD)
- Requires assistance with a balloon pump
- Less than 6 months old with a congenital or acquired heart disease with reactive pulmonary hypertension >50% of systemic
- Requires infusion of high-dose inotropes (dobutamine/dopamine >7.5 µg kg^{-1} min^{-1} or milrinone >0.5 µg kg^{-1} min^{-1} or multiple inotropes)
- Candidate who does not meet other criteria but has life expectancy <14 days without transplant
- 1A exception

A candidate listed as Status 1B meets at least one of the following criteria:
- Requires infusion of low-dose single inotropes (e.g., dopamine or dobutamine ≤7.5 µg kg^{-1} min^{-1} or milrinone <0.5 µg kg^{-1} min^{-1})
- Less than 6 months old and does not meet the criteria for Status 1A
- Growth failure, i.e., <5% for weight and/or height, or loss of 1.5 standard deviations of expected growth
- 1B exception or variance

A candidate listed as Status 2 meets the following criteria:
- On oral medications
- Does not meet criteria for Status 1A or 1B

associated with acute right ventricular failure and death immediately after operation [35]. For this reason, a pulmonary vascular resistance of >6 Woods units m^{-2} or a transpulmonary gradient of >15 mmHg have been used as exclusion criteria in adults for cardiac transplantation and an indication for heart–lung transplantation. Experience with children suggests that pulmonary vascular reactivity is a more important indicator of suitability for transplantation [36,37]. One goal of pre-transplant cardiac catheterization is evaluation of the pulmonary vascular resistance (indexed to body surface area) and, if it is elevated, assessment of pulmonary vascular reactivity with vasodilators. Furthermore, intensive treatment of cardiac failure over weeks in a patient with an initial unfavorable pulmonary vascular resistance can lower the pulmonary resistance to an acceptable level. Most institutions consider a child suitable for cardiac transplantation alone if able to achieve pulmonary resistance <6 Woods units m^{-2} or a transpulmonary gradient <15 mmHg with pulmonary vasodilators.

Listing process/donor selection

In the United States, transplantation is controlled nationally through the United Network for Organ Sharing (UNOS) [7,8]. All patients are listed in an online database, and all donor offers and information are disseminated through the donor information system Donornet. Donors are matched to recipients based on ABO compatibility, age, size, wait-list status (Table 70.3), distance, and waiting time. Patients with the greatest need (status 1A) have priority. Organs are offered to local and regional recipients (500 mile radius from the donor hospital) first to minimize the ischemic time, which should ideally be kept <4 h. Some studies report, however, no difference in graft failure or mortality with ischemic times

as long as 6 h [38–41]. The available hearts for children come from brain dead donors, typically from motor vehicle crashes, head trauma, non-accidental head injury, drowning, or asphyxia. The mechanism of death may play a role in the function of the donor organ, and mild to moderate inotropic support in a potential donor does not necessarily make that heart unsuitable for transplantation [5,42,43].

An increasing number of recipients have preformed HLA antibodies, from exposures from prior cardiac operations that used homograft material (i.e., valves, aorta, pulmonary artery), blood product exposures, pregnancy, or mechanical circulatory support devices [44–46]. Patients with antibodies to multiple HLA antigens are at increased risk of acute rejection [1,44–49]. Matching a donor to a recipient with antibodies to the donor's HLA antigens can be performed using a virtual crossmatch [50] performed by matching the donor to a recipient who does not have preformed donor-specific antibody to the donor's HLA antigens. Some patients with a "+" virtual crossmatch will not have a positive complement-fixing tissue crossmatch as anti-HLA antibodies may have low plasma concentration or low avidity. Some centers have adopted plasmapheresis protocols and aggressive early immunosuppression to lower the antibody titers to perform heart transplant with a positive donor–recipient crossmatch [48,49]. Additionally, some investigators use pre-transplant plasmapheresis, intravenous immunoglobulin, or immunosuppression to lower antibody levels before transplant, with variable success [51,52].

Immunosuppression after transplantation

Cardiac transplantation is not a cure or a repair; it exchanges a fatal cardiac disease for a chronic disease. Lifelong immunosuppressant medications are required to prevent acute heart

Table 70.4 Medications used for initial and maintenance immunosuppression.

Drug (trade name)	Mechanism	Pediatric dosing	Goal levels	Comments
Steroids				
Methylprednisolone (Solu-Medrol)	Nonspecific immunosuppression	I.v.: Initial: 5–10 mg kg^{-1} before transplant 0.8 mg kg^{-1} day^{-1} divided every 6 h		
Prednisone	Nonspecific immunosuppression	Maintenance: 1 mg kg^{-1} day^{-1} divided every 6 h, then tapered over 6–12 months		
Calcineurin inhibitors				
Cyclosporine (Sandimmune)	CsA–cyclophilin complex inhibits T-cell activation	I.v.: Initial: 5–6 mg kg^{-1} day^{-1} starting 4–12 h before transplant Maintenance: 2–10 mg kg^{-1} day^{-1} divided twice daily Oral: Initial: 14–18 mg kg^{-1} day^{-1} starting 4–12 h before transplant Maintenance: 5–15 mg kg^{-1} day^{-1} divided every 12–24 h, then tapered	Initial: Trough level 250–350 ng ml^{-1} Maintenance: Trough level 100–300 ng ml^{-1}	Dose should be divided three times per day in infants
Cyclosporine (Neoral)	CsA–cyclophilin complex inhibits T-cell activation	2–6 mg kg^{-1} day^{-1} oral divided twice daily	Initial: Trough level 250–350 ng ml^{-1} Maintenance: Trough level 100–300 ng ml^{-1}	Dose should be divided three times per day in infants
Tacrolimus/FK-506 (Prograf)	Tacro–FKBP12 complex inhibits T-cell activation	0.05–0.1 mg kg^{-1} day^{-1} divided twice daily	Initial: Trough level 10–15 ng ml^{-1} Maintenance: Trough level 5–10 ng ml^{-1}	Dose should be divided three times per day in infants
Antiproliferative agents				
Azathioprine (Imuran)	Inhibition of cell proliferation	1–2 mg kg^{-1} day^{-1}	WBC count of 4000–12 000 ml^{-1}	
Mcyophenolate mofetil (Cellcept)	Selective inhibitor of B- and T-lymphocyte proliferation	Initial: 100–125 mg kg^{-1} day^{-1} Maintenance: 25–50 mg kg^{-1} day^{-1}	Maintenance: Trough level 3–7 ng ml^{-1}	

rejection. Multiple chronic immunosuppression protocols have been developed to prevent immunologic destruction of the transplanted organ. Some protocols use induction therapy to alter favorably the immune environment at the time of transplant and decrease the incidence of early rejection [53–57]. ISHLT data support the use of induction agents to decrease the risk of early rejection, although data regarding effects on survival or incidence of cardiac allograft vasculopathy are lacking. Currently, >60% of children receive cytolytic induction agents, including either polyclonal antibody preparations (thymoglobulin or ATGAM) or newer anti-cytokine receptor antibodies (basiliximab or daclizumab) [1]. The maintenance immunosuppression protocols in general use triple immunosuppression to minimize toxic side effects of the medications. The protocols include steroids, a calcineurin inhibitor [cyclosporine or tacrolimus (FK-506)], and an antiproliferative agent (azathioprine or mycophenolate mofetil) [1]. The degree of immunosuppression is greatest in the first months after transplantation; however, there is clinical practice support for establishing a steroid-free regimen in selected patients by 1 year post-transplant to minimize the risk of steroid-associated morbidity [58,59]. The calcineurin inhibitors, which block interleukin-2 secretion and subsequent T lymphocyte activation and proliferation, are the cornerstone of chronic immunosuppressive therapy. Currently, based on the most recent ISHLT report, ~50% of patients are on cyclosporine and 50% are on tacrolimus. There is also increasing use of the newer antiproliferative agent mycophenolate mofetil, with now >50% of recipients receiving this over azathioprine [1]. Table 70.4 reviews the common immunosuppression medications, typical pediatric dosing, and goal levels.

Rejection

The goal of immunosuppression is to prevent rejection of the donor heart. Rejection is an immune response to mismatched human leukocyte antigens on the recipient and donor cells.

The resultant inflammation is mediated through T-cell and humoral immune mechanisms, causing eventual necrosis of the heart tissue. Rejection is most common in the first 6 months after transplant, but remains a risk lifelong and is the most common cause of death in the first 5 years after transplant [1]. Data from the PHTS from 1993 to 2005 [60] (Figure 70.4) demonstrate that pediatric heart transplant recipients on average experience one episode of rejection in the first year after transplant, although many never have such an episode. The frequency of rejection in the first year after transplant has been decreasing recently, likely from changes in initial and chronic immunosuppression strategies [61]. Neonates and infants seem to be more immunotolerant to heart grafts and have a decreased incidence of rejection
Figure 70.4 Cumulative episodes of rejection and infection in pediatric heart transplantation over time within the Pediatric Heart Transplant Study Database [60].

[1,62]. Preformed donor-specific antibody, especially when there is a positive donor–recipient crossmatch, is associated with an increased risk for rejection in the first 6 months after transplantation [48,49].

Pediatric heart transplant recipients continue to have late rejection episodes >1 year after transplantation (Figure 70.4). Approximately 25% of recipients have an episode of late rejection by 3 years after transplantation [63]. Late rejection occurs infrequently in infants [62]. Late rejection is a leading cause of mortality >1 year after transplantation [1] and increases the risk for developing transplant coronary disease [64]. Risk factors for late rejection include two or more episodes of rejection in the first year after transplant, older age, and black race. Late rejection is frequently attributed to patient non-compliance [65,66] with single-parent home, non-white race, and older age, especially adolescence identified as increasing the risk of medical non-compliance. The association of late rejection with black race is independent of age and socioeconomic circumstances, and is due to unfavorable genetic polymorphisms in black recipients [67].

Diagnosis

Endomyocardial biopsy is considered the "gold standard" for diagnosing T-cell associated or cellular rejection. Standardized grading systems have been formulated as outlined in Table 70.5, based on lymphocytic infiltrates and myocardial necrosis (Figure 70.5) [68]. Surveillance for rejection is most intense during the first 3 months after transplantation and gradually decreases to a 6 monthly schedule 18 months following transplantation. The relatively low rate of cellular rejection after the first 6–12 months post-transplantation has led some centers to eliminate surveillance endomyocardial biopsies after this time [59,69].

Table 70.5 International Society for Heart and Lung Transplantation cardiac biopsy grading scheme for the diagnosis of acute cellular rejection.

2004		1990	
Grade	**Description**	**Grade**	**Description**
Grade 0 R	No rejection	Grade 0	No rejection
Grade 1 R	Interstitial and/or perivascular infiltrate with up to one focus of myocyte damage	Grade 1, mild	
		A – focal	Focal perivascular and/or interstitial infiltrate without myocyte damage
		B – diffuse	Diffuse infiltrate without myocyte damage
		Grade 2, moderate(focal)	One focus of infiltrate associated with myocyte damage
Grade 2 R	Two or more foci of infiltrate with associated myocyte damage	Grade 3, moderate	
		A – focal	Multifocal infiltrate with myocyte damage
		B – diffuse	Diffuse infiltrate with myocyte damage
Grade 3 R	Diffuse infiltrate with multifocal myocyte damage ± edema, ± hemorrhage, ± vasculitis	Grade 4, severe	Diffuse, polymorphous infiltrate with extensive myocyte damage ± edema, ± hemorrhage, ± vasculitis

Reproduced with permission from Stewart S, Winters GL, Fishbein MC, *et al. J Heart Lung Transplant* 2005;**24**:1710–20.
Figure 70.5 Representative histology of various endomyocardial biopsy grades of rejection by the revised ISHLT grading scheme. Grade 0, no rejection; Grade 1R, focal, perivascular lymphocytic infiltrates without myocyte damage; Grade 2R, multiple foci of damaging lymphocytic infiltrate with normal myocardium intervening; Grade 3R, diffuse damaging lymphocytic infiltrates with encroachment of myocytes and disruption of normal architecture.

In adults, gene-expression profiling from peripheral blood specimens in selected patients is equivalent to surveillance of rejection by endomyocardial biopsy [70], but extrapolating this strategy to pediatric patients remains untested.

Serial endomyocardial biopsies in children have many challenges because of patient size, lack of vascular access, and need for sedation/anesthesia, but can generally be performed with low risk in children of all sizes [71]. In children, rejection has been diagnosed much more frequently by a combination of clinical signs and symptoms and non-invasive testing than in adult recipients. Decreased appetite, afebrile "flu" symptoms, irritability, gallop rhythm, enlarged cardiac silhouette on a chest radiograph, and decreased QRS voltages on an electrocardiogram have been considered signs of rejection. In many centers, echocardiography has been utilized as the primary diagnostic modality for rejection in infants [72]. However, pediatric heart transplant centers are increasingly using endomyocardial biopsy over noninvasive methods to diagnose cellular rejection [61].

Humoral or antibody-mediated rejection is increasingly recognized as an important cause of morbidity and mortality in heart transplantation [73–76]. It is generally associated with varying degrees of left ventricular dysfunction and heart failure. In addition, anti-HLA antibodies specifically directed to donor HLA antigens are found in the serum [73]. Although "mixed" instances of cellular and antibody-mediated rejection may occur [76], specific histopathologic findings in antibody-mediated rejection include tissue edema and endothelial swelling and macrophage infiltration [73]. In addition, tissue immunofluorescence and histochemistry demonstrate endothelial deposition of immunoglobulin or complement fragments C4d or C3d in the endothelium and/or + CD 68 staining for intra-endothelial macrophages (Figure 70.6).

Treatment

Asymptomatic mild rejection (old ISHLT 1A or 1B, new ISHLT 1R) is often not treated because of the high rate of spontaneous resolution and the lack of association with long-term graft survival and transplant cardiac allograft vasculopathy [77]. Most centers, however, treat a patient with a biopsy showing moderate rejection (old ISHLT grade 3A or greater, new ISHLT 2R or greater) with intensified immunosuppression, typically
Figure 70.6 Representative pathology consistent with antibody-mediated rejection. (a) Endothelial cell swelling and intravascular infiltration of macrophages. (b) Capillary deposition of immunoglobulin G by immunofluorescence. (c) Capillary deposition of complement fragment C4d by immunoperoxidase staining.

high-dose intravenous or pulsed oral steroids [78,79]. Refractory rejection is defined as ongoing rejection after 2–3 consecutive episodes treated with steroids. Experience in both adults and children supports the use of anti-lymphocytic antibodies in treating steroid-resistant rejection [80,81]. Other options include changing calcineurin inhibitors from cyclosporine to tacrolimus or changing antiproliferative agents from azathioprine to mycophenolate mofetil [82–86]. In extreme refractory rejection, total lymphoid irradiation [87–89] or photopheresis [90] have been used.

Specific treatments for antibody-mediated rejection typically include the same regimens as used for cellular rejection. Additionally, circulating donor-specific antibodies can be removed with intravenous immunoglobulin, plasmapheresis, or both [91–93]. Specific therapies, including cyclophosphamide and rituximab, have been used to target B-cells, and protocols for these agents are being developed [94–97].

If rejection is associated with heart failure or cardiogenic shock, treatment typically involves global immunotherapy, including treating cellular and antibody-mediated rejection with steroids, anti-lymphocyte antibodies, plasmapheresis, and cyclophosphamide [98,99]. Although these regimens often resolve acute heart failure, long-term outcomes after rejection with hemodynamic compromise are poor, with a high risk of mortality from recurrent rejection, infection, or transplant coronary disease [100].

Infection

Infection, along with primary graft failure and rejection, is an important cause of death early after pediatric cardiac transplantation (Figure 70.3) [1,2]. Similarly to rejection, serious infections most likely occur in the first 3 months after transplantation when immunosuppression is greatest. The intensity of immunosuppression and the degree of illness in

a patient before transplantation increase the risk of serious infection after transplantation [101].

Pediatric cardiac transplant recipients average approximately one infection requiring hospitalization or treatment with intravenous medications in the first year after transplantation (Figure 70.4) [1,102].

The type of infection varies at different times after transplantation [103]. Within the first month after transplantation, infections are related either to the surgical wound from bacteria or yeast or to related infection in the recipient or donor organ. Herpes simplex may reactivate in a recipient in the first 2 weeks after transplant. From 1 to 6 months after transplantation, infections from immunomodulating viruses [notably cytomegalovirus (CMV)] and opportunistic fungal or protozoal infections predominate. Late transplant infections are generally community-based infections or a recurrence of opportunistic infections in patients who require repeated exposure to high-dose immunosuppression with rejection episodes. Infants appear to have more chronic and recurrent infections late after transplant than older recipients [104]. Prophylactic nystatin and trimethoprim–sulfamethoxazole are routinely given after heart transplantation to prevent fungal or protozoal infections.

CMV and EBV infections

Cytomegalovirus (CMV) infections commonly occur as a result of primary exogenous infection, donor–recipient transfer of the virus, or reactivation of infection in the recipient [102]. CMV infection generally occurs 2–12 weeks after transplantation and can be associated with pneumonitis and gastroenteritis. CMV infection may be a risk factor for developing transplant coronary disease [105], but an association between CMV infection and transplant coronary disease was not observed in a recent PHTS analysis [106]. CMV infection is frequently treated with oral valgancyclovir or intravenous ganacylovir. Treatment may be prophylactic or at the time of detection of infection with serial monitoring of CMV viral

load in the bloodstream. Studies have [107] and have not [106] found prophylaxis to be a superior strategy to prevent complications from CMV infection.

Epstein–Barr virus (EBV) infections may also occur in the first year after transplant from the same pathways as CMV infections. The importance of EBV, especially a primary EBV infection, in these children is its association with the development of post-transplant lymphoproliferative disease (PTLD) [108,109]. EBV viral load in blood is often monitored early after transplant for adjustment of immunosuppression in the presence of EBV infection.

Immunizations

Immunosuppressed patients should avoid live virus vaccines (e.g., oral polio, measles–mumps–rubella, varicella, nasal influenza) and killed virus or protein vaccines, such as diphtheria, pertussis, and tetanus [110]. Salk polio, hepatitis B, *Haemophilus influenzae* type b, and influenza vaccines should be given (Table 70.6). Varicella as a primary or reactivated infection can be treated with oral or intravenous acyclovir [111]. If possible, children should receive as many live virus vaccinations as are feasible prior to transplantation.

Transplant cardiac allograft vasculopathy

A year after transplantation, transplant cardiac allograft vasculopathy (CAV) becomes a leading cause of cardiac mortality and morbidity (Figure 70.3) [1]. Transplant CAV is a progressive, concentric myointimal proliferation that initially appears as intimal thickening and may lead to luminal occlusion. Transplant CAV involves the entire length of the vessel. In contrast, traditional atherosclerosis is usually characterized by focal lesions with asymmetric intimal proliferation in the proximal vessels. Unlike atherosclerosis, transplant CAV lesions rarely calcify and are unassociated with disruption of the internal elastic lamina. Transplant coronary disease may result from an immunologic injury to the coronary endothelial cells, leading to stimulation and proliferation of smooth muscle cells elaborating growth factors, cytokines, and extracellular matrix proteins and producing intimal proliferation, impaired vascular function, and luminal narrowing [112,113].

Manifestations and risk factors

Because of variability in the reinnervation of the transplanted heart, myocardial infarction with CAV is usually not associated with angina. The manifestations of transplant coronary artery disease range from unexplained chest or abdominal pain to left ventricular dysfunction or sudden death. For these reasons, cardiac transplantation protocols routinely include coronary angiography yearly or biannually. Angiographic findings include diffuse lesions, rapid pruning of vessels, distal obliteration of small tertiary vessels, and focal stenoses (Videoclip 70.1), but angiography

may underestimate the presence and severity of transplant CAV because of the diffuse nature of the disease [114]. Intravascular ultrasound is a much more sensitive invasive test to determine the presence of transplant CAV and often shows intimal proliferation in apparently normal vessels (Figure 70.7) [115,116]. Exercise or dobutamine stress echocardiography may be the best relatively noninvasive tests to make the diagnosis in children. A negative test strongly supports the absence of angiographic transplant CAV, and wall motion abnormalities (positive test) correlate with angiographically identifiable disease ~80% of the time [117–119].

In children, angiographic evidence of transplant coronary artery disease is present in 15–25% of recipients 5 years after transplantation [1,120]. In both angiographic and intravascular ultrasound studies, transplant CAV occurs less frequently at a given time after transplant in younger children (Figure 70.8) [1,115,120]. Older donor age and rejection episodes >1 year after transplantation [115,121] have also been identified as risk factors for pediatric transplant CAV diagnosed by angiography or intravascular ultrasound. CMV infection has [105] and has not [106] been related to pediatric transplant CAV. Other factors associated with transplant CAV include "explosive sudden cerebrovascular death in the donor" and factors associated with traditional atherosclerosis, such as hyperlipidemia, hypertension, and smoking [122].

Treatment

Once present, CAV typically progresses and is irreversible. Coronary angioplasty, stenting, or bypass surgery can be performed for focal lesions [123]. Additionally, statins are now being instituted early after transplantation to prevent the development of CAV, utilizing both their lipid lowering properties and inherent anti-inflammatory and immune-modulating effects [124,125]. Preliminary studies with pravastatin suggest that it may be able to reverse intimal proliferation and halt progression of CAV [126].

Mycophenolate mofetil as part of maintenance immunosuppression reduces intimal thickening after heart transplantation [127,128]. Evolving strategies for preventing vasculopathy include newer agents such as sirolimus (rapamycin) and everolimus. These medications have a different mechanism of immunosuppression than other agents, and also inhibit smooth muscle and endothelial cell proliferation. In adults, sirolimus may slow progression of established transplant CAV [129], and everolimus or sirolimus decrease the magnitude of coronary intimal thickening if used for maintenance immunosuppression after transplant [130,131].

Pediatric transplant CAV associated with luminal narrowings ≥50% is associated with an ~50% risk of graft loss within 2 years [120]. Retransplantation is probably the only definitive treatment for substantial transplant CAV and is associated with survival similar to primary transplantation [132,133].

Table 70.6 Suggested immunization schedules for pediatric solid organ recipients before and after transplantation.

Vaccine	Inactivated/live attenuated (I/LA)	Recommended before transplant[a]/strength of recommendation	Recommended after transplant/strength of recommendation	Monitor vaccine titers?	Quality of evidence

[a]Whenever possible, the complete complement of vaccines should be administered before transplantation. Vaccines noted to be safe for administration after transplantation may not be sufficiently immunogenic after transplantation. Some vaccines, such as pneumovax, should be repeated regularly (every 3–5 years) after transplantation.

[b]Routine vaccine schedule recommended prior to transplant and as early in the course of disease as possible; vaccine poorly immunogenic after transplantation, and accelerated schedules may be less immunogenic. Serial hepatitis B surface antibody titers should be assessed both before and after transplantation to assess ongoing immunity.

[c]Serologic assessment recommended if available.

[d]Children older than 5 years should receive 23-valent pneumococcal polysaccharide vaccine. Children younger than 2 years should receive conjugated pneumococcal vaccine (Prevnar). Those 2–5 years of age should receive pneumococcal vaccine.

[e]Certain patients (members of the military, travelers to high-risk areas, properdin deficient, terminal complement component deficient, those with functional or anatomic asplenia, college freshmen living on campus) are candidates for the meningococcal vaccine.

[f]Not routinely administered. Recommended for exposures, or potential exposures due to vocation or avocation.

[g]The indications for BCG administration in the United States are limited to instances in which exposure to tuberculosis is unavoidable and where measures to prevent its spread have failed or are not possible.

[h]Transplant recipients who are face-to-face contacts of a patient with smallpox should be vaccinated; vaccinia immune globulin may be administered concurrently if available. Those who are less intimate contacts should not be vaccinated.

Other medical morbidities

Cardiac

Transplanted hearts in infants and children grow proportionately as the child ages [134]. Transplanted hearts, denervated at the time of implantation, may attain partial reinnervation with time, but the heart rate response to exercise is usually blunted. As in adult recipients, most pediatric cardiac transplant recipients have a lower than normal exercise capacity [135,136]. Infant recipients have had normal exercise capacities [137]. Sequential cardiac catheterization studies have demonstrated hemodynamics consistent with diastolic dysfunction and restrictive physiology in long-term survivors of pediatric cardiac transplantation [138]. Moderate to severe tricuspid regurgitation occurs in many pediatric heart transplant recipients due to surgical technique, postoperative right ventricular dysfunction, and trauma from repetitive endomyocardial biopsies [139].

Figure 70.7 (a) Coronary angiogram of the left anterior descending artery. Arrow points to the area of intravascular ultrasound imaging shown to the right. (b) Intravascular ultrasound image demonstrates severe intimal thickening noted on the ultrasound (line) within an angiographically normal coronary segment.

Arrhythmias are common. Significant bradycardia may occur immediately postoperation, usually improves, but may require permanent pacing. Right bundle branch block is typically present, most likely from injury to the right bundle with repeated endomyocardial biopsies. Isolated atrial or ventricular premature contractions, including nonsustained ventricular tachycardia, occur at a greater frequency than observed in normal hearts [140,141]. Supraventricular arrhythmias, including atrial flutter, ectopic atrial tachycardia, and atrioventricular reciprocating tachycardias, may occur in the first year after transplantation, with or without rejection [142–144]. Supraventricular tachycardias occurring late after transplantation are usually not associated with acute rejection, but more likely are a sign of transplant coronary arteriopathy.

Many medical problems can be attributed to side effects of immunosuppressive medications. Hypertension is common and associated with steroid and calcineruin inhibitor administration [1]. Children are at increasing risk for developing hypertension after transplant; the prevalence is ~50% at 1 year, 60% at 5 years, and >67% at 8 years after transplantation [145] (Table 70.7). Hypertension appears to occur more frequently with use of cyclosporine than with tacrolimus [146]. Calcium channel blockers are the most frequently used antihypertensive agents, but diuretics, angiotensin-converting enzyme inhibitors, β-blockers, and α-blockers have been used alone or in combination. Hyperlipidemia occurs in ~25% of pediatric heart transplant recipients [145] and may require therapy with statins.

Renal

Nephrotoxicity is frequently observed with calcineurin inhibitor therapy. Patients taking these agents typically demonstrate prerenal azotemia, with a level of blood urea nitrogen level disproportionately elevated compared with serum creatinine. Renal tubular acidosis, hyperuricemia, and hyperkalemia can also be observed. There may be reversible acute renal failure. Knowledge of the drugs that interact with cyclosporine and tacrolimus is important to avoid acute toxicity or underimmunosuppression. Drugs that inhibit the hepatic cytochrome-P450 system, such as ketaconazole, macrolide antibiotics, and calcium channel blockers, elevate calcineurin inhibitor levels whereas administration of anticonvulsants with calineurin inhibitors decreases their levels.

Long-term administration of calcineurin inhibitors in pediatric heart transplant recipients is associated with an increased risk for chronic kidney disease (Table 70.7). Less than 50% of pediatric thoracic transplant recipients have a normal glomerular filtration rate 1 year after transplantation, a level that declines to 14% 5 years after transplantation [147]. Overt renal dysfunction is present in ~6% of pediatric recipients 1 year after transplantation and increases to 10% by 8 years [145].

Neoplasms

Chronic immunosuppression is associated with an increased risk for developing neoplasms. The most common neoplasm observed after pediatric cardiac transplantation is lymphoproliferative disease (PTLD). It commonly occurs within the

Table 70.7 ISHLT registry data [1] on the proportion of patients with hypertension, renal dysfunction, hyperlipidemia, and diabetes at 1, 5, and 8 years after pediatric heart transplantation.

Outcome	Within 1 year	Within 5 years	Within 8 years
Hypertension	47.2% (*n* = 2428)	62.7% (*n* = 836)	68.3% (*n* = 325)
Renal dysfunction	5.8% (*n* = 2431)	9.9% (*n* = 862)	10.3% (*n* = 339)
Abnormal creatinine <2.5 mg dl^{-1}	3.9% (1.2%)[a]	8.2% (0.8%)[a]	7.7% (0.6%)[a]
Chronic dialysis	0.7%	0.6%	1.5%
Renal transplant	0.0%	0.2%	0.6%
Hyperlipidemia	10.8% (*n* = 2555)	25.1% (*n* = 902)	28.1% *n* = 356)
Diabetes	3.4% (*n* = 2436)	5.2% (*n* = 833)	4.0% (*n* = 323)

[a]Creatinine values in parentheses are >2.5 mg dl^{-1}.

first months after transplantation and is usually associated with either a primary or a reactivated EBV infection [108,109]. Approximately 5% of 5 year survivors and 8% of 10 year survivors develop PTLD [1]. Lymphoproliferative disease is a heterogeneous disorder ranging from a plasmacytic hyperplasia lacking oncogene and tumor suppressor gene alterations to an aggressive metastatic immunoblastic lymphoma, Burkitt's lymphoma, or multiple myeloma. It may present as an isolated disease process in the oropharyngeal nodes, lungs, or gastrointestinal tract or as a disseminated multisystem disease that can involve the central nervous system. The more benign forms of lymphoproliferative disease respond to reduction of immunosuppression; however, chemotherapy, anti-B cell monoclonal antibodies (rituximab), and radiation therapy, have been used to treat more malignant variants. Basal cell carcinomas, cervical carcinomas, and Kaposi's sarcoma have also been observed at higher frequency than in the general population.

Heart retransplantation

An increasing number of pediatric heart retransplant procedures have been performed over the last decade. Currently the ISHLT database reports ~40 of these procedures performed per year, comprising 6–7% of the heart transplantation performed in pediatric patients >1 year of age (Figure 70.1) [1]. Transplant coronary vasculopathy accounts for ~50% of retransplants, followed by graft failure and rejection [132]. Retransplantation performed >6 months after primary transplantation has a substantially higher survival that approaches the rate for primary transplants [132,133]. Current guidelines (Table 70.1) [5] state that cardiac retransplantation is indicated in patients with moderate–severe coronary vasculopathy, especially if associated with heart failure. Retransplantation within the first 6 months after transplantation or for acute rejection is discouraged.

Heart–lung and lung transplantation and pediatric cardiovascular disease

Primary pulmonary hypertension, CHD with pulmonary vascular disease, and pulmonary vein stenosis/veno-occlusive disease are the primary conditions leading to heart–lung and lung transplantation in children. The National Institutes of Health registry for primary pulmonary hypertension demonstrated an inverse correlation with duration of survival and magnitude of central venous pressure, pulmonary artery pressure, and pulmonary vascular resistance [148]. A smaller retrospective study demonstrated a similar relationship in pediatric patients with primary pulmonary hypertension or pulmonary vascular disease associated with CHD [149]. Pulmonary vasodilators, such as prostacyclin, sildenafil, and bosentan, have improved transplant-free survival in children with primary pulmonary hypertension [150] and patients with pulmonary vascular disease and CHD (Eisenmenger syndrome) [151]. Surgery and catheter interventional procedures may palliate pulmonary vein obstruction [152], but patients <18 months of age with associated pulmonary arterial hypertension and bilateral involvement often have progressive disease that can lead to early consideration for lung transplantation [153]. Adhesions from multiple prior thoracotomies can increase perioperative bleeding and be a relative contraindication to transplantation [154].

Heart–lung transplantation is currently reserved for co-existing heart lesions that are extensive or not easily repairable at the time of lung transplantation [154]. The ISHLT registry records <20 pediatric heart–lung transplants annually worldwide over the past decade. Pediatric heart–lung and lung transplantation have a similar higher mortality rate than cardiac transplantation, with a 12 month survival rate of 80–85% (Figure 70.9) [155]. Survival has improved recently with graft half-life
Figure 70.9 Kaplan–Meier survival curves for pediatric lung transplantation stratified by era from the ISHLT database. (Reproduced with permission from Boucek MM, Edwards LB, Keck BM, *et al. J Heart Lung Transplant* 2005;**24**:968–82.)

approaching 6 years. The need for ventilator support before transplantation is a risk factor for 1 and 5 year mortality.

The patterns of rejection and infection after lung transplantation resemble those observed after cardiac transplantation [156]. The transplanted lung, however, is more susceptible to infection because of its greater exposure to environmental pathogens. Bronchiolitis obliterans in pulmonary allografts is the counterpart to transplant coronary artery disease in cardiac allografts. Bronchiolitis obliterans can progress rapidly, leading to respiratory failure, or may stabilize after an acute decrease in lung function. In children, it has a prevalence of 25–30%, the prevalence increasing with longer follow-up [156,157]. The prevalence of bronchiolitis obliterans in heart–lung recipients equals or is greater than its prevalence in isolated lung transplant recipients [158,159]. The prevalence of transplant coronary artery disease, however, is less in heart–lung than heart transplant recipients [160].

71　Cardiac Failure

**Beth D. Kaufman, Kimberly Y. Lin, Akash R. Patel,
Maryam Y. Naim, Maully J. Shah & Robert E. Shaddy**
The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Pathophysiology

Heart failure is the clinical syndrome described below that results when, because of cardiac dysfunction, cardiac output does not meet the metabolic demands of the body. The etiologies of heart failure in children are diverse. In adults, coronary artery disease and hypertension are the major contributing factors of heart failure. Children most often present with heart failure because of congenital heart disease (CHD) with excessive volume loads (left-to-right shunts or valvar regurgitation) or excessive pressure loads (usually inflow or outflow tract obstruction), a cardiomyopathy, or extrinsic pressure on the heart as in a pericardial tamponade or constriction. Regardless of etiology, all heart failure syndromes are now thought of as a unified common pathway involving an index event, compensatory mechanisms, and secondary damage.

Our understanding of the pathophysiology of heart failure has grown in conjunction with an increased understanding of its cellular and neurohormonal mechanisms. Adrenergic nervous system activation, the renin–angiotensin–aldosterone system (RAAS), and left ventricular remodeling are the major maladaptive mechanisms. Adrenergic activation is a cornerstone of the neurohormonal response to heart failure. When cardiac output decreases, baroreceptors in the carotid sinus and aortic arch decrease their rate of firing, leading to increased sympathetic and decreased parasympathetic output. A short-term improvement in myocardial performance follows that is mediated by the β_1-adrenergic receptor, resulting in an increase in heart rate and ventricular contractility (thus augmenting cardiac output), and the α-adrenergic receptor, resulting in vasoconstriction (thus augmenting preload and blood pressure). In the long term, however, β-adrenergic stimulation is deleterious to

heart function. Norepinephrine causes direct myocyte toxicity, abnormal calcium handling, decreased macromolecular synthesis, and contractile dysfunction [1]. Adrenergic stimulation also increases myocardial oxygen demand at a time when oxygen delivery is limited.

The RAAS pathway is the other major limb of neurohormonal compensation that is activated in heart failure. In addition to direct β_2-adrenergic receptor stimulation by the adrenergic system at the juxtaglomerular level, renin secretion is also stimulated by decreased renal artery perfusion from low cardiac output and decreased salt delivery to the macula densa. Increased renin levels lead to the formation of angiotensin II, whose multiple effects include vasoconstriction, hypothalamic thirst stimulation, and aldosterone secretion via the adrenal cortex. Aldosterone, in turn, acts at the distal convoluted tubule of the kidney to promote sodium reabsorption and thus fluid retention. Again, although this compensatory increase in preload through angiotensin II and aldosterone is beneficial in the short term, chronic activation of this system promotes fluid overload in addition to a myriad of adverse cellular and genetic changes.

The chronic effect of neurohormonal activation includes myocyte toxicity leading to ventricular remodeling. The term remodeling refers to changes in chamber architecture; with respect to heart failure, a consensus statement defined cardiac remodeling as "genomic expression resulting in molecular, cellular, and interstitial changes that are manifested clinically as changes in size, shape, and function of the heart after cardiac injury" [2]. Elevated levels of bioactive molecules such as norepinephrine, endothelin, tumor necrosis factor, aldosterone, and angiotensin II all contribute to progressive left ventricular hypertrophy, enlargement, and cavity distortion. The development of left ventricular remodeling may subsequently cause a self-amplifying cycle of progressive

cardiac dysfunction, which may continue independent of adrenergic or RAAS activation [3].

The relationship of heart function to vascular stiffness, often referred to as ventricular-arterial (VA) or ventricular-vascular (VV) coupling, has spawned a great deal of interest in adult heart failure [4]. This has led to the recognition that the stiffening of the left ventricle is intimately related to stiffening of the large arteries; an increase in one often leads to an increase in the other. These changes have clear implications in the adult heart failure population, where increased vascular stiffness is seen with increasing age and also with co-morbidities such as hypertension, diabetes, and renal disease. With new and improved noninvasive methods, vascular stiffening has also been identified in multiple pediatric populations. The short- and long-term implications of such findings with respect to the development of heart failure in children, however, have not been clearly defined [5].

Differences in calcium homeostasis have been observed between mature and immature hearts [6]. In animal models and also human adults with heart failure, a decrease in sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA2a) and an increase in Na^+–Ca^{2+} exchanger have been observed, potentially contributing to progressive myocyte contractile dysfunction [7,8]. We know that the $Na^{+-}Ca^{2+}$ exchanger activity is higher and that sarcoplasmic reticulum is relatively immature in neonates as compared with adults; this has implications on the effects of therapies that target calcium-dependent pathways in younger populations.

Despite the variation in underlying etiology and the cellular, inflammatory, genetic, anatomic, and neurohormonal processes that ensue, most heart failure in adults and children eventually follows a final common pathway of ventricular remodeling and systolic and/or diastolic dysfunction. Unraveling those underlying processes has provided multiple targets for intervention in this otherwise progressive disease.

Diagnosis and evaluation

Heart failure presenting during infancy or childhood is of diverse etiology and differs significantly from that of adults. Diagnostic evaluation begins with a thorough history. In infants and small children, feeding intolerance and failure to thrive can be symptoms of heart failure. Ischemic pain, although uncommon in children, can present as severe colic and irritability in an infant. Heart failure can also present with gastrointestinal and/or respiratory symptoms due to ventricular dysfunction and resultant systemic and/or pulmonary venous congestion and low cardiac output. A history of asthma and frequent wheezing may be from pulmonary venous congestion rather than primary reactive airway disease. These symptoms, initially thought to be secondary to an infection, ultimately are diagnosed as cardiac

in origin. Conversely, in some children, the stress of an infection, and its resultant increased cardiac output from fever or dehydration, result in symptoms of a previously subclinical cardiac abnormality. Seizures, syncope, or presyncopal episodes may be related to arrhythmias or underlying cardiomyopathies associated with heart failure. Children with structural CHD, either before and/or after surgical repair, may present with heart failure from volume overload and/or ventricular dysfunction. Symptoms of heart failure may begin suddenly or can develop gradually. For instance, a careful history may reveal that a child has gradually stopped playing sports now deemed "boring," when he or she is actually self-limiting due to the onset of symptomatic heart failure. A history of a recognizable syndrome or genetic diagnosis must be sought, and has been reported in 27% of pediatric cardiomyopathies [9]. Cardiac disease can be associated with a systemic syndrome, such as neuromuscular or metabolic diseases that may manifest as skeletal myopathy in addition to cardiomyopathy [10,11]. Exposures to known cardiac toxins such as anthracyclines received as cancer therapy, or iron overload related to frequent blood transfusions, should be identified. History should also include questions related to motor strength and clumsiness, frequent infections, other systemic medical problems, deafness, hypertension, and developmental delay.

A careful family history of at least three generations is an important part of the diagnostic evaluation of heart failure in children, as cardiomyopathies of genetic etiology can be transmitted within families via autosomal dominant, autosomal recessive, X-linked, or maternal (mitochondrial) transmission patterns. A familial cardiomyopathy is defined by at least two family members affected by cardiomyopathy, even those of different phenotypes [12]. Family history should also include sudden death, any form of cardiac disease, and muscular diseases.

Detailed careful physical examination must include:
• Assessment of the child's wellbeing, including respiratory rate and effort, color, pallor, edema, nutritional state, and activity level.
• Assessment of vital signs (including oxygen saturation) and four-extremity blood pressures.
• Examination of the extremities to assess perfusion, pulses, and edema.
• Palpation of the precordium for bulges, heaves, increased impulses and/or thrills.
• Palpation of the abdomen for hepatomegaly or masses.
• In older children, neck examination should be performed to look for jugular venous distention; the triad of hepatomegaly, edema, and increased jugular venous pressure are pathognomonic of right heart failure.
• Auscultation for abnormal heart tones, irregular rhythm, systolic or diastolic murmurs, gallops, clicks or rubs. A loud second heart sound suggests pulmonary hypertension. In infants, auscultation of the head and the liver should be

performed to exclude arteriovenous malformations of the brain or liver, respectively.

• Auscultation of the lungs to listen for crackles in older children that suggest either pulmonary edema or pneumonia. Crackles from heart failure are very rare in infants and small children and, if heard, point towards an infectious etiology.

Physical examination must also include other noncardiac features such as body habitus (cachexia), abnormal facial features associated with genetic syndromes such as coarse facial features of glycogen disorders, skeletal muscle tone to assess for hypotonia, pseudohypertrophy of calves, and/or organomegaly.

An electrocardiogram may help to identify evidence of ischemia such as Q waves in lateral leads I and AVL, often associated with an anomalous left coronary artery from the pulmonary artery (ALCAPA), particularly in infants, or other coronary abnormalities. Myocarditis is often associated with low voltage and/or diffuse ST segment abnormalities, whereas large voltages and severe hypertrophy on ECG may be associated with infiltrative processes such as Pompe disease or hypertrophic cardiomyopathy. Atrial enlargement may indicate restrictive physiology or severe atrioventricular valve regurgitation. Atrial and ventricular arrhythmias may be either a primary cause of heart failure or secondary to an underlying cardiomyopathy.

Heart failure in children is often first recognized by an abnormal chest radiograph with pulmonary edema and cardiomegaly, although acute processes, such as myocarditis, may often have a normal cardiac silhouette.

An echocardiogram is essential for evaluating a child with heart failure to assess ventricular function and structural abnormalities (see Chapter 8). Each cardiac valve and chamber, and the aortic arch, must be carefully assessed. In the presence of left ventricular systolic dysfunction, etiologies for the dysfunction, including coronary artery abnormalities, need to be actively sought. Both visualizing coronary origins and demonstrating normal flow patterns and also the absence of any secondary signs of coronary abnormalities such as discrepant size of the coronary arteries are essential for assessing an ischemic etiology. Coronary artery abnormalities may not be easily detected by an echocardiogram, and coronary angiography may be useful for diagnosis. Other structural causes of left ventricular dysfunction and heart failure, including left ventricular outflow tract obstruction and aortic arch abnormalities, including coarctation of the aorta, should be excluded by echocardiogram. Volume overload from a large left-to-right shunt such as ventricular septal defect, large patent ductus arteriosus, and aortopulmonary window can also be assessed. Heart failure with a structurally normal heart and normal or hyperdynamic left ventricular function suggests an arteriovenous malformation or a metabolic cause.

After structural heart defects have been excluded, the most common cause of heart failure from left ventricular dysfunction in a child is a primary cardiomyopathy. Cardiomyopathies are typically categorized by phenotype on echocardiogram, based on the size of the atrial and ventricular chambers (dilated, normal, or small), ventricular wall thickness (hypertrophied, normal, or thin), pattern of wall abnormalities (concentric or asymmetric), regional wall motion abnormalities, and nature of myocardium (trabeculated or not). Careful echocardiographic assessment of chamber sizes in addition to systolic and diastolic performance usually allows accurate classification of the cardiomyopathy type: dilated, hypertrophic, restrictive, or noncompaction (see Chapter 58). The degree of systolic and diastolic dysfunction can vary greatly over time and is best assessed by serial measurements of ventricular performance.

Laboratory blood tests can contribute to the diagnosis of a metabolic etiology of heart failure in children. Blood analyses should include amino acids, carnitine, acylcarnitine profile, lactate-to-pyruvate ratio, and ammonia. Urine should be screened for carnitine and organic acids. Troponin and creatine kinase (MB fraction) can detect myocyte damage in myocarditis, ischemia, or cardiomyopathy. Liver and renal function tests are important to assess degree of end-organ damage. Brain-type natriuretic peptide can help to diagnose ventricular wall stress and its change over time. When myocarditis is suspected, serum and respiratory specimens can be screened for viral genome using the polymerase chain reaction (PCR). Although almost any virus can cause myocarditis, the most common are adenovirus, enteroviruses, parvovirus, coxsackie, respiratory syncytial virus, influenza, and parainfluenza.

Genetic testing may be performed using commercially available molecular studies and screening panels for sarcomere gene mutations (common genetic etiologies of hypertrophic cardiomyopathy and dilated cardiomyopathy) and also syndrome-specific testing. Genetic counseling should be considered prior to performing tests.

Cardiac magnetic resonance imaging may help in evaluating heart failure secondary to dilated cardiomyopathy for many reasons, including the ability to provide information that may help distinguish myocarditis from other forms of cardiomyopathy [13]. Cardiac catheterization may be indicated to perform coronary angiography to diagnose coronary abnormalities such as ALCAPA, coronary ostial atresia, or thrombi which may be responsible for heart failure associated with left ventricular dysfunction. Assessing hemodynamics may also be important to determine the degree of dysfunction through measurement of intracardiac pressures and cardiac output. Cardiac endomyocardial biopsy for histology, electron microscopy, and viral PCR may be useful in patients with new onset heart failure to look for evidence of acute myocarditis [14]. Skeletal muscle biopsy for histology, electron microscopy, and mitochondrial respiratory chain analysis may help diagnose cardiomyopathy

associated with related peripheral myopathy. Consultation with specialists in metabolism, genetics, and/or neuromuscular abnormalities can be very useful for diagnostic evaluation when there is concern about an underlying related systemic disorder.

Medical management of chronic heart failure

Chronic heart failure in children is increasingly recognized. Now that operative mortality for CHD has decreased significantly, the number of children surviving surgical palliation has grown and has been accompanied by an increased incidence of ventricular dysfunction and heart failure. The features of heart failure from cardiomyopathy have been well described [15,16]. Although the evidence base for the management of chronic heart failure in adults is broad, there is a paucity of evidence for the treatment of chronic heart failure in children [17,18]. With few exceptions, the management strategies for treating chronic heart failure in children have been extrapolated from large multicenter randomized trials in adults. Current medical management consists of diuretics, angiotensin-converting enzyme (ACE) inhibitors, β-adrenergic receptor blockers (β-blockers), aldosterone antagonists, and digoxin. Although no randomized trials have ever proven that diuretics are beneficial for survival in treating chronic heart failure, they do provide significant symptomatic improvement in patients with heart failure and fluid overload. Potential adverse effects associated with diuretic use include stimulating the renin–angiotensin–aldosterone system (RAAS) and potentially deleterious renal effects. However, when fluid retention is part of the heart failure syndrome, diuretics are an essential part of management. ACE inhibitors improve symptoms and survival in adults with symptomatic heart failure and in adults with asymptomatic left ventricular dysfunction [19–21]. Five large multicenter randomized placebo-controlled trials of β-blockers have also shown that β-blockers with heart failure produce improvements in symptoms, survival, and left ventricular function with mild, moderate, and severe heart failure [22–26]. The aldosterone antagonists spironolactone and eplerenone also afford a significant survival benefit in selected adults with heart failure [27]. Although digoxin has been the mainstay of treatment of heart failure for decades, large randomized trials have demonstrated only a benefit in reducing symptoms, and not mortality, in adults with heart failure. More recently, there has been increasing evidence that lower serum concentrations of digoxin may be better than higher serum concentrations [28]. Finally, angiotensin receptor blockers (ARBs) are essentially equal in efficacy to ACE inhibitors in adults with heart failure, but are currently only recommended for use in patients with heart failure who are intolerant to ACE

inhibitors [17]. In addition to medical therapy of chronic heart failure, electrophysiologic interventions such as cardiac resynchronization therapy and implantable cardioverters/defibrillators also improve symptoms and survival. These modalities are discussed below.

The management of chronic heart failure in children differs from that of adults for many reasons, including:
• different etiologies of heart failure (ischemic, hypertensive, and diabetic in adults compared with nonischemic, nonhypertensive, and nondiabetic in children)
• different ventricular morphologies
• different responses to medications (pharmacokinetic and pharmacodynamic) and electrophysiologic interventions
• different end-organ responses to heart failure
• lower incidence of sudden cardiac death in pediatric heart failure than adult heart failure.

For children with systemic left ventricular dysfunction, it is reasonable to consider the management strategies recommended in adults: diuretics for fluid overload, ACE inhibitors for asymptomatic and symptomatic ventricular dysfunction (ARBs for those who are intolerant to ACE inhibitors), and β-blockers, aldosterone antagonists, and possibly digoxin for symptomatic ventricular dysfunction [18]. For patients with a systemic ventricle that is not a left ventricle, the rationale for using these medications is much less clear. Diuretics for fluid overload continue to be a mainstay of therapy for heart failure with fluid retention, regardless of ventricular morphology. Studies in children and adults with single or right systemic ventricular morphology have failed to show any benefit from ACE inhibitors or ARBs [29–31]. Data from the Pediatric Carvedilol Study suggest that there may be a differential response to β-blockers in children, depending on the morphology of the systemic ventricle: those with a systemic left ventricle tended to show improvement when treated with β-blockers, whereas those with a systemic ventricle that was not a left ventricle did not [32]. There are no data to support or refute the use of aldosterone antagonists in children with heart failure due to systemic ventricular dysfunction in morphologically abnormal ventricles, but there could be theoretical benefit to using these agents due to their beneficial effects on reducing sympathetic nervous system innervation and myocardial fibrosis [33]. Newer medications such as sildenafil may have beneficial effects on selected patients with heart failure, especially those with Fontan physiology, but further study is needed before making recommendations. Despite all of these relatively new treatment modalities, some data suggest that the outcomes for children with heart failure are no better than they were before the development of therapies such as ACE inhibitors and β-blockers [34]. For those patients who "fail" medical therapy, the only option is to proceed towards heart transplantation. Indications include severe, refractory heart failure, severely restricted activity and

quality of life, and significant growth failure due to heart failure [35] (see Chapter 70).

Electrophysiologic management

Electrical device therapy in patients with heart failure has demonstrated additional clinical benefit and has become a mainstay in adult practice [36]. Implantable cardioverter defibrillators (ICDs) have clear survival benefit over standard medical therapy, which has resulted in their use for both primary and secondary prevention of sudden death [36]. Conventional pacemaker therapy has been applied to manage co-morbid electrophysiologic conditions. More recently, cardiac resynchronization therapy (CRT) has improved ventricular performance and benefited survival [36]. The role of these interventions in the management of children with heart failure with and without CHD remains limited, however, and in certain instances unclear [18].

The rationale for the use of ICDs is the increased incidence of sudden death mediated by ventricular arrhythmias in patients with heart failure [37]. Based on numerous adult trials for both primary and secondary prevention [37–43], ICDs have significantly improved survival in patients with heart failure.

Currently, the 2008 guidelines from the American Heart Association (AHA), American College of Cardiology (ACC), and Heart Rhythm Society (HRS) for device-based therapy of cardiac rhythms abnormalities and 2006 guidelines from the AHA, ACC, and European Society of Cardiology for the management of patients with ventricular arrhythmias and the prevention of sudden cardiac death have been used to manage adults with heart failure [36,44]. Based on these guidelines, ICDs are recommended or should be considered in patients with heart failure who meet various combinations of the following criteria: presence or absence of ischemia, time from infarction, degree of cardiac dysfunction, presence or absence of syncope, sudden cardiac arrest, documented ventricular tachycardia or ventricular fibrillation, presence or absence of structural heart disease, type of cardiomyopathy, and/or family history of sudden death [36,44].

The data for using ICDs in children with heart failure are limited [18,45,46]. Some small studies involving a heterogeneous population of children with and without CHD have demonstrated the efficacy of ICDs in terminating arrhythmias and, by extrapolation, improving survival [47–59]. A single study by Dubin *et al.* evaluated the role of ICD therapy in pediatric patients with heart failure [60]. This study evaluated 28 patients with and without CHD awaiting heart transplantation who underwent ICD placement due to ventricular tachycardia/fibrillation, syncope, aborted sudden death, ventricular ectopy, and/or poor cardiac function. A total of 55 ICD discharges occurred in 17 patients, of which 47 (85%) were appropriate [60]. The small numbers and heterogeneity of patients in this and other studies prevent the generalization of these findings with ICDs. Although the ICD terminated arrhythmias, these ventricular arrhythmias might not have been hemodynamically significant and might have self-terminated without therapy. The survival benefit of ICD intervention in children with heart failure is unknown. In a recent multicenter study, the incidence of sudden death in children with heart failure awaiting transplantation was low, 1.3% [61]. Hence the lack of data and the low incidence of death have prompted a more conservative stance for the use of ICDs in children [18].

Based on AHA/ACC/HRS 2008 and ISHLT 2004 guidelines, ICD use in children with heart failure is limited to secondary prevention indications [18,36]. Patients with heart failure usually should have survived a previous cardiac arrest, have symptomatic ventricular tachycardia, and/or have recurrent syncope in the setting of heart failure to be considered for device therapy. The application of ICDs is further limited in pediatrics by technical aspects and issues related to long-term morbidity with device therapy. In particular, the need for generator changes and lead extraction, the higher incidence of lead failure, limited vascular access and venous occlusion, complexity of anatomy, changing patient size, type of device, and psychological issues including the effect of inappropriate shocks should be considered [46,62]. Ultimately, the use of ICDs in children with heart failure is more complex than in adults and should be individualized.

In children with heart failure, regardless of the presence or absence of CHD, electrophysiologic abnormalities may exist. These include symptomatic bradycardia, loss of atrioventricular synchrony, that is, high-grade atrioventricular block, and intra-atrial re-entrant tachycardia, that is, atrial flutter/fibrillation [63]. Based on the AHA/ACC/HRS 2008 guidelines, these patients should be considered for pacemaker device therapy [36].

Most children who require conventional ventricular pacing undergo right ventricular apex pacing. The effect of this pacing site on further progression of heart failure is unknown in children, but data suggest that it may contribute to adverse left ventricular remodeling and diminished function [64–68]. This is illustrated by reports in patients with complete atrioventricular block of right ventricular pacing-induced cardiac dysfunction that function improved after conversion to biventricular pacing [69–73]. Right ventricular apex pacing in adult patients with heart failure with or without atrioventricular block has increased the risk of heart failure [74,75]. This has prompted further investigation in adults into the benefits of conventional versus biventricular pacing [76]. The implications of this study and others could alter the way in which pacing therapy is delivered in children who require long-term pacing to prevent progression of heart failure [64].

The rationale for the cardiac resynchronization therapy is based on observations that electric intraventricular conduction delay, that is, bundle branch block, causes

mechanical intraventricular dyssynchrony that can impair the efficacy of ventricular contraction and reduce ejection fraction [77]. Re-establishing "normal" ventricular conduction and uniform ventricular contraction using biventricular pacemakers improves measures of cardiac function, quality of life, symptoms, functional status, and survival [78]. Additionally, CRT can reverse remodeling of the abnormal myocardium [79,80]. Adult trials including the recent MADIT-CRT trial have shown improved survival and reduced heart failure events over conventional or ICD-only therapy [41,78,81]. Based on these trials, the use of CRT has become the standard of care for some adults. Device therapy is recommended for patients with an ejection fraction <35%, a QRS duration on ECG >120 ms, and a New York Heart Association (NYHA) Class III or ambulatory Class IV. It can also be considered in patients with NYHA Class I or II status who meet other indications for pacing or placement of an ICD [36]. The guidelines are clear, but not all patients respond to therapy and the pre-procedure identification of CRT responders remains elusive.

The clinical efficacy of CRT has led to its consideration for children [63]. To date, CRT with biventricular and multisite pacing in both acute and short-term settings has been described in patients with and without CHD [44,45,55–67,71,72, 82–90]. The two largest multicenter observational studies, by Dubin *et al.* and Janousek *et al.*, reported the effect of CRT on 212 pediatric and CHD patients who received device therapy for various indications. Short-term results demonstrated improvements in functional class, symptoms, and/or ventricular performance by echocardiographic parameters [68–70,91,92]. Unfortunately information about long-term improvement, survival, and improvement of heart failure events cannot be generalized from these studies. Attempts to extrapolate from the adult experience may also be invalid because of differences in etiologies of cardiac dysfunction, the complexities of pre- and postoperative CHD, and differences in the pattern and degree of intraventricular conduction delay, namely predominately right bundle branch block in children compared with left bundle branch block in adults. Also, the type of CHD may preclude or limit the use of this modality because of technical aspects and concern for alterations in medical management [93]. Investigations into the echocardiographic diagnosis of mechanical dyssynchrony have not been reliably useful in adults but may be more important in pediatrics. Based on the available data, no guidelines have been proposed for use of CRT in children with heart failure with or without CHD. CRT should therefore be individualized until further evidence regarding its utility is available.

Acute decompensated heart failure

Acute decompensated heart failure (ADHF) can be defined as the gradual or rapid deterioration in heart failure signs and symptoms requiring urgent therapy. Regardless of the underlying precipitant cause, patients present with symptoms of systemic volume overload with congestion, which can include dyspnea, hepatomegaly, peripheral edema, ascites, symptoms of low cardiac output with poor peripheral perfusion, fatigue, and end-organ dysfunction. In a recent cohort of children presenting to an emergency department with ADHF, the most common symptoms were those related to the gastrointestinal system, including nausea, vomiting, abdominal pain, and diarrhea [94].

In neonates with critical structural CHD presenting with acute heart failure from narrowing of the ductus arteriosus, prostaglandin therapy is the definitive management strategy. These neonates often require additional inotropic support for the myocardium, and invariably require careful attention to balance systemic and pulmonary circulations, until operative management can occur.

Children with ADHF from other causes require aggressive and timely treatment. In general, there is a stepwise approach to management by initiating therapies aimed at decreasing symptoms of congestion and improving myocardial performance. A general approach to management of ADHF includes pharmacologic and nonpharmacologic therapies.

Diuretics are the mainstay of pharmacologic therapy in patients with symptoms of systemic volume overload. The most commonly used agents are loop diuretics (e.g., furosemide and bumetamide), that promote natriuresis and diuresis by their actions on the loop of Henle in the kidney. Their effect can be augmented with thiazide diuretics (e.g., chlorothiazide) that act on the distal tubule. The combination of thiazides that retain calcium and furosemide that increases its excretion may be beneficial for prolonged treatment. The adverse effects of diuretic therapy include renal dysfunction, electrolyte abnormalities, and symptomatic hypotension from a rapid reduction in intravascular volume. These rapid shifts occur less frequently when continuous infusions of loop diuretics are used, and there is some evidence that continuous infusions are more advantageous than bolus injections [95].

Inotropes are the most commonly used agents for improving myocardial performance in children with ADHF. However, no inotrope improves contractility without increasing myocardial oxygen consumption and intracellular calcium accumulation, both of which can lead to arrhythmias and cell death. Inotropic agents include the catecholamines dopamine, dobutamine, and epinephrine, and the phosphodiesterase inhibitor milrinone. Dopamine, dobutamine, and epinephrine increase contractility by stimulating β_1-adrenergic receptors. In a study of hypotensive preterm infants, short-term use of dopamine was more effective than dobutamine; however, there were no benefits in mid- to long-term treatments [96]. Epinephrine and milrinone are agents commonly used in treating postoperative low cardiac output syndrome (LCOS) in children. In the PRIMACORP

study of pediatric postoperative LCOS in children, the incidence of LCOS was reduced significantly with milrinone therapy [97]. However, in the OPTIME-CHF study in adults with an acute exacerbation of heart failure [98], milrinone showed no benefit over placebo, but did increase the incidence of hypotension and arrhythmias. To date, no randomized studies have tested intravenous milrinone therapy in children with ADHF.

Nitroglycerin and nitroprusside are the most commonly used vasodilators in ADHF; both drugs act by conversion to nitric oxide, causing vasodilation, and thereby decreasing afterload on the failing ventricle. Nitroglycerin is primarily a venodilator, and nitroprusside is also an arterial vasodilator. Both agents improve cardiac function after heart surgery in children [99]; however, nitroprusside may cause thiocyanate poisoning after prolonged administration, and continuous use of nitroglycerin has caused tolerance. Both agents can result in hypotension and need to be used cautiously in ADHF with low blood pressure.

Nesiritide is a recombinant form of B-type natriuretic peptide that has primarily vasodilatory and secondarily natriuretic effects. In the VMAC trial in adults with ADHF, nesiritide therapy showed improved short-term symptomatic relief and hemodynamic profile when compared with nitroglycerin [100]. In the ADHERE study of adults hospitalized with ADHF, therapy with either nesiritide or nitroglycerin was associated with a significantly lower in-hospital mortality than with milrinone and dobutamine [101]. Although preliminary studies in children with heart failure suggest that nesiritide may be well tolerated and improve diuresis [102], there is some concern about its use based on a meta-analysis in adults that showed increased morbidity and mortality from renal failure [103].

Levosimendan is a calcium-sensitizing agent with unique dual activity. It improves myocardial contractility by increasing cardiac troponin C calcium sensitivity, without increasing myocardial oxygen consumption. Additional peripheral and coronary vasodilatory effects are facilitated by potassium channel opening. In the initial LIDO trial in adults with cardiogenic shock, levosimendan was superior to dobutamine in reducing pulmonary capillary wedge pressure and decreased long-term mortality at 6 months compared with placebo [104]. In preliminary studies in children with ADHF, levosimendan decreased catecholamine requirements and improved myocardial performance [105]. The most recent study in adults (SURVIVE), however, showed no benefit of levosimendan over dobutamine in 180 day mortality [106].

Arginine vasopressin is elevated in heart failure. This hormone acts through vasopressin-1 (V_1) receptors on the vasculature causing vasoconstriction, and vasopressin-2 (V_2) receptors on the kidneys leading to free water retention. Vasopressin receptor antagonists have been studied as potential therapies for ADHF. Drugs include the V_2 receptor antagonist tolvaptan, which promotes salt-free diuresis ("aquaresis") by selectively binding to renal V_2 receptors, and conivaptan, which by dual antagonism for V_1 and V_2 receptors also has the potential to decrease systemic vascular resistance and improve myocardial performance. In the EVEREST trial of adults with heart failure, oral tolvaptan therapy resulted in symptomatic relief with no mortality benefit [107,108].

The endothelins are a group of peptides with potent vasoconstrictor properties that can worsen outcomes of acute heart failure. However, the intravenous endothelin receptor antagonist tezosentan did not improve symptoms or clinical outcomes in an adult trial of acute heart failure, and the trial was terminated early because of futility [109].

Children with decompensated heart failure benefit from intubation and mechanical ventilation that reduce both left ventricular afterload by decreasing aortic transmural pressure, and also oxygen consumption by decreasing respiratory muscle work. Intubation has some risk in children with heart failure. Some children are overly sensitive to the myocardial depressant effects of sedative medications used for intubation. Other children do not tolerate the increased afterload and/or decreased preload on the right ventricle from increased intrathoracic pressure following intubation and initiation of mechanical ventilation.

Mechanical circulatory support with venoarterial extracorporeal membrane oxygenation (VA-ECMO), ventricular assist devices (VADs), and intra-aortic balloon pumps (IABPs) can augment cardiac output and allow myocardial rest either as a bridge to recovery or transplant (see Chapter 14). VA-ECMO is used for myocardial support and oxygenation, and can be used in children with intracardiac shunts. In children with a structurally normal heart, the left ventricle must be decompressed with an atrial septectomy, septostomy, or with a left atrial vent. VADs include devices that assist the right or left ventricle, or both. These devices cannot be placed in children with an intracardiac shunt and do not support oxygenation. The Berlin Heart EXCOR system has been used to support infants and children with severe circulatory failure. In the largest published series of VAD support in children, 73 children were supported with the Berlin Heart for a mean support time of 36 days; 62% survived to transplantation or were weaned off support, and 51% were discharged home [110]. IABPs are most commonly used in adolescents with heart failure. These devices provide intra-aortic balloon counterpulsation that augments coronary perfusion and provides mechanical circulatory assistance in cardiogenic shock [111]; however, like VADs, they do not support oxygenation.

In children with CHD and acute postoperative heart failure with atrioventricular and inter-/intraventricular conduction delay, resynchronization with temporary epicardial pacing wires may be a useful adjunct therapy, and significantly improves hemodynamics [82].

An alternative nonpharmacologic intervention to diuretic therapy being studied in adults is veno-venous ultrafiltration, which has been shown to alleviate symptoms of congestion by removing isotonic fluid. In adults with weight gain due to fluid overload from ADHF, in the UNLOAD trial ultrafiltration resulted in a greater reduction in weight compared with loop diuretics and a lower re-hospitalization rate at 90 days [112].

The prognosis of ADHF in children depends on the etiology and end-organ function. Children with acute fulminant myocarditis in general have a good prognosis; however, the time for myocardial functional recovery can be prolonged [113,114]. Worsening end-organ function is a poor prognostic sign and can indicate a need for mechanical circulatory support. In one series of children with ADHF, worsening renal function was associated with prolonged hospitalization, in-hospital death, and the need for mechanical circulatory assistance [115]. Transplantation should be considered early if there is no evidence of recovery of myocardial function. In a study of 1091 children with dilated cardiomyopathy and heart failure who underwent heart transplant, survival at 10 years post-transplantation was 72% compared with a 64% survival with conventional treatment at 5 years [116] (see Chapter 70).

Introduction

The burden of pediatric heart disease is significantly greater in underdeveloped than developed nations, even though it may not receive the same focus as more common problems such as AIDS, malaria, malnutrition, and trauma. The effect of cardiac disease in children is twofold. First, although the incidence of congenital heart disease (CHD) is the same as in developed countries, its impact is magnified by several factors. Although diagnostic capability exists (echocardiography), affordable treatment options are limited so that many children grow up with unrepaired anomalies not commonly encountered in developed countries. This is compounded by the very young mean age of the population (often below 20 years) and very high birth rate (2–3-fold higher than in the United States or Europe) [1]. Second, the incidence of acquired heart disease in children is much higher than in developed nations. This includes diseases that are endemic in almost all developing countries, most notably rheumatic heart disease, and problems that are regional, including endomyocardial fibrosis in East Africa and Chagas disease in Latin America. This chapter focuses on both congenital and acquired heart disease in children occurring in developing countries, drawing, in part, from the authors' personal experience in Uganda.

Burden of congenital heart disease

The incidence of CHD is relatively constant in most countries throughout the world, affecting ~1% of the population [2]. The incidence may be as high as 3%, however, in countries with high rates of consanguinity, and regional genetic and environmental factors may alter the distribution of congenital heart defects. Nearly half of children with CHD require intervention. In many developing countries, echocardiography is available for diagnosis, but not more advanced diagnostic or surgical care. Strikingly, the 4000 pediatric cardiology surgery units worldwide serve only 7% of the planet's children [3]. Even fewer pediatric cardiac catheterization laboratories are available. This discrepancy is most significant in sub-Saharan Africa. Recent estimates suggest that over 5.5 million children worldwide have potentially treatable (with a single staged intervention) CHD but do not have access to care [3]. Many of these children are very sick (with unrepaired ventricular septal defects and tetralogy of Fallot being the most prevalent) and it is a significant burden for their families to take care of them. Pollution and frequent respiratory infections likely increase pulmonary hypertension in patients with a left-to-right shunt and episodes of dehydration exacerbate cyanosis in patients with tetralogy of Fallot. These issues do not even include the numerous children with more complex conditions who die in infancy, often without cardiac diagnosis.

Several factors explain the huge discrepancy in care [4]. First and foremost, these countries, especially those in sub-Saharan Africa, are the most economically challenged in the world and the disparity is increasing; per capita aid has dropped by 40% in the last 10 years. As a result, there is often very poor health care infrastructure and limited health care education. Many countries face a huge burden of HIV/ AIDS, malnutrition, and very high infant (50–200 per 1000 live births) and maternal pre-/peripartum (3–11 per 1000 pregnancies) mortality. Unstable political systems and wars compound these problems.

Developing and maintaining a cardiac surgical program face many challenges [5,6]. Financing the necessary technology is often more expensive than in North America or Europe. Consumable products are especially hard to

acquire, and maintenance and repair of equipment are a huge challenge. Complete cardiovascular teams are difficult to maintain because the "brain drain" phenomenon is prevalent. Physicians, nurses, and other healthcare professionals (especially young people fresh out of training) are often offered attractive financial incentives to move abroad. Many of these personnel were sent abroad for a short period of time at hospital and/or government expense to receive training to improve local care. Some developed countries (e.g., the United Kingdom) have relatively strict regulations to prevent promoting the "brain drain" whereas others (e.g., the United States) have almost no rules against recruiting foreign trained medical personnel. Within most developing countries, private sector positions compete with government programs for the most highly qualified personnel. This is counterproductive to programs, such as cardiovascular surgery, that can only succeed if all local resources are pooled and care is performed at a single institution (usually the government/public hospital).

The levels of care for children with heart disease in need of cardiac intervention vary greatly between countries. Some countries offer open-heart surgery routinely whereas others have no or limited closed heart procedures (e.g., patent ductus ligation). Many programs have sufficient infrastructure to host visiting surgical teams for 1–2 week missions. Unfortunately, for most children, the only option is care abroad. The cost is almost always prohibitive relative to local income levels [5]. Even though many charitable organizations place children in established cardiac surgical centers throughout the world, only a small fraction of those in need receive care.

The only way to provide pediatric cardiac surgical care to this significant population of deserving children is to develop regional units that are sustainable. The cost of performing cardiac surgery in developing countries is often 10–20-fold less than it would be abroad. An argument can be made that the benefit (in terms of dollars spent per years of life saved) of performing open-heart surgery (at a cost of $4000–5000 per patient) compares favorably with vaccination and HIV treatment programs.

Coordination of several key individuals and organizations is required in order to create a sustainable cardiovascular surgery program in a developing country [1]. The intent is to build a partnership among cardiovascular specialists in all aspects of perioperative care, legal and financial advisors, nongovernmental and other international organizations invested in healthcare, and local cardiovascular specialists, governmental officials, and the private sector. The early stages of such a partnership will likely include caring for children abroad. In addition to the obvious benefit to the individual child and family, this effort can raise awareness and bring about important fund-raising opportunities.

Subsequently, a combination of relatively frequent medical missions by visiting teams of cardiologists, surgeons, and allied specialists focused on training local teams, training of key personnel abroad for short periods of time, international charitable support, and local governmental funding is critical for success. These missions must be coordinated and provide for a gradual increase in complexity, with local teams assuming more responsibility and performing their own operations between medical missions. The path and obstacles (as outlined above) to long-term sustainability must always be kept in mind. Visiting teams must create a safe and productive practice model but not recreate "first-world" practice that cannot be replicated when they leave. Additionally, "medical tourism," having individuals or teams visit without being part of a bigger picture with no eye towards sustainability, should be avoided.

Uganda case study

Uganda's population is 30 million, with a mean age that is the youngest on the planet. It is estimated that at least 5000 children in Uganda are candidates for single-stage "curative" open-heart surgery or catheterization [3]. Uganda has many favorable attributes that make it a candidate for establishing a sustainable open-heart surgery program. English being the official language, a relatively stable government, ease of travel to and from Uganda, and safety and modernization of the Ugandan capital and other cities make it attractive for international medical efforts.

Uganda had unmatched success, relative to other developing countries, in reducing the incidence of HIV infectivity in the 1990s because of a very aggressive mass publication education program [7,8]. In the first decade of this century Uganda was at the forefront of antiretroviral treatment, at first for pregnant woman and then for any HIV-infected patients. This success has led to multiple collaborations between medical and research institutions, NGOs, governmental healthcare agencies throughout the world, and the main teaching public hospital (Mulago Hospital) and medical school (Makerere University) over the last 20 years. The Uganda Heart Institute is a semi-private ward within Mulago Hospital, and its leadership reports directly to the Ugandan Minister of Health. High-quality pediatric echocardiography has existed for nearly a decade and two cardiovascular surgeons with extensive pediatric training in India are full-time staff members.

The senior author (C.S.) was invited in 2002 by the Ugandan Ambassador to the United States to visit Uganda, assess and collaborate with the local team (P.L. and T.M.), and attempt to provide care for Ugandan patients in the United States. The first mission in February 2003 involved one person (C.S.) and diagnostic echocardiograms were performed on 40 patients. Six children were subsequently cared for in Washington, DC. More importantly, a blueprint for long-term development of a sustainable cardiac surgical program was developed. Ongoing missions with the ultimate goal of building a sustainable heart surgery program include the following:

- diagnose children with heart disease
- teaching programs with focus on patient care, education, critical assessment of personnel, and equipment needs
Figure 72.1 Distribution of diagnoses among Ugandan children referred for cardiac evaluation. AS/AI, aortic stenosis/aortic insufficiency; ASD, atrial septal defect; AV, atrioventricular; DORV, double-outlet right ventricle; HLHS, hypoplastic left heart syndrome; PDA, patent ductus arteriosus; Sub AS, subaortic stenosis; TAPVR, total anomalous pulmonary venous return; TGA, transposition of the great arteries; ToF, tetralogy of Fallot; TR/Ebstein's, tricuspid regurgitation/Ebstein's anomaly; VSD, ventricular septal defect.

- facilitate treatment of children abroad as needed
- facilitate donation of technology
- meet with hospital and government officials
- develop ongoing sustainable financial model
- build a consortium of key individuals and groups.

To date, 10 missions have been carried out; the last five included performing open-heart surgery. Key team members on every surgical trip have included cardiologists, cardiac surgeons, intensivists, anesthesiologists, perfusionists, scrub nurses, critical care nurses (at least four per trip), respiratory therapists, and biomedical engineers. High-level cardiology and intensive care trainees from the United States have also been part of the team and work side-by-side with their Ugandan counterparts. A number of cardiovascular programs have played a major role in this effort, including those from Children's National Medical Center in Washington, DC, Wolfson Children's Hospital in Jacksonville, FL, University of North Carolina in Chapel Hill, NC, and Great Ormond Street Hospital in London, UK.

Key charitable groups involved at the beginning of the project and still actively supporting the program include the Samaritan's Purse Children's Heart Project and Larry King Cardiac Foundation. Other charities with a significant role include Gift of Life International, Garth Brooks Teammates for Kids, Save a Child's Heart, and Health Volunteers Overseas. Several vendors and pharmaceutical companies have given significant in-kind donations, including Philips Medical, Medtronics, and Sanofi-Aventis. Many of these organizations have very generous charitable arms that have official application sites available on the Internet.

It was also very important early on to receive the support of key individuals in Uganda. Ugandan President Yoweri Museveni visited the team in 2007 on the occasion of the first open-heart surgery in Uganda. He pledged ongoing Ugandan governmental financial support for pediatric heart surgery at Mulago Hospital. The authors have met with Ugandan First Lady Janet Museveni on several occasions and also the United States Ambassador to Uganda and the Ugandan Ambassador to the United States. Each mission visit includes meetings with hospital leadership and members of the Ministry of Health. The first two Ugandan patients who received care in the United States were hosted by then Senate Majority Leader Dr Bill Frist, who had operated at Mulago Hospital in 2002.

In the first 8 years of the program, the frequency of trips averaged one every 9 months; Participation by additional medical teams will enable this to increase to one every 3 months. An average of 150 echocardiograms and 10 operations were performed during the last five five medical missions dating from March 2007. A number of patients have been seen on multiple visits. Echocardiography (both images and reports) and surgical data have been maintained since collaboration began. Rheumatic heart disease and cardiomyopathy are under-represented in the data acquired during medical missions. This is related to the difficulty in getting patients who need valve replacement accepted abroad or by initial visiting surgery teams because of the concern of compliance with warfarin anticoagulation regimens.

Complete data are available for 532 children cared for during the missions. The most common diagnoses (Figure 72.1) were ventricular septal defect ($n = 118$), tetralogy of Fallot ($n = 110$), atrial septal defect ($n = 58$), and pulmonary stenosis ($n = 28$). Of note, truncus arteriosus was more common ($n = 15$) and coarctation ($n = 3$) was less common than
Figure 72.2 Diagnoses of Ugandan children undergoing cardiac surgery. Abbreviations as in Figure 72.1, and AVSD, atrioventricular septal defect; CA, coronary artery; Coarct, coarctation of the aorta; PS, pulmonary stenosis; RHD, rheumatic heart disease; Truncus, truncus arteriosus; Vasc, vascular.
Figure 72.3 Location of surgery for Ugandan children.

Figure 72.4 Patients receiving treatment by diagnosis. Abbreviations as in Figures 72.1 and 72.2.

expected from known prevalence data. We speculate that there is incomplete blood pressure assessment for noncritical coarctation and early death without diagnosis for critical coarctation. Future studies of genetic and environmental factors contributing to the high number of truncus arteriosus patients are warranted.

The mean ages at diagnosis were 11 years for atrial septal defect, 3.5 years for ventricular septal defect and 6.4 years for tetralogy of Fallot; the distribution reflects the natural history of congenital heart disease not seen in developed nations. Survival into the second decade of life is frequent in tetralogy of Fallot. Some older children with ventricular septal defect may develop irreversible pulmonary vascular disease, but many are still likely operable. Medical management of cyanotic tetralogy of Fallot was primarily with propranolol. Medical management of congestive heart failure (ventricular septal defects and large atrial septal defects) was with digoxin and furosemide for most patients.

Many were also treated with captopril and/or carvedilol. β-Blockers were much more commonly used for left-to-right shunts than in developed nations. Only pills are available (digoxin 250 μg, furosemide 40 mg, and propranolol 40 mg). Pills are halved or quartered by the pharmacy operated by the Uganda Heart Institute. Most children aged under 1 year take one half or quarter pill once per day.

After the Idi Amin era, a cardiac surgical program was rebuilt in the 1980s by Dr Francis Omaswa. Before 2007, however, the only cardiac surgical procedures performed in Uganda were patent ductus ligation, pericardiectomy (often for tuberculosis), pacemaker insertion (either epicardially or transvenously with single-plane C-arm guidance), and for cardiac trauma. Ductus ligation was often performed in patients with a coexisting large membranous ventricular septal defect to decrease the ductal shunt, hoping to decrease left-sided volume sufficiently to improve symptoms and promote shrinkage of the ventricular septal defect. This was observed anecdotally in several patients.

Patients in our program began to receive care abroad in 2003 and the first open-heart surgical procedure in Uganda (atrial septal defect repair in an 11 year old) was performed in October 2007. The Ugandan team performed the first of five atrial septal defect repairs on its own in May 2009. To date, 216 patients have received cardiac repair in our program, including 75 in Uganda (55 open-heart patients). This includes patients with pulmonary stenosis or atrial septal defects treated abroad via interventional catheterization. The distribution of surgical patients by diagnosis and location is shown in Figures 72.2 and 72.3. The percentage of patients accepted for treatment by diagnosis is shown in Figure 72.4. The decision to accept a patient is determined by several factors, including urgency, risk, and finances. Because of financial support in North America it is more challenging to place surgical than interventional catheterization patients. Atrial septal defects, pulmonary stenosis, patent ductus, and subaortic stenosis have had the highest acceptance rate abroad. Ventricular septal defect patients between the ages

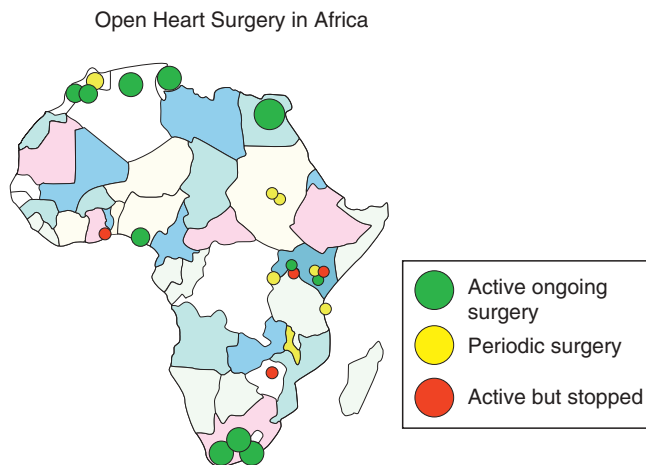
Open Heart Surgery in Africa


Figure 72.5 Location of open-heart surgery programs in Africa.

of 1 and 3 years had a very high acceptance rate, but infants and older children have not.

In the first 2 years, surgery in Uganda has focused on repair of atrial septal and ventricular septal defects in an effort to increase the local surgeons' skills. One tetralogy of Fallot repair, three subaortic stenosis resections, and one right atrial myxoma removal have also been performed in Uganda. In addition to Ugandan citizens, children from Kenya, Congo, and Sudan have come to Mulago Hospital for surgery because of the higher success rate than in their own countries. Very few programs are currently performing open-heart surgery in Africa (Figure 72.5).

Overall survival for the entire program is 98%; no patient operated on in Uganda has died. The diagnoses of the five children who died were ventricular septal defect (with pulmonary hypertension), tetralogy of Fallot, pulmonary stenosis/hypoplastic right ventricle, aortic stenosis/insufficiency, and rheumatic mitral regurgitation. Twenty children who did not receive surgery have died and others with more complex diagnoses have probably died without our knowledge.

The outpatient screening process is a key to the early success of this program. Patients undergo echocardiography on digital ultrasound units with storage on a digital echocardiography image and reporting system in Uganda (Xcelera, donated by Philips Medical, Andover, MA, USA) and in the United States. Patient data are compiled and stored in parallel, and easy access to all the data exists. This resulted in a database of over 500 children that can be reviewed together by Ugandan and visiting teams before the medical missions to optimize surgical planning and minimize diagnostic errors. Echocardiograms are repeated on all patients undergoing surgery at the beginning of the medical mission and reviewed with the entire team. Intraoperative transesophageal echocardiography (pediatric and adult omniplane) is available for all open-heart operations and performed by Ugandan cardiologists under the supervision of visiting echocardiographers. All demographic data, including family cell phone contact information, is kept by a local charity (Samaritan's Purse) and the Ugandan Heart Institute. As a result, the percentage of patients lost to follow-up or who do not show up for scheduled appointments is <5%. Follow-up care is also very good. Compliance is very high even though patients may travel significant distances, and Samaritan's Purse provides home assessment of each patient who has undergone surgery. Advancing telemedicine technology allows for communication and sharing of patient information on pre- and postoperative patients. The Ugandan team is participating in an international quality assurance initiative that also helps track postoperative patients.

The way forward to a sustainable open-heart surgical program will require the Ugandan team to be able to perform a wide variety of procedures, including repair of tetralogy of Fallot and rheumatic heart disease. Currently, skilled surgeons, anesthesiologists, perfusionists, scrub nurses, and cardiologists are in place. A modern cardiac bypass machine is operational and most of the other large equipment in the operating room is up-to-date. Monitors in the intensive care unit are state of the art. Three modern echocardiography systems are available with all sizes of transducers and digital storage capability. Most medicines are available, but not in the quantity or variety that those practicing in developed nations are used to.

Many obstacles remain to achieve long-term success. The intensive care unit is the weakest link in the current process. There are few skilled intensive care unit nurses and no critical care physicians; the surgeons provide all the postoperative care. Many additional nurses require training and remuneration is not sufficient to avoid losing nurses to local private hospitals or programs abroad. The frequency of operations is not sufficient to maintain nursing skills as less than one open-heart procedure is performed per week between our visits. As mission frequency increases, it will be important to adhere to consistent practice and education protocols.

The cost of disposable items remains a significant factor. Important examples include cartridges for blood gas machines and cardiac bypass circuits and oxygenators. Electric power is relatively stable and the operating room has a backup generator. Nonetheless, there are significant power surges that can affect the function of the operating room and intensive care unit. No cardiac catheterization is available; there is no Ugandan physician capable of performing catheterizations and the cost of maintaining a catheterization laboratory is prohibitive.

Ongoing funding is critical. The cost of an open-heart surgery procedure in Uganda from admission to discharge is ~$5000. Although this may be more than 10-fold less than in North America, the average Ugandan family income is 100-fold less. Only a small number of families can afford surgery; no public health insurance exists. Government

subsidization of the costs of surgery will be essential as the program moves forward. Growth of such a high profile program cannot be separated from politics; political stability is always tenuous.

Currently, we are in the second of a 5 year plan that we hope will include four medical missions per year each performing 10 operations, with Ugandan teams performing one open-heart operation per week between missions. The complexity of patients cared for will gradually increase. Ongoing teaching and training will occur on each mission and will be complemented by developing a telemedicine program and participating in an international quality initiative. Funding for a catheterization laboratory had been allocated and should move forward when the program is ready. Ultimately, the hope is that the Uganda Heart Institute will be a referral source for all of East Africa and this will help supplement the program financially.

Acquired heart disease

The prevalence of acquired heart disease is often much higher than that of congenital heart disease in children in developing countries. Rheumatic disease is the most common acquired disease throughout the world. It is estimated that ~16 million, the majority being children, have rheumatic heart disease worldwide; ~500 000 new patients are diagnosed and ~250 000 deaths occur each year [9]. The diagnosis and treatment of rheumatic heart disease is addressed in detail in Chapters 61 and 62. A brief discussion of the unique challenges and solutions to primary and secondary rheumatic fever prevention will be presented here. We will also discusses two other diseases affecting the heart and having a significant impact: endomyocardial fibrosis and Chagas disease. Over 100 million people are thought to be at risk for Chagas disease, with nearly one million affected [10]. Endomyocardial fibrosis affects nearly 20% of the population in endemic regions of Mozambique, with children bearing the brunt of the disease [1,11].

Rheumatic heart disease

In many developing countries, rheumatic fever/rheumatic heart disease (RF/RHD) is a common cause of cardiovascular morbidity and mortality that imposes a great burden on health care services for children. Unfortunately, most children are diagnosed late, after valve damage is already advanced. Many factors cause this unfortunate situation, including genetics, poor socio-economic conditions, and ignorance. Lack of prevention from inadequate diagnosis and treatment of streptococcal sore throat or rheumatic fever and failure to provide ongoing prophylaxis play an important role. This failure to provide preventive measures probably results from poor parental education and lack of adequate medical facilities and medical personnel. The long-term effect is that rheumatic heart disease is one of the commonest causes of admission with heart failure among children and young adults in developing countries. Because RF/RHD is a preventable disease, programs are needed that are aimed at educating the public about the disease, detecting affected individuals at an early stage, and encouraging the establishment of protective measures aimed at the most vulnerable age group, children 5–15 years old.

The A.S.A.P. model, coordinated by the Pan African Society of Cardiology (PASCAR) in collaboration with the World Health Federation, which arose following the Drakensberg Declaration by delegates at the 1st All Africa Workshop on Rheumatic Fever and Rheumatic Heart Disease in South Africa in October 2005, focuses on **A**wareness, **S**urveillance, **A**dvocacy, and **P**revention [12]. Increased awareness has been proven to reduce the incidence of RF/RHD. A 10 year educational study from two French–Caribbean Islands (1981–1991) started with widely distributed posters and pamphlets, television advertisements, and educational videos, and the reported instances of RF increased by 10–20% from baseline numbers. The increase was attributed to increased awareness. Furthermore, over the 10 years of study, RF declined on both islands by approximately 75% [13].

As stated in the 2001 WHO report on RF/RHD, collecting epidemiologic data is crucial for planning and implementing a national program for preventing and controlling RF and RHD [14]. Epidemiological data allow policymakers and practitioners to identify groups or locations that are most affected by RF/RHD in order to direct and concentrate control effort appropriately. The WHO STEPwise approach states that, in resource-constrained settings, collecting a small amount of accurate data is more valuable than large quantities of inaccurate data, or no data at all [14]. PASCAR has outlined a four-step approach for surveillance to be completed in order to maximize results: (1) creating and maintaining RF/RHD registries, (2) prospective RF incidence surveys, (3) cross-sectional RHD prevalence surveys, and (4) epidemiology of streptococcal throat and skin infections.

Effective methods of RF/RHD prevention have been available for over 50 years, yet the developing world has not succeeded in controlling the disease whereas the developed world has nearly eradicated it. The unfortunate side effect is de-emphasis of the disease toll on populations around the globe. Advocacy efforts to encourage increased public demand to give this disease priority will result from community awareness of the link between streptococcal sore throat and RF/RHD. This should lead to policy makers advocating government-based programs focusing on education and prevention strategies.

Preventing RF/RHD can be achieved through two discrete strategies, namely primary and secondary prevention. Primary prevention works by treating the preceding streptococcal infection with antibiotics. Secondary prevention is used after the initial RF attack to prevent the recurrence of

RF and progression of RHD. Both primary and secondary prevention are efficacious for preventing RF. Barriers making primary prevention difficult in the developing world include lack of awareness among the public and health care providers with regard to the link between RF and streptococcal infections, lack of policy for preventing RF based on use of antibiotics in the appropriate setting, and the high prevalence of subclinical group A streptococcal infection.

Endomyocardial fibrosis

Endomyocardial fibrosis (EMF) is the most common cause of restrictive cardiomyopathy globally. EMF is characterized by patchy fibrosis of the endocardial surface that leads to decreased compliance and restrictive physiology. Patients usually present late with signs of right and/or left heart failure and striking ascites with little or no peripheral edema. While the disease has been reported from around the globe, it clusters in the tropical and subtropical regions around the Equator. The populations in sub-Saharan Africa, in particular Uganda, are disproportionately affected.

The natural history, pathogenesis, and etiology of EMF remain poorly understood, despite its recognition for >60 years as a major cause of heart disease in these regions. EMF strikes its victims in the prime of life. Once symptoms develop, prognosis is very poor. There is considerable hemodynamic compromise and risk of sudden death. Surgical options are limited and medical therapy has little effect on symptoms or survival.

Incidence and epidemiology

The incidence and distribution of EMF are difficult to determine, in part because its victims reside disproportionately in regions that are poorly equipped to diagnose and treat cardiovascular disease. Before imaging technology became more widespread, diagnosis was often made on autopsy [15] or by clinical presentation alone [16]. Most cases of EMF appear within 15° of the Equator [17]. Roughly half come from sub-Saharan Africa, and almost one-quarter come from Uganda alone [18]. Within Uganda, EMF is one of the most common forms of heart disease, historically comprising 20% of patients referred for echocardiography [19]. Other significant clinical series have been reported from Nigeria [20,21], coastal Mozambique [22], Kerala State in India [23,24], Brazil [25], and the Ivory Coast [26].

Regional variations exist, even within endemic countries. High-prevalence areas tend to be low-lying, humid, and tropical. Residents of the coastal forests of Mozambique [16], the tropical forests in India's Kerala region [17], and Guangxi province in southern China [27] suffer high incidence of EMF, even though neighboring regions see few if any patients. Similarly large dichotomies appear elsewhere, usually between adjacent tropical regions of contrasting elevations; for example, Uganda has a strikingly large burden of EMF, whereas cooler, higher regions of Kenya and Rwanda/Burundi have little if any, and Brazil and Columbia report some patients, but Peru and Ecuador none.

Only one epidemiological study of EMF in an African population exists. Echocardiographic screening of 948 residents, aged 4–45 years, of the Inharrime district of Mozambique revealed a prevalence rate of 19.8%, much higher than previously suspected. These data suggest that the amount of mild subclinical disease may be grossly underestimated [28]. An increased prevalence was noted if a family member was affected: 24% among persons with one or more affected family members (95% CI, 20.6–27.4); 28.3% among those with two or more (95% CI, 23.4–33.2); and 38.3% among those with three or more (95% CI, 31.2–46.4). These results are corroborated by series in Uganda [29] and Zambia [30], which also showed an increased incidence among family members.

At least one country has also seen an ethnic predisposition. Even though Uganda features the world's highest incidence of EMF, the disease affects Rwandan and Burundian immigrants living in Uganda at a much higher rate than it does Rwandans, and Burundians living in their native countries and native Ugandans living in Uganda [31–33]. In Rwanda and Burundi themselves very few patients are reported. Autopsy data gathered at a Ugandan hospital from 1950 to 1965 showed 172 examples of EMF, 63% of which occurred in Rwandan immigrants, even though that population accounted for just 24% of total autopsies [34].

EMF strikes in the prime of life. Data from Uganda show a bimodal peak incidence: children between the ages of 8 and 10 years and young adults between the ages of 20 and 30 years and native Ugandans living in Uganda [33,34]. The childhood peak is equally distributed between the sexes, but females outnumber males 2:1 in the young adult peak [35,36]. In Nigeria, some studies reported that twice as many males are affected, although others showed no differences between the sexes [37].

Etiology

Many theories have attempted to explain EMF's unique pathology and regional distribution. Its tropical concentration suggests environmental or infectious causes. Some believe that it may part of a spectrum of eosinophilic carditis that includes Loffler endocarditis, but any link between eosinophils and EMF is inconsistent at best. No one theory has been proven and very few investigators have directly tested the proposed causes.

Investigators have examined geochemical and nutritional factors. In a case–control study in Uganda, markers of poverty independently predicted EMF [33]. These included farming, lack of shoes, a cassava-based diet, and a diet low in animal protein. Serotonin is the only potential cause that has been rigorously tested through prospective studies; however, EMF lesions could not be reproduced in animal models [38–40], nor did human EMF patients see a rise in their 5-HT levels after a plantain-rich diet [41]. High concentrations of soil

cerium or thorium [23], magnesium deficiency [42], and protein deficiency [43] have all been examined as possible etiologies of EMF, with inconclusive results.

The role of eosinophilia has been highly debated. Eosinophils contain major basic proteins, cationic protein, protein X, and other substances released during degranulation and thought to be toxic to the endo- and myocardium [44]. Histological and echocardiographic arguments often link EMF and Loffler endocarditis. A comparison of 30 patients with Loffler endocarditis and 32 patients with EMF from Uganda, Nigeria, and Brazil showed a final fibrotic stage in Loffler endocarditis identical with that of EMF [45]. Another study detected no echocardiographic difference between 47 EMF patients and 11 Loffler endocarditis patients [35].

Studies exploring an eosinophilia–EMF link, however, are inconsistent. Endomyocardial biopsies fail to demonstrate an eosinopilic myocarditis even early in the disease [29]. Some studies show no difference in eosinophil levels between patients with EMF and controls [46,47], and others show that EMF patients have higher peripheral eosinophilia than controls [48]. In a recent study, 60% of patients with echocardiographic evidence of EMF had at least mild peripheral eosinophilia when compared with 10% of controls (odds ratio 4.6) [18]. Bukhman *et al*. found that eosinophilia was an independent risk factor for EMF not attributable to parasitism. In addition, their data showed that the eosinophil morphology in EMF is unusual, with a tendency towards multilobular forms with evidence of degranulation [18]. Recent data from Nigeria may explain these discrepancies. Andy *et al*. found an inverse relationship between eosinophil levels and the duration of illness in EMF [49]. In their series, only 20% of patients who presented within 6 months of symptoms had normal eosinophil levels, whereas those with long-standing illness were rarely found to have peripheral eosinophilia. Rutakingirwa *et al*. suggested that this finding may represent a "hit-and-run" phenomenon, where EMF represents the end-stage of an acute eosinophilic injury [33].

Investigators have also sought a more direct connection between EMF and an infectious agent. In Nigeria, a seasonal pattern of acute disease appeared, peaking in the rainy season. This suggests that the mechanism may reside in a vector-mediated host [50]. Uganda's consistent predominance of disease in Rwanda/Burundi immigrants (since the 1960s) raises questions about geography and tribal origin. Some think that the key lies in altered exposure to malaria [18,51], a year-round threat in Uganda that only strikes seasonally, if at all, in Rwanda/Burundi. When compared with the local Ganda tribe, immigrants over the age of 15 years also have heavier spleens than the local Gandans [52], and are at higher risk of developing malarial hypersplenomegaly syndrome [53] (thought to be a hyperimmune response to repeated malarial exposure). In fact, in a series

of five Ugandan families (all Rwanda/Burundi immigrants) with nine instances of EMF, four patients had a history of malarial hypersplenomegaly syndrome [54].

Laboratory results also support the link between EMF, malaria, and a hyperimmune response. A histologic study of early-stage endomyocardial biopsy specimens found cardiac tissue swollen with mucopolysaccharides and endocardium covered in fibrin [55], suggesting a hypersensitivity trigger [56]. In addition, anti-heart antibodies are significantly more frequent (29 versus 3%) and significantly more intensely positive in EMF than in all other African heart diseases combined. The same study also showed a clear relationship between the frequency of anti-heart antibodies and the titer of malaria antibodies (1/200 malaria antibodies = 10% chance of anti-heart antibodies, 1/1600 malaria antibodies = 62% chance of anti-heart antibodies) [57].

Not everyone believes malaria to be EMF's inciting agent; the global distribution of *Plasmodium* does not match the global distribution of EMF. Immunological sensitization, an autoimmune reaction incited by exposure to a new highly immunogenic organism, might provide the common pathway. Many Europeans who have lived and worked in tropical Africa have developed EMF [58,59]. Some surely were exposed to malaria, but other foreign infectious agents were undoubtedly present also. In Nigeria, Brockington's group found almost 100% rates of filariasis (onchocerciasis) in 42 patients with angiographic findings of EMF [60], suggesting a second infectious agent as a potential immune trigger. In addition, Uganda's age/gender pattern fits with an autoimmune theory: a bimodal distribution with the peak after adolescence heavily in favor of women. Recent work has shown autoantibodies against myocardial proteins in EMF patients [61–63]. In one study, 54/56 EMF patients tested positive for IgG class anti-myocardial antibodies, a statistically significant increase from healthy controls [64].

Pathology and pathophysiology

EMF is characterized by patchy fibrosis of the endocardial surface of the inflow tract and the apex of one or both ventricles. There can be a striking amount of endomyocardial thickening – up to several millimeters – leading to reduced compliance and restrictive physiology. Progressive obliteration of the right ventricular cavity typically appears in right-sided involvement as the right ventricular apex draws toward the tricuspid valve. The tricuspid valve, the papillary muscles, and valve apparatus can also be fibrotic; this in turn may lead to tethering of valve leaflets and valvar regurgitation [45]. Left ventricular disease tends to affect the posterior mitral cusp and the chordae attached to this cusp, sparing the anterior mitral apparatus. The posterior cusp involvement can occur with or without apical involvement, and often features a well-defined "skip" of tissue demarcation between apical and valvar involvement [65]. Normally a well-defined cleavage plane divides the endocardium and

myocardium. This plane can be interrupted by strands of fibrous tissue that extend into the underlying myocardium, usually limited to the inner third of the muscle [66]. Thrombus, adherent to the involved ventricular endocardial surface, commonly appears in both right and left heart disease [34,67].

Histologically, the changes are very uniform, despite their variations in gross appearance. Endocardial fibrosis is divided into three zones. The most superficial, zone 1, is usually acellular and often hyalized. Any calcification appears in this layer. The intermediate zone 2 consists of loosely textured fibrous tissue, with occasional macrophages and lymphocytes, but only rarely neutrophils or eosinophils. Next to the myocardium is zone 3, a granulation tissue layer containing small blood vessels and a few chronic inflammatory cells [66].

Clinical course and outcomes

EMF's natural history is not well understood. Many patients recall an early stage of acute illness with symptoms such as urticaria, facial edema, fever, appetite loss, and general malaise [50]. At this point, patients appear ill and usually have a fever. Their physical examinations may reveal an enlarged and tender liver, peripheral edema, tachypnea, or tachycardia. This is when an acute carditis, with or without eosinophilia, likely occurs. Patients do not always present at this stage; when they do, the active carditis is often misdiagnosed or missed entirely. Signs of raised venous pressure, coupled with a third heart sound and tachycardia out of proportion to fever, should raise concern about the possibility of early disease. Even when active carditis is correctly diagnosed, it is difficult to know whether it will lead to EMF. Thus far no predictive tests exist.

Patients usually present in the late stages of disease, exhibiting finger and toe clubbing, failure to develop secondary sexual characteristics, growth retardation, and cachexia [61,68]. These late-stage victims tend to have a peculiar appearance: big, bright eyes with an icteric hue [69]. Patients with right-sided disease have signs of chronic systemic venous congestion, with elevated jugular venous distension, gross hepatomegaly, and congestive splenomegaly. Patients with left-sided disease often have significant pulmonary edema. Striking ascites with little or no peripheral edema is a puzzling part of the typical clinical presentation. The ascitic fluid is almost always exudative (75%), unlike the transudative ascites commonly seen with right ventricular failure. It is also associated with peritoneal fibrosis [70]. Significant ascites is a poor prognostic sign. Brazilian EMF patients with ascites were found to have higher mortality than those without (30% at 2 years versus 15% at 2 years, p = 0.002), plus lower New York Heart Association (NYHA) functional class scores, longer duration of illness, and high rates of atrial fibrillation [71].

Historically, EMF has had a very poor prognosis. Autopsy data collected between 1959 and 1969 in Uganda showed only a 2 year average survival after patients sought medical attention [15]. Later series show greater variability, with some patients having a rarer fulminant course, and most patients having a longer indolent period [50,56,72]. The 1970s saw the introduction of surgical resection. Since then, 10 year survival rates are as high as 68% for some patients [73], although the risk of perioperative mortality remains high [74,75]. Biventricular involvement, right ventricular fibrosis, and AV valve regurgitation all predicted increased early mortality in Brazilian EMF patients, regardless of whether patients received surgical intervention or medical management alone [72]. Other predictors of early mortality include hemoglobin <10 g dl^{-1}, cyanosis, embolic episodes, QRS duration >0.12 s, and short symptomatic history before hospital admission [56].

Diagnostic studies

Electrocardiogram
The electrocardiogram is nonspecific. The most common abnormalities are low-voltage QRS due to myocardial fibrosis, intraventricular conduction delays, right and/or left atrial enlargement, and atrioventricular blocks [76]. Atrial fibrillation can occur in one-third of patients [56].

Chest X-ray
The cardiac silhouette commonly exhibits significant enlargement of the involved atria. Right atrial enlargement seen with predominately right-sided EMF creates a cardiac silhouette resembling the African continent and has been dubbed the "Heart of Africa."

Echocardiography
Conventional transthoracic echocardiography correlates well with angiographic assessment [77]. Echocardiography accurately predicts the presence and distribution of fibrosis when compared with autopsy data [19]. The disease's hallmark is obliteration of the involved ventricular cavity, usually associated with a grossly dilated ipsilateral atrium and normal sized ventricle [78]. Figure 72.6 shows a patient with severe right atrial enlargement. In addition, patients with left- or right-sided involvement often exhibit thickening of the posterior left ventricular wall or anterior interventricular septum, respectively [79,80]. Additional findings include right ventricular outflow dilation, AV valve regurgitation, and a restrictive-type flow pattern. Pericardial effusion, often large, is present in up to 43% of patients [81].

In 2008, Yacoub and colleagues described a set of echocardiographic criteria designed to help study disease progression and understand its staging (Table 72.1). They based their criteria on advanced disease features and also early-stage pathologic features described in postmortem studies [11]. Six major and seven minor criteria comprise their classification system. Two major criteria, or one major and two minor criteria, signal a definite diagnosis. A total
Figure 72.6 Apical four-chamber echocardiographic image of a patient with severe endomyocardial fibrosis of right ventricle. Right atrium is severely dilated, tricuspid valve does not coapt, and spontaneous contrast is seen in right heart. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; TV, tricuspid valve.

Table 72.1 Criteria for diagnosis of endomyocardial fibrosis

Criteria	Score
Major criteria	
Endomyocardial plaques >2 mm in thickness	2
Thin (<1 mm) endomyocardial patches affecting more than one ventricular wall	3
Obliteration of the right left ventricular apex	4
Thrombi or spontaneous contrast without severe ventricular dysfunction	4
Retraction of the right ventricular apex (right ventricular apical notch)	4
Atrioventricular valve dysfunction due to adhesion of the valve apparatus to the ventricular wall	1–4[a]
Minor criteria	
Thin endomyocardial patches localized to one ventricular wall	1
Restrictive flow pattern across mitral or tricuspid valves	2
Pulmonary valve diastolic opening	2
Diffuse thickening of the anterior mitral leaflet	1
Enlarged atrium with normal-sized ventricles	2
Movement of the interventricular septum and flat posterior wall	1
Enhanced density of the moderator or other intraventricular bands	1

[a]Depending on the severity of the regurgitation.

score <8 indicates mild EMF, 8–15 signals moderate disease, and >15 represents severe disease [28]. Although these criteria have not been validated across multiple studies, they provide the first formal criteria for the echocardiographic diagnosis and staging of EMF.

MRI

MRI is unnecessary for diagnosis, but characteristic findings are worth noting as MRI becomes more available. Patients with EMF have normal systolic function but delayed endocardial enhancement with no significant myocardial-delayed enhancement [82]. This finding is unique to EMF and amyloidosis, but whereas both display the classic findings of restrictive ventricular physiology (dilated atria, valvar regurgitation, and decreased diastolic function), only EMF shows a thrombotic mass extending into the ventricular cavity [83].

Management

Medical

No well-designed studies have examined EMF's responsiveness to medical management. If patients present early, with active myocarditis and with or without hypereosinophilia, corticosteroids and immunosuppression are probably beneficial. Formal guidelines for dosing and intervals of treatment, however, do not exist. Patients more often present during the disease's late stages, when caregivers can only attempt to relieve symptoms. As in other patients with diastolic dysfunction who do not tolerate tachycardia well, we assume that EMF patients may benefit from heart rate modulation through β-blockers or Ca^{2+} channel blockers. Diuretics provide symptomatic relief to patients with left-sided disease and pulmonary congestion, but have little effect on patients with right-sided disease. Paracentesis may provide relief from ascites, which can be massive, but frequent paracentesis leads to significant protein loss and fluid often reaccumulates quickly. In addition, a significant number of EMF patients suffer thromboembolic complications [84]. At a minimum, these patients should probably receive aspirin; clopidogrel or warfarin might also prove beneficial, although their safety and efficacy are limited in the resource-poor settings where the disease is endemic. In general, medical management alone does not seem to slow the disease progression, and leads to only minimal relief of symptoms.

Surgical

Endocardial decortication is the procedure of choice for surgical treatment of EMF. It is a basic procedure that has changed very little since its first description: surgeons remove diseased tissue by excavating along the well-defined cleavage plane between the fibrotic endocardium and the healthy myocardium [85]. In many patients, surgical advances have made it possible to perform valve-preserving surgery. Perioperative mortality is high, usually 15–20% [86–88]. In one very small study, where surgeons preserved all valves, the perioperative mortality was only 4.6% [89]. In one of the largest surgical series to date, Moraes *et al.* reported 83 EMF patients in Brazil, operated on between December 1977 and December 1997 [74]. Patients' ages ranged from 4 to 59 years, with a mean of 31 years. Thirty-seven (44.5%) had biventricular disease, 34 (41%) had isolated right ventricular

disease, and 12 (14.5%) had isolated left ventricular disease. All patients were in NYHA Class III or IV at time of surgery. Sixty-eight (81.9%) patients survived the operation. Follow-up ranged from 2 months to 17 years (mean 92 months). There were 15 late deaths, but only nine related to the underlying disease. Only 24 (45%) of the 53 surviving patients were found to be in NYHA Class I or II at last follow-up [74].

Surgical treatment is only palliative; it does not alter the disease's progression. Moreover, surgical mortality is high. Objectively, patients with left-sided disease have better late surgical outcomes than those with right-sided disease [90]. Cardiac transplantation has been successful and is available – if only rarely so – as a last resort.

Chagas disease

Chagas disease, also known as American trypanosomiasis, was first reported in 1909 by Carlos Chagas [91], but there is evidence for its existence long before that; Charles Darwin may have contracted Chagas disease [92]. Chagas disease is one of the world's most under-recognized epidemics.

Epidemiology

The greatest burden of Chagas disease is in Central and South America; the most endemic countries are Paraguay, Ecuador, Belize, and Honduras. Today, Chagas disease threatens 20% of the Latin American population (50% in the four countries listed above); >100 million people are at risk. Nearly 7.7 million people were infected in 2005 [10]. Several initiatives, including vector control and blood bank screening, have reduced the number of infected individuals by >50% over the last 20 years in endemic countries [93]. Between 1990 and 2006, there were significant decreases in the number of annual deaths (from 50 000 to 12 500) and new patients (from 700 000 to 40 000) [94]. Emigration of people from Latin America, however, has resulted in more widespread disease; over 300 000 individuals (most from Mexico) in the United States are estimated to be infected [95,96]. Spain is the second most common destination for Latin American emigrants with Chagas disease.

Pathophysiology

The causative agent of Chagas disease is the protozoan parasite *Trypanosoma cruzi* [10]. The disease is transmitted to humans and domestic and wild animals by blood-sucking triamotine bugs [97], also known as the "kissing bugs." Chagas disease can also be transmitted through blood transfusions (the risk is 10 –20% per unit of infected blood) or vertically from mother to infant. Maternal transmission rates vary from 1 to 5% [98]. Disease has also been reported from solid organ transplantation [99]. There are rare reports of contraction of Chagas disease by oral ingestion of contaminated food or drink [100]. The pathophysiology of Chagas disease is related to the parasite and immune system in both the acute and chronic phases [101].

Clinical course

Although the clinical manifestations of Chagas disease primarily affect adults, many are infected in childhood. The acute infective phase of *T. cruzi* usually lasts 4–8 weeks and is usually asymptomatic or shows as merely a brief febrile illness [102]. Occasionally, ECG changes, including sinus tachycardia, first degree atrioventricular block, low voltages, or T wave changes and/or cardiomegaly on chest X-ray are seen during the infectious phase [103]. If symptoms appear, it is usually after 1–2 weeks of exposure to triatomine bugs (longer after transfusion exposure). Treatment with benznidazole or other appropriate antiparasitic drugs cure the acute infection. Rarely (<5% of patients), death occurs in the acute phase secondary to acute myocarditis or meningoencephalitis. Acute symptoms resolve in 90% patients, even if untreated. Two-thirds of these individuals never develop clinically significant manifestation of Chagas disease; they have an indeterminate form of chronic Chagas disease, only having positive antibodies [10]. Reactivation can occur in immune compromised patients [104]. Approximately one-third of patients initially infected with *T. cruzi* 10–30 years after infection develop a determinant form of chronic Chagas disease characterized by a cardiac, digestive (megaesophagus or megacolon), or cardiodigestive form of the disease. The cardiodigestive form is most frequently marked by the development of megaesophagus before involvement of the heart and colon.

A slowly progressive incessant myocarditis develops in the cardiac form of chronic Chagas disease and ultimately leads to dilatation of all four chambers and impairment of ventricular contractility. An apical left ventricular aneurysm and other regional wall motion abnormalities are common early in the chronic phase [105]. Progressive myocyte death and fibrosis along with damage to the coronary microvasculature result in heart failure, ventricular arrhythmias, thromboembolism, and ultimately death [103]. Biventricular failure is the hallmark of late Chagas disease, with a predominance of right-sided symptoms (especially ascites and liver congestion) in the more advanced phases. Conversely, isolated left heart failure is present in the early phases. The conduction system is affected, resulting in bradycardia, atrioventricular block, and bifascicular block [106]. Premature ventricular beats and ventricular tachycardia are also common. Systemic, especially cerebral, and pulmonary emboli from mural ventricular thrombi are very common [107]. Sudden death is the most common cause of death (nearly two-thirds) in Chagas disease, especially in the earlier stages [108]. It is often due to ventricular tachyarrhythmias and can occur in otherwise asymptomatic patients. Chronic heart failure and embolic disease can also cause death [109].

Congenital Chagas disease

Neonatal Chagas disease may be apparent at birth or develop a few weeks after delivery [110]. Symptoms include hypotonia, fever, anemia, and hepatosplenomegaly. *In utero*

death secondary to placental infection can occur. A woman infected with *T. cruzi* can give birth to an infected infant during no, one, or multiple pregnancies at any stage of the disease. Neonatal diagnosis can be made by examining cord or infant blood. Testing for *T. cruzi* antibodies should be deferred until 9 months (when maternal antibodies are no longer present). Polymerase chain reaction (PCR) for *T. cruzi* DNA is available at some centers [111].

Diagnosis, prognosis, and treatment

Acute infection is diagnosed by detecting parasites in blood. In the chronic phase, two different serologic methods should be performed to detect IgG antibodies against *T. cruzi* [112]. PCR can be performed but is not widely available. Asymptomatic patients with positive antibodies should be monitored every 12–24 months with an ECG and for signs of gastrointestinal involvement. If cardiac involvement is suspected, more thorough evaluation including echocardiography and ambulatory 24h ECG monitoring should be carried out. Prognosis is variable in patients with cardiac disease and is worse in those with NYHA Class III or IV, ventricular tachycardia, and ventricular dysfunction. The 10 year mortality varies from 10 to >80% based on risk stratification scoring [113].

There are two goals of treatment, eradicating the parasite and treating symptoms. Anti-trypanosomal treatment, with benznidazole or nifurtimox, is recommended for anyone with acute, congenital, and reactivated infection, and for all children <18 years old with chronic disease [96]. Benznidazole is the safest and most effective; in children it should be given for 60 days (5–10 mg kg⁻¹ per day in two or three divided doses after meals). Drug treatment should be given to adults aged 19–50 years without advanced heart disease but has not been proven beneficial in older patients. Benznidazole and nifurtimox are contraindicated in pregnancy and in patients with advanced heart failure, severe hepatic or renal disease, and advanced megaesophagus. The BENEFIT trial questioned anti-trypanosomal therapy in adults with mild to moderate cardiac involvement [114].

Some data support the use of amiodarone for patients with Chagas disease with sustained ventricular tachycardia or the combination of nonsustained ventricular tachycardia and ventricular dysfunction [115]. Implantable defibrillators have been used in patients with refractory ventricular arrhythmias and resuscitated sudden death, despite data that show no protection from mortality in this population [116]. Standard treatment for heart failure is often used in patients with Chagas disease; however, the use of higher dosages is often warranted with right heart failure. There are no studies to date supporting the use of β-blockers. There should be a low threshold for using anticoagulation. Results for surgery, including cardiomyoplasty and partial left ventriculectomy, are poor and these procedures should not be offered. Conversely, results in transplant recipients for Chagas disease have been promising [117].

Disease prevention

In the past 30 years, significant progress has been made in preventing and controlling Chagas disease. This has resulted from measures such as rigorous screening of blood donors in endemic areas, aggressive use of insecticides in highly infective areas, and public education. A vaccine is not available, however, and the risk of resurgence of vector-borne disease continues in several Latin American countries. Furthermore, areas such as the United States and Spain are at increasing risk from non-vector transmission. Ongoing vigilant anti-parasitic treatment is important for all acutely and many chronically affected patients. Improved rapid diagnostic testing, both before and after treatment, and more ready access to benznidazole and nifurtimox (especially pediatric formulations) are needed [118].
